The Ikhshīdid dynasty (935–969). For 30 years the governors were unable to restore stability in Egypt. During this time, Egypt was subjected to attacks from the Fāṭimid state based in North Africa and to the rampages of an unruly domestic army. The appointment of Muḥammad ibn Ṭughj, from Sogdiana in Central Asia, as governor in 935 led to a repetition of Ibn Ṭūlūn's achievement; by bold measures Muḥammad established his authority over the treasury and the army, reasserted Egyptian influence in Syria, and won the governorship of the Holy Cities of Arabia (Mecca and Medina). In addition, he founded a dynasty; his sons inherited his Sogdian princely title of *ikhshīd*, but their authority was usurped by their Abyssinian slave tutor, Kāfūr, who ruled Egypt with the caliph's sanction. When Kāfūr died in 968 the Ikhshīdids were unable to maintain order in the army and the bureaucracy. In the following year the Fāṭimids took advantage of the disorder in Egypt to launch still another attack, this one so successful that it led to the occupation of the country by a Berber army led by the Fāṭimid general Jawhar.

The Fāṭimid dynasty (969–1171). The establishment of the Fāṭimid caliphate in 973 in the newly built palace city of Cairo had dramatic consequences for the evolution of Islāmic Egypt. Politically, the Fāṭimids went a step further than the Ṭūlūnids by setting up Egypt as an independent rival to the ʿAbbāsid caliphate. In fact, an avowed aim of the early Fāṭimid propagandists was to achieve world dominion, eradicating the ʿAbbāsid caliphate in the process. For a variety of reasons they achieved neither of these goals; nevertheless, at the height of Fāṭimid power in the mid-11th century, the Fāṭimid caliph could claim sovereignty over the whole North African coastal region, Sicily, the Hejaz and Yemen in Arabia, and southern Syria. Although actual politico-military control was never firm except in Egypt, allegiance paid to the Fāṭimids by their provinces was just as meaningful as that paid to the ʿAbbāsids and for a time was certainly more widespread. Even when the Fāṭimid state fell into decline in the 11th century and abandoned its imperial vision, Egypt continued to play an independent role in the Islāmic world under the leadership of Armenian generals who had gained control of the Fāṭimid armies.

Egypt set up as a rival to the ʿAbbāsid caliphate

Islāmization. It is difficult to estimate the religious change effected by the new dynasty except on the level of the governmental elite, which espoused the official doctrine of Ismāʿīlī Shīʿism—that the leader of the Islāmic community must be descended from ʿAlī, the fourth caliph. Because they believed that the Fāṭimid caliph was the only legitimate leader, the practice of Sunnī (orthodox) Islām was theoretically outlawed in Fāṭimid domains. But the practical difficulties which the Ismāʿīlī minority faced in imposing its will on the Sunnī majority meant that the Muslim population of Egypt remained predominantly Sunnī throughout the Fāṭimid period. Certainly there was no public outcry when Saladin, who founded the Ayyūbid dynasty, restored Egypt to Sunnī rule in 1171. Regarding non-Muslims, the Fāṭimids, with one notable exception, were known for their tolerance, and the Copts continued to serve in the bureaucracy. Several Copts held the highest administrative post—the vizierate—without changing their religion. Jews also figured prominently in the government; in fact, a Jewish convert to Islām, Ibn Killis, was the first Fāṭimid vizier and is credited with laying the foundations of the Fāṭimid administrative system. Christians and Jews even managed to survive the reign of the mad caliph al-Ḥākim (ruled 996–1021), who ordered the destruction of Christian churches in Fāṭimid territory, including the Church of the Holy Sepulchre in Jerusalem, and offered his non-Muslim subjects the choice of conversion to Islām or expulsion from Fāṭimid territory. This period of persecution undoubtedly accelerated the rate of conversion to Islām, if only on a temporary and superficial level.

In comparison with Iraq, Egypt contributed relatively little to Arabic literature and Islāmic learning during the early ʿAbbāsid period. But the Fāṭimids' intense interest in propagating Ismāʿīlism through a network of missionary propagandists made Egypt an important religious and intellectual centre. The foundation of the mosque–college of al-Azhar as well as of other academies drew Shīʿī scholars to Egypt from all over the Muslim world and stimulated the production of original contributions in literature, philosophy, and the Islāmic sciences.

Lack of literature and learning

Arabization. The Arabization of Egypt continued at a gradual pace. The early Fāṭimids' reliance on Berber troops was soon balanced by the importation of Turkish, Sudanese, and Arab contingents. The Fāṭimids are said to have used thousands of nomadic Arabs in the Egyptian cavalry and to have further stimulated Arabization by settling large numbers of Arabian tribesmen in Upper Egypt to deprive the Qarmaṭians—their Ismāʿīlī enemies in Iraq and Arabia—of Arab tribal support. On the other hand, the Fāṭimids reduced the Arab population of Egypt in the mid-11th century, when they incited the Banū Hilāl and the Banū Sulaym tribes to emigrate from Egypt into the neighbouring Berber kingdom of Ifrīqīyah.

Growth of trade. One of the most far-reaching changes in Fāṭimid times was the growth of Egyptian

Egyptian commerce

commerce, especially in Fusṭāṭ, which had become the port city for Cairo, the Fāṭimid capital. Theretofore, Iraq in the east and Tunisia in the west had been flourishing centres for trade conducted both within the Muslim world and between the Muslim and the Christian empires of the West. A number of factors contributed to alter this situation in favour of Egypt. As centralized power declined in Iraq, Mesopotamia, and Syria during the 9th and 10th centuries, traffic on the trade routes across these areas also declined. In Egypt, however, the establishment of a strong government, which soon controlled the Red Sea and maintained a strong navy in the eastern Mediterranean, offered an attractive alternative for the international transit trade between the Orient and Christendom. In addition to having the political stability essential for trade, the Fāṭimids encouraged commerce by their low tariff policy and their noninterference in the affairs of merchants who did business in Egypt. These factors, along with increased European mercantile activity in the Italian cities, helped restore Egypt as a great international entrepôt.

The end of the Fāṭimid dynasty. The Fāṭimid achievement in restoring to Egypt a measure of its ancient glory was remarkable but brief. Halfway through their history the political-religious authority of the Fāṭimid caliphs was vitiated by military uprisings that could be put down only by force. By 1163 the Fāṭimid caliph had been shunted aside in a power struggle betwen the vizier and the chamberlain, who were themselves so impotent that they had to seek help from the Sunnī and even from the crusader powers of Syria and Palestine. Thus began a series of invasions at the behest of Fāṭimid officials, which ended in 1169 with the occupation of Egypt by an army from Syria, one of whose commanders—Saladin—was appointed Fāṭimid vizier. Two years later Saladin restored Egypt to ʿAbbāsid allegiance, abolished the Fāṭimid caliphate, and, in effect, established the Ayyūbid dynasty.

The Ayyūbid dynasty (1171–1250). Under Saladin and his descendants, Egypt was reintegrated into the Sunnī world of the Eastern caliphate. Indeed, Egypt became champion of that world against the crusaders and, as such, chief target of the crusader armies. But this was a gradual process that required Saladin first to build an army strong enough to establish his power in Egypt and then to unite the factions of Syria and Mesopotamia under his leadership against the Franks. By so doing he reconstituted the Egyptian empire, which included, in addition to the areas just named, Yemen, the Hejaz, and, with the fall of Jerusalem (1187), a major part of the Holy Land.

Return to the Eastern caliphate under Saladin

The abolition of the Fāṭimid caliphate and the official reinstitution of Sunnī Islām seems to have caused little perturbation in Egypt except for an uprising by the Fāṭimid palace guard, quickly suppressed. This undoubtedly means that Ismāʿīlī Shīʿism was confined to Fāṭimid ruling circles.

Saladin's policies. Saladin's remission of all taxes not explicitly sanctioned by Islāmic law must have contributed to his own popularity as well as to the stability of his regime. To ensure the defense of his state against both internal and external enemies, he strengthened the fortifications of Cairo by building a citadel and extending the Fāṭimid city walls. Despite the major military and propagandistic efforts mounted against the crusaders, Saladin continued to treat the Christians of Egypt with tolerance; the Coptic Church thrived under the Ayyūbids, and Copts still served the government. Saladin even treated the Christians of Jerusalem with magnanimity after the conquest of that city.

Much to the consternation of the popes, trade between Egypt and the Italian city-states remained brisk, and the Egyptians were able to use raw materials provided by the Italian merchants to forge weapons against the crusaders. The administration of Egypt stayed in the hands of the vast bureaucracy; it was staffed mainly by scribes but was supervised by military officials.

Power struggles. The Ayyūbids introduced a significant change in the governance of their empire that was decisive for the history of their rule in Egypt. Though the Ayyūbids were themselves of Kurdish descent, Saladin followed the Turkish practice of assigning the provinces as fiefdoms to members of his family. In theory, such a measure would ensure the loyalty of the provinces to the central government of Egypt through the loyalty of Ayyūbid kinsmen to their family leader. In practice, however, the measure led to recurrent power struggles in which each governor used his province as a base from which to defy the supreme Ayyūbid power of Egypt. The sultans al-Malik al-ʿĀdil (died 1218) and al-Malik al-Kāmil (died 1238) eventually succeeded in reuniting Syria and Egypt under their leadership. Kāmil, especially, was able to exploit Frankish attacks—in the form of the Fifth Crusade, directed against Damietta—to rally family and provincial support for the defense of Egypt. Nevertheless, given the dissension within the Ayyūbid empire, it was clearly in the interest of the Egyptian sultan to reach a peaceful settlement with the crusaders; this was achieved in 1229 by a truce between Kāmil and the Holy Roman emperor Frederick II, by which Kāmil exchanged possession of Jerusalem and other territory in the Holy Land for Frederick's guarantee to support the sultan against aggression from any source.

Growth of Mamlūk armies. The only real security for Ayyūbid Egypt lay in its independent military strength. This explains why one of the last sultans, al-Malik aṣ-Ṣāliḥ Ayyūb (died 1249), resorted to increased purchase of Turkish slaves—Mamlūks—as a means of manning his armies. Although slave troops had formed an important part of Egyptian armies since the time of Aḥmad ibn Ṭūlūn, their strength had been checked by racial dissension among the various slave units and by the presence of nonslave elements. But after the death of aṣ-Ṣāliḥ Ayyūb in the course of the Sixth Crusade, which the Egyptians defeated thanks to the Mamlūk corps, the Mamlūks were able to exploit a palace feud and to elevate a member of their own ranks to the sultanate. Thus was established the Mamlūk sultanate, which lasted for two and a half centuries and brought Egypt to the peak of its evolution in the medieval period.

THE MAMLUK AND OTTOMAN PERIODS (1250–1800)

The Mamlūk dynasty (1250–1517). During the Mamlūk period Egypt became the unrivalled political, economic, and cultural centre of the eastern Arabic-speaking zone of the Muslim world. Symbolic of this development was the re-establishment in 1261 under the Mamlūks of the ʿAbbāsid caliphate in Cairo (the Mongols had abolished the caliphate when they invaded Baghdad in 1258). Although the caliph enjoyed little authority and had no power, the mere fact that the Mamlūks chose to maintain the institution in Cairo is a measure of their determination to dominate Arabic Islām. It is curious that the Mamlūks—all of whom were of non-Arab, non-Muslim origin and some of whom knew little if any Arabic—established a regime that saved a substantial portion of Muslim territory from pagan domination and established Egypt's supremacy in Arabic culture.

Egypt as the centre of eastern Islām under the Mamlūks

Political life. The political history of the Mamlūk state is complex; during their 264-year reign, no fewer than 45 Mamlūks gained the sultanate, and once, in desperate circumstances, a caliph (in 1412) was briefly installed as sultan. At times individual Mamlūks succeeded in establishing dynasties, most notably Sultan Qalāʾūn (ruled 1279–90), whose progeny ruled Egypt, with two short interruptions, until 1382. Often the Mamlūks chose to allow a sultan's son to succeed his father only for as long as it took another Mamlūk to build up enough support to seize the throne for himself. In reality there was no principle of legitimacy other than force, for without sufficient military power a sultan could expect to be overthrown by a stronger Mamlūk.

Nevertheless, several sultans succeeded in harnessing the energies of the Mamlūk system to establish internal stability and to embark on foreign conquests. Sultan Baybars I (ruled 1260–77), the true founder of the Mamlūk empire, led the Mamlūks to victory against the Mongols at ʿAyn Jālūt in 1260 and captured most of the re-

maining crusader fortifications in Palestine and Syria. During the long reign of al-Malik an-Nāṣir (ruled 1293–1341), the Mamlūks concluded a truce with the Mongols (1323) after several major battles and, despite widespread famine, outbreaks of religious strife, and Bedouin uprisings, maintained economic prosperity in Egypt and peaceful relations with foreign powers, both Muslim and Christian.

Although the state began to decline politically and economically after the death of Nāṣir in 1341, Egypt continued to dominate Eastern Arabdom. But the cumulative effect of the plague, which swept Egypt in 1348 and 1481, Timur's victory in Syria in 1400, and Egypt's loss to the Portuguese of control over the Indian trade, along with the sultans' inability to keep their refractory Mamlūk corps under control, gradually sapped the strength of the state. The best efforts of such a vigorous sultan as Qā'it Bāy (ruled 1468–96) failed to make Egypt strong enough to defend its Syrian empire against raids by the Turkoman states of Anatolia and Azerbaijan and campaigns of the Ottoman Turks.

Contributions to Arabic culture. By the time of the Mamlūks, the Arabization of Egypt must have been almost complete. Arabic had been the language of the bureaucracy since the early 8th century and the language of religion and culture even longer. Moreover, the prevalence of Arabic as a written and spoken language is attested by the discovery in the geniza (storeroom) of a Cairo synagogue of thousands of letters and documents —called the "Geniza Documents"—dating from the 11th through the 13th centuries. Though often written in Hebrew characters, the actual language of most of these documents is Arabic, which proves that Arabic was widely used even by non-Muslims. The main incentive for learning Arabic must have come from the desire of a subject population to learn the language of the ruling elite. The immigration of Arab tribesmen during the early centuries of the occupation, and their intermarriage with the indigenous inhabitants, must also have contributed to the gradual spread of Arabic in Egypt.

Prevalence of Arabic in Mamlūk Egypt

The specific Mamlūk contribution to Arabic culture, however, lay above all in the military achievement. By defeating the Mongols, the Mamlūks provided a haven in Syria and in Egypt for Muslims fleeing from Mongol devastation. The extent of this haven was narrowed by subsequent Mongol attacks against Syria, one of which led to a brief Mongol occupation of Damascus in 1294–95, so that Egypt received an influx of refugees from Syria itself as well as from areas farther east.

This accidental displacement of scholars and artisans into Egypt does not, however, wholly account for the efflorescence of certain types of cultural activity under the Mamlūks. In the same way as they supported the caliphate as a visible symbol of their legitimate claim to rule Islāmic territory, the Mamlūks cultivated and patronized religious leaders whose skills they needed in administering their empire and in directing the religious sentiments of the masses into safe (*i.e.*, nondisruptive) channels. Those divines who cooperated with the state were rewarded with government offices, in the case of the *'ulamā'* (religious scholars), and with endowed monasteries, in the case of the Ṣūfīs (mystics). On the other hand, those who dared criticize the prevailing social and moral order were thrown into prison (such was the fate of the famous legist, Ibn Taymīyah, who, having emigrated from Mesopotamia in order to escape the Mongols, was incarcerated in Cairo by the Mamlūks and their religious functionaries for spreading seditious doctrines).

Concrete evidence of the stimulus the Mamlūks gave to cultural life can be found chiefly in the fields of architecture and historiography. Dozens of public buildings erected under Mamlūk patronage are still standing in Cairo and include mosques, colleges, hospitals, monasteries, and caravansaries. Historical writing under the Mamlūks was equally monumental, in the form of immense chronicles, biographical dictionaries, and encyclopaedias.

Religious life. The Mamlūk period is also important in Egyptian religious history. With few and therefore notable exceptions, the Muslim rulers of Egypt had seldom interfered with the lives of their Christian and Jewish subjects so long as these groups paid the special taxes levied on them in exchange for state protection. Indeed, both Copts and Jews had always served in the Muslim bureaucracy, sometimes in the very highest administrative positions. Even the Crusades apparently failed to upset the delicate balance between Muslims and Christians. Trade with the Italian city-states had certainly continued, and there is no evidence that the local Christians were held accountable for the crusader invasions of Egypt. While it is true that Saladin dismissed all Copts from the bureaucracy and imposed sumptuary laws on them, this policy was abandoned by his successors in their desire to reach an accommodation with the crusaders.

With the establishment of the Mamlūk dynasty, however, it is generally agreed that the lot of the Christians, both in Egypt and in Syria, took a distinct turn for the worse. One indication of this change is the increased production of anti-Christian polemics written by Muslim theologians. A possible reason for the change may have been the association of Christians with the Mongol peril. Because the Mongols used Christian auxiliaries in their armies—Georgians and Armenians in particular—they often spared the Christian populations of towns they conquered, while slaughtering the Muslims. Also, the diplomatic efforts aimed at uniting the Mongols with Christian European powers in a joint crusade against the Muslims might have contributed to the Mamlūks' distrust of the Christians. But the dissatisfaction seems to have originated not so much with the Mamlūk rulers as with the masses, and it seems to have been directed not so much against Christians' sympathy for the Mongols as against their privileged position and role in the Mamlūk state.

Anti-Christian feelings

On several occasions popular resentment against the Copts' conspicuous wealth and their employment in the government was manifested in public demonstrations. Both Muslims and Christians resorted to arson, burning the others' sanctuaries, to express their hatred. Under such pressure, the Mamlūk government dismissed Christians from the bureaucracy on no fewer than nine occasions between 1279 and 1447, and in 1301 it ordered all the churches in Egypt closed. As a result of these intermittent persecutions and the destruction of churches, it is believed that the rate of conversion to Islām accelerated markedly in the Mamlūk period and that Coptic virtually disappeared except as a liturgical language. By the end of the Mamlūk dynasty, the Muslims may well have reached the same numerical superiority that they enjoy in modern times—a ratio of more than ten to one.

Economic life. In trade and commerce, the Mamlūk period marks the zenith of medieval Egyptian economic history. During the 13th and 14th centuries (as long, that is, as the sultanate was able to maintain order in Egypt), trade was heavy with Mediterranean and Black Sea ports and with India. The Oriental trade was controlled largely by a group of Muslim merchants known as the Kārimīs; the Mediterranean trade was left to European traders, whom the Mamlūks allowed certain privileges in Alexandria. By the 15th century, however, Egypt's commercial importance rapidly deteriorated as the result of population losses, increased government interference in commerce, Bedouin raiding, and Portuguese competition in the Indian trade.

The Ottomans (1517–1798). With the Ottomans' defeat of the Mamlūks in 1516–17, Egyptian medieval history had come full circle, as Egypt reverted to the status of a province governed from Istanbul. Again the country was exploited as a source of taxation for the benefit of an imperial government and as a base for foreign expansion. The economic decline that had begun under the late Mamlūks continued, and with it came a decline in Egyptian culture.

Economic decline under Mamlūks

Some historians attribute the lethargy of Ottoman Egypt solely to Ottoman domination. But although Ottoman policy was geared to imperial, not Egyptian needs, it was obviously to the rulers' benefit to provide a stable government that would maintain Egyptian agriculture at a high level of productivity and would promote the transit

trade. To a certain extent Ottoman actions served these purposes. The decisive factor that ultimately undermined Ottoman policies was the perpetuation of the former Mamlūk elite; though they collaborated with the Ottoman government, they often defied it and in the end they dominated it. By and large the history of Ottoman Egypt concerns the process by which the conquered Mamlūks reasserted their power within the Egyptian state.

The Ottoman conquest. From the conquest itself, the Ottoman presence in Egypt was entangled with Mamlūk factionalism. There is no doubt that the Ottomans invaded Syria in 1516 in order to break an incipient coalition against Ottoman expansion between the Ṣafavids of Persia and the Mamlūks of Egypt and Syria. The long-standing enmity between the Ottomans and the Mamlūks arose from their contest to control the Turkoman frontier states north of Syria. After the Ottomans strengthened their hold over eastern Anatolia in 1514, it was only natural that the Mamlūks should attempt to bolster their forces in northern Syria and exchange diplomatic missions with the Ṣafavids. The Ottoman Sultan Selim the Grim responded by attacking the reinforced Mamlūk army in Syria, probably as a preliminary step in a new campaign against the Ṣafavids. In 1516, after Selim had defeated the Mamlūks at Marj Dābiq (north of Aleppo), Ottoman goals had probably been met, especially since the Mamlūk sultan Qānṣūh al-Ghaurī died in the battle. But the Mamlūks rallied around a new sultan in Cairo, who refused to accept Selim's terms for a settlement. Spurred on by the Mamlūk traitor Khair Bey, Selim marched against Egypt in 1517, defeated the Mamlūks, and installed Khair Bey as Ottoman governor. Khair Bey died in 1552; thereafter, the Ottoman viceroy (called *vali*), with the title of pasha, was sent from Istanbul.

Mamlūk factionalism

Ottoman administration. In 1525 the Ottoman administration of Egypt was defined and codified by the Ottoman grand vizier, Ibrāhīm Pasha, who was dispatched to Egypt for this purpose by the Sultan Süleyman the Magnificent. According to the terms of Ibrāhīm Pasha's decree (*qanun-name*), Egypt was to be ruled by a viceroy aided by an advisory council (divan) and an army comprised of both Ottoman and local corps. The collection of taxes and the administration of the four provinces into which Egypt was divided were assigned to inspectors (*kashifs*). Although the Egyptian government was headed by bureaucratic officials sent from Istanbul, and supported by Ottoman troops, the Mamlūks were able to penetrate both the bureaucracy and the army. The *kashifs* were often drawn from Mamlūk ranks; three of the seven military corps formed by the Ottomans in the 16th century were recruited in Egypt, one of which—the Circassians—was composed of Circassian Mamlūks. Their service in the army enabled the Mamlūk amirs to secure high-ranking military posts that entitled them to serve on the divan itself.

The beys

By the 17th century a distinct elite bearing the title of bey had emerged, which consisted largely of Mamlūk amirs. These beys held no specific offices but were nevertheless paid a salary by the Ottoman government. The elite was perpetuated through the old Mamlūk system of purchasing slaves, giving them military training, then freeing them and attaching them to one of the great Mamlūk houses of Egypt. Thus, for all practical purposes, the Mamlūks maintained themselves as an elite throughout the Ottoman period. They were no longer the only politico-military elite, as they had been in the past, but they ultimately succeeded in re-establishing their dominance. Yet the chief obstacle to the growth of their power was not so much the Ottoman ruling hierarchy as it was their own factionalism. During the 17th and 18th centuries the Mamlūks were divided into two great rival houses—the Faqariyya and the Qasimiyya—whose mutual hostility often broke out into fighting and impaired the strength of Mamlūks as a bloc.

Mamlūk power under the Ottomans. In spite of internal dissension and the resistance of the non-Mamlūk hierarchy, the Mamlūks had emerged by the early 18th century as the supreme power in Egyptian politics. While the beys continued to acknowledge the authority of the Ottoman viceroy and to send tribute to Istanbul, the strongest single figure in Egypt was the bey who held the newly coined title of *shaykh al-balad* ("chief of the city"), which signified that he was recognized by the other beys as their chief. The Mamlūks' rise to power was climaxed by the careers of two amirs—ʿAlī Bey and Abū Dhahab—both of whom secured from the Sublime Porte (Ottoman government) de facto recognition of their autonomy in Egypt (1768–76) and even undertook military campaigns in Syria and the Hejaz. The Ottomans attempted to end the Mamlūk domination by sending an army to Egypt in 1786. Initially successful, this attempt failed and the troops were withdrawn a year later. A Mamlūk duumvirate was re-established, which lasted until Napoleon invaded Egypt in 1798.

Expansion. During the 16th century, when their regime in Egypt was strongest, the Ottomans used Egypt as a base for expansion to the south. Like the Mamlūk rulers before them, they attempted to control the southern approaches to Egypt by instituting their authority in Nubia; this they achieved by annexing Nubia as far south as the Third Cataract. Elsewhere, they undertook to reassert Egyptian command of the Red Sea, which the Portuguese had begun to contest during the early 16th century. Ottoman fleets and troops captured Yemen and Aden (1536–46) and thus dominated the lower Red Sea; in 1557 they strengthened this position by setting up a colony on the Abyssinian coast at Mitsiwa (Massawa). In the 17th century these outposts began to lose their importance as Ottoman and Portuguese power began to decline and the Dutch took over the spice trade.

Culture. Given the political instability and the economic decline that had prevailed in Egypt since late Mamlūk times, it is not surprising that the culture of Ottoman Egypt lacked vitality. Perhaps the most telling example of intellectual quiescence was the dramatic decline in the quantity of historical works produced in Egypt. As already noted, the Mamlūk period is renowned for the number and quality of its historians, partly because the amirs patronized court historians; by contrast, in almost three centuries of Ottoman rule Egypt produced only one historian worthy of note, al-Jabartī (died 1825) famous for his observations on the French occupation. The Ottomans also fell short of the Mamlūks' achievement in architecture; there is no lack of public buildings erected under Ottoman patronage, but even the best of these are imitations of the Byzantine basilica, which had been adopted as the model for mosques.

Impact of political instability

Religious affairs. Like all previous Muslim governments, the Ottomans continued to employ Copts in the financial offices of the bureaucracy. The Ottomans allowed the caliphate, so assiduously preserved in its nominal form by the Mamlūks, to lapse. At first the caliph was installed in Istanbul by Selim the Grim. Later the caliph—the last of the ʿAbbāsid line—returned to Egypt, where he died in the reign of Süleyman. The claim that the caliph had transferred his authority to the Ottoman sultan is an 18th-century invention. (D.P.L.)

V. Egypt since c. 1800

FROM THE FRENCH TO THE BRITISH OCCUPATION (1798–1882)

The French occupation and its consequences (1798–1805). Although several projects for a French occupation of Egypt had been advanced in the 17th and 18th centuries, the purpose of the expedition that sailed under Napoleon Bonaparte from Toulon in May 1798 was specifically connected with the war against Britain (see FRENCH REVOLUTIONARY AND NAPOLEONIC WARS). Bonaparte had discounted the feasibility of an invasion of England but hoped by occupying Egypt to damage British trade, to threaten India, and to obtain assets for bargaining in any future peace settlement. Meanwhile, as a colony under the benevolent and progressive administration of Revolutionary France, Egypt would be regenerated and regain its ancient prosperity. The military and naval forces were therefore accompanied by a commission of scholars and scientists to investigate and report upon the past and present condition of the country.

Eluding the British Mediterranean fleet under Lord Nelson, the French landed at Abū Qīr (Aboukir) Bay on July 1 and took Alexandria the next day. In an Arabic proclamation, Bonaparte assured the Egyptians that he came as a friend to Islām and the Ottoman sultan, to punish the usurping Mamlūks and to liberate the people. From Alexandria the French advanced on Cairo, defeating Murad Bey at Shubrākhīt (July 13), and again decisively at Imbābah, opposite Cairo in the so-called Battle of the Pyramids on July 21. Murad fled to Upper Egypt, while his colleague, Ibrāhīm Bey, together with the Ottoman viceroy, made his way to Syria.

Battle of the Pyramids

After entering Cairo (July 25), Bonaparte sought to conciliate the population, especially the religious leaders (*'ulamā'*), by demonstrating his sympathy with Islām and by establishing councils (divans) as a means of consulting Egyptian opinion. The destruction of the French fleet at Abū Qīr by Nelson in the so-called Battle of the Nile on August 1 virtually cut Bonaparte's communications and made it necessary for him to consolidate his rule and to make the expeditionary force as self-sufficient as possible. The savants, organized in the Institut d'Égypte, played their part in this. Meanwhile, Egyptian resentment at alien rule, administrative innovations, and the growing fiscal burden of military occupation, was exacerbated when the Ottoman sultan, Selim III (1789–1807), declared war on France, on September 11. An unforeseen revolt in Cairo, on October 21, was suppressed after an artillery bombardment that ended any hopes of cordial Franco-Egyptian coexistence.

Ottoman Syria, dominated by Ahmed Jezzar Paşa, the governor of Acre, was the base from which French-occupied Egypt might most easily be threatened, and Bonaparte resolved to deny it to his enemies. His invasion force crossed the frontier in February 1799 but failed to take Acre after a protracted siege (March 19–May 20), and Bonaparte evacuated Syrian territory. A seaborne Ottoman invading force landed at Abū Qīr in July but failed to maintain its bridgehead. At this point Bonaparte resolved to return to France and succeeded in slipping away on August 22, past the British fleet.

His successor as general in chief, Jean-Baptiste Kléber, viewed the situation of the expeditionary force with pessimism and, like many of the soldiers, wished to return to the theatre of war in Europe. He therefore entered into negotiations with the Ottomans and by the Convention of al-'Arīsh (January 24, 1800) agreed to evacuate Egypt. Sir Sydney Smith, the British naval commander in the eastern Mediterranean, sponsored the convention, but in this he had exceeded his powers and was instructed by his superior officer, Admiral Lord Keith, to require the French to surrender as prisoners of war. Although the Ottoman reoccupation was well under way, Kléber and the French determined on resistance and defeated the Turkish forces at the Battle of Heliopolis (March 20). A second revolt of Cairo, fomented by Ottoman fugitives, took about a month to suppress; but French authority had been restored when Kléber was assassinated by a Syrian Muslim, Sulaymān al-Ḥalabī, on June 14.

His successor, 'Abd Allāh Jacques Menou, a French officer (and former nobleman) who had turned Muslim, was determined to maintain the occupation and administered at first a tolerably settled country, although he lacked the prestige of his two predecessors. In 1801 a threefold invasion of Egypt began. British troops were landed at Abū Qīr in March, while the Ottomans advanced from Syria. Shortly afterward, British Indian forces were landed at Quṣayr on the Red Sea coast. The French garrison in Cairo capitulated in June, and Menou himself at Alexandria in September.

Surrender of the French

The brief episode of the French occupation was to be significant for Egypt in several ways. The arrival of a European army accompanied by scholars and scientists appropriately inaugurated the impact of the West, which was to be felt increasingly in the next 150 years. Egypt, protected for five centuries by the Mamlūk and Ottoman sultanates, was no longer immune from European attack: it had become an object of the contending policies of France and Britain, a part of the "Eastern Question." Bonaparte's savants had little success in interpreting Western culture to the traditionalist *'ulamā'* of Cairo; their achievement was rather to unveil Egypt to Europe. They uncovered the celebrated Rosetta Stone, which held a trilingual inscription making it possible to decipher hieroglyphics and which thus laid the foundation of modern Egyptology. Their reports and monographs were collected in the monumental *Description de l'Égypte* (1809–13, Paris).

Of more immediate consequence for Egypt was the effect of the French occupation upon internal politics. The Mamlūk ascendancy was fatally weakened. Murad Bey, who had made his peace with the French, died shortly before their capitulation in 1801; and Ibrāhīm Bey, who returned to Egypt with the Ottomans, had henceforward little power. The new Mamlūk leaders, 'Uthmān Bey al-Bardīsī and Muḥammad Bey al-Alfī, former retainers of Murad, headed rival factions and had in any case to reckon with the British and Ottoman occupation forces. In March 1803 the British were evacuated in accordance with the Peace of Amiens. But the Ottomans, determined to reassert their control over Egypt, remained, establishing their power through a viceroy and an occupying army, in which the most effective fighting force was an Albanian contingent. The Albanians, however, acted as an independent party and in May 1803 mutinied and installed their own leader as acting viceroy. When he was assassinated shortly afterward, the command of the Albanians passed to his lieutenant, Muḥammad 'Alī (born 1769), who, during the ensuing two years, cautiously strengthened his own position at the expense both of the Mamlūks and the Ottomans.

Ottomans remain in Egypt

Muḥammad 'Alī and his successors (1805–82). In May 1805 a revolt broke out in Cairo against the Ottoman viceroy, Khūrshīd Pasha. The *'ulamā'* invested Muḥammad 'Alī as viceroy. For some weeks there was street fighting and Khūrshīd was beseiged in the Citadel. In July Sultan Selim III confirmed Muḥammad 'Alī in office and the revolt ended.

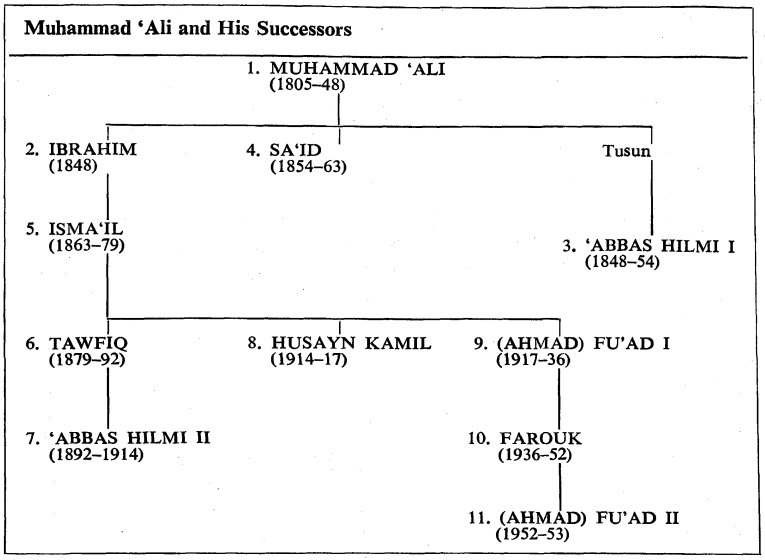
Muḥammad 'Alī's viceroyalty was marked by a series of military successes, some of which were attended by political failures that frustrated his wider aims. After the renewal of war between Britain and Napoleonic France in 1803, Egypt again became an area of strategic significance. A British expedition occupied Alexandria in 1807 but failed to capture Rosetta and, after a defeat at the hands of Muḥammad 'Alī's forces, was allowed to withdraw.

Military expansion. In Arabia, the domination of Mecca and Medina by fanatical Wahhābī Muslims was a serious embarrassment to the Ottoman sultan, who was the titular overlord of the Arabian territory of the Hejaz and the leading Muslim sovereign. At the invitation of Sultan Mahmud II (1808–39), Muḥammad 'Alī sent an expedition to Arabia that between 1811 and 1813 expelled the Wahhābīs from the Hejaz. In a further campaign (1816–18), Ibrāhīm Pasha, the viceroy's eldest son, defeated the Wahhābīs in their homeland of Najd, and brought central Arabia within Egyptian control. In 1820–21 Muḥammad 'Alī sent an expedition up the Nile and conquered much of what is now the northern Sudan. By so doing, he made himself master of one of the principal channels of the slave trade and began an African empire that was to be expanded under his successors.

After the outbreak of the Greek insurrection against Ottoman rule, Muḥammad 'Alī, at Sultan Mahmud II's request, suppressed the Cretan revolt in 1822. In 1825 Ibrāhīm began a victorious campaign in the Morea in southern Greece, where his military success provoked intervention by the European powers and brought on the destruction of the Ottoman and Egyptian fleets at the Battle of Navarino in October 1827. The Morea was evacuated the following year.

In 1831 Muḥammad 'Alī embarked upon the invasion of Syria. His pretext was a quarrel with the governor of Acre, but deeper considerations were involved, particularly the growing strength of the Sultan, which might threaten his own autonomy. Syria, moreover, was strategically important; and its products, especially timber,

Muḥammad 'Alī's invasion of Syria



usefully complemented the Egyptian economy. The Ottoman army was defeated near Konya in Anatolia (December 1832), and in 1833 the Sultan ceded the Syrian provinces to Muḥammad ʿAlī.

In 1839 Ottoman forces re-entered Syria but were defeated by Ibrāhīm at the Battle of Nizip (Nezib). A fortnight later Mahmud II died, and the Ottoman Empire seemed on the verge of dissolution; it was saved only by European intervention. In 1840 Ibrāhīm was compelled to evacuate Syria. Muḥammad ʿAlī's Arabian empire (which since 1833 had extended into the Yemen) crumbled at the same time. Although in June 1841 the new sultan, Abdülmecid I (1839–61), conferred on the family of Muḥammad ʿAlī the hereditary rule of Egypt, the viceroy's powers were declining. Because of his growing senility, Ibrāhīm succeeded him (July 1848) but died in the following November. The next viceroy was ʿAbbās I, the eldest grandson of Muḥammad ʿAlī. The old viceroy himself died in 1849.

Administrative changes. Muḥammad ʿAlī's military exploits would not have been possible but for radical changes in the administration of Egypt itself. Muḥammad ʿAlī was a pragmatic statesman whose principal object was to secure himself and his family in the unchallenged possession of Egypt. His immediate problem on his accession was to deal with the Mamlūks, who still dominated much of the country, and the *ʿulamāʾ*, who had helped him to power. The strength of these two groups rested largely on their control of the agricultural land of Egypt and the revenues arising therefrom. Gradually, between 1805 and 1815, Muḥammad ʿAlī eroded the system of tax farming that had diverted most of the revenues to the Mamlūks and other notables, imposed the direct levy of taxes, expropriated the landholders, and carried out a new tax survey. In 1809 he worsted the *ʿulamāʾ*, and in 1811 he massacred many of the Mamlūk leaders in Cairo, while Ibrāhīm expelled their survivors from Upper Egypt.

Restructuring of taxation

Muḥammad ʿAlī thus became effectively the sole landholder, with a monopoly over trade in crops, in Egypt, although later in his reign he made considerable grants of land to his family and dependents. The monopoly system was extended in due course from primary materials to manufactures, with the establishment of state control over the textile industry. Muḥammad ʿAlī's ambitious hopes of promoting an industrial revolution in Egypt were not realized, fundamentally because of the lack of available sources of power. The monopolies were resented by European merchants in Egypt and clashed with the economic doctrine of free trade upheld by the British government. Although a free-trade convention between Britain and the Ottoman Empire in 1838 (the Convention of Balta Liman) was technically binding on Egypt, Muḥammad ʿAlī succeeded in evading its application up to and even after the reversal of his fortunes in 1840–41.

Reform of the military

The old-style military forces (including the Albanians) on whom Muḥammad ʿAlī relied against his internal opponents and who conquered the Hejaz, Najd, and the northern Sudan, were heterogeneous and unruly. An attempt to introduce Western methods of training in 1815 provoked a mutiny. Muḥammad ʿAlī then decided to form an army of slave-troops dependent wholly upon himself and trained by European instructors. The conquest of the Sudan was intended to provide the recruits. But the slaves, encamped at Aswān, died wholesale, and, for the mass of his troops Muḥammad ʿAlī had to look elsewhere. In 1823 he took the momentous step of conscripting Egyptian peasants for the rank and file of his "new model army." On the other hand, the officers were mostly Turkish-speaking Ottomans, while the director of the whole enterprise, Sulaymān Pasha (Colonel Sève), was a former French officer. The conscription was brutally administered and military life harsh. There were several ineffective peasant revolts, while flight to the towns and (before 1831) to Syria produced rural depopulation and a decline in cultivation.

As reorganization proceeded, the viceroy gradually built a new administrative structure. While institutions were created and discarded according to his changing needs, Muḥammad ʿAlī depended essentially upon the members of his own family, particularly Ibrāhīm, and loyal servants, such as his Armenian confidant Boghos Bey. Characteristic of his governmental system were councils of officials, convened to deliberate on public business, and administrative departments (divans) that bore some resemblance to the ministries of European governments. In local administration, Muḥammad ʿAlī established a highly centralized system with a clear chain of command from Cairo through the provincial governors, down to the village headmen. Initiative was not encouraged, but firm control had taken the place of anarchy.

These changes necessitated the training of officers and officials in the new Europeanized ways of working; and this in turn resulted in the creation of a range of educational institutions alongside the traditional Muslim schools that prepared the *ʿulamāʾ*. Much of the foundation work was done by expatriates, while missions of Egyptian students were sent to Europe, especially to Paris. One of these, Rifāʿa Rāfiʿ aṭ-Ṭahṭāwī (1801–73), played the leading part in inaugurating the translation of European works into Arabic and so was a pioneer both in the interpretation of European culture to Egypt and in the renaissance of literary Arabic. The establishment of a government printing press (*c.* 1822) made possible the wide dissemination of the new books.

ʿAbbās I and Saʿīd, 1848–63. The reign of ʿAbbās I (1848–54) indicates how precarious was the advance of westernization in Egypt. The effort had already been relaxed in the last decade of Muḥammad ʿAlī's rule, and ʿAbbās showed himself to be a traditionalist. It was typ-

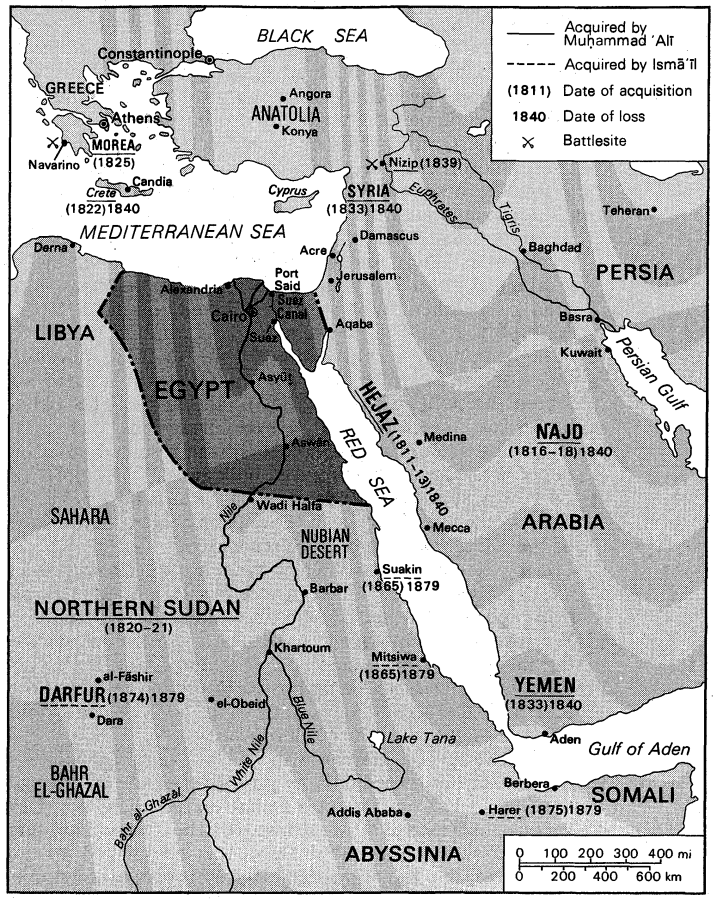
ical of his policy that he closed the school of languages and the translation bureau and sent their director, aṭ-Ṭahṭāwī, to virtual exile in the Sudan. The French, who had played so large a part in Muḥammad ʿAlī's reforms, fell into disfavour, and for diplomatic support ʿAbbās turned to their British rivals, whose support was needed against the Ottomans. Although initially ʿAbbās was ostentatiously loyal to the Sultan, he resented an attempt made at this time to curtail his autonomy. The British, for their part, had their communications with India facilitated by the grant of a concession to build a railway from Alexandria to Cairo; the line was completed between 1851 and 1856 and was extended to Suez two years later. Saʿīd (1854–63), who succeeded on ʿAbbās' mysterious and violent death, inaugurated another reversal of policy. While he lacked Muḥammad ʿAlī's energy and ability, he was not unsympathetic to the westernizers. To his French friend Ferdinand de Lesseps he granted in 1854 a concession for the cutting of a canal across the isthmus of Suez. This embroiled him both with the Sultan, whose prerogative had been encroached upon, and the British, whose overland railway route was threatened by the project; a deadlock lasted throughout his reign.

The concession to Ferdinand de Lesseps

Ismāʿīl, 1863–79. Ismāʿīl, the son of Ibrāhīm Pasha, who succeeded on the death of Saʿīd, displayed some of his grandfather's dynamic energy and enthusiasm for modernization. He lacked caution, however, and his reign ended in catastrophe. From his predecessors he inherited a precarious economy and a burden of debt. The American Civil War (1861–65) produced a boom in Egyptian long-staple cotton. This had been introduced and developed in Muḥammad ʿAlī's time, but its production had languished until the interruption of supplies of American cotton caused a fourfold increase in price during the war years. When peace returned, prices collapsed with disastrous consequences for the Egyptian economy. In the management of his finances, Ismāʿīl was both extravagant and unwise and laid himself open to unscrupulous exploitation. Ismāʿīl was committed to the Suez Canal project, but he modified the grant in two important respects: by withdrawing the cession of a strip of land from the Nile to the Suez isthmus, along which a fresh water canal was to be constructed; and by refusing to provide unlimited peasant labour for the project. The matter was submitted to arbitration; an indemnity of over £3,000,000 was imposed on Ismāʿīl, who also agreed to pay for a large block of shares put by de Lesseps to Saʿīd's account. French pressure on the Sultan succeeded at last in overcoming resistance to the canal project at Istanbul, and a firman (decree from the sultan) authorizing its construction was granted in March 1866. Work had in fact already been going on for seven years, and in November 1869 the Suez Canal was opened to shipping by the empress Eugénie, the wife of Napoleon III of France. The incident symbolized the political and cultural orientation of Egypt in the middle decades of the 19th century.

Ismāʿīl, in other ways, presented himself as the ruler of a new and important state. Although his relations with his suzerain, Sultan Abdülaziz (1861–76), were normally friendly, he was no less anxious than his predecessors to secure the autonomy of his dynasty. In 1866 he obtained a firman establishing the succession by primogeniture in his own line—abandoning the contemporary Ottoman rule of succession by the eldest male. A year later a firman conferred the special title of khedive, which had in fact been used unofficially since Muḥammad ʿAlī's time and which distinguished the viceroy of Egypt from other Ottoman governors. A period of strained relations developed between the Khedive and the Sultan arising from Ismāʿīl's implied pretensions to sovereignty at the time of the opening of the Suez Canal, but the two were later reconciled; a firman reconfirmed the Khedive's privileges in 1873. These concessions by the Sultan, however, cost Ismāʿīl heavy expenditure and an increase in the annual Egyptian tribute and formed another factor in the growth of Ismāʿīl's indebtedness.

Ismāʿīl had inherited an African empire in the northern



Expansion of Egypt under Muhammad ʿAlī and Ismāʿīl.

Sudan. Since the middle of the century, in consequence of the abolition of the monopolies, merchants had penetrated south and southwest, up the White Nile and the Baḥr al-Ghazāl, in search of ivory. An ancillary slave trade had developed that was repugnant to the European conscience. Humanitarian and expansionist motives thus coincided to persuade Ismāʿīl to extend Egyptian rule into these remoter regions. He made considerable use of expatriates, notably the Englishmen Sir Samuel Baker and Charles George ("Chinese") Gordon, who extended the Khedive's nominal authority to the African Great Lakes. Another series of events led to the conquest in 1874 of the sultanate of Darfur in the west. The Khedive also wished to make Egypt the dominant power in the Red Sea region. The Sultan granted him the old Ottoman ports of Suakin and Mitsiwa in 1865. Egyptian control was established on the Somali coast, and in 1875 Harar was captured. Attempts to invade Abyssinia in 1875 and 1876 were, however, unsuccessful and marked the limits of Ismāʿīl's imperial expansion.

Penetration southward

Like other parts of the Ottoman Empire, Egypt was bound by the Capitulations—a system of privileges derived from ancient treaties with former sultans. Under the Capitulations, European and American residents in Egypt were exempt from local taxation and were subject only to their own consular courts. By patient negotiations over several years, Nūbār Pasa, Ismāʿīl's Armenian minister, succeeded in establishing the Mixed Courts in 1875. These had jurisdiction in cases involving Egyptians and foreigners, or foreigners of different nationalities, and had both foreign and Egyptian judges, who administered codes based on French law.

By this time the social consequences of the agrarian and political changes inaugurated by Muḥammad ʿAlī were clearly appearing. The Khedive and his family were the principal landholders in Egypt, possessing extensive personal estates quite apart from the state lands. Around the khedivial family was a parvenu aristocracy that held the principal civil and military offices. Many of its mem-

bers were also great landowners; most of them were Turkish or Circassian by origin. Although the condition of the peasantry had been adversely affected by military conscription, by corvées for public works (including large-scale demands for labour on the railways and the Suez Canal), and by ill-considered economic and industrial experiments, the rights of cultivators on their land gradually increased. The richer peasants, from whom the village headmen were recruited, in particular increased in importance. When Ismāʿīl set up a consultative council (November 1866), the Assembly of Delegates, chosen by indirect election, the great majority of its members were village headmen. While Ismāʿīl did not intend that the Assembly should limit his power, its establishment and composition were indications of the political development of the Egyptians in 60 years. Conscription had affected the political significance of the army. The ascendancy of the entrenched Turco-Circassians was challenged by native Egyptian officers, who resented the privileged position of their foreign colleagues. The defeat of the Circassian commander in chief, Rātib Pasha, by the Abyssinians in 1876 was a blow from which the prestige of the old officer group never recovered.

Creation of the Assembly of Delegates

In the Assembly and the army, and among the westernized intelligentsia, politically conscious individuals and groups began to emerge who drew their ideas from both Western and Islāmic sources. Their organization was for the most part small scale and ephemeral, and their outlook was subversive, being hostile to the autocracy of the Khedive, the ascendancy of the Turco-Circassians, and the pervasive power of the Europeans.

Political tension increased in the last years of Ismāʿīl's reign. Various expedients to postpone bankruptcy (*e.g.*, the sale in 1875 of his Suez Canal shares to Britain) had failed, and in 1876 the Caisse de la Dette Publique (Commission of the Public Debt) was established for the service of the Egyptian debt. Its members were nominated by France, Britain, Austria, and Italy. In the same year, Egyptian revenue and expenditure were placed under the supervision of a British and a French controller (the Dual Control). After an international enquiry in 1878, Ismāʿīl accepted the principle of ministerial responsibility for government and authorized the formation of an international ministry under Nūbār. Ismāʿīl, however, was not prepared to yield his autocracy tamely. In 1879 he profited from an army demonstration against the European ministers to dismiss Nūbār, and he worked in alliance with the Assembly of Delegates to destroy international control over Egypt. By this time, however, his standing outside Egypt had been lost; and in June 1879, Sultan Abdülhamid II (1876–1908), at the instigation of France and Britain, deposed him in favour of his son, Tawfīq.

Renewed European intervention, 1879–82. European domination was immediately reasserted. The Dual Control was revived, the British controller being Evelyn Baring, later Lord Cromer. By the Law of Liquidation (July 1880), the annual revenues were divided into two approximately equal portions, one of which was assigned to the Caisse de la Dette. The Assembly of Delegates was dissolved. The forces of resistance that Ismāʿīl had stimulated were not, however, allayed by these means. There had already come into existence a nationalist group within the Assembly, prominent among whom was Sharīf (Chérif) Pasha, prime minister from April to August 1879. In the army, a group of Egyptian officers, whose leader was ʿUrābī (Arabi) Pasha, was disaffected from the Khedive and resentful of European control of Egypt. By 1881 these two groups had allied to form the National Party, al-Ḥizb al-Waṭanī.

Open tension appeared with a petition drawn up in January 1881 by ʿUrābī and two of his colleagues against the war minister, Rifqī Pasha, a Circassian. They were arrested and court-martialled but released by mutineers. Tawfīq capitulated, dismissed Rifqī, and appointed Bārūdī Pasha, one of ʿUrābī's friends, as war minister. But the ʿUrābists still felt themselves endangered; a military demonstration in Cairo in September 1881 compelled Tawfīq to appoint a new ministry under Sharīf and to convoke the Assembly. But the alliance between the military group and Sharīf was uneasy.

Meanwhile, the European powers were becoming alarmed. An Anglo-French note sent in January 1882 with the intention of strengthening the Khedive against his opponents had the contrary effect. The Assembly of Delegates swung toward the ʿUrābists. Sharīf resigned and Bārūdī became prime minister with ʿUrābī as war minister. Rioting ensued on June 11 after British and French naval forces had been sent to Alexandria. From this point Britain took the initiative. The French refused participation in a bombardment of Alexandria (July 11), while an international conference held at Istanbul was boycotted by the Turks and produced no solution of the problem. The British government finally resolved on intervention and sent an expeditionary force to the Suez Canal. The ʿUrābists were rapidly defeated at Tall al-Kabīr (September 13, 1882), and Cairo was occupied the next day.

European intervention

THE PERIOD OF BRITISH DOMINATION (1882–1952)

The British occupation and the Protectorate (1882–1922). The British occupation marked the culmination of developments that had been at work since 1798: the de facto separation of Egypt from the Ottoman Empire, the attempt of European powers to influence or control the country, and the rivalry of France and Britain for ascendancy in the country. Through the last minute withdrawal of the French, the British had secured the sole domination of Egypt. W.E. Gladstone's Liberal government was, however, reluctant to prolong the occupation or to establish formal political control, which it feared would antagonize both the Sultan and the other European powers; but the British were unwilling to evacuate Egypt without securing their strategic interests, and this never seemed possible without maintaining a military presence there.

An incident at the outset of the occupation was significant of future tensions. On British insistence, the Khedive's government was obliged to place ʿUrābī and his associates on public trial and to commute the resulting death sentences to exile. Tawfīq's prestige, slight enough at his accession, and diminished in the three years before the occupation, was still further undermined by this intervention of the British government. Meanwhile, Lord Dufferin, the British ambassador in Istanbul, visited Egypt and prepared a report on measures to be taken for the reconstruction of the administrative system. The projects of reform that he envisaged would necessitate an indefinite continuation of the occupation. The implications of this for British policy were slowly and reluctantly accepted by the ministry in London, under pressure from its representative in Cairo, the British agent and consul general, Sir Evelyn Baring, who in 1891 became Lord Cromer.

Public trial of ʿUrābī

Two principal problems confronted the occupying power: first, the acquisition of some degree of international recognition for its special but ambiguous position in Egypt; secondly, a definition of its relationship to the khedivial government, which formed the official administration of the country. The main European opponents of recognition of the British position were the French, who resented the abolition of the Dual Control (December 1882). The Caisse de la Dette remained in existence and until 1904 the British had to tread warily in order to circumvent French opposition in this institution. In the early years of the occupation, when Egyptian finances were in disarray, French hostility was a serious problem, but from 1889 onward there was a budget surplus and consequently greater freedom of action for the Egyptian government. A moderate degree of international agreement over Egypt was attained by the Convention of London (1885), which secured an international loan for the Egyptian government and added two further members (nominated by Germany and Russia) to the Caisse de la Dette. In 1888 the Convention of Constantinople (Istanbul) provided that the Suez Canal should always be open in war and peace alike. This was, however, a statement of principle rather than fact; without British cooperation it remained a dead letter.

Cromer's personal rule

In matters concerning the international status of Egypt, the decisions were taken in London, but where the internal administration of the country was concerned, Cromer's opinions were usually conclusive. Although throughout the occupation the facade of khedivial government was retained, British advisers attached to the various ministries were more influential than their ministers, while Cromer himself steadily increased his control over the whole administrative machine. Tawfīq himself gave little trouble: he owed his throne to the British and was unpopular with the Egyptians. His prime ministers were more tenacious of their rights. Sharīf Pasha, prime minister at the beginning of the occupation, opposed the proposal, made by the British government through Baring, that the Egyptians should abandon the Sudan, where the Mahdī was conducting a successful revolutionary war (see NILOTIC SUDAN, HISTORY OF THE). In January 1884 Baring, who had obtained from London a declaration that British "advice" was mandatory on Egyptian ministers and governors, obtained Sharīf's resignation. He was succeeded by Nubar Pasha, who resented the power of the British advisers, especially in the Ministry of the Interior. In 1888 Nubar challenged Baring and was dismissed. Riyāḍ (Riaz) Pasha, another elder statesman, who succeeded as prime minister, was a man of determined character—he had resigned from Sharīf's ministry in 1882 over ʿUrābī's trial, and he was as unwilling as Nubar to allow further British invasion of the internal administration. A clash developed over the Ministry of Justice, and Riyāḍ resigned in 1891. Thereafter, until November 1908, with a break in 1893–95, the prime minister was Muṣṭafā Fahmī Pasha, who showed himself an obedient instrument of Cromer.

ʿAbbās Ḥilmī II, 1892–1914. The death of Tawfīq and the accession of his 17-year-old son, ʿAbbās Ḥilmī II, in 1892 marked the beginning of a new phase of opposition to the occupation. The new khedive was not content to accept Cromer's tutelage, while the British agent resented the attempts of one so much his junior to play a serious role in Egyptian politics. ʿAbbās dismissed Muṣṭafā Fahmī in January 1893 and tried to appoint his own nominee as prime minister. Cromer, backed by the British government, frustrated his endeavours, and Fahmī returned to office in November 1895. ʿAbbās provoked another crisis in January 1894 by public criticism of the British officers who had reorganized the Egyptian army after the occupation, and especially H.H. Kitchener, the sirdar (commander in chief). Once again Cromer intervened, and ʿAbbās was compelled to make humiliating amends.

Other considerations apart, the behaviour of ʿAbbās in the early years of his reign indicated the emergence to political consciousness and activity of a new generation who had only been children when the occupation began.

Muṣṭafā Kāmil

One of ʿAbbās' contemporaries was the lawyer and journalist Muṣṭafā Kāmil (1874–1908), who had studied in France and then had entered a circle of anglophobe writers and politicians. On returning to Egypt in 1894 he had reached an understanding with the Khedive on the basis of their common detestation of the British occupation. By his speeches and writings (in 1900 he founded his own newspaper, *al-Liwāʾ*) he endeavoured to create a spirit of Egyptian patriotism that would appeal to all classes and communities and rally the nation around the Khedive. A boost was given to nationalism by the campaigns for the reconquest of the Sudan (1896–98) and still more by the Condominium Agreement of 1899, which nominally gave Egypt and Britain joint responsibility for the administration of the reconquered territory but in effect made the Sudan a British possession. This was humiliating for the Egyptians, who had ruled there in the past and had taken a major part in its reconquest.

A final episode in the reconquest of the Sudan, the confrontation of British and French at Fashoda on the White Nile in 1898, was followed by the reconciliation of the two powers in the Entente Cordiale (1904), which in effect gave Britain a free hand in Egypt. This was a blow to the hopes of Muṣṭafā Kāmil and to his alliance with the Khedive, who showed himself more willing to cooperate with Cromer. Muṣṭafā Kāmil now turned to Sultan Abdülhamid. When a dispute (the Tābah Incident, 1906) arose between the Ottomans and the occupying power over the Sinai Peninsula, Muṣṭafā Kāmil sought to rally Egyptian nationalist opinion in favour of the Sultan. In this he was not wholly successful since moderates and Christians were disturbed by the pan-Islāmic tone of his propaganda.

British domination in Egypt and Cromer's personal ascendancy never seemed more secure than in the period following the Entente Cordiale. But the "veiled protectorate" had hidden weaknesses. Cromer was both out of touch and out of sympathy with the new generation of Egyptians. The occupation had become to all intents and purposes permanent, and the consequent growth of the British official establishment created frustration among educated Egyptians, whose resentment was increasingly articulate. The British, however, saw themselves as the benefactors of the Egyptian peasantry, whom they had delivered from the corvée and the lash.

The Dinshawāy Incident

The Dinshawāy Incident showed them in another light. In June 1906 a fracas between villagers at Dinshawāy and a party of British officers out pigeon shooting resulted in the death of a British officer. The special tribunal set up to try the matter imposed exemplary and brutal sentences on the villagers. In the bitter aftermath of this affair, Cromer retired in May 1907.

The breakdown of the understanding between the Khedive and Muṣṭafā Kāmil, and the latter's handling of the Tābah Incident, stimulated the formation of new political groupings. Some moderate nationalists founded the newspaper *al-Jarīdah* in March 1907 and organized themselves as the Umma (Nation) Party in September. In the following month, Muṣṭafā Kāmil produced a program for his own followers, who revived the old name of the Nationalist Party. The Khedive, for his part, found a new ally in Shaykh ʿAlī Yūsuf, who since 1889 had been publishing a newspaper called *al-Muʾayyad* and now organized the so-called Constitutional Reform Party. These "parties" were all outgrowths of political journalism, were centred around single individuals or small groups, and were lacking in both a coherent ideology and a mass appeal. Their existence was precarious: the Nationalist Party never recovered from Muṣṭafā Kāmil's death in February 1908, while the Constitutional Reform Party expired with its founder in 1913.

Sir Eldon Gorst, who succeeded Cromer, had served in Egypt from 1886 to 1904 and brought a fresh mind to bear on the problems of the occupation. He obtained an understanding with the Khedive and endeavoured to diminish the growing power and numbers of the British establishment. At the same time he tried to give more effective authority to Egyptian political institutions. Muṣṭafā Fahmī's long premiership ended and he was followed by a Copt, Buṭrus Ghālī Pasha. When Gorst died prematurely in July 1911, he had attained only limited success. Many British officials resented his policies, which at the same time failed to conciliate the nationalists. A project for the extension of the Suez Canal Company's 99-year concession by 40 years was thrown out by the General Assembly (a quasi-parliamentary body, set up in 1883), while Buṭrus Ghālī, who had advocated it, was assassinated a few days later by a Muslim extremist. The appointment of Lord Kitchener to succeed Gorst portended the end of conciliation of the Khedive. But Kitchener, although autocratic, was not wholly illiberal; his attempts to limit the power and influence of ʿAbbās Ḥilmī served the interests of the nationalists. The Organic Law of 1913 created a new and more powerful Legislative Assembly that served as a training ground for the nationalist leaders of the postwar period. At the same time, the peasants were helped by the improvement of agriculture and by legal protection of their holdings from seizure for debt.

World War I and independence. In November 1914 Britain declared war on the Ottoman Empire and in December proclaimed a protectorate over Egypt, deposed ʿAbbās, and appointed his uncle, Ḥusayn Kāmil, with the title of sultan. Kitchener was succeeded by Sir Henry

MacMahon, and he by Sir Reginald Wingate, both with the title of high commissioner. Although Egypt was not required to provide troops, the people, and particularly the peasantry, suffered from the effects of war. The declaration of martial law and the suspension of the Legislative Assembly curbed the activities of middle class nationalists. In October 1917 the amenable Ḥusayn Kāmil died, and was succeeded as sultan by his ambitious brother, Aḥmad Fu'ād.

Attempt of Zaghlūl to secure Egypt's independence

On November 13, 1918, two days after the Armistice, Wingate was visited by three Egyptian politicians headed by Sa'd Zaghlūl Pasha. Zaghlūl had held ministerial office, had sat in the Legislative Assembly before the war, and was coming into prominence as a nationalist spokesman. He demanded autonomy for Egypt and announced his intention of leading a delegation (Arabic *wafd*) to state his case in England. The British government's refusal to accept a delegation, followed by the arrest of Zaghlūl, produced a widespread revolt in Egypt; and Lord Allenby, the victor over the Turks in Palestine, was sent out as special high commissioner. Although regarded in Britain as a strong man who would save the situation, he insisted on concessions to the nationalists in the hopes of reaching a settlement. Zaghlūl was released, and the Wafd, now a country-wide organization, dominated Egyptian politics. The Milner Commission (1919–20), sent to report on the establishment of constitutional government under the protectorate, was boycotted, but Milner subsequently had private talks with Zaghlūl in London. Finally, hoping to outmanoeuvre Zaghlūl and to build up a group of pro-British politicians in Egypt, Allenby pressed his government to promise independence without previously securing British interests by a treaty. The declaration of independence (February 28, 1922) ended the protectorate but, pending negotiations, reserved four matters to the discretion of the British government: the security of imperial communications, defense, the protection of foreign interests and of minorities, and the Sudan. On March 15 the Sultan became King Fu'ād I of Egypt.

The Kingdom of Egypt (1922–52). The new kingdom was in form a constitutional monarchy. The constitution, based on that of Belgium and promulgated in April 1923, defined the King's executive powers and established a bicameral legislature. An electoral law provided for universal manhood suffrage and the indirect election of deputies to the lower house: the Senate was half elected and half appointed. But Egyptian constitutionalism was as illusory as Egyptian independence. A political struggle was continually waged among three opportunist contestants—the King, the Wafd, and the British.

The Wafd and the King. Fu'ād shared the autocratic tendencies of his predecessors. He was never popular and felt insecure, particularly in the early years of his rule, since his accession excluded claimants with greater legitimacy. Hence he was prepared to intrigue with the nationalists or with the British to secure his position and powers. The Wafd, with its mass following, elaborate organization, and (until his death in 1927) charismatic leader in Zaghlūl, was the only truly national party in Egypt. Ideologically, it stood for national independence against British domination and for constitutional government against royal autocracy. In practice—and increasingly as time went on—its leaders were prepared to make deals with the British or the King to obtain or retain power. Personal and political rivalries led to the formation of splinter parties, the first of which, the Liberal Constitutionalist Party, broke off as early as 1922. The primary aim of the British government, represented by its high commissioner (after 1936, its ambassador), was to secure imperial interests, especially the control of communications through the Suez Canal. The need for a treaty to safeguard these interests led Britain on more than one occasion to conciliate nationalist feeling by supporting the Wafd against the King.

The repetitive course of events from 1923 to the outbreak of the World War II reflects the interplay of these three forces. The first general election, in January 1924, gave the Wafd a majority, and Zaghlūl became prime minister. His few months of office were marked by unsuccessful treaty discussions with the British prime minister Ramsay MacDonald and by tension with the King. When in November 1924 Sir Lee Stack, the sirdar and governor-general of the Sudan, was assassinated in Cairo, Allenby immediately presented an ultimatum that, although later modified by the British government, caused Zaghlūl to resign. The general election of March 1925, in spite of manipulation by the new government, left the Wafd still the strongest party, but the Parliament no sooner met than it was dissolved. For over a year Egypt was governed by decree. The third general election, in May 1926, again gave the Wafd a majority. The British frowned on a return of Zaghlūl to the premiership, which went to the Liberal Constitutionalist, 'Adlī Yegen (Yakan), while Zaghlūl held the presidency of the Chamber of Deputies until his death in the following year. Once again tension developed between the parliament and the King, and in April 1927 'Adlī resigned, to be succeeded by another Liberal Constitutionalist, 'Abd al-Khāliq Tharwat (Sarwat) Pasha, who negotiated a draft treaty with Sir Austen Chamberlain, the British foreign secretary. The draft treaty, however, failed to win the approval of the Wafd. Tharwat resigned (March 1928), and Muṣṭafā an-Naḥḥās (Nahas) Pasha, Zaghlūl's successor, became prime minister. But he was unacceptable both to the British and the King, who dismissed him in June and dissolved the Parliament in July. In effect, the constitution was suspended, and Egypt was again governed by decree under a Liberal Constitutionalist premier, Muḥammad Maḥmūd Pasha.

An-Naḥḥās prime minister

Negotiations between Maḥmūd and Arthur Henderson, the British foreign secretary, resulted in agreement on draft treaty proposals in June 1929; but since Maḥmūd was unable to overcome Wafdist opposition, British influence was thrown behind a return to constitutional government, hoping that a freely elected Parliament would approve the proposals. In the fourth general election (December 1929), the Wafd won a majority, and an-Naḥḥās again became prime minister. Resumed negotiations with Henderson broke down over the problem of the Sudan, from which the Egyptians had been virtually excluded since 1924. An-Naḥḥās also clashed with the King, whose influence he sought to curtail. He resigned in June 1930, and Fu'ād appointed Ismā'īl Ṣidqī (Sidki) Pasha to the premiership. The constitution of 1923 was abrogated, and another promulgated by royal decree. This, with its accompanying electoral law, strengthened the King's power. By this and other measures, Ṣidqī sought to break the power of the Wafd, which boycotted the general election of June 1931. The strong government of Ṣidqī lasted until September 1933, when he was dismissed by the King. Thereafter, for over a year, palace-appointed governments ruled Egypt.

But Fu'ād, whose health was failing, could not hold out indefinitely against the internal pressure of the Wafd and the external pressure of Britain, which was becoming increasingly anxious for a treaty with Egypt as relations with Italy deteriorated over the Abyssinian question. In April 1935 the constitution of 1923 was restored, and a general election in May 1936 gave the Wafd a majority once more. Fu'ād had died in the previous month and was succeeded by his son Farouk (Fārūq), still a minor. An-Naḥḥās became prime minister for the third time. In the changed national and international situation, agreement was quickly reached with Britain, and a treaty of mutual defense and alliance was signed in August 1936. At the conference of Montreux, held in the following year, Egypt, with the backing of Britain, obtained the immediate abolition of the Capitulations and the extinction of the Mixed Courts after 12 years. In 1937 also, Egypt became a member of the League of Nations.

Treaty with Britain

An-Naḥḥās was now at the height of his power but was soon to be overthrown. In July 1937 King Farouk came of age and assumed his full royal powers. He was both popular and ambitious to rule, and tension rapidly developed between him and his prime minister. A split developed in the Wafd: Maḥmūd Fahmī an-Nuqrāshī (Nokrashy) Pasha and Aḥmad Māhir (Maher) Pasha were expelled and formed the Sa'dist Group. The Wafdist youth

movement, the Blueshirts, was opposed by the Greenshirts of Young Egypt, a fascist organization. In December 1937 Farouk dismissed an-Naḥḥās. In the ensuing general election, the Wafd won only 12 seats.

World War II and its aftermath. Although at the outbreak of World War II, in September 1939, Egypt provided facilities for the British war effort, few Egyptians were enthusiastic supporters of Britain, and many expected its defeat. In 1940 the British brought pressure on the King to dismiss his prime minister, ʿAlī Māhir, and to appoint a more cooperative government. When, early in 1942, German forces prepared to invade Egypt, British intervention compelled King Farouk to accept an-Naḥḥās as prime minister. The Wafd, its power confirmed by overwhelming success in the general election of 1942, cooperated with Britain. Nevertheless, the intervention in February 1942 had disastrous consequences. It confirmed Farouk's hostility to both the British and an-Naḥḥās and tarnished the Wafd's pretensions as the standard-bearer of Egyptian nationalism. The Wafd was damaged also by internal rivalries.

An-Naḥḥās was dismissed by the King in October 1944. His successor, Aḥmad Māhir, was acceptable to the British, but he was assassinated in February 1945 at the moment of Egypt's declaration of war on Germany and Japan. He was succeeded by a Saʿdist, an-Nuqrāshī Pasha.

At the end of World War II, Egypt was in a thoroughly unstable condition. The Wafd declined, and its political opponents took up the nationalist demand for a revision of the treaty of 1936—in particular for the complete evacuation of British troops from Egypt and the ending of British control in the Sudan. Politics were passing into the hands of radicals. The Muslim Brotherhood, founded in 1928, developed from an orthodox Islāmic reformist movement into a militant mass organization. Demonstrations in Cairo became increasingly frequent and violent. The pressure rendered it impossible for any Egyptian government to attempt a settlement of its two main external problems: treaty revision with Britain, and Palestine. Negotiations with Britain, undertaken by an-Nuqrāshī and (after February 1946) by his successor, Ṣidqī, broke down over the British refusal to prejudice the possible independence of the Sudan. Although Egypt referred the dispute to the United Nations in July 1947, the deadlock continued.

Anti-British demonstrations

Until the interwar period neither the Egyptian public nor the politicians had shown much interest in Arab affairs generally; Egyptian nationalism had developed as an indigenous response to local conditions. After 1936, however, Egypt became involved in the Palestine problem, and in 1943–44 it played a leading part in the formation of the Arab League. After World War II, Egypt became increasingly committed to the Arab cause in Palestine, but its unexpected and crushing defeat in the first Arab–Israeli War (1948–49) contributed to disillusionment and political instability. The Muslim Brotherhood increased its terrorist activities. An-Nuqrāshī, again prime minister, endeavoured to suppress the organization and was assassinated in December 1948. The brotherhood's leader was murdered two months later.

A general election in January 1950 gave the Wafd a majority, and an-Naḥḥās again formed a government. Failing to reach agreement with Britain, in October 1951 he abrogated both the 1936 treaty and the Condominium Agreement. Anti-British demonstrations were followed by guerrilla warfare against the British garrison in the Canal Zone. British military action in Ismailia was followed on January 26, 1952, by the burning of Cairo by demonstrators. An-Naḥḥās was dismissed, and there were four prime ministers in the ensuing six months.

THE REVOLUTION AND THE REPUBLIC

The Wafd and the old political parties were thoroughly discredited, the King hardly less so. Since late 1949 a number of young officers had been organizing a conspiratorial movement. The King became aware of the challenge at the end of 1951, and when he tried to regain control of the situation by appointing his brother-in-law as war minister, the Free Officers (as they were now known) carried out an armed coup in July 1952. Farouk was forced to abdicate and leave Egypt, his infant son being proclaimed king as Fu'ād II with a council of regency.

Abdication of Farouk

Struggle for power. For the next 12 months the chief Free Officers, organized as the Revolution Command Council (RCC), groped their way toward the establishment of a new regime. Their leader, Col. Gamal Abdel Nasser, was at first less prominent than an older officer, Gen. Mohammad Naguib. In September 1952, Naguib took over from ʿAlī Māhir, the last civilian prime minister, and two days later an Agrarian Reform Law was decreed. This was not only a token measure of radical social legislation but also an attack on the landholders who were closely associated with the old regime. Meanwhile, both the Muslim Brotherhood and the old political parties were active. In December 1952 the constitution of 1923 was abolished, and a month later the parties were dissolved and their funds seized. To build up mass support, an organization headed by Nasser and styled the Liberation Rally was set on foot. Finally, in June 1953, Egypt was formally declared a republic, Naguib combining the posts of president and prime minister, with Nasser as his deputy and minister of the interior. Publicized trials of former politicians and the propagandist activities of a Ministry of National Guidance were used to strengthen the new regime.

The Muslim Brotherhood had hoped to profit from the downfall of the monarchy and of the old parties to acquire power, and it was a serious challenge to the RCC. An attempt by a Muslim Brother to assassinate Nasser in October 1954 was followed by rigorous measures against the movement, and its power was at last broken. In the meantime, a division had appeared in the RCC itself, between a faction associated with Naguib and another headed by Nasser. An attempt to remove Naguib in February 1954 proved premature, but Nasser finally became prime minister in April. Naguib was still president, but he was dismissed and held under house arrest in November. The recognition of Nasser's supremacy came with the promulgation of a new constitution in January 1956, establishing a presidential system of government. In the following June a plebiscite approved the constitution and formally elected Nasser as president.

Ascendancy of Nasser

The abolition of the old regime and the creation of a new political establishment in Egypt between 1952 and 1956 was accompanied by analogous developments in foreign affairs. Coming to power without previous commitments, and with the means to dominate the manifestation of public opinion imprudently encouraged by its predecessors, the military government was able rapidly to reach a settlement with Britain of the two problems of the Sudan and the Canal Zone. An agreement signed in 1953 established a transitional period of self-government for the Sudan, and it became an independent republic in January 1956. Its subsequent relations with Egypt have varied in cordiality. A second Anglo-Egyptian agreement, in 1954, terminated the 1936 treaty and provided for the British evacuation of the Canal Zone. In June of the following year, the last British troops left Egypt.

Egypt and the U.A.R. Signs were already appearing of a rift between Egypt and the West. The negotiation by Britain of the Baghdad Pact with Pakistan, Iran, Turkey, and Iraq was seen by the military government as an attempt to isolate Egypt. In reaction, Nasser turned in 1955 to association with the Afro-Asian states in the Bandung Conference and obtained arms from Czechoslovakia. Matters came to a head in the following year, when, in reply to the denial of funds previously promised by the U.S. and Britain for the construction of a high dam at Aswān, Nasser announced the nationalization of the Suez Canal and expropriated the company. The ensuing crisis culminated in hostilities against Egypt by Israel, threatened by Egypt's emancipation from British control; by France, alarmed at Egyptian aid to the revolt in Algeria; and by Britain, resentful of the policies pursued by the military government. Pressure on Britain and France by the U.S. and the Soviet Union ended the brief Suez War (October 29–November 7, 1956), but a casualty was the

Suez War

Anglo-Egyptian agreement on the Canal Zone, abrogated by Egypt early in 1957.

The unsuccessful Franco-British intervention increased Nasser's prestige in Egypt and the Arab world generally, and from that date he confidently pursued for a decade a more radical line in both domestic and foreign policy. His ambitious attempts to acquire a dominating position in the Islāmic world were disappointing. Early in 1958 Syria combined with Egypt to form the United Arab Republic (U.A.R.), but it was a reluctant marriage of convenience and was dissolved in September 1961, with Egypt retaining the new designation. After the secession of Syria, an elected National Congress the next spring approved a National Charter, which set up still another organization to associate the masses with the government, the Arab Socialist Union (ASU). In March 1964 a new National Assembly was elected, and a new constitution (again placing supreme power in the hands of the president) was proclaimed by Nasser.

Throughout this period, the potential military danger from Israel was an important factor in the calculations of the U.A.R. government. Fear of Israel was a motive in turning the U.A.R. toward the Soviet bloc and led to a series of initiatives for cooperation among the Arab states, which, however, had little practical outcome. For 10 years peace on the borders of Israel was precariously maintained by the presence of observers from the United Nations. When, in June 1967, they were withdrawn from the U.A.R. frontier on Nasser's demand, the Israeli government launched a pre-emptive strike on the U.A.R. and Jordan. When the Six-Day War ended, Israeli forces occupied the whole of the Sinai Peninsula. The Suez Canal ceased to be a strategic and commercial artery and became a fortified ditch between the two belligerents. Small-scale military activity continued during the following years, with the U.A.R. becoming steadily more dependent upon the Soviet Union to safeguard its cities and air space against Israeli attack. In the summer of 1970, pressure by the U.S. and the Soviet Union on Israel and the U.A.R., respectively, brought both sides to initiate negotiations through the UN. The talks, however, broke down; and in September a new crisis appeared in Jordan, where operations of King Hussein's forces against the Palestinian guerrillas and refugees resulted in civil war. Nasser's mediation secured an agreement between Jordan and the Palestine Liberation Organization (PLO), but Nasser died a few hours later (September 28, 1970).

Six-day Arab–Israeli war

(P.M.Ho.)

Sadat succeeds Nasser. Nasser was succeeded as president by his friend and colleague Anwar as-Sadat. After nearly 18 years of strong leadership by one man, Sadat had to shift policies and governments frequently. This period was marked by a gradual lessening of restrictions, including the reformation of the ASU and a new constitution in 1971 and the abolition of censorship in 1974; this was not accomplished, however, without political opposition and street demonstrations.

Sadat completed negotiations with Libya and Syria (Syria replaced The Sudan as the originally planned third partner) in the federation of the Arab Republic of Egypt in September 1971. It was agreed that Cairo would serve as the capital and Sadat as the head of a three-man Presidential Council. Relations among the partners, however, and especially between Egypt and Libya, continued under frequent strain, and by 1974 the federation virtually ceased to exist.

Although Pres. N.V. Podgorny of the Soviet Union had joined Sadat in the opening of the Aswān High Dam in January 1971, and the Soviet Union had agreed to finance the resulting rural electrification program, Egyptian–Soviet relations deteriorated to the extent that in July 1972 Sadat announced the withdrawal of all Soviet military advisers and personnel. In 1973 Sadat made progress in his relations with West Germany, Jordan, and Saudi Arabia; but in the period of détente between the U.S. and the Soviet Union the "no peace, no war" policy with Israel appeared likely to perpetuate the Israeli occupation of Egyptian and Syrian territories.

Egyptian–Soviet relations

Therefore, after frequent, but unfulfilled, warnings, on October 6, 1973, Egypt and Syria attacked Israel on both fronts. They met with initial success, but by October 23 the Egyptian Third Army was surrounded on the west bank of the Suez Canal, and the Israelis had driven the Syrians to within 20 miles of Damascus. UN peacekeeping forces were brought in, and beginning October 28 Egyptians and Israelis negotiated directly for the first time since 1956. A Middle East peace conference began in December at Geneva, and Henry A. Kissinger, the U.S. secretary of state, became the leading arbitrator; agreements were reached on January 18, 1974, on the Suez front and May 29 on the Syrian–Israeli border. The resulting disengagement changed little except that the canal was cleared of mines and sunken ships and was reopened on June 5, 1975, the eighth anniversary of its closing.

Tensions between Egypt and the Arab world, on one side, and Israel, on the other, continued, with the question of the Palestinian refugees a major issue. Sadat played an important role in 1974 in persuading King Hussein of Jordan to recognize the PLO as representing all Palestinians.

Kissinger continued to serve as a mediator, resulting in a pact signed in Geneva in September 1975, with Egypt renouncing the use of force and guaranteeing Israel merchant-shipping rights to the Suez Canal in return for a further Israeli withdrawal in the Sinai.

In 1976 the Egyptian economy was plagued by a large trade deficit and foreign debt and an annual rate of inflation of about 30 percent. Despite these difficulties, Sadat was re-elected on September 16 and the ASU won more than two-thirds of the seats in parliamentary elections. Economic unrest culminated in major rioting on January 18–19, 1977, in Cairo, Alexandria, and other Delta cities. Troops were called in to quell the disturbances, and 1,600 persons were arrested. The government then attempted to tighten its control of political activity, and on June 29 a law was passed to reform the country's political structure.

Election of 1976

Sadat initiated a move to bring peace to the Middle East when he spoke before the Israeli Knesset in Jerusalem on November 20, 1977. This was followed by his announcement on November 27 of a conference to be held in Cairo to clear away obstacles to the resumption of the Geneva conference. These moves were strongly opposed by Algeria, Libya, Syria, Iraq, Yemen (Aden), the PLO, and the Soviet Union but were supported by Israel and the United States. The conference opened in Cairo on December 14, with Egypt and Israel participating, and the Israeli prime minister, Menahem Begin, met with Sadat in Ismailia on December 25–26. Negotiations continued into 1978, with Sadat maintaining that resolution of the claims of the Palestinians was essential to any total peace settlement.

(Ed.)

BIBLIOGRAPHY.

Ancient Egypt: *The Cambridge Ancient History,* 3rd ed., vol. 1 and 2, each in 2 pt. (1970–71), an up-to-date account, newly written by a team of international scholars—for Egypt it takes the story down to the end of the 21st dynasty; ETIENNE DRIOTON and JACQUES VANDIER, *L'Égypte,* 4th ed. (1962), a student's history, with excellent detailed notes on particular problems; SIR ALAN H. GARDINER, *Egypt of the Pharaohs* (1961), a very personal history, notable for the use made of Egyptian texts, by one of the greatest modern scholars; WILLIAM C. HAYES, *The Scepter of Egypt,* 2 pt. (1953–59), a cultural history of Egypt down to the end of the 20th dynasty, based on the collections in the Metropolitan Museum of Art, New York, by the leading U.S. scholar of the postwar period; WILLIAM C. HAYES, *Most Ancient Egypt* (1965), a fragment of a general history of Egypt that deals brilliantly with the earliest periods down to Badarian times; HERMANN KEES, *Das alte Ägypten,* 2nd ed. (1958; Eng. trans., *Ancient Egypt,* 1961), a cultural topography of ancient Egypt in which all of the great cities and districts are treated (a mine of information); W.S. SMITH, *The Art and Architecture of Ancient Egypt* (1958), the best general account of Egyptian art available, especially good for the Old and Middle Kingdoms.

Egypt from the 18th dynasty to 332 BC: Basic general histories with chapters on the 18th dynasty until 332 BC are SIR ALAN H. GARDINER, *Egypt of the Pharaohs* (1961); ETIENNE DRIOTON and JACQUES VANDIER, *L'Égypte,* 4th ed. (1962), containing extensive bibliography; and WOLFGANG HELCK (ed.), *Geschichte des Alten Ägypten* (1968). In JOHN A. WILSON,

The Burden of Egypt (1951), the discussion of this period is more selective and interpretative. The history and culture of the New Kingdom receive excellent treatment in GEORGE STEINDORFF and KEITH C. SEELE, *When Egypt Ruled the East*, 2nd ed. (1957); and WILLIAM C. HAYES, *The Scepter of Egypt*, pt. 2 (1959). *The Cambridge Ancient History*, rev. ed., vol. 2, ch. 8, 9, 19, 23, and 35 issued in fascicles (1962–66), are detailed discussions by various scholars on certain phases of New Kingdom history. Indispensable for foreign relations during the New Kingdom is WOLFGANG HELCK, *Die Beziehungen Ägyptens zu Vorderasien im 3. und 2. Jahrtausend v. Chr.* (1962). The rise of the New Kingdom is admirably treated in JURGEN VON BECKERATH, *Untersuchungen zur politischen Geschichte der zweiten Zwischenzeit in Ägypten*, ch. 5 (1964). DONALD B. REDFORD, *History and Chronology of the Eighteenth Dynasty of Egypt: Seven Studies* (1967), includes an excellent chapter re-evaluating Hatshepsut. An informative account of the height of the empire is ELIZABETH RIEFSTAHL, *Thebes in the Time of Amunhotep III* (1964). Both CYRIL ALDRED, *Akhenaten, Pharaoh of Egypt* (1968); and F.J. GILES, *Ikhnaton: Legend and History* (1970), contain interesting interpretations of the controversial Amarna period, though a long co-regency period is assumed. A comprehensive account of Tutankhamen and his tomb is CHRISTIANE DESROCHES-NOBLECOURT, *Vie et mort d'un pharaon: Toutankhamon* (1963; Eng. trans., *Tutankhamen: Life and Death of a Pharaoh*, 1963). Since the dated discussion of JURGEN VON BECKERATH, *Tanis und Theben* (1951), no comprehensive work on the Ramesside period has appeared. EDWARD F. WENTE, *Late Ramesside Letters* (1967), deals with material from the very end of the period. A good general work treating Egyptian society and culture is CYRIL ALDRED, *The Egyptians* (1961). WOLFGANG HELCK, *Zur Verwaltung des mittleren und neuen Reichs* (1958), is basic for the administration and civil service, while HERMANN KEES, *Das Priestertum im ägyptischen Staat, vom neuen Reiche bis zur Spätzeit* (1953), is a scholarly analysis of the priesthoods, more popularly treated in SERGE SAUNERON, *Les Prêtres de l'ancienne Égypte* (1957; Eng. trans., *The Priests of Ancient Egypt*, 1960). For the period of the 21st to 25th dynasties, HERMANN KEES, *Die Hohenpriester des Amun von Karnak von Herihor bis zum Ende der Äthiopenzeit* (1964), is important. The best work on the Saite 26th dynasty until Alexander is F.K. KIENITZ, *Die politische Geschichte Ägyptens vom 7. bis zum 4. Jahrhundert vor der Zeitwende* (1953), with Egyptian and classical sources.

Hellenistic and Roman Egypt: The most important works on this period include: H.I. BELL, *Egypt, from Alexander the Great to the Arab Conquest* (1948); E.R. BEVAN, *A History of Egypt Under the Ptolemaic Dynasty* (1927); AUGUSTE BOUCHE-LECLERCQ, *Histoire des Lagides*, 4 vol. (1903–07); N. LEWIS, "Greco-Roman Egypt, Fact or Fiction?," *Proceedings of the Twelfth International Congress of Papyrology*, American Studies in Papyrology VII, pp. 3–14 (1970); M.I. ROSTOVTZEFF, *The Social and Economic History of the Hellenistic World*, 3 vol. (1941); *The Social and Economic History of the Roman Empire*, 2nd ed., 2 vol. (1957); C.B. WELLES, *Alexander and the Hellenistic World* (1970); J.G. MILNE, *A History of Egypt Under Roman Rule*, 3rd ed. rev. (1924); A.H.M. JONES, *The Later Roman Empire, 284–602: A Social, Economic, and Administrative Survey*, 2 vol. (1964); CLAIRE PREAUX, *L'Économie royale des Lagides* (1939); J. MODRZEJEWSKI, "La Règle de droit dans l'Égypte ptolémaïque," *Essays in Honor of C. Bradford Welles*, American Studies in Papyrology I, pp. 125–173 (1966); "La Règle de droit dans l'Égypte romaine," *Proceedings of the Twelfth International Congress of Papyrology*, American Studies in Papyrology VII, pp. 317–377 (1970); LUDWIG MITTEIS and U. WILCKEN, *Grundzüge und Chrestomathie der Papyruskunde* (1912); M.I. ROSTOVTZEFF, *A Large Estate in Egypt in the Third Century B.C.* (1922); and S.L. WALLACE, *Taxation in Egypt From Augustus to Diocletian* (1938).

Egypt from c. 630–c. 1800: There are two standard works that survey medieval Egyptian history as a whole: STANLEY LANE-POOLE, *A History of Egypt in the Middle Ages* (1901); and GASTON WIET, *L'Égypte arabe de la conquête arabe à la conquête ottomane, 642–1517 de l'ère chrétienne*, vol. 4 of *Histoire de la nation égyptienne*, ed. by GABRIEL HANOTAUX (1938). Each of these is outdated in many respects, but each has the virtue of presenting an accurate summary of the political history of the period, based on primary Arabic sources; also, both are strong on Egyptian architecture as an insight into political, social, and economic history. For the economic history, SUBHI LABIB, *Handelsgeschichte Ägyptens im Spätmittelalter, 1171–1517* (1965), is a pioneering work; Labib has summarized this book in English in the form of an article: "Egyptian Commercial Policy in the Middle Ages," in *Studies in the Economic History of the Middle East*, ed. by M.A. COOK, pp. 63–77 (1970). Labib's book should be supplemented by another article: ROBERT LOPEZ, HARRY MISKIMIN, and ABRAHAM UDOVITCH, "England to Egypt, 1350–1500: Long-Term Trends and Long-Distance Trade," *Studies in the Economic History of the Middle East*, pp. 93–128 (1970). AZIZ S. ATIYA, *A History of Eastern Christianity* (1968), is authoritative for Coptic history. For the beginnings of Muslim Egypt, ALFRED J. BUTLER, *The Arab Conquest of Egypt and the Last Thirty Years of the Roman Dominion* (1902), has not yet been superseded; however, it should be supplemented by FRANCESCO GABRIELI, *Maometto e le grandi conquiste arabe* (1967; Eng. trans., *Muhammad and the Conquests of Islam*, 1968), for the conquest; and by DANIEL C. DENNETT, *Conversion and the Poll Tax in Early Islam* (1950), for Muslim tax policy in Egypt. For the Ṭūlūnids, there is only ZAKY MOHAMED HASAN, *Les Tulunides* (1933). MARIUS CANARD, *Les Institutions des Fâtimides en Égypte* (1957), is good for Fāṭimid history, but Fāṭimid studies have been recently transformed by S.D. GOITEIN with the publication of his *Mediterranean Society: The Jewish Communities of the Arab World as Portrayed in the Documents of the Cairo Geniza*, vol. 1, *Economic Foundations* (1967). Three articles by H.A.R. GIBB are definitive for Egypt under the Ayyūbids and during the Crusades, all published in *A History of the Crusades*, ed. by KENNETH M. SETTON, 2nd ed., 2 vol. (1969): "The Caliphate and the Arab States," 1:81–98; "The Rise of Saladin," 1:563–89; "The Aiyūbids," 2:693–714. For Mamlūk and Ottoman Egypt, see the bibliography for the article MAMLUKS; this should be supplemented by F.R.C. BAGLEY, "Egypt and the Eastern Arab Countries in the First Three Centuries of the Ottoman Period," in *The Muslim World*, vol. 3, ed. by F.R.C. BAGLEY, pp. 50–96 (1969).

Egypt since 1800: J.M. AHMED, *The Intellectual Origins of Egyptian Nationalism* (1960), particularly concerned with the nationalists of the period from 1892 to 1914, by a Sudanese scholar; GABRIEL BAER, *A History of Landownership in Modern Egypt 1800–1950* (1962), essential to the understanding of the social and economic history of modern Egypt; P.M. HOLT, *Egypt and the Fertile Crescent, 1516–1922* (1966), outlines the political history of modern Egypt in relation to that of neighbouring Arab lands; P.M. HOLT (ed.), *Political and Social Change in Modern Egypt* (1968), a collection of papers by various scholars on aspects of political, social, and economic history; J.C. HUREWITZ, *Middle East Politics: The Military Dimension* (1969), a general study of the phenomenon of military rule in the Middle East, with a section on Egypt since the revolution of 1952; JACOB M. LANDAU, *Parliaments and Parties in Egypt* (1953), an important investigation of constitutional and political developments under the khediviate and monarchy; HELEN ANNE B. RIVLIN, *The Agricultural Policies of Muḥammad ʿAlī in Egypt* (1961), covers a wider range of topics than the title suggests—*e.g.*, the administrative, technological, and military developments under Muḥammad ʿAlī; R.L. TIGNOR, *Modernization and British Colonial Rule in Egypt, 1882–1914* (1966), an examination of the British system of government in Egypt; P.J. VATIKIOTIS, *The Modern History of Egypt* (1969), a comprehensive and detailed study of particular value for recent times.

Egyptian Law

Egyptian law is the law that evolved from the beginnings of Nile civilization in the 4th millennium BC down to the era of Roman occupation, from 30 BC. Thus, Egyptian law has a history of some three millennia—longer than that of any other civilization. Its earliest traces date from the time of the unification of Upper and Lower Egypt (roughly corresponding to the Nile Valley and the Delta) under King Menes, about 3100 BC. He stood first in the long line of pharaohs constituting 31 dynasties, the most important of which are traditionally grouped into the Old Kingdom (*c.* 2686–*c.* 2160 BC), the Middle Kingdom (*c.* 2040–1786), and the New Kingdom (1567–1085). Between these high moments there were periods of decline in political institutions and in both public and private law. In the period following the New Kingdom (or Empire), the central authority weakened, and the country split up into small states, with a theocratic regime in Upper Egypt. Egypt was successively conquered by Ethiopians, Assyrians, Persians, and Alexander the Great. When one of Alexander's Macedonian generals, Ptolemy, seized the Egyptian throne in 305 BC, there was inaugurated a period of Hellenistic influence, followed by a period of Roman influence, with certain aspects of Egyptian law slowly merging with Greek and

Roman imperial law. Evidence from the late Roman period (3rd to 5th centuries AD) shows, however, that, even though Egyptian law was submerged for many centuries in the great cities, it had been retained, along with the Egyptian language, in the country as a whole.

The administration of ancient Egyptian law was closely related to the institution of kingship and the concept of a divine pharaoh. The pharaoh's will was supreme; government was by royal decree. The complexity and all-embracing nature of the king's official duties as head of all branches of administration, however, forced him, at an early period, to delegate his powers. From the period of the Old Kingdom these delegated powers were largely in the hands of province governors. But the most powerful man in the state, next to the pharaoh himself, had become the vizier, who oversaw virtually every branch of state administration, domestic and foreign. In the area of law, he tried cases and appointed lower magistrates. In his office were filed records of every department of government, private wills and contracts, and royal decrees.

Sources of Egyptian law

Although, according to Greek historians, several pharaohs had reputations as lawgivers, no Egyptian code of laws has been preserved. Before the Late Period, only traces of law from writings on papyri and stone exist, together with remnants of such items as accounts, deeds, and contracts. Excerpts from acts that have been saved are imprecise, because the Egyptians reproduced only the essentials, and the essentials are at times so brief as to inspire considerable argument among modern historians. With the advent of the demotic language in the 7th century BC, documents became more numerous, because many transactions that had previously been accomplished orally now required written deeds. Yet there still is no code of law, but it may perhaps be possible in the future to reconstruct such a code from the hundreds of legal documents discovered, many of which remain to be published. From the information that is available, it is possible to know some elements of the legal relationships that existed among the people of the Nile Valley during their long history.

SUBJECTS AND INSTITUTIONS OF EGYPTIAN LAW

The law of persons. *Status.* In Egypt both public and private law emphasized the importance of the individual, and, as a result, women as well as men had full rights under the law. A woman could own and alienate property, be a party to a contract, file suit, make a will, and bear witness without the assistance of a father or husband. These rights were not exclusively limited to the wealthier classes. Workers, too, had certain rights of possession, alienation, suit, witness, and contract. Even slaves, although they could be purchased as merchandise, had a measure of civil status, since they could possess property and dispose of it as they wished.

Marriage. In Egypt, marriage was monogamous, although exceptions were made for the king and princes during feudal times. Each party had definite rights within the marriage, so it is likely that the union was brought about without restrictions being imposed by the respective families. The marriage contract, on the other hand, was very strict. The couple set up certain property as conjugal property, in which the man had an interest in two-thirds, the woman in the remainder. The man administered this property and saw that acquisitions were distributed in accordance with prescribed proportions. In addition to this, each party was able to possess his or her own property.

Having children was the purpose of marriage, and those who did not have any were advised to adopt. In a particular case, three children were born to a female slave, the father apparently being the master of the household. Since he had no children within his marriage, his wife adopted the children born to the slave, after his death. From the moment of adoption they were automatically free, without having to submit to any emancipation procedures (the same was true when a slave married a free woman). In addition, the children became her heirs.

It is necessary to point out that the slave who bore the children had been purchased during the marriage and constituted an acquisition of the joint estate. The wife was able to adopt the children only because she had been made universal heir by her husband; otherwise, she would have been able to have only one-third of the slaves and one-third of the offspring at her disposal, with the property representing the husband's two-thirds passing to his nearest blood relative.

Divorce. There is no evidence that divorce occurred before the Late Period (1085–332 BC). When its occurrence is recorded, it appears to have been accomplished with a minimum of discomfort to the parties and with considerable respect for the rights of each. The Egyptian method of divorce apparently influenced the practices of diverse peoples living under Egyptian rule. Aramaic texts from the city of Elephantine in the 5th century BC show that members of the Jewish colony gave up divorce by repudiation in order to practice that pronounced by judicial decision.

Family and succession. It is not known at what age children reached legal majority, but paternal authority over them then ceased to exist. In certain periods this authority, as well as the family property, passed on to the eldest son; but at other times masculine primogeniture was not followed, and the inheritance was divided equally among the children. At the very end of the 18th dynasty (1567–1320 BC), because of the individualistic pressures of the time, the vizier was forced to allow the division of a military benefice among the various members of a family, even though the benefice had been transmitted through one member since the beginning of the dynasty. Even when masculine primogeniture predominated, there is evidence that the remaining children as well as the spouse had some guarantee of receiving a share in the estate. The wife could become universal heir only if there were no children, although she was always permitted at least a partial legacy. The property of the wife passed to her children at the moment of her death, with the exception of that part of the property acquired in common, which was to be maintained for the enjoyment of the surviving spouse.

Egyptians were able to will part of their belongings, with the surplus being governed by the law of succession. Men and women could depart from this law by drawing up an act called an *imyt-per* or enregistered document. There is, for example, a record of a woman disinheriting some of her children; and there is a record of a man favouring one of his daughters by explicitly upholding her rights over the part of his property that should have gone to the rest of his children.

The house document

Children, as coheirs of their parents, were responsible for the cost of burying them, even if they were not charged with the actual act. For this reason, most people set up perpetual foundations to pay for these expenses and those associated with maintaining the tomb after death. Often members of the family would be appointed "funerary priests" with the responsibility for tomb maintenance; they would have usufructuary rights (rights of use and enjoyment) in the products of the foundation but could not divide it among their children.

Property and contracts. Each person was able to dispose of his property as he wished, even to the extent of making such property inalienable, as with a perpetual foundation for the maintenance of one's tomb. Originally, transfer of property was accomplished orally before a local, or the central, bureau, and recorded by a scribe, and the earliest documents of transfer specified a definite price. The agreement took place without actual payment or delivery, but it is possible that at least one of the two operations was required in order to make the agreement perfect. Later, with the rise of the demotic language, different procedures were initiated; every buyer had to have in his hands a written deed that gave to him the right of ownership and another that ensured him the enjoyment of it.

In Egyptian law, property transfers were not separated from contractual agreements. Indeed, such things as the hiring out of slaves for a day's work were considered to be sale, and work was freely traded for cattle and other commodities. Any agreement created certain obligations,

and the law that was to be applied to them was determined by the wishes of the parties involved. Guarantees were offered against defects in the property and restrictions in its use and against defects in the law.

Court procedures. Egyptian judicial procedure was accusatory, and it was the responsibility of the plaintiff to bring the matter before the tribunal. If the court held the issue to be admissible, the defendant was cited to appear before the court. The two parties acted for themselves without the aid of professional advocates, but the scribes working for the judicial administration were able to furnish necessary information on procedures and other matters. After both parties spoke, documentary information was presented, then both parties spoke again; debate ended at this point unless there was a call for witnesses. The decision was made, as a rule, on the documents; if convincing ones were not available, then the judge ruled on previous testimony. The judgment settled the issue, explaining the grounds, the legal foundation for the decision, and the disposition of the case, along with the administrative procedures for the keeping of the written record of the case.

Criminal law and tort. A judicial hierarchy existed in the area of criminal justice. Certain lesser crimes could be handled by lower officials, whereas more severe ones were taken directly to the vizier; still others could be handled only by the king. An example of this hierarchy can be seen in records dealing with the workers at the Theban necropolis. The workers evidently had the right to group themselves into an assembly that had administrative and judicial powers. In one particular case they took some workers who had slandered their chief and sentenced them to be beaten with sticks. In the case of a woman who had stolen the tool of a worker, and things in a chapel, and then committed perjury, the workers could only conduct the investigation, because the case exceeded their competence. In very serious crimes, this procedure was repeated at a higher level, with the vizier directing the investigation and then turning the matter over to the king for judgment. There were even instances when the king would appoint a special commission to sit in judgment. One such case occurred when there was a plot against Ramses III (ruled 1198–1166 BC), who nominated a special commission to whom he gave full responsibility to deal with the matter. He told the commission members that they were to judge forcefully but should not depart from strict justice.

In general, punishment was severe; beatings and floggings were commonplace, as was mutilation. For more serious crimes, penal servitude and execution were resorted to.

CHARACTERISTICS AND IMPORTANCE OF THE EGYPTIAN LEGAL SYSTEM

Because there is no extant code and few commentaries, any theory of Egyptian law as such must be ascertained from those documents available. One such document, dating from the beginning of the second millennium BC, contains instructions from the king to his vizier, who is told to judge all suits in conformity with the law. Since the laws were general, the vizier had a certain amount of latitude and was able to employ a degree of equity. Still, it seems that he was accountable to the public and was in some cases to use previous judgments as sources for his decisions.

Ancient Egyptian law was remarkable in terms of its lines of application, since it had as its primary objective the promotion of basic human rights. There were, certainly, periods of regression, but these were balanced by others in which great forward strides were made. It is interesting that the work of Bocchoris (last king of the 24th dynasty, 8th century BC), who was deemed a great lawgiver, occurred during a period of social and economic stagnation when a large part of the population had the status of tenant on the great domains owned by the temples. Yet Bocchoris freed the individual, suppressed imprisonment for debt, prohibited the interest of a debt from doubling the capital, and fixed the rules of written contracts; he also initiated certain reforms dealing with the mobility of private property. All these changes were eminently important, but corresponded with the spirit of the Egyptian law in the high points of its history.

Furthermore, Egyptian law had a definite effect on Greek law during the Hellenistic period and later on Roman imperial law. Even before this time, Egyptian influence had been felt on Greek law, for in the early 6th century BC Solon, an early Athenian lawgiver, came to Egypt and was inspired by the legislative work of Bocchoris. The result was a decisive turn in Greek law, although the Greeks never emancipated women as had the Egyptians.

BIBLIOGRAPHY. J. PIRENNE and ARISTIDE THEODORIDES, *Droit égyptien, introduction bibliographique* (1966), contains a thorough bibliography relating to the sources of ancient Egyptian law and the authors who have dealt with the subject, with commentaries and evaluations. J. PIRENNE, *Histoire des institutions et du droit privé de l'ancienne Égypte*, 3 vol. (1932–35), is the major historical description of Egyptian law, although the same author's *Histoire de la civilisation de l'Égypte ancienne*, 3 vol. (1961–63), is a later work containing information on law. E. SEIDL has offered a systematic description of the subjects relating to the private law in *Einführung in die ägyptische Rechtsgeschichte bis zum Ende des Neuen Reiches*, 2nd ed. (1951); *Ägyptische Rechtsgeschichte der Saiten- und Perserzeit*, 2nd ed. (1968); and *Ptolemäische Rechtsgeschichte*, 2nd ed. (1962). Each year since 1957 in the *Revue Internationale des Droits de l'Antiquité*, ARISTIDE THEODORIDES has examined the documents of Egyptian law, with a view toward forming a "corpus" of the texts and a dictionary of technical terms. The juridical texts of the Old Kingdom have been brought together again, with translation, explanations, and commentary, by H. GOEDICKE in *Königliche Dokumente aus dem Alten Reich* (1967) and *Die privaten Rechtsinschriften aus dem Alten Reich* (1970). See also P.W. PESTMAN, *Marriage and Matrimonial Property in Ancient Egypt* (1961); and TYCHO MRSICH, *Untersuchungen zur Hausurkunde des Alten Reiches: Ein Beitrag zum altägyptischen Stiftungsrecht* (1968).

(A.E.T.)

Egyptian Religion

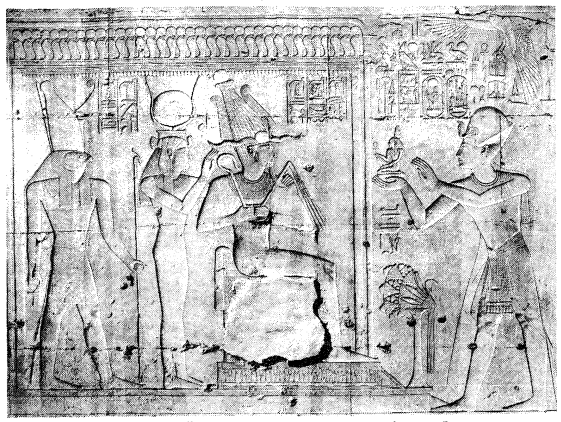
The term Egyptian religion here refers to the indigenous religion of ancient Egypt from the Late Neolithic Period to the first centuries AD, and includes both folk traditions and the court religion of the pharaohs.

NATURE AND SIGNIFICANCE

Egyptian religion shared two characteristics with Egyptian culture in general: longevity and a development that, on the whole, was undisturbed by foreign influence. All manifestations of cultural and social life were so deeply permeated with religious ideas that an understanding of Egyptian culture is impossible without an understanding of Egyptian religion, and vice versa. Egyptian religion had a widespread influence on the neighbouring cultures of its time and on the cultures of later eras. One of the most striking aspects of Egyptian religion was the immense number of gods in human, animal, and material forms, who represented both the powers of nature and abstract ideas. They were never grouped systematically, though tendencies toward systematization were manifest in local groupings of gods and mythical associations. Another characteristic was their lack of distinct personality; *i.e.*, one god could easily be equated with another on the basis of one common feature or embodied power. In addition, they were all immanent, and there was no contrast between the divine and the world. The divinity of the world (cosmos, nature, mankind, society) implied a view of life that extended beyond physical life. The state of death was regarded as part of the well-ordered life cared for by the gods. Various material and ritual guarantees for life after death aided in the realization of this idea.

The divine world order

Thus the world appeared as a large, permanent unity in spite of the multitude of gods and their cults. It was regulated by the rule of pharaoh, whose main task is to establish *maʿat* instead of disorder. *Maʿat* stands for all order in life. The translations "order," "justice," and "truth" indicate its diverse aspects. In social life the demands of ethics help to realize *maʿat*.



King Seti I offering a figure of the goddess Ma'at to Osiris, Isis, and Horus. Relief from the temple of King Seti I, Abydos, *c.* 1300 BC.

Characteristic of Egyptian religious thinking and national character was the toleration of ideas that, from the point of view of later cultures, contradict each other. This toleration was accompanied by the desire to retain ideas and forms once conceived, even when they had been replaced by new ones. As a consequence, the number of mythical, ritual, and theological creations increased in the course of time. It is difficult, therefore, to fix the time of origin and the primary life span of an idea that has become fixed in tradition.

The basic feature of religious feeling was optimism. Notions of an end of the world and skepticism rarely arose, as death was viewed as part of life and the realization of *ma'at* was always possible. Both magic and ritual acts were means to preserve the security of life, as they protected against danger and menace. Egyptian religion can therefore be classified among the typical ritual religions in which faith is less important than correct rites.

SOURCES AND THEIR INTERPRETATION

Tombs

Nonliterary. Tombs provide sources for the knowledge of Egyptian religion in prehistoric as well as later times. Their offering places indicate belief in an afterlife: the dead need offerings of food and drink. A false door enables communication with the world of the living.

Funerary gifts and paintings. Real objects or models provided the deceased with household goods, articles of daily use, and servants, as in life. In the late Old Kingdom after *c.* 2250 BC, and in the First Intermediate Period (*c.* 2160–*c.* 2040 BC), friezes of objects (*i.e.*, paintings of funerary gifts) were added. In this way, it was thought, the property of the dead could be preserved in case the tomb was plundered. From the early 4th dynasty (*c.* 2613–*c.* 2494 BC) on, tomb decorations (reliefs or paintings) occur. The main subjects are the so-called offering lists (lists of the food, drink, clothes, oils, and ointments that the dead needed) and representations of offering rituals and revivification ceremonies (*e.g.*, the "Opening of the Mouth," from the 18th dynasty—1567–1320 BC). In addition, there are the so-called scenes from life (agriculture, cattle breeding, crafts) and, occasionally, from the 6th dynasty (*c.* 2345–*c.* 2181 BC) on, representations of biographical events. Ritual scenes are not represented in tombs, and the king does not appear until the 18th dynasty. In the Old Kingdom (*c.* 2686–*c.* 2160 BC), the pyramid temples of the kings attest the existence of a royal funerary cult similar to that of private persons. From the 5th dynasty (*c.* 2494–*c.* 2345 BC) on they are decorated with scenes from the king's life.

Temples and images. The sun temples are limited to the 5th dynasty for the cult of the sun god, Re. Numerous temples for the gods date from the 18th dynasty to the time of the Roman emperors. The image of the god was kept in the holy of holies ("chamber of the cultic image"), where a daily offering ritual was performed. During festivals it was carried in procession before the public and taken to visit other temples. The ritual scenes decorating the temples of the New Kingdom (1567–*c.* 1085 BC) enable scholars to determine to a large extent the function of the different rooms.

Sculptures of gods in human form are found from prehistoric times on (*e.g.*, Min of Coptos). The different gods are not distinguished by personal features but by attributes or shape—animal, hybrid, or human. Cult implements—portable wooden statues of gods, censers, libation vessels, altars, offering tables—provide clues to religious practices.

Literary sources. *Pyramid Texts and Coffin Texts.* The oldest text collections are the Pyramid Texts inscribed in the subterranean rooms of the pyramids of the kings and the queens from the end of the 5th (*c.* 2345 BC) to the end of the 6th dynasty (*c.* 2181 BC). They contain spells for the offering and funerary rituals, magical texts, and texts pertaining to the king's existence in the hereafter. The Coffin Texts (found on coffins of the First Intermediate Period and the Middle Kingdom—*c.* 2040–1786 BC—and on several papyri) are a collection of spells for private individuals containing copious extracts from the Pyramid Texts, texts from the mortuary cult and the temple ritual, and purely mythological texts.

Book of the Dead. The latest collection is the Book of the Dead: spells written on papyrus and deposited with the dead in the tomb for their use in the hereafter (from the 18th dynasty to the Late Period). Although derived in part from the Coffin Texts, they retain little connection with rituals but are meant to provide the dead with power in the hereafter (which explains why there are so many spells for transformation of the dead into powerful beings). Best known is chapter 125, with the so-called negative confession and the psychostasia (weighing of the soul) in the judgment of the dead.

Psychostasia

Other texts. Further mortuary literature includes offering liturgies (already on a papyrus from the Old Kingdom), texts for the revivification ceremony ("Opening of the Mouth"), and guidebooks to the hereafter (from the 18th dynasty on: *Book of the Two Ways, Amduat,* and others). Ritual texts throwing light on the temple cult and hymns are preserved on temple walls and on papyri from the 18th dynasty on. Rare, however, are theological treatises like the "Memphite Theology," in which the creation of the world, its regulation by Ptah, and the supremacy of Memphis are confirmed theologically. Prayers are handed down in fixed formulas and, beginning in the 18th dynasty, in free form. Mythical subjects mainly are dealt with in ritual texts. Narrated myths form a part of the narrative literature, and the so-called tales are often built upon mythical material.

Later literary sources. The main source in the Old Testament is the story of Joseph in Genesis and Exodus. The Psalms and the apocryphal Wisdom of Solomon show Egyptian influence. Some things have been learned from the correspondence between the pharaohs and the rulers of Syria and Palestine preserved in Tell el-Amarna. The accounts of Greek and Roman historians and travellers are of particular value: Hecataeus of Miletus (6th century BC), Herodotus (5th century BC), Diodorus Siculus (1st century BC), Strabo, the geographer (1st century BC–1st century AD). Egyptian ideas in retouched form are to be found in Plutarch's *De Iside et Osiride* ("Concerning Isis and Osiris") and Apuleius' *Metamorphoses* (*The Golden Ass*). Other important sources are the late lexicographers such as Isidore of Seville (about AD 600) and Suidas (10th century AD).

RELIGIOUS BELIEFS

The gods. Egyptian gods have different forms and personify different powers. There are numerous animal forms: bull gods like Apis at Memphis, Mnevis at Heliopolis, Buchis at Hermonthis; rams like Khnum at Elephantine and the ram of Mendes; falcons like Horus, the god of the king; doglike animals such as the god of the cemeteries, Anubis, and Wepwawet, the "Opener-of-the-Ways"; vulture goddesses like Mut in Karnak and Nekhbet in Elkab. They may also have a human form or a

Table 1: Major Gods and Goddesses

	alternative names	areas of responsibility	principal sanctuary	relations to other deities	symbols and emblems
Amon	Amen, Ammon, Amun	king of the gods; patron deity of the pharaohs; identified with the sun god Re as Amon-Re	originally Khnum, later Thebes	husband of Mut; member of the Theban triad	male figure with a ram's head, or a ram wearing the triple crown
Anubis	Anpu	god of the dead, particularly the aspects of the funeral cult and the care of the dead	Cynopolis	son of Re, or son of Osiris by Nephthys	black jackal, or a male figure with the head of a jackal or dog
Aton	Aten	represented the sun at its zenith; later, for a short time was made the chief and only god (with the exception of the pharaoh)	Akhetaton (Tell el-Amarna)	a form of the sun god Re	a red solar disk with rays terminating in hands
Atum	Tem, Tum	creator of gods, men, and the divine order; founder of the Heliopolitan Ennead; represented the setting sun	Heliopolis	merged with the cult of Re, becoming Atum-Re	old, bearded man wearing the double crown and carrying the *ankh;* sometimes, a male figure with the head of an ichneumon
Bast	Bastet, Ubasti	goddess of music, dance; originally symbolized the fertilizing warmth of the sun; during the New Kingdom thought to be a lioness war goddess	Bubastis	wife of Ptah; member of the Memphite triad; sometimes identified with Sekhmet	cat, or cat-headed woman, holding in her hand either a sistrum or an aegis
Bes	Bisu	originally, protector of the royal house; later, popular god of recreation; also associated with childbirth; the enemy of noxious beasts; protector and bringer of peace to the dead	originated in the Sudan; later adopted throughout Egypt	husband either of Beset, his female counterpart, or of Taurt	dwarf with large head, goggle eyes, protruding tongue, bowlegs, and a bushy tail
Buto	Edjo, Udjo, Wadjet, Wadjit	tutelary goddess of Lower Egypt; defender of the king; personification of the sun's burning heat	Buto	later thought to be the nurse of the infant god Horus	female figure wearing a *uraeus* or the red crown of Lower Egypt; or, a *uraeus* twined around a papyrus stem or as part of the king's diadem
Geb	Keb, Seb	god of the earth; the physical support of the world	Heliopolis	husband and brother of Nut; son of Shu and Tefnut; father of the Osirian gods	a goose or a male figure with his head surmounted by a goose
Hathor	Athyr	originally a personification of the sky; at Dandarah, goddess of festivity and love; protectress of women; at Thebes patroness of the region of the dead; later identified locally with tree, lion, or cow goddesses	originally, Dandarah; later, Ombos, Edfu, and western Thebes	daughter of Nut and Re	cow, cow-headed goddess, or goddess with a human head adorned with horns or cow's ears and heavy tresses framing her face
Horus	Hor	originally the god of Lower Egypt; later identified with the reigning king and thus the opponent of Seth	Nekhen, Edfu, later all of Egypt	son of Osiris	falcon or falcon-headed male figure
Isis	Aset, Eset	queen of the gods; great mother goddess figure; retriever and embalmer of the body of Osiris; protector of the child Horus	originally, Sebennytos; later spread throughout Egypt, the Near East, and the classical world	wife of Osiris; mother of Horus	female figure with both a vulture headdress and a throne or disk flanked by cow's or ram's horns on her head
Ma'at	Mayet	goddess of law, truth, and justice; served as the balance in the scale used to weigh the heart of the deceased	a deified abstract *par excellence;* thus, she had no single cult centre	daughter of Re; wife of Thoth	female figure standing or sitting on her heels, wearing an ostrich feather on her head
Min		personification of the generative force in nature; god of fertility and harvest; protector of desert travellers and god of the road	Coptos, Akhmīm	son of Re, or of Shu	ithyphallic bearded man, his crown surmounted by two tall plumes, and holding a flail or thunderbolt in his right hand
Mut		a vulture goddess of Thebes; a great and mighty divine mother	Thebes	wife of Amon-Re	female figure whose head or headdress was in the form of a vulture or who wears a heavy wig surmounted by the double crown
Nekhbet	Nekhebet	tutelary goddess of Upper Egypt; protectress of childbirth	Elkab (Nekheb)	daughter of Re; wife of Khenti-Amentiu or of Hapi	woman or vulture wearing the white crown of Upper Egypt; often shown spreading wings above king
Nut	Neuth, Nuit	goddess of the sky, arch of the heavens; protectress of the dead	Memphis and the Delta region; also, Dandarah	wife and sister of Geb; mother of the Osirian gods	elongated female figure arched over Shu; often wearing a water-pot or pear-shaped vessel on her head
Osiris	Usire	originally a fertility god and giver of civilization; later, with Re, the supreme god of Egypt and ruler of the dead	Busiris, Abydos	son of Nut and Geb; father of Horus	represented as a dead king in mummy wrappings, the hands holding the crook and flail and wearing the *atef* crown on his head
Ptah	Phthah	god of fertility, creator of the universe, maker of things; the patron of craftsmen and fine arts	originally Memphis, later, all of Egypt	husband of Sekhmet; father of Nefertum; member of the Memphite triad	mummified man with a shaven head his hands holding the *djed* symbol and a sceptre
Re	Phra, Ra	personification of the sun at its zenith; king of the gods and father of mankind; protector of kings; chief state god	Heliopolis	father of Shu and Tefnut, or, alternatively, son of Geb and Nut	falcon-headed man crowned with the sun disk encircled by the *uraeus;* held the *ankh* and a sceptre
Sebek	Sebeq, Sobk, Suchos	originally, perhaps associated with fertility, death, and burial; later, a protector of reptiles and patron of kings; occasionally, a personification of evil	Crocodilopolis; later, Ombos, Thebes, and Lake Moeris	son of Neith; sometimes identified with Seth or with Re (as Sebek-Re)	crocodile or crocodile-headed man wearing on his head either a solar disk and *uraeus* or a pair of horns surmounted by a disk and a pair of plumes
Sekhmet	Sekhet	warlike solar goddess	Memphis and the Delta region	wife of Ptah; mother of Nefertum; member of the Memphite triad	lioness or woman with a lion's head, on which she wore the solar disk and *uraeus*
Seth	Set, Setekh, Setesh	partner and rival of Horus in the Osirian myths	Ombos	brother or son of Osiris	the "typhonian animal": a composite creature with a grey hound's body, slanting eyes, square-tipped ears, and long forked tail
Shu		god of light and air and supporter of the sky; later, personification of the divine intelligence	Dandarah, Edfu, Apollinopolis Magna, Memphis	son of Re; husband and brother of Tefnut	male figure with an ostrich feather on his head
Thoth	Djhowtey	moon god; later the god of reckoning and of learning in general; inventor of writing, scribe of the gods; lord of magic	Hermopolis Magna	protector of Isis during her pregnancy; healer of her son Horus' injury; husband of Ma'at	male figure with an ibis' head on which were placed the moon crescent and disk

hybrid form with an animal head. Powers of nature like Re, the sun; Nut, the sky; Geb, the earth; and Thoth, the moon (and therefore "the reckoner of time"), are mainly rendered in human form but can also assume animal form (*e.g.*, Thoth as ibis or baboon). Ptah of Memphis, the creator-god; Min of Coptos, the god of fertility; Khons of Thebes as moon god; and Osiris as chthonian (underworld) fertility god are mostly human-shaped. Amon-Re of Karnak, usually in human form, can also have the form of a ram or a Nile goose and is looked upon as "breath of life" too. In theological theories each god is attributed as many powers as possible, hence the wide variety of divine manifestations.

Ma'at, the central conception of order, can be called a goddess insofar as she is represented as such, has a temple in Karnak, and is called "daughter of Re." But actually she is an abstract idea apart from the world of the gods.

Cosmogonies

Myths. Cosmogonies and other myths illustrate the order of the world and the cooperation of the gods. One cosmogony presents the image of a primeval hill emerging from the primeval flood (Nu) and bearing the first life. The Heliopolitan cosmogony says that the primeval god, Atum, spat out or coughed up the first couple of gods, Shu and Tefnut (air and moisture), or created them by self-generation. Shu separated heaven (Nut) from earth (Geb). These five gods are thought of as three generations. Osiris, the chthonian fertility god, is joined by Isis, his wife, and Seth, his murderer, who is married to Nephthys, the "Hostess of the House." Horus, the king's god and the son and heir of Osiris, rules here on earth. The myth of Osiris, the dead god, who begets a son out of the underworld, is connected with the cult of the first kings at Abydos. There, the so-called Osiris mysteries, annually re-enacting the mysterious event, developed. To the Egyptian they mean the central point in his hope for life; to the Hellenists they symbolize the mysterious teachings of ancient Egypt. The connection of the gods of the Heliopolitan cosmogony with the gods of the Osiris family as "Children of Nut" makes up a family tree, reaching from the creator-god, Atum, to the ruling king, the "Living Horus."

Human nature and destiny. Man possesses spiritual power extending in part beyond his personal life.

Concepts of soul. First of all there is the *ka*, which, created with the person, can be defined as "vital force" and outlasts man. The bird-shaped *ba*-soul seems to be set free only after death. Gods too have *ba*- and *ka*-souls. The bird-shaped *akh*-soul is also preserved after death and can appear as a ghost or revenant. The heart is considered as the seat of the power of discrimination, and therefore the word "heart" also has the meaning "conscience." Image and name, which mainly play a part in magic, are to a certain extent regarded as independent.

Ethics. Ethics is part of social life. Its rules, preserved in biographies and teachings, do not refer to an absolute good or evil but are meant to guarantee a harmonious coexistence free from the use of force. They differ as to the social rank of the individual. They can be taught and aim to convince by common sense. It is only in the New Kingdom that ethics is directed at man's reflective nature and thus comes into intimate relationship with religion. The first conceptions of this kind can be found in the First Intermediate Period, but it is only later that they become popular belief. Right actions spring from a god-fearing mind, and God inspires man's mind in the right way.

FORMS OF EGYPTIAN RELIGION

Funerary religion. Many rites deal with the provisions for life after death. The dead man's body is preserved by mummification; numerous amulets guarantee its invulnerability. Offerings at the burial and on funerary festivals in the tombs provide him with food and drink. The mortuary equipment, with all its useful and luxurious articles, is at his disposal. All serve the subsistence of the dead, who live in the tombs or return to them. Imagination created various conceptions of the hereafter. In one of them it is situated in heaven. The soul ascends or flies to heaven, lives among the stars or the entourage of the sun, and finds food and all its needs in the fields of the blessed. According to other conceptions, the hereafter is situated in the underworld. The soul finds its way there through passages and doors guarded by doorkeepers, trying to ward it off. It also has to cross watercourses. In books of the hereafter, the underworld is divided into 12 regions, visited by the sun on its nightly course, bringing life for a short period. The idea of a judgment of the dead developed from the hope that the dead person could find a tribunal in the hereafter, where he could sue for his claims. In the early period the dead king or Re or Osiris is the supreme judge. From the First Intermediate Period on, the conception changes; the dead person has to prove his right to enter the hereafter. It is not until the 18th dynasty that the classical picture of the judgment of the dead is formed, with Osiris and 42 judges, before

Conceptions of the afterlife

The judgment of the dead. While Osiris, the ruler of the dead, watches from his throne, the jackal-headed god Anubis weighs the heart of the deceased against the figure of Ma'at. Funerary papyrus from Thebes, *c.* 1025 BC.

whom the heart is weighed against *ma'at* and the deceased recites all the uncommitted transgressions listed in chapter 125 of the Book of the Dead. In spite of all the darkness and dangers, the hereafter is still part of life. It guards against the Egyptians' greatest dread: complete extermination, "repeated death."

Divine kingship: pharaoh as god

The state religion. Pharaoh, the incarnation of the god Horus here on earth, heir to the kingship of Atum, son of the sun god Re, is the centre of the world. The world of the gods is determined by his existence insofar as certain gods (Re, Atum, Ptah, etc.), following his example, acquire the rank of "King of the Gods," are arranged in dynasties, and are placed in traditional histories as god-kings before the earthly kings. The existence of a legitimate pharaoh guarantees the order of the cosmos. This is expressed above all in the king's designation as "Lord of the Ritual." In theory he is the only priest who can perform the daily temple ritual and the festival rituals in accordance with *ma'at*, thus preserving the order of the cosmos, the fertility of the land, and the order and welfare of the empire.

The temple cult. The temple was "god's house," in which the god lived in the form of his cult statue. The daily ritual included the opening of the shrine, the decorating and dressing of the statue, and the offering of food and drink following the daily routine of the king.

Priesthood. The ritual was performed by official priests as representatives of the king. Knowledge of the ritual and maintenance of the rules of purity were the essential requisites for priestly service; a differentiation between priests and laymen seems to have occurred late. The priesthood itself consisted of numerous classes. Large temples had four main priests ("prophets"), numerous minor priests, singers, musicians, scribes, and temple employees. As each temple owned land, villages, workshops, and sometimes even quarries and foreign landholdings, it was virtually an independent economic

unit, with personnel corresponding to its size. During the temple service, hymns and songs describing his nature and activity accompanied the appearance of the god. Formulas naming the objects (incense, food offerings, jewelry, clothes) and identifying both the ritual as a whole and the different objects with mythical elements were part of the ritual. Thus the ritual acts were elevated to a mythical level and drawn into manifold connections with mythical ideas.

Festivals. The numerous festivals were partly of local, partly of general importance. They were held on birthdays of gods, on special calendar days (New Year, first days of the months), at seasonal events (harvest festival), king's ceremonies (coronation, so-called jubilees), and victory celebrations. Important festivals lasted several days. Most of the temple festivals were connected with a procession of the god's image and often with a visit to other temples. On these occasions the god was visible to the public and gave oracles.

Religious, social, and economic roles. Since Egyptian religion was centred on temple ritual, individual faith (*i.e.*, personal piety) was never of primary importance and was therefore perceptible only in later periods. On the other hand, religion played a decisive part in social and economic life. A large part of the population was integrated into the official hierarchy of priests and temple

Table 2: Minor Gods and Goddesses

	alternative names	areas of responsibility	principal sanctuary	relations to other deities	symbols and emblems
Anhur	Onouris	symbolized the creative power of the sun; frequently invoked against enemies and noxious animals	Sebennytus, This	probably a war-like personification of Re	warrior wearing a long embroidered robe and a headdress with four tall plumes; often carries a lance
Anuket	Anqet, Anquet	personification of the Nile as the nourisher of the fields	island of Sahal near Elephantine	second wife of Khnum; sister of Sati; member of the triad of Elephantine	woman wearing a crown of feathers and carrying a sceptre and the *ankh*
Apepi	Apep, Apophis, Rerek	personification of darkness and evil; attempted to obstruct the passage of the solar barque	as the embodiment of evil, Apepi had no worshippers	eternal enemy of the sun god Re	huge serpent
Hapi	Hap, Hep	god of the Nile, particularly of the inundation; bringer of fertility; nourisher of the gods and man	region of the First Cataract	husband of Nekhbet	bearded man coloured green or blue, with female breasts and a clump of water plants on his head
Khenty-Imentiu	Khenti-amentiu, Ophis (or Ophois)	warrior god; god of the dead until deposed by Osiris; at times piloted the sun's boat during its nocturnal voyage	Abydos, Asyut	associated with Osiris during that god's conquest of the world, later identified with Upuaut (Wepwawet)	male figure with the head of a wolf or a jackal
Kheper	Khepera, Khepri	symbolized the daily cycle of the sun across the sky; sometimes thought to be a symbol of the rising sun	Heliopolis	one of the forms of the sun god Re	a scarab pushing the sun across the sky or a man with a scarab on his head
Khnum	Khnemu	god of the cataract region; earlier associated with the abyss of the netherworld; in some places thought to be the potter god who formed the world and its inhabitants	Elephantine	husband of Sati and Anuket; member of the triad of Elephantine	ram-headed male figure
Khons	Khensu, Khonsu, Chons	moon god; during the New Kingdom, an exoroist and healer	Thebes; later all of Egypt	adopted son of Amon and Mut	swathed figure with its head shaven except for the braid of royal progeny and the skull cap holding the lunar disk and crescent
Mont	Mentu, Month	war god of Upper Egypt; during the Middle Kingdom, lord of the sun and sky with Re	Hermonthis	a form of the sun god Re	male figure with the head of a hawk surmounted by the solar disk and two plumes; often carried a curved scimitar
Nefertum	Nefertem, Nefertemu	god of the lotus, thus having a life-giving aspect	Memphis	son of Ptah and Sekhmet (or Bast), third member of the Memphite triad	lion-headed man wearing a headdress composed of a lotus flower, two plumes and two menats
Neith	Neit	goddess of war and the loom	Sais	self-begotten virgin; according to some legends, the mother of Re	carried arrows crossed on an animal skin; on her head, wore the Red Crown of Lower Egypt or a weaver's shuttle
Nephthys	Nebhat	associate of Isis in the Osiris cycle	Heliopolis	mother of Anubis, wife of Seth; sister of Isis, Osiris, Seth, and Horus	female figure wearing horns and the solar disk on her head
Nu	Nun	personification of the primordial watery abyss from which the world was created; and, therefore, the oldest and wisest of all gods	Hermopolis	guarded Shu and Tefnut at birth	male or female figure, sometimes with the head of a frog; occasionally shown plunged up to his waist in water
Sati	Satet, Satis	goddess of the inundation and of fertility	Island of Sahal near Elephantine	principal wife of Khnum; sister of Anuket; member of the triad of Elephantine	female figure wearing the crown of the South and a pair of horns, and holding a sceptre and the *ankh* (or a bow and arrows)
Seker	Sokar, Sokaris	deity of darkness and decay in the earth	Memphis	identified with Ptah and Osiris as Ptah-Seker-Osiris	hawk or hawk-headed mummy
Seshat	Sesheta	goddess of writing and history; measurer of time; foundress of temples	Hermopolis Magna	principal wife of Thoth	female figure wearing a leopard skin and holding a writing reed and a scribe's palette; on her head, a crescent (or two turned-down horns) and two plumes
Taurt	Apet, Opet, Taweret, Thoueris	goddess of maternity, presided over childbirth; during the New Kingdom, a protective household deity	Thebes	often appeared with Bes	pregnant hippopotamus standing on hind legs and holding two plaits of rolled papyrus
Tefnut	Tefnet	personification of the life-giving dew and moisture; received, with Shu, the sun as it broke free from the eastern horizon	Heliopolis	sister and wife of Shu	lioness or a woman with the head of a lion wearing the solar disk and the *uraeus* (occasionally, represented as the *uraeus* itself)

personnel. As knowledge of the holy scriptures and the ability to interpret and reformulate them was required, the higher priesthood achieved a high standard of education. Since the temples were economic units, which at times owned large estates, they constituted a major factor in the national economy. The lands administered by them were in many cases more favourably taxed than private property.

Magic, divination, and popular religion. Magical power—through knowledge of the name, possession of the image, application of the "right" word, and the use of amulets—was a weapon in man's fight against supernatural powers. The boundaries between magic and ritual were fluid. The results desired from ritual actions (fertility, order in nature, etc.) can be ascribed to both magical power and divine activity. Oracles certainly date from early periods, but their importance increased from the New Kingdom on. Political decisions (*e.g.*, the election of the king) and personal affairs (*e.g.*, the beginning of a journey, the choice of a profession) as well as judicial investigations were brought before the god in the form of alternative questions and were apparently decided by movements of the image.

Oracles

Since the public was generally excluded from the temple cult (apart from festival processions), they turned to divine beings and objects outside the temples (*e.g.*, the "Western Peak" at Thebes) or to certain images of gods and kings in the outer districts of the temples (*e.g.*, "Ptah in the Door-Frame" at Madīnat Habu). Statues and tombs of famous deceased were also adored. Some of these "popular gods" were recognized by Egyptian theology and integrated into theological systems (*e.g.*, Imhotep, the architect of King Djoser, is first patron of scribes, later a god and the son of Ptah). The religious revival following the heresy of Amenhotep IV (Akhenaton) originated apart from the official theology and influenced religion for centuries.

RELIGIOUS SYMBOLISM AND ICONOGRAPHY

In accordance with the faculty for abstraction and the limited sense of individuality typical of Egyptian culture as a whole, the representation of religious conceptions was characterized by a series of religious symbols and emblems rather than by the creation of individual god figures. Of all the images of gods, that of Isis with the child Horus on her lap, perhaps the prototype of the Madonna with the Child, is the most noteworthy. The image of the youthful sun god on a lotus blossom also exerted an influence outside Egypt. Among the symbols that were used as ornaments were the *crux ansata* (the symbol of life), the divine eye as symbol of prosperity, the scarab beetle standing for eternal regeneration, the knot of Isis as protective symbol, the crook as sign of kingship, the winged sun as symbol of the sun god, the *djed*-pillar as symbol of endurance, and the *was*-sceptre (a shepherd's staff) and *nefer*-sign as symbols of both fortune and welfare. Significant among architectural forms are pyramids, obelisks, and cavetto cornices, the last, however, having no symbolic value (see also EGYPT, HISTORY OF).

HISTORICAL DEVELOPMENT

A large number of the gods go back to prehistoric times. The images of a cow and star goddess (Hathor), the falcon (Horus), and human-shaped figures of the fertility god (Min) can be traced back to that period. Some rites, such as the "running of the Apis-bull," the "hoeing of the ground," and other fertility and hunting rites (*e.g.*, the hippopotamus hunt), presumably date from early times. To explain the existence of a variety of gods at different places, the following theory is often referred to: Egypt consisted of numerous nomes, or provinces, each having its own gods. When they were united at the beginning of the 3rd millennium BC, they retained their local gods, thus creating the pantheon. This theory cannot be proved. Connections with the religions in southwest Asia cannot be traced with certainty. It is doubtful whether Osiris can be regarded as equal to Tammuz or Adonis or whether Hathor is related to the "Great Mother." There are closer relations with northeast African religions. The numerous animal cults (especially bovine cults and panther gods) and details of the ritual dresses (animal tails, masks, grass aprons, etc.) probably are of African origin. The kingship in particular shows some African elements, such as the king as the head ritualist (*i.e.*, medicine man), the limitation and renewal of the reign (jubilees, regicide), and the position of the king's mother (a matriarchal element). Some of them can be found among the Ethiopians in Napata and Meroe, others among Prenilotic tribes (Shilluk).

The pantheon as synthesis of earlier local gods

The religion of independent Egypt. The history of Egyptian religion is less one of change in cults and gods than one of change in ideas and beliefs within the existing mythological and ritual sphere. In the Old Kingdom the state religion in particular was developed: the king as Horus and son of Re at the head of an ordered and well-organized world. Evidence concerning personal beliefs is almost wholly lacking. The collapse of the Old Kingdom brought with it the dissolution of the old social and intellectual bonds. At this time questions concerning the origin of evil, the end of the world, the responsibility of man, and life in the hereafter were passionately discussed, with the traditional religious forms and figures receding into the background. The concept of the gods became personal and undogmatic.

Although the Middle Kingdom returned to the old forms, the following period showed that the ideas of the First Intermediate Period had not been lost. At the beginning of the New Kingdom, the Egyptian sphere expanded enormously. The boundaries of the empire reached from the Fourth Cataract of the Nile to the upper Euphrates, and the acquaintance with Syrian and Palestinian cultures and religions enriched Egyptian thinking. Foreign gods (Resheph, Astarte, Baal) were worshipped in Egypt. This expansion took place under the supremacy of the god Amon-Re at Karnak. Tensions with his priesthood led to the heresy of Amenhotep IV. Opposing the claim to authority of Amon-Re of Karnak and his priesthood and intending to give an all-uniting god to the empire, Amenhotep IV (Akhenaton) made the sun disk, Aton, the supreme god and proclaimed himself his only interpreter. The attempt to establish a new religion followed the old sun belief and was accompanied by the attempt to create a new style of life and art. His attempt failed because of the god's claim to exclusiveness, his struggle against the existing economic order, his political failure, and, last but not least, his underrating of the belief in Osiris. His death was followed by a restoration period, which tried to extinguish all traces of his innovations. The breakdown of the movement was followed by an apparent restoration of the traditional cults. But religious thought was strongly influenced by the rise of a feeling of guilt and sin that brought the individual into a new ethical relationship to the gods. Individual confessions and prayers and moral justifications of the teachings were symptomatic of the new religious climate.

Amenhotep IV (Akhenaton): the Amarna heresy

In the Late Period various tendencies of religious development can be distinguished. The ethicizing and personalizing of religion continued. The importance of Amon-Re, who was closely linked to the policy of the New Kingdom, decreased, while that of Osiris and his so-called mysteries increased in response to the religious demands of the time. In addition, popular beliefs and their cults came increasingly to the fore: animal cults and oracles grew in number, local gods in importance. Cult prescriptions and purity laws apparently separated priests from laity to a greater extent than before. A discrepancy between cult forms and beliefs can be said to have begun.

Egyptian religion in the Greco-Roman world. When Egypt came under the rule of the Macedonian Ptolemies and later of the Roman emperors, the ancient cults continued to exist in their external forms. According to representations in the temples, the Ptolemaic kings and Roman emperors took the role of the pharaoh. Yet differences are still apparent. The layout of the temples (Dan-

darah, Edfu, Ombos, etc.) was standardized. All sorts of religious texts were written on temple walls, often in purposely mysterious spelling. A special cult for the Ptolemaic kings and queens was introduced in the temples, and some Hellenistic ideas seem to have been adopted and combined with native ideas by the Egyptian priests. The influence of the Egyptian on the Hellenistic mind was undoubtedly stronger than the reverse influence. In the Hellenic world Egyptian gods and cults were widely known through the histories of Hecataeus and Herodotus and the accounts of Greek merchants and mercenaries. Herodotus thought the Egyptian gods to be identical with the Greek ones (Zeus = Amon, Pan = Min, Athena = Neith, etc.).

For political reasons Ptolemy I Soter wanted to create a cult common to Egyptians and Macedonians. The deified Memphite Apis-bull, Osiris-Apis, became the prototype of the god Sarapis and acquired a Greek cultic image alleged to be from Sinope on the Black Sea. Its cultic centre was the new capital, Alexandria, whence the cult migrated to Europe more than to Egypt. The Hellenistic world, which favoured mystery religions with special zeal, adopted the cults of Osiris, Isis, and Horus (Harpocrates), transforming them in the manner of the mysteries of the late classical world. They were spread over the entire Roman Empire. The hymns to Osiris or Harpocrates preserved in Greek are translations of Egyptian texts. The conception of Isis as the goddess of navigation was formed in Alexandria. Not only Sarapis but also Osiris, Isis, and Horus adopted new forms in Hellenistic and Roman art; similarly Anubis was seen as a Roman warrior and Apis as an emperor. Particularly significant as the initiator of theosophy—a system of beliefs concerning God and the world based on mystical insights—is Hermes Trismegistos (in Egyptian, "Thoth the Very Great"), who is said to be the author of the Hermetic Scripts. As the so-called Thrice Great he was acknowledged by Christianity to some degree, because he was supposed to have expounded the Trinity. Egyptian theories often found their way, in many cases newly interpreted, into the philosophy of the late classical world (Plotinus, Neoplatonism) and Gnosticism—a Hellenistic religious movement that viewed spirit as good and matter as evil—(see also HELLENISTIC RELIGIONS; MYSTERY RELIGIONS; PLATONISM AND NEOPLATONISM).

Mystery religions

Egyptian conversion to Christianity and the coming of Islām. Egypt was Christianized very early, probably in the time of the Apostles. St. Mark, the author of the First Gospel, is regarded as the founder of Egyptian Christianity. It is certainly no accident that the Egyptian Christian Church (the Coptic Church) adhered to the Monophysite theory that Christ had one nature (a view held heretical by the Council of Chalcedon in AD 451). This is surely connected with the Egyptian understanding of deity, which made a distinction between a divine and human person unnecessary. Besides that, however, hardly anything of ancient Egyptian religion can be found in Egyptian Christianity. Yet even after the Islāmic conquest (AD 641), many individual features have continued to survive in popular belief and may still be found in the veneration of saints, and in popular customs and superstitions.

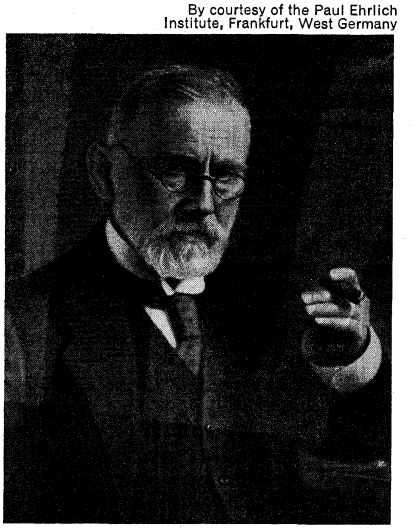
(E.O.)

Ehrlich, Paul

A German medical scientist of great intuitive capacity and rare versatility, Paul Ehrlich, who helped to develop the medical specialties of hematology and immunology, is best remembered for his pioneering work in chemotherapy, especially as the discoverer of the first cure for syphilis. An advocate of "chemical thinking" in medicine and biology, he was among the first to promote teamwork between research and industry. He shared the Nobel Prize for Physiology and Medicine in 1908 for his work on immunity.

By courtesy of the Paul Ehrlich Institute, Frankfurt, West Germany



Ehrlich.

Ehrlich was born on March 14, 1854, at Strehlen, in Prussian Silesia (now Strzelin, Poland), of a Jewish family prominent in business and industry. Although he lacked all formal training in experimental chemistry and applied bacteriology, he did independent work even as a

medical student at the University of Leipzig, writing about the distribution of foreign substances in the body and proving, with the aid of early discoveries in colour analysis, that the chemical mechanism that operates in therapeutic and toxic processes also determines cell nutrition. As a result of this work, Ehrlich was invited to do research at the famous Charité Hospital in Berlin, where he invented a new staining technique for the tuberculosis bacillus discovered by the German bacteriologist Robert Koch. This was an advance that proved to be of decisive importance for the microscopic diagnosis of tuberculosis. While developing new methods for the dyeing of live tissue, he discovered the uses of methylene blue in the treatment of nervous disorders. In other diagnostic advances, he traced a specific chemical reaction in the urine of typhoid patients, tested various medications for reducing or removing fever, and made valuable suggestions for the treatment of eye diseases. Of the 37 scientific contributions that he published between 1879 and 1883, Ehrlich considered the last as the most important: "The Requirement of the Organism for Oxygen." In it he established that oxygen consumption varies with different types of tissue and that these variations constitute a measure of the intensity of vital cell processes. In 1883 he married Hedwig Pinkus, with whom he had two daughters.

A bout with tuberculosis forced Ehrlich to interrupt his work and to seek a cure in Egypt. When he returned to Berlin in 1889, the disease had been permanently arrested. After working for some time in a tiny and primitive private laboratory, he transferred to Koch's "Institute for Infectious Diseases," where he concentrated on the problem of immunity. Very little was known at this time about the precise manner in which bacteria bring about disease, and even less was known about the body's defenses and about therapeutic effects. The working hypothesis that Ehrlich developed and by which he proceeded was the side-chain theory, according to which each cell has a vital centre of protein substance and a series of side chains, or receptors, which absorb and assimilate nutrients and certain toxic substances as well. Only if the haptophore group of a toxic molecule combines with the side chain of the cell can a bacterial toxin act upon a cell. The affected organism then produces great quantities of side chains, all of them "gauged" to the disease-producing toxic agent. These immune bodies prevent a renewed infection, so that the organism is actively immunized (see IMMUNITY).

Side-chain theory

This much-debated hypothesis in all its ramifications was destined to have a profound influence on Ehrlich's later work and on that of his successors. Thus Ehrlich was able to show experimentally that rabbits subjected to a slow and measured increase of toxic matter were able to survive 5,000 times the fatal dose. In the end, he established the precise quantitative patterns of immunity. These findings assumed great importance in 1890, when he met Emil von Behring, who had succeeded in creating an antitoxin against diphtheria. Behring had tried to prepare a serum that could be used in clinical practice, but it was only by adopting Ehrlich's technique of using the blood of live horses that the preparation of a serum of optimum antitoxic effectiveness became possible. Ehrlich developed a way of measuring the effectiveness of sera that was soon adopted all over the world for the standardization of diphtheria serum.

On the basis of these achievements Ehrlich was made director of a government-supported institute in Berlin, which was transferred to Frankfurt on Main in 1899 as the "Royal Institute for Experimental Therapy." No restrictions of any kind were placed upon the direction of his research. While this corresponded to Ehrlich's own talents and inclinations, it did not please Behring, who endeavoured to have his colleague specialize in immunology and serum therapy. The strained relationship between the two men was exacerbated by personality differences. Ehrlich, utterly indifferent to monetary rewards, had no ambition to become an industrialist like Behring; he was content to do his research in study and laboratory.

He had by now recognized the limitations of serum therapy. Many infectious disorders, in particular those caused by protozoa rather than bacteria, failed to respond to serum treatment. The recognition of this fact marks the birth of chemotherapy. Ehrlich started experimenting with the identification and synthesizing of substances, not necessarily to be found in nature, that could kill parasites or inhibit their growth without damaging the organism. He began with trypanosomes, a species of protozoa that he unsuccessfully attempted to control by means of coal-tar dyes. There followed compounds of arsenic and benzene; other compounds proved to be too toxic. Instead of declaring himself vanquished by these difficulties, Ehrlich now turned his attention to the *Spirochaeta pallida*, the causal organism of syphilis.

He had at this time several institutes at his disposal as well as sizeable research funds. He also had a staff of highly competent collaborators; in fact, his colleague, Sahachiro Hata, contributed much to Ehrlich's eventual success in combating syphilis. His preparation 606, later called Salvarsan and still later Neosalvarsan, was extraordinarily effective and harmless despite a large arsenic content. Already the first tests, undertaken in the spring of 1910, proved to be surprisingly successful in the treatment of a whole spectrum of diseases; in the case of yaws, a tropical disease akin to syphilis, a single injection was sufficient. It seemed, indeed, as if a "magic bullet," to use a favourite expression of Ehrlich's, had been found.

Cure for syphilis

Given the devastation wrought by syphilis, a worldwide demand soon arose for a new weapon against the disease. Ehrlich, however, would not yet release his discovery for general use, believing as he did that the usual few hundred clinical tests did not suffice in the case of an arsenic preparation, the injection of which required special precautions. In an unheard-of transaction, the manufacturer with whom Ehrlich had collaborated closely, Farbwerke-Hoechst, released a total of 65,000 units gratis to physicians all over the globe. Although harmful side effects remained nominal in number, some envious competitors did not hesitate to attack Ehrlich. Eventually he was forced to sue the most slanderous among them, and this detractor was given a jail sentence. The greatest distinction bestowed by the Prussian State was the title, "Wirklicher Geheimer Rat," or Privy Councillor, with the predicate of "Exzellens." Along with many other honors, Ehrlich was given honorary doctorates by the Universities of Oxford, Chicago, and Athens, and an honorary citizenship by Frankfurt am Main, where the institute he founded still bears his name.

Having suffered a first stroke in December 1914, Ehrlich succumbed to a second stroke on August 20 of the following year. In its obituary the London *Times* acknowledged Ehrlich's achievement in opening new doors into the unknown, saying, "the whole world is in his debt."

BIBLIOGRAPHY. F. HIMMELWEIT edited Ehrlich's writings in 1956, with a bibliography and four volumes of text in German, English, and French, but this publication does not cover all the posthumous work. There is as yet no comprehensive biography of Ehrlich. See the article by C.H. BROWNING, "Emil Behring and Paul Ehrlich: Their Contributions to Science," *Nature*, 175:570–575, 616–619 (1955); HEINRICH SATTER, *Paul Ehrlich, Begründer der Chemotherapie* (1962); H. LOEWE, *Paul Ehrlich* (1950); and W. GREILING, *Im Banne der Medizin-Paul Ehrlich* (1954).

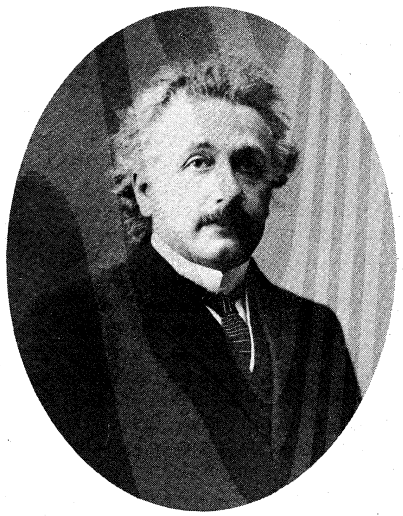
(H.Sa.)

Einstein, Albert

Recognized in his own time as one of the most creative intellects in human history, Albert Einstein, in the first 15 years of the 20th century, advanced a series of theories that for the first time asserted the equivalence of mass and energy and gave entirely new concepts of space, time, and gravitation. His theories of relativity were a profound advance over the old Newtonian physics and revolutionized scientific and philosophic inquiry.

Herein lay the unique drama of Einstein's life: a self-confessed lone traveller, his mind and heart soared with the cosmos, yet he could not armour himself against the

intrusion of the often horrendous events of the human community. Almost reluctantly he admitted that he had a "passionate sense of social justice and social responsibility." His celebrity gave him an influential voice that he used to champion such causes as pacifism, liberalism, and Zionism. The irony for this idealistic man was that his famous postulation of an energy–mass equation,



Einstein.
By courtesy of the Nobelstiftelsen, Stockholm

which states that a particle of matter can be converted into an enormous quantity of energy, had its spectacular proof in the creation of the atomic and hydrogen bombs, the most destructive weapons ever known.

Early life and career. Albert Einstein was born in Ulm, Germany, on March 14, 1879. The following year his family moved to Munich, where Hermann Einstein, his father, and Jakob Einstein, his uncle, set up a small electrical plant and engineering works. In Munich Einstein attended rigidly disciplined schools. Under the harsh regimentation of 19th-century German education, which he found intimidating, he showed little scholastic ability. At the behest of his mother, Einstein also studied music, and, though he played exclusively for relaxation, he became an accomplished violinist. It was then only the influence of Uncle Jakob that stimulated in Einstein a fascination for mathematics and the influence of Uncle Cäsar Koch that stimulated a consuming curiosity about science.

By the age of 12 Einstein had decided to devote himself to solving the riddle of the "huge world." Three years later, with poor grades in history, geography, and languages, he left school with no diploma and went to Milan to rejoin his family, who had recently moved because of his father's business setbacks. Albert Einstein resumed his education in Switzerland, culminating in four years of physics at the renowned Polytechnic Academy in Zürich.

After his graduation in the spring of 1900, he became a Swiss citizen, worked for two months as a mathematics teacher, and then was employed as examiner at the Swiss patent office in Bern. With his newfound security, Einstein married his university sweetheart, Mileva Marić, in 1903.

First contributions to science

Early in 1905 Einstein published in the prestigious German physics monthly *Annalen der Physik* a thesis, "A New Determination of Molecular Dimensions," that won him a Ph.D. from the University of Zürich. Four more important papers appeared in *Annalen* that year and forever changed man's view of the universe.

The first of these, "Über die von der molekularkinetischen Theorie der Wärme geforderte Bewegung von in ruhenden Flüssigkeiten suspendierten Teilchen" ("On the Motion of Small Particles Suspended in a Stationary Liquid According to the Molecular Kinetic Theory of Induction") provided a theoretical explanation of Brownian motion. In "Über einen die Erzeugung und Verwandlung des Lichtes betreffenden heuristischen Gesichtspunkt" ("On a Heuristic Viewpoint Concerning the Production and Transformation of Light"), Einstein postulated that light is composed of individual quanta (later called photons) that, in addition to wavelike behaviour, demonstrate certain properties unique to particles. In a single stroke he thus revolutionized the theory of light and provided an explanation for, among other phenomena, the emission of electrons from some solids when struck by light, called the photoelectric effect.

Einstein's special theory of relativity, first printed in "Zur Elektrodynamik bewegter Körper" ("On the Electrodynamics of Moving Bodies") had its beginnings in an essay Einstein wrote at age 16. The precise influence of work by other physicists on Einstein's special theory is still controversial. The theory held that if, for all frames of reference, the speed of light is constant and if all natural laws are the same, then both time and motion are found to be relative to the observer.

In the mathematical progression of the theory, Einstein published his fourth paper, "Ist die Trägheit eines Körpers von seinem Energieinhalt abhängig?" ("Does the Inertia of a Body Depend Upon Its Energy Content?"). This mathematical footnote to the special theory of relativity established the equivalence of mass and energy, according to which the energy E of a quantity of matter, with mass m, is equal to the product of the mass and the square of the velocity of light, c. This relationship is commonly expressed in the form $E = mc^2$.

Public understanding of this new theory and acclaim for its creator were still many years off, but Einstein had won a place among Europe's most eminent physicists, who increasingly sought his counsel, as he did theirs. While Einstein continued to develop his theory, attempting now to encompass with it the phenomenon of gravitation, he left the patent office and returned to teaching —first in Switzerland, briefly at the German University in Prague, where he was awarded a full professorship, and then, in the winter of 1912, back at the Polytechnic in Zürich. He was later remembered from this time as a very happy man, content in his marriage and delighted with his two young sons, Hans Albert and Edward.

In April 1914 the family moved to Berlin, where Einstein had accepted a position with the Prussian Academy of Sciences, an arrangement that permitted him to continue his researches with only the occasional diversion of lecturing at the University of Berlin. His wife and two sons vacationed in Switzerland that summer and, with the eruption of World War I, were unable to return to Berlin. A few years later this enforced separation was to lead to divorce. Einstein abhorred the war and was an outspoken critic of German militarism among the generally acquiescent academic community in Berlin, but he was primarily engrossed in perfecting his general theory of relativity, which he published in *Annalen der Physik* as "Die Grundlagen der allgemeinen Relativitätstheorie" ("The Foundation of the General Theory of Relativity") in 1916. The heart of this postulate was that gravitation is not a force, as Newton had said, but a curved field in the space–time continuum, created by the presence of mass. This notion could be proved or disproved, he suggested, by measuring the deflection of starlight as it travelled close by the Sun, the starlight being visible only during a total eclipse. Einstein predicted twice the light deflection that would be accountable under Newton's laws.

General theory of relativity

His new equations also explained for the first time the puzzling irregularity—that is, the slight advance—in the planet Mercury's perihelion, and they demonstrated why stars in a strong gravitational field emitted light closer to the red end of the spectrum than those in a weaker field.

While Einstein awaited the end of the war and the opportunity for his theory to be tested under eclipse conditions, he became more and more committed to pacifism, even to the extent of distributing pacifist literature to sympathizers in Berlin. His attitudes were greatly influenced by the French pacifist and author Romain Rolland, whom he met on a war-time visit to Switzerland. Rol-

land's diary later provided the best glimpse of Einstein's physical appearance as he reached his middle thirties:

> Einstein is still a young man, not very tall, with a wide and long face, and a great mane of crispy, frizzled and very black hair, sprinkled with gray and rising high from a lofty brow. His nose is fleshy and prominent, his mouth small, his lips full, his cheeks plump, his chin rounded. He wears a small cropped mustache. (By permission of Madame Marie Romain Rolland.)

Einstein's view of humanity during the war period appears in a letter to his friend, the Austrian-born Dutch physicist Paul Ehrenfest:

> The ancient Jehovah is still abroad. Alas, he slays the innocent along with the guilty, whom he strikes so fearsomely blind that they can feel no sense of guilt. . . . We are dealing with an epidemic delusion which, having caused infinite suffering, will one day vanish and become a monstrous and incomprehensible source of wonderment to later generations. (From Otto Nathan and Heinz Norden [eds.], *Einstein on Peace;* Simon and Schuster, 1960.)

It would be said often of Einstein that he was naïve about human affairs; for example, with the proclamation of the German Republic and the armistice in 1918, he was convinced that militarism had been thoroughly abolished in Germany.

International acclaim. International fame came to Einstein in November 1919, when the Royal Society of London announced that its scientific expedition to Príncipe Island, in the Gulf of Guinea, had photographed the solar eclipse on May 29 of that year and completed calculations that verified the predictions made in Einstein's general theory of relativity. Few could understand relativity, but the basic postulates were so revolutionary and the scientific community was so obviously bedazzled that the physicist was acclaimed the greatest genius on Earth. Einstein himself was amazed at the reaction and apparently displeased, for he resented the consequent interruptions of his work. After his divorce he had, in the summer of 1919, married Elsa, the widowed daughter of his late father's cousin. He lived quietly with Elsa and her two daughters in Berlin, but, inevitably, his views as a foremost savant were sought on a variety of issues.

Proof of the general theory of relativity

Despite the now deteriorating political situation in Germany, Einstein attacked nationalism and promoted pacifist ideals. With the rising tide of anti-Semitism in Berlin, Einstein was castigated for his "Bolshevism in physics," and the fury against him in right-wing circles grew when he began publicly to support the Zionist movement. Judaism had played little part in his life, but he insisted that, as a snail can shed his shell and still be a snail, so a Jew can shed his faith and still be a Jew.

Although Einstein was regarded warily in Berlin, such was his demand in other European cities that he travelled widely to lecture on relativity, usually arriving at each place by third-class rail carriage, with a violin tucked under his arm. So successful were his lectures that one impresario guaranteed him a three-week booking at the London Palladium. He ignored the offer, but, at the request of the Zionist leader Chaim Weizmann, toured the United States in the spring of 1921 to raise money for the Palestine Foundation Fund. Frequently treated like a circus freak and feted from morning to night, Einstein nevertheless was gratified by the standards of scientific research and the "idealistic attitudes" prevailing in the United States.

During the next three years Einstein was constantly on the move, journeying not only to European capitals but also to the Orient, to the Middle East, and to South America. According to his diary notes, he found nobility among the Hindus of Ceylon, a pureness of soul among the Japanese, and a magnificent intellectual and moral calibre among the Jewish settlers in Palestine. His wife later wrote that on steaming into one new harbour, Einstein had said to her, "Let us take it all in before we wake up."

The Nobel Prize

In Shanghai a cable reached him announcing that he had been awarded the 1921 Nobel Prize for Physics "for your photoelectric law and your work in the field of theoretical physics." Relativity, still the centre of controversy, was not mentioned.

Though the 1920s were tumultuous times of wide acclaim, and some notoriety, Einstein did not waver from his new search—to find the mathematical relationship between electromagnetism and gravitation. This would be a first step, he felt, in discovering the common laws governing the behaviour of everything in the universe, from the electron to the planets. He sought to relate the universal properties of matter and energy in a single equation or formula, in what came to be called a unified field theory. This turned out to be a fruitless quest that occupied the rest of his life. Einstein's peers generally agreed quite early that his search was destined to fail because the rapidly developing quantum theory uncovered a probability factor in all measurements of the movement of electrons: the movement of a single electron simply could not be predicted because its position and speed at any instant could not be measured with equal precision, which means, in effect, that the future of any physical system at the subatomic level cannot be predicted. While fully recognizing the brilliance of quantum mechanics, Einstein rejected the idea that these theories were absolute and persevered with his theory of general relativity as the more satisfactory foundation to future discovery. He was widely quoted on his belief in an exactly engineered universe: "God is subtle but he is not malicious." On this point, he parted company with most theoretical physicists. The distinguished German quantum theorist Max Born, a close friend of Einstein, said at the time: "Many of us regard this as a tragedy, both for him, as he gropes his way in loneliness, and for us, who miss our leader and standard-bearer." This appraisal, and others pronouncing his work in later life as largely wasted effort, will have to await the judgment of later generations.

The year of Einstein's 50th birthday, 1929, marked the beginning of the ebb flow of his life's work in a number of aspects. Early in the year the Prussian Academy published the first version of his unified-field theory, but, despite the sensation it caused, its very preliminary nature soon became apparent. The reception of the theory left him undaunted, but Einstein was dismayed by the preludes to certain disaster in the field of human affairs: Arabs launched savage attacks on Jewish colonists in Palestine; the Nazis gained strength in Germany; the League of Nations proved so impotent that Einstein resigned abruptly from its Committee on Intellectual Cooperation as a protest to its timidity; and the stock market crash in New York City heralded worldwide economic crisis.

Crushing Einstein's natural gaiety more than any of these events was the mental breakdown of his younger son Edward, who had worshipped his father from a distance but now blamed him for deserting him and runining his life. Einstein's sorrow was eased only slightly by the amicable relationship he had with his older son, Hans Albert.

As visiting professor at Oxford University in 1931, Einstein spent as much time espousing pacifism as he did discussing science. He went so far as to authorize the establishment of the Einstein War Resisters' International Fund in order to bring massive public pressure to bear on the World Disarmament Conference, scheduled to meet in Geneva in February 1932. When these talks foundered, Einstein felt that his years of supporting world peace and human understanding had accomplished nothing. Bitterly disappointed, he visited Geneva to focus world attention on the "farce" of the disarmament conference. In a rare moment of fury, Einstein stated to a journalist,

> They [the politicians and statesmen] have cheated us. They have fooled us. Hundreds of millions of people in Europe and in America, billions of men and women yet to be born, have been and are being cheated, traded and tricked out of their lives and health and well-being.

Shortly after this, in a famous exchange of letters with the Austrian psychiatrist Sigmund Freud, Einstein suggested that people must have an innate lust for hatred

and destruction. Freud agreed, adding that war was biologically sound because of the love–hate instincts of man and that pacifism was an idiosyncrasy directly related to Einstein's high degree of cultural development. This exchange was only one of Einstein's many philosophic dialogues with renowned men of his age. With Rabindranath Tagore, Hindu poet and mystic, he discussed the nature of truth. While Tagore held that truth was realized through man, Einstein maintained that scientific truth must be conceived as a valid truth that is independent of humanity. "I cannot prove that I am right in this, but that is my religion," said Einstein. Firmly denying atheism, Einstein expressed a belief in "Spinoza's God who reveals himself in the harmony of what exists." The physicist's breadth of spirit and depth of enthusiasm were always most evident among truly intellectual men. He loved being with the physicists Paul Ehrenfest and Hendrick A. Lorentz at The Netherlands' Leiden University, and several times he visited the California Institute of Technology in Pasadena to attend seminars at the Mt. Wilson Observatory (now part of Hale Observatories), which had become world renowned for astrophysical research. At Mt. Wilson he heard the Belgian scientist Abbé Georges Lemaître detail his theory that the universe had been created by the explosion of a "primeval atom" and was still expanding. Gleefully, Einstein jumped to his feet, applauding. "This is the most beautiful and satisfactory explanation of creation to which I have ever listened," he said.

In 1933, soon after Adolf Hitler became chancellor of Germany, Einstein renounced his German citizenship and left the country. He later accepted a full-time position as a foundation member of the school of mathematics at the new Institute for Advanced Study in Princeton, New Jersey. In reprisal, Nazi storm troopers ransacked his beloved summer house at Caputh, near Berlin, and confiscated his sailboat. Einstein was so convinced that Nazi Germany was preparing for war that, to the horror of Romain Rolland and his other pacifist friends, he violated his pacifist ideals and urged free Europe to arm and recruit for defense.

Flight from Europe

Although his warnings about war were largely ignored, there were fears for Einstein's life. He was taken by private yacht from Belgium to England. By the time he arrived in Princeton in October 1933, he had noticeably aged. A friend wrote,

> It was as if something had deadened in him. He sat in a chair at our place, twisting his white hair in his fingers and talking dreamily about everything under the sun. He was not laughing any more.

Later years in the United States. In Princeton Einstein set a pattern that was to vary little for more than 20 years. He lived with his wife in a simple, two-story frame house and most mornings walked a mile or so to the Institute, where he worked on his unified-field theory and talked with colleagues. For relaxation he played his violin and sailed on a local lake. Only rarely did he travel, even to New York. In a letter to Queen Elisabeth of Belgium, he described his new refuge as a "wonderful little spot, . . . a quaint and ceremonious village of puny demigods on stilts." Eventually he acquired American citizenship, but he always continued to think of himself as a European. Pursuing his own line of theoretical research outside the mainstream of physics, he took on an air of fixed serenity. "Among my European friends, I am now called *Der grosse Schweiger* ("The Great Stone Face"), a title I well deserve," he said. Even his wife's death late in 1936 did not disturb his outward calm. "It seemed that the difference between life and death for Einstein consisted only in the difference between being able and not being able to do physics," wrote Leopold Infeld, the Polish physicist who arrived in Princeton at this time.

Development of the atomic bomb

Niels Bohr, the great Danish atomic physicist, brought news to Einstein in 1939 that the German refugee physicist Lise Meitner had split the uranium atom, with a slight loss of total mass that had been converted into energy. Meitner's experiments, performed in Copenhagen, had been inspired by similar, though less precise, experiments done months earlier in Berlin by two German chemists, Otto Hahn and Fritz Strassmann. Bohr speculated that, if a controlled chain-reaction splitting of uranium atoms could be accomplished, a mammoth explosion would result. Einstein was skeptical, but laboratory experiments in the United States showed the feasibility of the idea. With a European war regarded as imminent and fears that Nazi scientists might build such a "bomb" first, Einstein was persuaded by colleagues to write a letter to President Franklin D. Roosevelt urging "watchfulness and, if necessary, quick action" on the part of the United States in atomic-bomb research. This recommendation marked the beginning of the Manhattan Project.

Although he took no part in the work at Los Alamos, New Mexico, and did not learn that a nuclear-fission bomb had been made until Hiroshima was razed in 1945, Einstein's name was emphatically associated with the advent of the atomic age. He readily joined those scientists seeking ways to prevent any future use of the bomb, his particular and urgent plea being the establishment of a world government under a constitution drafted by the United States, Britain, and Russia. With the spur of the atomic fear that haunted the world, he said "we must not be merely willing, but actively eager to submit ourselves to the binding authority necessary for world security." Once more, Einstein's name surged through the newspapers. Letters and statements tumbled out of his Princeton study, and in the public eye Einstein the physicist dissolved into Einstein the world citizen, a kind "grand old man" devoting his last years to bringing harmony to the world.

The rejection of his ideals by statesmen and politicians did not break him, because his prime obsession still remained with physics. "I cannot tear myself away from my work," he wrote at the time. "It has me inexorably in its clutches." In proof of this came his new version of the unified field in 1950, a most meticulous mathematical essay that was immediately but politely criticized by most physicists as untenable.

Compared with his renown of a generation earlier, Einstein was virtually neglected and said himself that he felt almost like a stranger in the world. His health deteriorated to the extent that he could no longer play the violin or sail his boat. Many years earlier, chronic abdominal pains had forced him to give up smoking his pipe and to watch his diet carefully.

On April 18, 1955, Einstein died in his sleep at Princeton Hospital. On his desk lay his last incomplete statement, written to honour Israeli Independence Day. It read in part: "What I seek to accomplish is simply to serve with my feeble capacity truth and justice at the risk of pleasing no one." His contribution to man's understanding of the universe was matchless, and he is established for all time as a giant of science. Broadly speaking, his crusades in human affairs seem to have had no lasting impact. Einstein perhaps anticipated such an assessment of his life when he said "Politics are for the moment. An equation is for eternity."

MAJOR WORKS

SCIENTIFIC PAPERS: "Über einen die Erzeugung und Verwandlung des Lichtes betreffenden heuristischen Gesichtspunkt," in *Annalen der Physik* (1905); "Über die von der molekularkinetischen Theorie der Wärme geforderte Bewegung von in ruhenden Flüssigkeiten suspendierten Teilchen," in *Annalen der Physik* (1905); " Zur Elektrodynamik bewegter Körper," in *Annalen der Physik* (1905), the initial paper on special relativity; "Ist die Trägheit eines Körpers von seinem Energieinhalt abhängig?" in *Annalen der Physik* (1905); "Zur Theorie der Brownschen Bewegung," in *Annalen der Physik* (1906), translated separately as *Investigations on the Theory of the Brownian Movement* (1926); "Zur Theorie der Lichterzeugung und Lichtabsorption," in *Annalen der Physik* (1906); "Planckschе Theorie der Strahlung und die Theorie der spezifischen Wärme," in *Annalen der Physik* (1907); "Entwurf einer Verallegemeinerten Relativitätstheorie und einer Theorie der Gravitation," in *Zeitschrift für Mathematik und Physik* (1913); "Grundlagen der allgemeinen Relativitätstheorie," in *Annalen der Physik* (1916), on the general theory of relativity; "Strahlungs-emission und -absorption nach der Quantentheorie," in *Verhandlungen der Deutschen physikalischen Gesellschaft* (1916); "Quantenthe-

orie der Strahlung," in *Physikalische Zeitschrift* (1917); "Quantentheorie des einatomigen idealen Gases," in *Sitzungsberichte der Preussischen Akademie der Wissenschaften* (1924 and 1925). Some of Einstein's important papers were collected in the joint work (with H.A. Lorentz and H. Minkowski), *H.A. Lorentz: Das Relativitätsprinzip, eine Sammlung von Abhandlungen* (1913; trans. as *H.A. Lorentz: The Principle of Relativity: A Collection of Original Memoirs on the Special and General Theory of Relativity*, 1923). See also *The Meaning of Relativity*, which includes the generalized theory of gravitation (1953), the first edition of Einstein's unified field theory.

OTHER WORKS: *About Zionism: Speeches and Letters*, Eng. trans. by Sir Leon Simon (1931); *Builders of the Universe* (1932); with Sigmund Freud, *Warum Krieg? (Why War?*, Eng. trans. by Stuart Gilbert, 1933); with Leopold Infeld, *The Evolution of Physics* (1938); *The World As I See It* (Eng. trans. by Alan Harris, 1949); *Out of My Later Years* (1950).

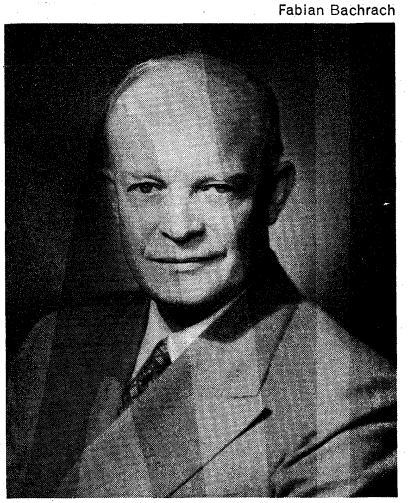
BIBLIOGRAPHY. PAUL A. SCHILPP (ed.), *Albert Einstein: Philosopher-Scientist*, 2nd ed. (1951), a discussion by eminent scholars of Einstein's impact on science and philosophy; PHILIPP FRANK, *Einstein: His Life and Times* (Eng. trans. 1947), a scientific biography on Einstein's early life and achievement; ANTONINA VALLENTIN, *Einstein: A Biography* (Eng. trans. 1954), a personal story of Einstein's European years; PETER MICHELMORE, *Einstein: Profile of the Man* (1962), a popular biography, richly anecdotal, of Einstein as man and scientist; LINCOLN BARNETT, *The Universe and Dr. Einstein*, 2nd rev. ed. (1957), a lucid exposition of Einstein's contribution to science; RONALD W. CLARK, *Einstein: The Life and Times* (1971), a distinguished, definitive work (well illustrated); BANESH HOFFMAN, with the collaboration of HELEN DUKAS, *Albert Einstein: Creator and Rebel* (1972), a significant biography, laced with a thorough but exciting interpretation of Einstein's scientific work.

(P.Mi.)

Eisenhower, Dwight D.

After a slow rise in the military hierarchy, Dwight David Eisenhower became commander of the Allied forces in World War II, and in 1952, a popular hero both through his achievements and his personality, was elected the 34th president of the United States. A colonel at the outbreak of World War II, his ability to transform strategic theory into effective action, his winning personality, and his singular diplomatic gifts won him rapid promotion. His command of the successful amphibious landing in North Africa in 1942 led to his appointment as supreme commander of the invasion of the continental mainland in 1944, and in 1952 he was swept to victory in the presidential election. Although his two terms in office were devoid of notable achievement either at home or abroad, he succeeded in keeping the United States out of war.

Fabian Bachrach



Eisenhower, 1952.

He was born in Denison, Texas, on October 14, 1890, the third of seven sons of David Jacob and Ida Elizabeth (Stover) Eisenhower. In the spring of 1891 the Eisenhowers returned to Abilene, Kansas, where their ancestors had settled as part of a Mennonite colony. Dwight's father worked in a creamery; the family was poor, and Dwight and his brothers were introduced to hard work and a strong religious tradition at an early age.

Early career. "Ike," as Dwight was called, was a fun-loving, personable youth who enjoyed sports and an occasional fistfight, while taking only a moderate interest in his studies. He graduated from Abilene High School in 1909, supported a brother's college education for a year, and then entered the United States Military Academy at West Point. He excelled in football but injured a knee in his second year at the Academy and was forced to stop playing. In the remarkable class of 1915—which was to produce 59 generals—he ranked 61st academically and 125th in discipline out of the total of 164 graduates.

Education

Commissioned a second lieutenant, he was sent to San Antonio, Texas, where he met Mamie Geneva Doud, daughter of a successful Denver meat packer. They were married in 1916 and had two sons: Doud Dwight, born in 1917, who died of scarlet fever in 1921, and John Sheldon Doud, born in 1922.

During World War I Eisenhower commanded a tank training centre, was promoted to captain, and received the Distinguished Service Medal. The war ended just before he was to be sent overseas. From 1922 to 1924 he was assigned to the Panama Canal Zone and there came under the inspiring influence of his commander, Brig. Gen. Fox Conner. With Conner's assistance, Eisenhower was selected to attend the army's command and general staff school at Ft. Leavenworth. Then a major, he graduated first in a class of 275 in 1926 and two years later graduated from the Army War College. He then served in France, writing a guidebook of World War I battlefields, and in Washington, D.C., before becoming an aide to army chief of staff Gen. Douglas MacArthur in 1933. Two years later he accompanied MacArthur to the Philippines to assist in the reorganization of the commonwealth's army and while there was awarded the Distinguished Service Star of the Philippines and the rank of lieutenant colonel. He returned to the United States shortly after Germany's invasion of Poland initiated the European phase of World War II and in March 1941 became a full colonel. Three months later he was made chief of staff of the 3rd Army and soon won the attention of army chief of staff Gen. George C. Marshall for his role in planning war games involving almost 500,000 troops.

Supreme commander in World War II. When the United States entered World War II in December 1941, Marshall appointed Eisenhower to the army's war plans division in Washington, where he prepared strategy for an Allied invasion of Europe. Having become a brigadier general in September 1941, he was promoted to major general in March 1942 and named head of the operations division of the War Department. In June, Marshall selected him over 366 senior officers to be commander of United States troops in Europe. Eisenhower's rapid advancement, after a long army career spent in relative obscurity, was due not only to his knowledge of military strategy and a talent for organization but also to his ability to persuade, to mediate, and to be agreeable. Men from a variety of backgrounds and nationalities, impressed by his friendliness, humility, and persistent optimism, liked and trusted him.

Promoted to lieutenant general in July 1942, Eisenhower was named to head Operation Torch, the Allied invasion of French North Africa. This first major Allied offensive of the war was launched on November 8, 1942, and successfully completed in May 1943. Eisenhower's decision to work during the campaign with the French admiral Jean-François Darlan, who had collaborated with the Germans, aroused a storm of protest from the Allies; but his action was defended by Pres. Franklin D. Roosevelt. A full general since February, Einsenhower then directed the amphibious assault of Sicily and the Italian mainland, which resulted in the fall of Rome on June 4, 1944.

During the fighting in Italy, Eisenhower participated in plans to cross the English Channel for an invasion of

Invasion of Europe

France. On December 24, 1943, he was appointed supreme commander of the Allied Expeditionary Forces, and the next month he was in London making preparations for the massive thrust into Europe. On June 6, 1944, he gambled on a break in bad weather and ordered the Channel crossed. About 1,000,000 men in 4,000 ships landed in Normandy and began to fight their way into the heart of France. On August 25 Paris was liberated. The Allied forces continued eastward, following Eisenhower's "broad-front" plan, which ultimately distributed armies along Germany's entire western border. After overcoming a fierce German counterattack in the Ardennes in December, the Allies crossed the Rhine on March 7, 1945. Germany surrendered on May 7, and the war in Europe was over. In the meantime, in December 1944, Eisenhower had been promoted to the five-star rank of general of the army.

He was given a hero's welcome upon returning to the United States for a visit in June 1945. His intended retirement was delayed by Pres. Harry S. Truman when he was named in November to replace General Marshall as chief of staff. For over two years Eisenhower directed demobilization of the wartime army and worked to unify the armed services under a centralized command. He ended speculation that he might run for the presidency in 1948 by refusing to permit his name to appear on an early primary ballot.

In May 1948 he left active duty, the most popular and respected soldier in the United States, to become president of Columbia University. His book *Crusade in Europe*, published that fall, became a best seller and made him a wealthy man.

Eisenhower's brief career as an academic administrator was not especially successful. His technical education and military experience prepared him poorly for the post, and his distrust of intellectuals made relations with faculty members difficult. In the fall of 1950 President Truman asked him to become supreme commander of the North Atlantic Treaty Organization (NATO), and in early 1951 he flew to Paris to assume his new position. For the next 15 months he devoted himself to the task of creating a united military organization in western Europe to be a defence against the possibility of Communist aggression.

Supreme commander of NATO

First term as president. As early as 1943 Eisenhower was mentioned as a possible presidential candidate. His personal qualities and military reputation, rather than his often vague pronouncements on public policy, prompted both parties to woo him. As the campaign of 1952 neared, Eisenhower let it be known that he was a Republican, and the Eastern wing of the party, headed by Gov. Thomas E. Dewey of New York, made an intensive effort to persuade him to seek the Republican presidential nomination. His name was entered in several state primaries against the more conservative Sen. Robert A. Taft of Ohio. Although the results were mixed, Eisenhower decided to run. In June 1952 he retired from the army, after 37 years of service, returned to the United States, and began to campaign actively. At the party convention in July, after a bitter fight with Taft supporters, Eisenhower won the nomination on the first ballot. His running mate was Sen. Richard M. Nixon of California. Democrats nominated Gov. Adlai E. Stevenson of Illinois for president and Sen. John Sparkman of Alabama for vice president.

Despite his age, Eisenhower campaigned tirelessly, impressing millions with his warmth and sincerity. He urged economy and honesty in government and promised to visit Korea to explore the possibilities for ending the Korean War, which had broken out in 1950 between Communist North Korea and pro-Western South Korea and soon involved United Nations (mainly United States) and Communist Chinese forces. Many Republicans, including Nixon, spoke of pro-Communist disloyalty within the Truman administration and called for stringent anti-subversive measures. The Eisenhower–Nixon ticket won handily, carrying 39 states, winning the electoral vote, 442 to 89, and collecting more than 33,000,000 popular votes. The Republican Party won control of Congress by a slim margin but lost both houses two years later.

Conception of the presidency

Unlike his two Democratic predecessors, Eisenhower did not believe in strong executive leadership of the federal government. Because of his military background and limited knowledge of government and politics, he liberally delegated authority to his advisers and cabinet members and did not participate actively in the detailed work of the executive departments. His assistant, former New Hampshire governor Sherman Adams, was a powerful figure in the administration. The Chief Executive, Adams wrote,

> expected me to manage a staff that would boil down, simplify and expedite the urgent business that had to be brought to his attention and to keep as much work of secondary importance as possible off his desk.

Policies emanating from the White House, even after Adams' resignation in 1958, usually involved the President only in the final stages.

Eisenhower's basically conservative views on domestic affairs were shared by his influential secretary of the treasury, George M. Humphrey. The Administration's domestic program, which came to be labelled "modern Republicanism," called for reduced taxes, balanced budgets, a decrease in government control over the economy, and the return of certain federal responsibilities to the states. Controls over rents, wages, and prices were allowed to expire, and in 1954 there was a slight tax revision. At Eisenhower's insistence, Congress transferred title to valuable tideland oil reserves to the states. But there was no sharp break with policies inherited from previous Democratic administrations. The needs of an expanding population (from 155,000,000 to 179,000,000 during the Eisenhower era) and the nation's overseas commitments caused budget deficits during five out of eight years. The minimum wage was increased to $1 per hour, the Social Security System was broadened, and in the spring of 1953 the Department of Health, Education, and Welfare was created.

The right wing of his party clashed with the President more often than did the Democrats during his first term. In part to preserve party unity, he refused to condemn publicly Sen. Joseph R. McCarthy's irresponsible charges of Communist influence within the government. Although privately Eisenhower expressed his distaste for the Senator, at times he seemed to encourage the attacks of McCarthyites. Hundreds of federal employees were fired under his expanded loyalty-security program. With his approval, Congress passed a law designed to outlaw the American Communist Party. Following the sensational hearings on McCarthy's charges against army officers and civilian officials, televised nationally for five weeks in the spring of 1954, McCarthy's popularity waned, as did much of the anti-Communist hysteria of the postwar years.

Foreign policy

Foreign affairs drew much of Eisenhower's attention; he and his secretary of state John Foster Dulles worked hard at achieving world peace and constructing collective defense agreements designed to check the spread of Communism. As promised, Eisenhower visited Korea shortly after his inauguration. Partly, perhaps, because of Joseph Stalin's death in March 1953, the President was able to negotiate a truce for the Korean War in July 1953. In December of that year, he proposed that the nations of the world pool atomic information and materials under the auspices of an international agency. This "Atoms for Peace" suggestion bore fruit in 1957, when 62 countries formed the International Atomic Energy Agency.

In July 1955 the President met with leaders of Great Britain, France, and the Soviet Union at a summit conference in Geneva. His "open-skies" proposal, by which the United States and the Soviet Union would permit continuous air inspection of each other's military installations, was welcomed by world opinion but was rejected by the U.S.S.R.

In September 1954, Eisenhower and Dulles succeeded in creating the Southeast Asia Treaty Organization (SEATO) to prevent further Communist expansion in that

part of the world. It was composed of the United States, France, Great Britain, Australia, New Zealand, the Philippines, Thailand, and Pakistan. NATO was strengthened in 1955 by the inclusion of West Germany.

Critics contended that there were frequent disparities between the administration's words and deeds in the field of foreign relations. While threatening to "unleash" Nationalist Chinese leader Chiang Kai-shek, the United States signed a defense treaty with Nationalist China in December 1954 that inhibited Chiang's ability to attack the Communist Chinese. Dulles spoke of "liberating" captive peoples in Communist nations, but the administration limited itself to protests when uprisings occurred in East Germany (1953) and Hungary (1956). While the Secretary of State promised "massive retaliation" against Communist aggression, the President made the decision to limit America's role in the Indochina crisis between France and Ho Chi Minh's guerillas to only financial and military aid. Many observers praised Eisenhower for his restraint and moderation under pressure, however.

Second term. A heart attack in September 1955, and an operation for ileitis in June 1956, raised considerable doubt about Eisenhower's ability to serve a second term. But he recovered quickly, and the Republican convention unanimously endorsed the Eisenhower–Nixon ticket on the first ballot. Democrats again selected Adlai E. Stevenson and named Sen. Estes Kefauver of Tennessee as his running mate. Eisenhower's great personal popularity turned the election into a landslide victory, the most one-sided race since 1936. He won 35,500,000 votes against Stevenson's 25,000,000; the electoral count was 467 to 74. The Democrats, however, once more captured both houses of Congress, a feat they were to duplicate in 1958. Eisenhower was the first president to serve with three Congresses controlled by the opposition party.

The election campaign of 1956, however, had been complicated by a crisis in the Middle East over Egypt's seizure of the Suez Canal. The subsequent attack by Great Britain, France, and Israel on Egypt and Egypt's support by the Soviet Union prompted the President to go before Congress in January 1957 to urge adoption of what came to be called the Eisenhower Doctrine, a pledge to send United States armed forces to any Middle Eastern nation requesting assistance against Communist aggression. In July 1958 American troops were sent to Lebanon to protect its government from attack by Communist-inspired rebels.

Role in racial desegregation

When the United States Supreme Court, on May 17, 1954, declared racial segregation in public schools unconstitutional, controversy and violence broke out, especially in the south. In September 1957 Eisenhower dispatched 1,000 federal troops to Little Rock, Arkansas, to halt an attempt by Gov. Orval E. Faubus to obstruct a federal court order integrating a local high school. This action was the most serious challenge of his presidency. On several occasions Eisenhower had expressed his distaste for racial segregation, though he doubtless believed that the process of integration would take time. The Civil Rights Act of 1957 was the first such law passed since 1875.

On October 4, 1957, the Soviet Union launched Sputnik I, the first man-made satellite to orbit the Earth. Americans were shocked by the achievement, and many blamed Eisenhower for the administration's insistence on low military budgets and its failure to develop a space program. Steps were taken to boost the nation's missile and space research and to provide funds to increase the study of science. The National Aeronautics and Space Administration was created in July 1958.

The administration again came under fire in the fall of 1957 for a recession in the economy that lasted through the following summer. The President refused to lower taxes or increase federal spending to ease the slump for fear of fuelling inflation.

Following the death of Dulles in the spring of 1959, Eisenhower assumed a more personal role in the direction of American foreign policy. He travelled to Europe, Africa, and Asia in December 1959 and toured Latin America in February and March 1960 seeking friendship for the United States.

The U-2 incident

To improve relations with the Soviet Union, the President invited Premier Nikita S. Khrushchev to visit the United States. Khrushchev toured parts of the country in September 1959 and held private talks with Eisenhower. Another summit meeting was planned, and a new era of personal diplomacy seemed at hand. But when a United States U-2 reconnaissance plane was shot down over the U.S.S.R. in May 1960 Khrushchev scuttled the talks and angrily withdrew his invitation to the President to visit the Soviet Union. Eisenhower admitted that the flights had gone on for four years and shouldered much of the blame for the ill-timed affair. In January 1961, during the last weeks of the Eisenhower administration, the United States broke diplomatic relations with Cuba, for two years under the control of Fidel Castro.

Though his administrations had a great many critics, Eisenhower remained extraordinarily popular with the American people. When he left office, the oldest president in the nation's history, Congress restored his rank as general of the army. He retired to his farm in Gettysburg, Pennsylvania, and devoted much of his time to his memoirs. In 1963 he published *Mandate For Change*, which was followed in 1965 by *Waging Peace*. A lighter work, *At Ease: Stories I Tell to Friends*, appeared in 1967. On March 28, 1969, after a series of illnesses, he died of heart failure in a hospital in Washington, D.C. He was buried in Abilene, Kansas.

Eisenstein, Sergey

Three of the undisputed classics of the art of the cinema —*Potemkin* (1925), *Alexander Nevsky* (1938), and *Ivan the Terrible* (*Part One*, 1944; *Part Two*, 1946, released 1958)—are the work of the Russian director and theorist Sergey Eisenstein, whose writings, largely on the achievement of rhythms of mood and meaning through editing, or montage, and films have been instrumental in creating a film aesthetic. Since even his lesser films reflect his searching genius, his total body of work has had an immense impact on the development of the art. If sensitivity to the expressive possibilities of his medium is the mark of a great artist, then Eisenstein must be counted, as many of his followers proclaim him, the greatest master of the art of the film.

Birth and early life

Of Jewish descent through his paternal grandparents, Sergey Mikhaylovich Eisenstein was born on January 23, 1898, at Riga, where his father, Mikhail, a civil engineer, worked in shipbuilding. In 1910 the family left Riga for St. Petersburg (now Leningrad).

After studying in 1916–18 at the Institute of Civil Engineering, Eisenstein decided on a career in the plastic arts and entered the School of Fine Arts.

With the outbreak of the Russian Revolution of 1917, he enlisted in the Red Army and helped to organize and construct defenses and to produce entertainment for the troops. Having now found his vocation, he entered, in 1920, the Proletkult Theatre (Theatre of the People) in Moscow as an assistant decorator. He rapidly became the principal decorator and then the co-director. As such, he designed the costumes and the scenery for several notable productions. At the same time, he developed a strong interest in the Kabuki theatre of Japan, which was to influence his ideas on film. For his production of *The Wise Man*, an adaptation of Aleksandr Ostrovsky's play, he made a short film, "Glumov's Diary," which was shown as part of the performance in 1923. Soon afterward the cinema engaged his full attention, and he pro-

Eisenstein, on location for *October* in 1927.
Sovfoto

duced his first film, *Strike*, in 1924, after having published his first article on theories of editing in the review *Lef*, edited by the great poet Vladimir Mayakovsky. He said there that in place of the static reflection of an event, expressed by a logical unfolding of the action, he proposed a new form: the "montage of attractions"—in which arbitrarily chosen images, independent of the action, would be presented not in chronological sequence but in whatever way would create the maximum psychological impact. Thus, the film maker should aim to establish in the consciousness of the spectators the elements that would lead them to the idea he wants to communicate; he should attempt to place them in the spiritual state or the psychological situation that would give birth to that idea.

First films and cinematic theory

These principles guided Eisenstein's entire career. In the realistic films that he undertook, however, such a technique is effective only when it utilizes the concrete elements implicit in the action; it loses validity when its symbols are imposed upon reality instead of being implied by it. Thus, in *Strike* (1924), which recounts the repression of a strike by the soldiers of the tsar, Eisenstein juxtaposed shots of workers being mowed down by machine guns with shots of cattle being butchered in a slaughterhouse. The effect was striking, but the objective reality was falsified.

Possessed by his theory, Eisenstein was bound to succumb often to this failing. *Potemkin* (1925), also called *The Battleship Potemkin*, happily escaped it. Ordered by the Central Executive Committee of the U.S.S.R. to commemorate the Revolution of 1905, the film, made in the port and the city of Odessa in 1925, had a momentous impact and still remains among the masterpieces of the world cinema. (In 1958 it was voted the best film ever made, by an international poll of critics.) Its greatness lies not merely in the depth of humanity with which the subject is treated, nor in its social significance, nor in the formal perfection of its rhythm and editing; but rather, it is each of these magnified and multiplied by the others.

Having by this accomplishment earned recognition as the epic poet of the Soviet cinema, Eisenstein next made a film entitled *October* (1928) or *Ten Days that Shook the World*, which in the space of two hours dealt with the shifts of power in the government after the 1917 Revolution, the entrance on the scene of Lenin, and the struggle between the Bolsheviks and their political and military foes. If the film was sometimes inspired, it was also disparate, chaotic, and often confused.

Also uneven, but better balanced, was *Old and New* (originally titled *The General Line*), filmed in 1929 to illustrate the collectivization of the rural countryside. Eisenstein made of it a lyric poem, as calm and as expansive as *Potemkin* had been violent and compact.

In 1929, putting to profit a visit to Paris, he filmed *Romance sentimentale* (*Sentimental Melody*), an essay in counterpoint of images and music. Engaged by Paramount studios in 1930, he left for Hollywood, where he worked on adaptations of the novels *L'Or* ("Sutter's Gold"), by Blaise Cendrars, and *An American Tragedy*, by Theodore Dreiser. Refusing to modify his scripts to meet studio demands, however, he broke the contract and went to Mexico in 1932 to direct *Que viva Mexico!*, with capital collected by the novelist Upton Sinclair.

The film never was completed. After disagreements between Eisenstein and Sinclair, some of the negatives were sold and released as the films *Thunder over Mexico*, *Eisenstein in Mexico*, and *Death Day* (1933–34). In 1939 a fourth film, entitled *Time in The Sun*, was made from the footage. None of these films bears more than a distant resemblance to the original conception.

After his return to Moscow in 1933, Eisenstein undertook *Bezhin Meadow*. Several weeks before its completion, however, he was ordered to suspend its production. The scenes already shot were put together by Eisenstein, but the film, which was never released, was attacked as "formalistic" because of its poetic interpretation of reality. Eisenstein thus suffered from the same governmental policies toward art that had embroiled the composer Sergey Prokofiev, the writer Isaac Babel, and many other artists in difficulties with Soviet officialdom.

The Russian epics

Having expressed contrition for the errors of his past works, Eisenstein was able to make a film recounting the medieval epic of *Alexander Nevsky*, in accordance with Stalin's policy of glorifying Russian heroes. Made in 1938, this film transfigured the actual historical events, majestically leading to a final resolution that represented the triumph of collectivism. As in medieval epics, the characters were the strongly stylized heroes or demigods of legend. Produced in close collaboration with Prokofiev, who wrote the score, the film represented a blend of images and music into a single rhythmic unity, an indissoluble whole.

During World War II Eisenstein achieved a work of the same style as *Alexander Nevsky* and even more ambitious—*Ivan the Terrible*—about the 16th-century tsar Ivan IV, whom Stalin admired. Begun in 1943 in the Ural Mountains, the first part was finished in 1944, the second at the beginning of 1946. A third part was envisaged, but Eisenstein, suffering from an angina of the chest, had to take to his bed for several months. He was about to return to work when he was laid low again. He died on February 11, 1948, only a few days after his 50th birthday.

Most critics would agree that though Eisenstein's three greatest films stand far above the others, all of his work is significant; their flaws are those common to artists probing the limits of their craft. It may be that in the entire history of motion pictures, no other film maker has surpassed him in his understanding of his art.

MAJOR WORKS

FILMS: *Strike* (1924); *The Battleship Potemkin* (1925); *October* (*Ten Days That Shook the World;* 1928); *Old and New* (*The General Line;* 1929); *Alexander Nevsky* (1938); *Ivan the Terrible, Part One* (1944); *Ivan the Terrible, Part Two* (1958).

COLLECTIONS OF WRITINGS: *The Film Sense* (1942); *Film Form* (1949); *Notes of a Film Director* (1958); *Film Essays* (1968).

BIBLIOGRAPHY. MARIE SETON, *Eisenstein* (1952; Eng. trans., 1952); JEAN MITRY, *S.M. Eisenstein* (1955), in French; LEON MOUSSINAC, *Serge Eisenstein* (1964; Eng. trans., 1970).

Ekman, Vagn Walfrid

Vagn Walfrid Ekman, a Swedish physical oceanographer who pioneered in developing the science of oceanography, is particularly noted for his fundamental hydrodynamic theories concerning ocean currents.

Born on May 3, 1874, in Stockholm, Ekman was the youngest son of Fredrik Laurentz Ekman, a Swedish physical oceanographer. After finishing secondary school in Stockholm, Ekman studied at the University of Uppsala, where he majored in physics. But lectures on hydrodynamics in 1897 by Vilhelm Bjerknes, one of the founders of meteorology and oceanography, definitely decided the direction of Ekman's work.

While still a student at Uppsala, Ekman made important contributions to oceanography. When it was observed, during the Norwegian North Polar Expedition, that drift ice did not follow the wind direction but deviated by 20° to 40°, Bjerknes chose Ekman to make a theoretical study of the problem. In his report, published in 1902, Ekman took into account the balance of the frictions between the wind and sea surface, within layers of water, and the deflecting force due to the earth's rotation (Coriolis force).

After taking his degree at Uppsala in 1902, he joined the staff of the International Laboratory for Oceanographic Research in Oslo, where he remained until 1909. During those years he proved to be a skilled inventor and experimentalist. The Ekman current meter, an instrument with a simple and reliable mechanism, has been used, with subsequent improvements, to the present, while the Ekman reversing water bottle is used in freshwater lakes and sometimes in the ocean to obtain water samples at different depths with a simultaneous measurement of water temperatures. He displayed his theoretical and experimental talents in his study of "dead water," which causes slow-moving boats to become stuck because of a thin layer of nearly fresh water spreading over the sea from melting ice. This phenomenon, often occurring in fjords, seriously impeded the Norwegian explorer Fridtjof Nansen in Arctic waters. Ekman demonstrated by experiments in a wave tank that the resistance to the motion of the vessels is increased by the waves that are formed at the interface between layers of water of different densities.

Ekman, 1928.

Study of "dead water" from melting ice

He also derived an empirical formula for the mean compressibility (compression ratio divided by pressure) of seawater as a function of pressure and temperature. This formula is still in use today to determine density of deep seawater which is compressed by hydrostatic pressure.

From 1910 to 1939, Ekman was professor of mechanics and mathematical physics at the University of Lund in Sweden, where he pursued his main interest, the dynamics of ocean currents. He published theories on wind-driven ocean currents including the effects of coasts and bottom topography, and on the dynamics of the Gulf Stream. He also tried, with partial success, to solve the complex problem of ocean turbulence.

In 1925 Ekman participated in a cruise of a German research ship to the Canary Islands. Again, on finding that data on currents obtained for several days at several marine stations between the Bay of Biscay and the Canary Islands, were not sufficient to obtain an average figure, he and a colleague, during the years 1922–29, improved the technique for measuring currents for a prolonged period by collecting data from an anchored ship. After several preparatory cruises for that purpose off the Norwegian coast aboard a Norwegian research vessel, they made a cruise to the trade-wind region off northwestern Africa in the summer of 1930 to determine the average current at various ocean depths at stations occupied for two weeks or longer. Preliminary reports were published soon after the cruise, but Ekman wrote the final report in 1953 at the age of 79. The long delay in publication, partly because of the loss of important data during the German occupation of Norway, also indicates the unparalleled care he took with his work.

Influence and assessment

His name is used in current terminology: "Ekman layer" denotes either the layers of the ocean or the layers of the atmosphere at the air–sea, air–ground, and sea–ground interfaces; "Ekman spiral" for velocity distributions of the wind or ocean currents in these layers; and also "Ekman transport" for water transport caused by wind.

Although his name and achievements were well known among oceanographers, he rarely attended international meetings—but his genuine kindliness prevented him from becoming a recluse. Most of his teachers and friends, such as Nansen and Bjerknes, were Norwegian; he spent many vacations in Bergen. He sang a beautiful bass, spent much time at the piano, and occasionally composed music. In the fall of 1953, he began a study of turbid currents, which he continued until a few days before his death, on March 9, 1954 at Gostad, near Stockaryd, Sweden.

(T.Ic.)

Elasticity

In the broadest sense, a body has elasticity when it has the power of recovery. Thus, a china cup is not considered elastic when it falls to the floor and breaks. A straight strip of tempered steel will spring back from a bent position, even when it has been held so for a long time, whereas a strip of lead will not; the steel is considered to be elastic, the lead is not. The word elasticity was coined in the 17th century when some appreciation was being gained of the fact that all substances are more or less elastic, whether inanimate or part of living organisms, though elastic behaviour terminates rather early with some substances due either to their plasticity or to their brittleness. Even a gas may be said to spring back to its original volume when it has been compressed, and in 1662 Robert Boyle, the English physicist, noted the "elastical power" of air. In 1678, Robert Hooke, another English physicist, maintained that in any "springy body" displacement is proportional to load. Not until much later were stress and strain given precise meanings. This lack of definition, however, did not deter the mathematicians of the 18th century from examining problems such as flexure of beams; the essential steps toward a sound theory of elasticity were taken between 1820 and 1830 by French mathematicians, notably by Louis-Augustin Cauchy.

The phenomenon of elasticity. In 1807 Thomas Young, the English physicist and physician, proposed an elastic modulus, or a constant, relating unidirectional stress and strain. If a bar of uniform cross-sectional area

A is stretched by a force T, so that the stress (σ) denotes the force per unit area, then stress is expressed by $\sigma = T/A$. Under this stress the bar, of original length L, will stretch by a length indicated by δL to give a total length of $L + \delta L$. Unidirectional strain e is the fractional elongation; that is, the increase in length divided by the original length, so that $e = \delta L/L$. From this, the modulus of elasticity, called Young's modulus, can now be defined. A modulus is a numerical measure of some effect, in this case of elasticity, stated in terms of a unit condition: force per unit area of the medium divided by the fractional elongation, or the strain, is a measure of the effect of elasticity. Young's modulus, therefore, is the constant of proportionality between stress and strain: $E = \sigma/e$. It expresses the inherent stiffness of the material under tensile stress (stress resulting in a longitudinal stretching), regardless of the size of the bar.

Young's modulus

Although Young had some knowledge of numerical modulus values, it was somewhat later that testing machines came into regular use for examining constructional materials. Sensitive extensometers for measuring extensions of the order of $\frac{1}{100,000}$ of an inch (10^{-5} inch) were also needed for accurate determination of elastic behaviour. Notable advances in the techniques of testing materials, particularly in the use of optical extensometers, were made in German research schools from about 1870.

At the present time, dynamic methods are often used for measuring Young's modulus. A bar of uniform section may be vibrated along its length (in its fundamental longitudinal mode) using a piezoelectric vibrator. The periodic time is the time required for a stress pulse to travel from one end of the bar and back, or twice the bar length L; however, the velocity v of the propagation of this stress pulse turns out to be such that $v^2 = E/\rho$, ρ being the density of the bar. Hence E, the modulus, may be calculated from the equation that relates E to the product of the density ρ and the square of the length of the bar, L^2, and the square of observed resonant frequency, f^2, that is, $E = 4\rho L^2 f^2$.

The idea that torsional stiffness (resistance to twisting) depends on a shear modulus was accepted before the theory of torsion was put on a firm general basis by the French engineer A.J.C. Barré de Saint-Venant in 1853. A cylindrical shell with length L and radius r may be thought of as fixed at one end. If the other end of the shell is twisted through an angle theta (θ) the engineering shear strain phi (ϕ) is defined as the angle θ multiplied by the ratio of radius r to length L; that is, $\phi = \theta r/L$. Shear modulus G (also called the rigidity modulus) is the constant that relates shear strain phi, (ϕ), to shear stress tau, (τ), in an elastic body: shear stress equals the shear modulus times the shear strain, so that $\tau = G\phi$. By considering a solid bar of outside radius R to be made up of a series of such shells, it is possible to calculate the total torsional moment M as equal to the product of four terms: (1) pi (π), (2) the outside radius to the fourth power, (3) the sheer modulus, and (4) the shear strain, all divided by twice the length of the shell. In equation form, $M = \pi R^4 G\theta/2L$. Hence, from a graph of measured M and θ values, G can be found.

Shear modulus

Elasticity in viscous and crystalline bodies. Although matter in a condensed state is inherently elastic, by reason of bonding forces between molecules, distortional elasticity can become evident only when relative sliding between molecules is inhibited and the resulting resistance to flow is relatively high. In materials made up of crystals, the atoms within each crystal are tightly packed in a regular array. Other materials are amorphous; that is, they consist of randomly assembled atoms, for example, glass and viscous liquids. On an atomic scale, flow in an amorphous substance depends on the existence within the material of holes sufficiently large to allow the transfer of an atom from one position to another. Because there is thermal agitation of atoms within all materials at normal temperatures, the frequency with which an atom will gain enough energy to accomplish a transfer may be predicted theoretically by the application of certain equations of the Maxwell-Boltzmann type derived from kinetic molecular theory. Such methods of statistical mechanics (see THERMODYNAMICS, PRINCIPLES OF) have been used to explain the linear relation between stress and strain rate in a viscous liquid (which is then termed a Newtonian liquid) and also the effect of temperature and free volume on the coefficient of viscosity (equal to shearing stress divided by the rate of shear). It is a familiar observation that amorphous materials, such as wax or pitch, will soften progressively when heated but will behave elastically when cold or when subjected to stress applied rapidly.

When a liquid contains a moderate concentration of solid particles in suspension, its apparent viscosity (a property that inhibits the motion of one part of the liquid relative to another) is increased. Many concentrated solutions of organic substances, however, tend to form a gel (jellylike, having elastic properties), when allowed to rest, through the growth of a network of solute molecules. Gelatinous material, for example, develops a definite yield strength, or resistance to stress, on setting that enables it to oscillate when it is shaken.

Polymers, substances of high molecular weight made up of a large number of identical (or practically identical) smaller molecules, can exist as fluids or gels, or they may be glassy or crystalline. A polymer such as rubber contains long molecules twisted around each other, and the extension by pulling or twisting of such a substance involves straightening or crumpling of molecular chains. Distortion involves viscous shearing as parts of the molecular chains of rubber move relative to each other. On release of stress the chains resume their former convoluted shape and the strain due to elasticity is gradually recovered. Fillers such as carbon modify the open structure of rubber, increasing its elastic modulus. Internal structure obviously has an important effect on the elastic modulus of fibre-reinforced plastics; it is at a maximum when stress is applied in the direction of the fibres, and when the fibres are kept straight during molding.

A piece of metal generally consists of an aggregate of large numbers of crystals formed during solidification, and these crystals persist through subsequent heating or forging. Although creep (a slow change in shape) can be due partly to movements of atoms around vacant lattice sites, the plastic deformation of metals takes place chiefly through movement of dislocations. These defects in the stacking arrangement of atoms within crystals have the effect of reducing the yield strength to about one-hundredth part of the strength of a perfect crystal. Studies of dislocations, carried out extensively in many countries since about 1945, have succeeded in explaining many aspects of the mechanical behaviour of metals.

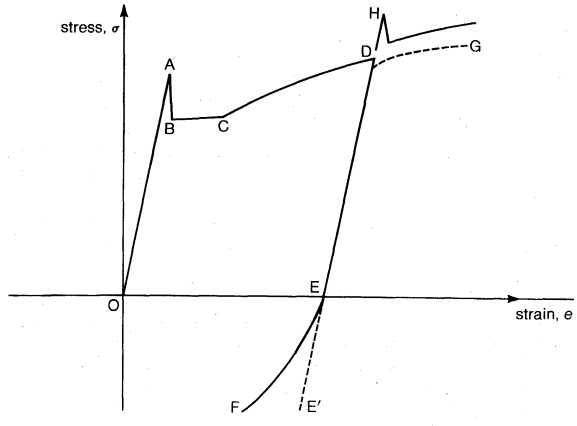

Figure 1: Behaviour of low-carbon steel during stretching in a testing machine (see text).

If, for example, a specimen of low-carbon steel is stretched in a testing machine, stress (σ) and strain (e) may be plotted as in Figure 1. The first application of any stress produces strain indicated by the straight line OA, its slope being equal to Young's modulus. An upper yield point A is reached and plastic extension, as strain is

increased, occurs along BC at a slightly lower stress; this reduction is associated with the spread of what are called Lüders bands, lines or markings on the formerly smooth surface, through the specimen. After C, strain-hardening occurs along CD. When stress is released at point D, recovery along DE is substantially elastic. Application of compressive stress at point E, however, is not found to give an elastic compression EE′, but instead a curved inelastic line EF is followed. This is called the Bauschinger effect, and it is associated with an easy reverse flow of dislocations that have become piled up against obstacles such as locked groups of dislocations and grain boundaries. An immediate reapplication of tensile stress gives flow DG, as if loading had not been interrupted. If the specimen is rested for a few days, a new yield point H is encountered.

Bauschinger effect

Yield points in steel can be associated with the presence of interstitial atoms of carbon and nitrogen. These diffuse through the iron (ferrite) lattice, and by gathering around dislocations, prevent their movement until an upper yield stress is applied. The large numbers of free dislocations present in a plastically strained material are thus gradually immobilized. The effect is called Cottrell-Bilby locking, and it is accelerated by heating to about 200° C. This treatment restores elasticity and eliminates the Bauschinger effect.

When a piece of steel is subjected to continuous rapid cycles of stress that do not exceed the static yield stress, a thin hysteresis loop develops (a graph of the resistance to a cycle of applied force due to a former state of the system, most often plotted for the changes in the magnetic permeability of a substance; see MAGNETISM). If the hysteresis is attributed to a limited number of atoms breaking away, it can be understood why the loop is widened by overstraining that provides more free dislocations, and why it is reduced in width by heat treatment.

It is well known that a bar of steel emits a ringing sound when it is struck, but a bar of cast iron does not because of the higher internal damping (resistance to oscillations) of cast iron. As an idealization for use in studying inelastic response of materials, a constitutive equation has been proposed that includes rates of stressing and straining with respect to time. Constitutive equations give the relationship between deformation and force (see DEFORMATION AND FLOW; also see below *Mathematical considerations*, equation [1]).

Constitutional equations

Three-dimensional strain and stress. The general properties of strain are concerned with the shape of an object, whereas those of stress derive from equilibrium of forces; therefore, these properties are independent of whether or not the body is elastic. If the position of a particle in the unstrained body is described by coordinate values x_1, x_2, and x_3, and if the amount of distortion is small, the position of this particle can be described with sufficient accuracy by the same coordinate values, even though small displacements have occurred. Then, if these displacements are u_1 in the x_1 direction, u_2 in the x_2 direction, and u_3 in the x_3 direction, normal strain will be equal to fractional elongation. Taking an element of length dx_1 lying along the x_1 axis of the coordinate system in the body, the displacement of the outer end will exceed that of the inner end by the partial derivative of the displacement in the x_1 direction with respect to x_1 multiplied by dx_1: $(\partial u_1/\partial x_1)dx_1$.

This is the rate of change of u_1 with respect to x_1, multiplied by the incremental distance. Hence the component of strain becomes $e_{11} = \partial u_1/\partial x_1$, in which e_{11} represents normal strain along the x_1 coordinate. The other normal strains follow by simply replacing the coordinate x_1 with either coordinate x_2 or x_3, and replacing the displacement u_1 with either displacement u_2 or u_3.

A rectangular element, Figure 2, may be considered next, having sides initially parallel to the x_1 and x_2 axes. Shear strain in the theory of elasticity, according to the mathematical definition, is equal to half the decrease in angle of the corner that is outermost with respect to the positive coordinate axes. (The angle A becomes B under the stress.) Small changes in inclination of the outer sides can be written in terms of displacement derivatives (Figure 2), leading to an expression for shear strain in which e_{12} represents strain in two dimensions:

$$e_{12} = \frac{1}{2}\left(\frac{\partial u_2}{\partial x_1} + \frac{\partial u_1}{\partial x_2}\right).$$

Strain-displacement equations

Two further components are obtained by replacing symbols x_1,x_2 with x_2,x_3 or x_3,x_1 and by replacing symbols u_1,u_2 with u_2,u_3 or u_3,u_1. These equations of strain-displacement give six components of strain in terms of three displacement components, and thus continuity of displacements in a solid body imposes compatibility conditions on any permissible strain distribution.

A stress component in the theory of elasticity is specified

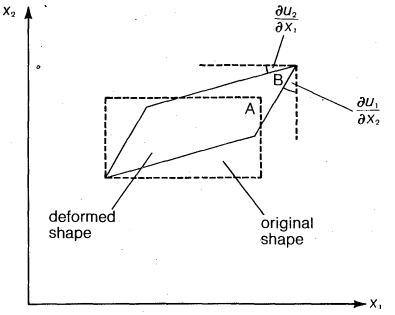

Figure 2: Calculation of shear strain in two dimensions, using angular changes (see text).

by means of two subscripts. Normal stress, σ_{11}, means the stress having a line of action parallel to the x_1 axis and acting on an element of area perpendicular to the x_1 direction. It is a positive value when tensile stress is being measured. Shear stress, σ_{12}, means a stress acting along a line parallel to the x_1 direction on an element of area perpendicular to the x_2 direction. In the x_1,x_2 plane this stress is positive if it acts in the positive x_1 direction on the side of an element situated at the larger positive x_2 value, or if it acts in the negative x_1 direction on the opposite side of the element. Equilibrium of moments (*e.g.*, forces that can rotate a body) of shear stresses acting on the edges of rectangular elements leads to equivalences between the following shear stresses: $\sigma_{12} = \sigma_{21}$, $\sigma_{32} = \sigma_{23}$ and $\sigma_{13} = \sigma_{31}$ or in general $\sigma ij = \sigma ji$ for $ij = 1,2,3$. Hence, there are three independent shear stresses that, with the three normal stresses, make a total of six components acting at any point. These components can be transformed so as to give the components referred to any alternative set of axes. The particular set of three axes on which shear stresses are zero are known as the principal axes.

Stresses acting on any element must be in equilibrium. If stresses, σ_{11}, acting on opposite sides of the element are equal, they will exert no resultant force. It is assumed that this normal stress may increase across the element so as to have an excess value $(\partial\sigma_{11}/\partial x_1)\delta x_1$ on the outside face (Figure 3), which has an area represented by the product

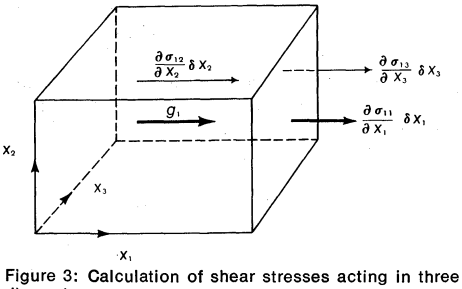

Figure 3: Calculation of shear stresses acting in three dimensions.

of the two deltas, representing the elements of length, δx_2 δx_3. Similar increases are permitted in shear stresses acting in the x_1 direction, and these excess values of stress are shown in Figure 3. Also, a body-force vector such as might be produced by gravity or inertia, is supposed to have component g_1 acting in the x_1 direction, this being a force per unit volume. By equating to zero the sum of

all net forces acting in the x_1 direction, and removing the common factor equal to the volume of the element, an equation is obtained that may be written:

Stress equilibrium equations

$$0 = g_1 + \frac{\partial \sigma_{11}}{\partial x_1} + \frac{\partial \sigma_{12}}{\partial x_2} + \frac{\partial \sigma_{13}}{\partial x_3}.$$

Two more stress equilibrium equations representing equilibrium in the X_2 and X_3 directions can be obtained by interchange of coordinate values.

These equations define the restrictions to permissible distribution of stress, and they form the starting point in the analysis of stress in any deformable medium.

Linear elasticity and elastic constants. Arguments in favour of the existence of two independent elastic moduli were clarified by Sir George Gabriel Stokes, British physicist and mathematician, in 1845. He maintained that a change in volume and a change in shape are physically distinct processes. A bulk modulus K may be defined by the statement that average stress, σ, produces a fractional change in volume. If e is the average linear strain, the law of volume elasticity is represented by an equation in which average stress—that is, the average of the three stress components—equals three times the product of the bulk modulus and average linear strain: $\sigma = 3Ke$.

Isotropic material

In an isotropic material—that is, a material having equal properties in all directions—a single constant can be used for relating reduced stresses and strains because this constant is a measure of rigidity, or of resistance to change of shape. General components of stress and the linear relation can be expressed in an equation that contains the shear modulus. The proportionality between stresses and small strains is calculated without reference to the property of springing back on removal of stress, though this property would need to be assumed if one wished to predict the final strain produced by a succession of stresses having dissimilar signs.

It should also be noted that, although a structure may consist of parts made from linear elastic material, there may be reasons due to its shape why the structure gives a nonlinear variation of deflection with applied load. Examples are struts loaded near the point of elastic instability and thin plates having large transverse deflections imposed (for calculations, see below *Mathematical considerations*, Equation 2).

It is found that Young's modulus for an alloy is not much affected by mechanical and thermal treatments, and it is given approximately by the (volumetric) average of values (of the modulus) for each of the constituent metals. For example, all steels with a content of alloying elements less than about 10 percent can be assumed for most purposes to have the same elastic constants as mild steel. Progressive cold working of metals, however, may lead to varying orientations of the crystallographic axes of individual grains, with development of elastic anisotropy; that is, of a variation in modulus depending on the direction of the specimen axis relative to the direction of cold-working.

Molecular packing

The bulk modulus increases with pressure because of a decrease in the space between molecules. Water at 20° C, for example, has a bulk modulus value $K = 320{,}000$ pounds per square inch (psi). According to experimental results this should be multiplied by a factor containing pressure. (The factor is $[1 + 20 \times 10^{-6}p]$, in which p is pressure in psi). The increase in K with pressure is in part caused by a decrease in size of the molecules themselves. Because this decrease is relatively small, it might be expected that solids having closely packed molecules would show only a small variation of K with pressure; experiment proves this to be true. For similar reasons, the increase in shear modulus G is small for most metals. (The correction factor here is approximately $[1 + 0.15 \times 10^{-6}p]$). The elastic moduli of metals usually decrease with temperature due to the atoms moving farther apart, and there is a rapid fall at higher temperatures. This change in modulus may be nonlinear and sometimes irregular, but for many metals a decrease of two to six percent per 100° C may be expected over moderate ranges of temperature on either side of room temperature (for a treatment of invariants, energy, and yield criteria, see below, *Mathematical considerations*).

Mathematical theory of elasticity. It has been seen that three sets of equations must be satisfied at all interior points in a linear-elastic body; namely, the strain-displacement equations, the stress-equilibrium equations, and the stress-strain relations. A typical problem posed in the theory of elasticity is to find stresses and displacements at all interior points, given the external shape of the body and the stresses or displacements imposed over the boundary of the body or part of the boundary. Occasionally the basic equations can be used as they stand, by inserting a simple system of stresses or displacements into the first order differential equations.

Various idealized stress systems can be formulated, such as that appropriate for symmetry on planes, or about an axis, or for flexure of plates. The procedure is to look for solutions of the differential equations that can be made to fit the specified boundary conditions. Rectangular coordinates cannot be conveniently used for describing stresses and displacements on curved boundaries. In such problems, the differential equations need to be recast in curvilinear coordinates, which may call for many specialized techniques of applied mathematics.

It is often possible to verify theoretical solutions by means of experimental methods, for example, by using photoelastic models or electrical resistance strain gauges. The extensive range of techniques in modern experimental stress analysis can also be used in situations where no theoretical methods can be applied; for example, in the measurement of internal stresses set up in components during manufacturing processes.

Mathematical considerations. Equations (1) and (2), referred to earlier, as well as invariant functions, strain energy, and yield criteria, are treated below.

Equation (1): The constitutive equation of an anelastic solid is expressed

$$\sigma + t_1 \frac{d\sigma}{dt} = E\left(e + t_2 \frac{de}{dt}\right)$$

in which t_1 and t_2 are time constants. For very slow straining, the rate terms can be dropped, leaving the static elasticity relation $\sigma = Ee$. If straining is extremely rapid so that the rate terms predominate, however, the apparent modulus is given by $E' = Et_2/t_1$. Response to periodic stressing at frequency $\omega/2\pi$ can be found by inserting $\sigma = \sigma_0 \sin \omega t$ and $e = e_0 \sin(\omega t - \phi)$. The angle of lag ϕ is then obtained as

$$\tan \phi = \omega(t_2 - t_1)/(1 + \omega^2 t_1 t_2).$$

This predicts a maximum angle of lag at imposed frequency $\omega = 1/\sqrt{t_1 t_2}$, and it is found that many materials do exhibit such a maximum value.

Equation (2): It is usually convenient to use total stresses and strains rather than reduced values. New elastic constants, ν, called Poisson's ratio, and E may be introduced to obtain equations relating normal stress and strain of the type

$$e_{11} = \frac{1}{E}[\sigma_{11} - \nu(\sigma_{22} + \sigma_{33})],$$

provided the new constants are related to the previous ones by

$$E = \frac{9KG}{3K + G} \text{ and } \nu = \frac{3K - 2G}{2(3K + G)}.$$

These expressions lead to the useful expressions for Young's modulus $E = 2(1 + \nu)G = 3(1 - 2\nu)K$. To illustrate the significance of Poisson's ratio ν, the axis of a tensile specimen is made to coincide with the z direction, and the longitudinal stress is set equal to $\sigma_{zz} = T$, with transverse stresses $\sigma_{xx} = \sigma_{yy} = 0$. The strains are then $e_{zz} = T/E$ and $e_{xx} = e_{yy} = -\nu T/E$. This means that the fractional transverse contraction is ν times the fractional longitudinal extension.

An invariant function of components of stress or strain

Invariants, energy, and yield criteria

at a point is a function having the same numerical value for any choice of coordinate axes. There are three independent invariants of stress. The first is average stress σ, defined as one third of the sum of the three normal components of stress. The second is conveniently written in terms of reduced stresses in which the reduced values of stress are distinguished by a prime, $\sigma'_{11} = \sigma_{11} - \sigma$, $\sigma'_{12} = \sigma_{12}$, and similarly for the other components;

$$2\bar{\sigma}^2 = \sigma'_{11}{}^2 + \sigma'_{22}{}^2 + \sigma'_{33}{}^2 + 2\sigma_{12}{}^2 + 2\sigma_{23}{}^2 + 2\sigma_{31}{}^2.$$

It is seen that when only a single shear stress σ_{12} is present, the other components being zero, then $\bar{\sigma} = \sigma_{12}$, so that this invariant is sometimes called the equivalent shear stress. The third invariant is essentially a third-order combination of stress components that may be shown to have a one-to-one relationship with Lode's variable, $\mu = 3\sigma'_2/(\sigma_1' - \sigma_3')$. These reduced principal stresses are designated in such a way that $\sigma'_1 > \sigma'_2 > \sigma'_3$. This variable, as defined here, can have values ranging from minus one for uniaxial tensile stress to plus one for compressive stress.

Strain energy U per unit volume is essentially the summation of products of internal forces and displacements, and for any linear material this can be written

$$U = \frac{1}{2}(\sigma_{11}e_{11} + \sigma_{22}e_{22} + \sigma_{33}e_{33} + 2\sigma_{12}e_{12} + 2\sigma_{23}e_{23} + 2\sigma_{31}e_{31}).$$

These stresses and strains may be separated into isotropic and reduced parts so that the basic stress-strain relations for an isotropic solid can be used. As might be expected, the result can be expressed in terms of stress invariants, $U = \frac{1}{2}(\sigma^2/K + \bar{\sigma}^2/G)$. Alternatively, total stresses may be used together with elastic constants E and ν to obtain the strain energy per unit volume,

$$U = \frac{1}{2E}[\sigma_{11}{}^2 + \sigma_{22}{}^2 + \sigma_{33}{}^2 - 2\nu(\sigma_{11}\sigma_{22} + \sigma_{22}\sigma_{33} + \sigma_{33}\sigma_{11}) + 2(1 + \nu)(\sigma_{12}{}^2 + \sigma_{23}{}^2 + \sigma_{31}{}^2)].$$

A similar expression can be obtained, if required, in terms of strain components alone.

The stress at which plastic flow commences in crystalline materials is not affected by superposition of moderate values of average stress. This fact has been demonstrated by carrying out tensile and torsion tests with specimens enclosed within a pressure vessel and subjected to high fluid pressures. Hence, the criterion of plastic yielding in an isotropic solid can be written in terms of the remaining stress invariants, in the form $\bar{\sigma}(\mu) = k$, in which k is some fixed numerical value. This function of μ is called a yield locus and can be represented in various geometrical ways. The simplest kind of yield locus is when $\bar{\sigma} = k$, which is known as the Mises criterion. An alternative, the Tresca criterion, states that yielding occurs when the maximum shear stress acting within the material reaches a certain value, and as this shear stress is equal to half the difference between the greatest and least of the principal stresses, this criterion becomes $(\sigma_2 - \sigma_3) = 2k$.

BIBLIOGRAPHY. Apart from isolated chapters in many physics textbooks, most works dealing with elasticity are for advanced studies. The standard texts include: S.P. TIMOSHENKO, *History of the Strength of Materials* (1953); A.H. COTTRELL, *The Mechanical Properties of Matter* (1964); W.D. BIGGS, *The Mechanical Behaviour of Engineering Materials* (1965); J.M. LESSELLS, *Strength and Resistance of Metals* (1954); A.M. FREUDENTHAL, *Introduction to the Mechanics of Solids* (1966); I.S. SOKOLNIKOFF and R.D. SPECHT, *Theory of Elasticity* (1946); and N.I. MUSKHELISHVILI, *Some Basic Problems of the Theory of Elasticity* (1953; orig. pub. in Russian, 1935).

(D.S.D.)

Elbe River

The Elbe, one of Europe's major waterways, runs from Czechoslovakia to the North Sea. It is formed at Spindleruv Mlyn by the confluence of numerous headwater streams originating in the Riesengebirge (Giant Mountains) on the border of Czechoslovakia and Poland. Starting southward, the river makes a wide arc to the west as it flows across Bohemia (where it is known as the Labe). It cuts northwest through the Erzebirge (Ore Mountains) in a gorge four miles long and enters Germany. From Dresden it flows northwest to Magdeburg and then north to Werben, where it again turns northwestward. Between Wittenberg and Lauenburg the boundary between the Federal Republic of Germany and the German Democratic Republic lies in midstream. Above Hamburg the Elbe splits into several branches; these rejoin farther downstream and the river now broadens from a width of 0.3 mile at Hamburg to a width of 9 miles at Cuxhaven, where it flows into the North Sea. Although Hamburg lies 68 miles upstream from the mouth of the river, the width of the estuary has made that city the largest seaport on the continent of Europe.

The total length of the Elbe is 724 miles (1,165 kilometres), of which 352 miles are in the German Democratic Republic. Its total drainage area is 55,620 square miles. Major tributaries are the Vltava (Moldau) and the Ohře (Eger), the Mulde and the Saale, all of which join it from the left; and the Iser, Black Elster, Havel, and Alster, from the right.

The flow of water in the Elbe varies considerably with the amount of precipitation and thawing in its drainage basin. At Dresden, the discharge rate averaged 14,609 cubic feet per second in the period 1937–47, but the rate varied from a low of 9,387 cubic feet in one year to 25,054 in another. At Neu-Darchau, about 140 miles above the mouth, the discharge rate was 24,700 cubic feet per second in the period 1926–65, with extremes of 5,117 and 127,741. These great variations sometimes hinder navigation. While there are dams on the Saale River in the Thüringer Wald (Thuringia Forest), these are not sufficient to control the water level of the Elbe.

The lower course of the Elbe is tidal as far as Altengamme, above Hamburg, where the river flow periodically reverses its direction. The average tide at Hamburg is 8.2 feet, and during storms the water may rise much higher, occasionally even flooding parts of the city.

Traffic on the Elbe

By means of the Elbe and its connecting waterways, vessels from Hamburg can navigate to Berlin, central Germany, and Czechoslovakia. The Mittelland Kanal, a short distance below Magdeburg, runs westward about 202 miles to the Dortmund–Ems Kanal, carrying barges of up to 1,000 tons to the industrial cities of Osnabrück, Hannover, Salzgitter, Hildesheim, Peine, and Wolfsburg, and connecting with the Weser and Rhine rivers. The Havel Kanal carries traffic from Magdeburg eastward to the network of waterways around Berlin and farther on to Poland. The Kiel Canal runs from the mouth of the Elbe to the Baltic Sea, and the Elbe–Lübeck Kanal, starting at Lauenburg, also runs to the Baltic, following an older (14th-century) canal. Another canal connects the lower Elbe with Bremerhaven on the Weser River. In the early 1970s the Nord–Süd Canal was under construction, intended to connect the Elbe a short distance upstream from Hamburg with the Mittelland Kanal at Fallersleben, thus linking the harbour of Hamburg directly with the industrial district of Salzgitter. The Elbe itself is navigable for 700-ton barges as far as Usti nad Labem in Bohemia, and for smaller barges as far as Prague through the tributary of the Vltava (Moldau). In East Germany it serves the important river ports of Magdeburg, Schönbeck, Aken, Dessau, Riesa, and Dresden, carrying bituminous coal, lignite, coke, metal, potash, grain, and piece goods. A new six-line railway tunnel under the Elbe at Hamburg, under construction in the early 1970s, was likely to have a considerable effect on trans-European traffic flows.

Historical importance

The basin of the Elbe has been settled since prehistoric times. Until the Middle Ages the river was the western boundary of the area inhabited by the northern Slavs. In the 12th century the Germans began to colonize the lands east of the Elbe and along the Baltic Sea. In World War II a point on the Elbe, near Torgau, was the meeting place of the United States and Soviet armies. Later, the river formed part of the demarcation between the German Democratic Republic and the Federal Republic of Germany.

The city of Hamburg dates from about 810. Together with Lübeck, Hamburg established the Hanseatic League in 1241. Today it is West Germany's largest city, excluding West Berlin, with a population (in 1970) of about 1,794,000. Another ancient city on the Elbe is Magdeburg, which in the early 9th century was a trading post on the border between the Germans and the Slavs. In the 13th century it was a flourishing commercial city and an important member of the Hanseatic League. Today it is the largest inland harbour of the German Democratic Republic. The other chief city of the Elbe is Dresden, founded about 1200. During the 18th century Dresden developed into a great centre of the fine arts, known as "Florence on the Elbe." Much of its beautiful architecture was destroyed during World War II. (H.F.)

Elburz Mountains

The Elburz (alternate spellings are Elburs, Alburz, or Albourz) Mountains in northern Iran separate the lowlands along the Caspian coast from the inland plateau. In its widest sense, Elburz designates the whole chain of ranges, some 560 miles (900 kilometres) long, which extends in a crescent-shaped arc from the Soviet frontier southwest of the Caspian Sea to the Khorāsān *ostān* (province) southeast of the sea, where it merges into Ālādāgh, the more southerly of the two principal ranges there. More commonly, however, the mountains northwest of the Safīd Rūd gorge, which lies to the southwest of the sea, are called the Talish (Talysh, Talesh, or Tavālesh) Range, or the Bogrov Dāgh; the Elburz Range, in its strictest sense, forms part of the central stretch of the chain, which also includes Iran's two highest peaks, Mt. Damāvand and Alām Kūh. The Elburz system traverses four of Iran's *ostāns* (provinces)—Āzarbāījān-e Khavari (East Azerbaijan), Gīlān, Central (Tehrān), and Māzandarān.

Geology. The Elburz chain is not as truly alpine (*i.e.*, resembling the European Alps) in its structure as is often suggested. On the one hand, continental conditions regarding sedimentation are reflected by thick Devonian sandstones (formed 395,000,000 to 345,000,000 years ago), called Old Red Sandstone in Britain, and by shales containing coal seams; on the other hand, marine conditions are reflected by Permo-Carboniferous (*i.e.*, younger Paleozoic) strata that are composed mainly of limestones, as well as by very thick beds of green volcanic rocks known as tuffs and lavas. Orogenetic (mountain-building) phases of importance date from the younger Tertiary (Mio-Pliocene) Epoch (between 26,000,000 and 2,500,000 years ago). Over large areas they produced only a loose folding; but in the Central Elburz a number of folds were formed into blocks thrust mainly southward but in places northward, with cores made of Paleozoic rocks. There is a distinct zonation of the whole area according to which rock formations predominate in forming mountain crests. Structurally and topographically, the Elburz system is less clearly defined on the southern than on the Caspian side of the chain, since various offbranching elements interconnect it on the southern side with the adjoining Iranian Plateau.

The Western, Central, and Shāhkūh ranges

Relief. The Western Elburz Range runs south-southeastward for 125 miles. Varying in width from 15 to 20 miles, it consists of a single asymmetric ridge, the long slope facing the Caspian. Few of its peaks approach or exceed 10,000 feet in height. There is a low pass west of Āstārā, near the Soviet frontier, 5,000 feet above sea level. The Safīd Rūd, formed by the junction of the Qezel Owzan (Qisil Uzun) and Shāhrūd rivers, is the only river to cross the whole width of the chain: its gorge, giving access to the low pass of Qazvīn, offers the best passage, although by no means an easy one, between Gīlān on the shores of the Caspian and the inland plateau.

The Central Elburz is 250 miles long. East of the longitude of Teheran (*q.v.*), which lies to the south of the range, it reaches a width of 75 miles. Longitudinal valleys and ridges follow the structural pattern; some of them are important centres of settlement, with towns such as Deylamān, Razan, Kojūr, and Namar located on the Caspian side, and Shāhrūd, Lār, Damāvand, and Fīrūzkūh on the southern side. There are likewise many gorges, by which the rivers find their way down one or another of the slopes. Only two passes allow a relatively easy crossing in a single ascent—these are the Kandevān Pass, between the Karaj and the Chālūs rivers, and the Gadūk Pass, between the Hableh and the Tālā rivers. The main divide runs generally south of the highest crest, which—with the exception of the towering and isolated cone of the extinct volcano Damāvand (18,386 feet [5,604 metres])—culminates in the glaciated massif (mountainous mass) of Takht-e Sulaimān, with Alām Kūh (15,827 feet, [4,824 metres]) at its summit.

The Eastern, or Shāhkūh, Elburz runs about 185 miles in a northeasterly direction. Since two ranges branch off on its southern side and no compensatory elements appear on the northern side, its width dwindles to less than 30 miles. With the exception of the Shāhkūh Range proper (which reaches an altitude of 12,359 feet, [3,767 metres]), the chain decreases in height toward the east. Longitudinal valleys are found less and less frequently east of the Shāhkūh. There are several passes at low altitudes.

Climate, soils, and vegetation. The Caspian and the inland, or southern, slopes of the Elburz differ markedly from each other in climatic and vegetational aspects.

Characteristics of the northern and southern slopes

The Caspian slope has a distinctly humid climate, thanks to northerly air movements, enriched with moisture from the sea, which collide with the steep faces of the mountains to cause precipitation. This precipitation amounts to more than 40 inches annually in the lowlands of Gīlān and is even more plentiful at higher altitudes. Although it decreases toward the east, it still suffices to nourish a humid forest for the whole length of the chain on the Caspian side, where the soils are mostly of the brown-forest type.

The natural vegetation of this slope grows in distinct zones: the luxuriant Hyrcanian forest on the lowest levels; a beech forest in the middle zone; and a magnificent oak forest from the altitude of 5,500 feet up to the levels where gaps in the divide allow the moist air to overflow into the inland basins. Above the cloudy zone, which expands and recedes depending on conditions, a steady current of dry air from the south or southwest causes the vegetation of the inland slope to overlap the divide on all the higher ranges; this circumstance changes in winter and in summer, when frequent large-scale cyclonic wind and pressure systems from the Mediterranean make their way eastward over the Iranian Plateau. In some sheltered valleys there are extensive stands of wild cypress; sheltered valleys adjacent to the Safīd Rūd constitute the only olive-growing areas of note in Iran.

The southern slope of the Elburz, by direct contrast, shares the arid character of the Iranian Plateau. Annual precipitation varies between 11 and 20 inches and is very irregular. The soils are of the type associated with steppe (treeless, grassy, or shrubby type of vegetation) or, less widely, are of the chestnut variety. The slope has become even more steppe-like ever since the almost complete destruction of its original dry forest of junipers.

Animal life. The Hyrcanian tigers for which the Caspian forests were famous are now very rare; but other wild cats, such as the leopard and the lynx, are still numerous in the Elburz. The bear, the wild boar, red and roe deer, the moufflon (wild mountain sheep), and the ibex are also present. Eagles and pheasants are notable among birds.

Demography. The basic elements in the population of the two *ostāns* bordering the Caspian—Gīlān and Māzandarān—are considered to possess distinguishing characteristics; they speak Iranian dialects of their own. Their tendencies to separatism, however, have caused successive governments to implant tribal groups of Turkic, Kurdish, and even Arab origin in these provinces. A gradual migration from the highland into the humid area, where manpower has always been short—not least because of the high mortality due to malaria—was also

noticeable. The total population of the Elburz chain, estimated at about 1,000,000 in 1966, is very unevenly distributed. While large areas are almost empty—some being occupied only by nomads and others having been depleted by Turkmen raids in the 19th century—there are still several well-settled districts, including Deylamān, Alāmut, Tālaqān, and Lārījān (at the foot of Mt. Damāvand), all of which have various historical associations.

The Caspian and the inland slopes have different characteristic types of settlement; the landscape of the Caspian slopes is characterized by forest clearings with shingle-roofed loghouse villages and by lush fields and pastures. The landscape of the inland slopes is of the oasis type. *Qeshlāqs*, or winter villages, are found both on the inland foothills and in the low valley bottoms (terraced for rice growing) of the Caspian side. *Yeylāqs*, or summer villages, mostly half deserted in winter, are spread over a broad zone higher up. Extensive grain cultivation occurs on both slopes, and cattle raising occurs on the Caspian side. Alpine pastures, seasonally dotted with thousands of flocks, with the black tents of the semi-nomads, and with the huts or white tents of the village shepherds, cover an extensive zone yet higher. The land-distribution pattern prevailing in the Elburz includes a high proportion of peasant ownership. The holdings often are much fragmented.

Summer and winter villages

Many of the traditional ways of livelihood of the mountaineers, including charcoal burning (now prohibited because of devastation of the forests), the transportation of goods (especially of rice and of charcoal for Tehrān) by pack animals, and the working of hundreds of small coal mines, have been displaced by the 20th-century modernization of Iran. Modernization likewise, together with the lure of the nearby capital city of Tehrān, has not only set a new course for seasonal emigration but also has tended to turn that seasonal movement into a definite exodus from the countryside.

Transportation. Apart from the main line of the trans-Iranian railroad, which links Tehrān with Bandar-e Shāh via the Gadūk Pass, there are six asphalted roads across parts of the Elburz. From west to east, these run between Ardebīl and Āstārā, between Qazvin and Rasht, between Tehrān and Chālūs, between Tehrān and Āmol (via Damāvand); between Tehrān and Bābol (via Fīrūzkūh), and between Shāhrūd and Gorgān (via Kotal-e Zardāneh Pass).

Economic resources. The wild (natural or original) forests of the Elburz Mountains cover more than 8,000,000 acres, of which some 3,000,000 can be exploited commercially for timber and other wood. There are also a few modern coal mines, which yield about 250,000 tons of coal a year, as well as some deposits of iron and other ores. But most important is the water of the rivers, which is used for irrigation, for generating hydroelectric energy, and for supplying the fast-growing Tehrān. Spectacular dams have been built. These include the Safīd Rūd Dam, used for the irrigation of the Safīd Rūd Delta; the Karaj Dam and the Jajrūd Dam, used mainly for supplying water to Tehrān and partly for irrigation; and a series of dams on other rivers of the Māzandarān *ostān* also used for irrigation.

In the early 1970s, further dams were either under construction or projected, and it was anticipated that the establishment of such facilities in the mountains as skiing, health, and tourist resorts could provide another economic resource in the future.

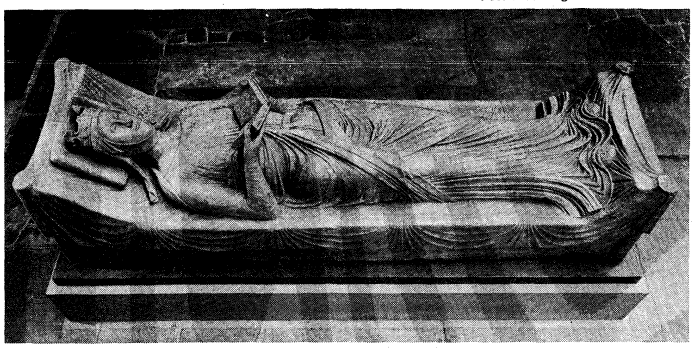
Eleanor of Aquitaine

Queen consort of both Louis VII of France and Henry II of England, and mother of Richard I the Lion-Heart and John of England, Eleanor of Aquitaine was probably the most powerful woman of her era. Her political daring made her the equal of most contemporary sovereigns, and, as patroness of the arts, she provided at the court of Poitiers a congenial environment for the burgeoning literary culture of 12th-century Europe.

Foto Marburg



Eleanor of Aquitaine, plaster cast of her tomb effigy, 13th century, in the abbey church at Fontevrault-l'Abbaye, France.

Eleanor, born about 1122, was the daughter and heiress of William X, duke of Aquitaine and count of Poitiers, who possessed one of the largest domains in France—larger, in fact, than those held by the French king. Upon William's death in 1137 she inherited the duchy of Aquitaine and, in July 1137, married the heir to the French throne, who succeeded his father Louis VI the following month. Eleanor became queen of France, a title she held for the next 15 years. Beautiful, capricious, and adored by Louis, Eleanor exerted considerable influence over him, often goading him into undertaking perilous ventures.

Heiress of Aquitaine

From 1147 to 1149 Eleanor accompanied Louis on the Second Crusade to protect the fragile Latin kingdom of Jerusalem, founded after the First Crusade only 50 years before, from Turkish assault. Eleanor's conduct during this expedition, especially at the court of her uncle Raymond of Poitiers at Antioch, aroused Louis's jealousy and marked the beginning of their estrangement. After their return to France and a short-lived reconciliation, their marriage was annulled in March 1152. According to feudal customs, Eleanor then regained possession of Aquitaine, and two months later she married the grandson of Henry I of England, Henry Plantagenet, count of Anjou and duke of Normandy. In 1154 he became, as Henry II, king of England, with the result that England, Normandy, and the west of France were united under his rule. Eleanor had only two daughters by Louis VII; to her new husband she bore five sons and three daughters. The sons were William, who died at the age of three; Henry; Richard, the Lion-Heart; Geoffrey, duke of Brittany; and John, surnamed Lackland until, having outlived all his brothers, he inherited, in 1199, the crown of England. The daughters were Matilda, who married Henry the Lion, duke of Saxony and Bavaria; Eleanor, who married Alfonso VIII, king of Castile; and Joan, who married successively William II, king of Sicily, and Raymond VI, count of Toulouse. Eleanor would well have deserved to be named "grandmother of Europe."

During her childbearing years, she participated actively in the administration of the realm and even more actively in the management of her own domains. She was instrumental in turning the court of Poitiers, then frequented by the most famous troubadours of the time, into a centre of poetry and a model of courtly life and manners. She was the great patron of the two dominant poetic movements of the time: the courtly love tradition, conveyed in the romantic songs of the troubadours, and the historical matière de Bretagne, or "legends of Britanny," which originated in Celtic traditions and in the *Historia regum Britanniae*, written by the chronicler Geoffrey of Monmouth some time between 1135 and 1139.

Cultural activities

The revolt of her sons against her husband in 1173 put her cultural activities to a brutal end. Since Eleanor, 11 years her husband's senior, had long resented his infidelities, the revolt may have been instigated by her; in any case, she gave her sons considerable military support. The revolt failed and Eleanor was captured while seeking refuge in the kingdom of her first husband, Louis VII. Her imprisonment for nearly 15 years (1174–89) in England ended only with the death of Henry II. On her release, Eleanor played a greater political role than ever before. She actively prepared for Richard's coronation as king, was administrator of the realm during his crusade to the Holy Land, and, after his capture by the Duke of Austria on Richard's return from the east, collected his ransom and went in person to escort him to England. During Richard's absence, she succeeded in keeping his kingdom intact and in thwarting the intrigues of his brother John Lackland and Philip II Augustus, king of France, against him.

In 1199 Richard died without leaving an heir to the throne, and John was crowned king. Eleanor, nearly 80 years old, fearing the disintegration of the Plantagenet domain, crossed the Pyrenees in 1200 in order to fetch her granddaughter Blanche from the court of Castile and marry her to the son of the French king. By this marriage she hoped to insure peace between the Plantagenets of England and the Capetian kings of France. In the same year she helped to defend Anjou and Aquitaine against her grandson Arthur of Brittany, thus securing John's French possessions. In 1202 John was again in her debt for holding Mirebeau against Arthur, until John, coming to her relief, was able to take him prisoner. John's only victories on the Continent, therefore, were due to Eleanor.

Assessment

She died on April 1, 1204, in the monastery at Fontevrault, Anjou, where she had retired after the campaign at Mirebeau. Her contribution to England extended beyond her own lifetime; after the loss of Normandy (1204), it was her own ancestral lands and not the old Norman territories that remained loyal to England. She has been misjudged by many French historians who have noted only her youthful frivolity, ignoring the tenacity, political wisdom, and energy that characterized the years of her maturity. "She was beautiful and just, imposing and modest, humble and elegant"; and, as the nuns of Fontevrault wrote in their necrology: a queen "who surpassed almost all the queens of the world."

BIBLIOGRAPHY. AMY KELLY, *Eleanor of Aquitaine and the Four Kings* (1950), is a major work with complete notes and a good bibliography and sources. H.G. RICHARDSON, "The Letters and Charters of Eleanor of Aquitaine," *English Historical Review*, 74:193–213 (1959), adds some unpublished sources to those gathered by Amy Kelly. REGINE PERNOUD, *Aliénor d'Aquitaine* (1965), gives more attention to the personality and politics of Eleanor herself, independently from the history of her two husbands.

(R.Pe.)

Eleaticism

One of the principal schools of ancient Pre-Socratic philosophy was Eleaticism, so-called from its seat in the Greek colony of Elea (or Velia) in southern Italy. This school, which flourished in the 5th century BC, was distinguished by its radical monism; *i.e.*, its doctrine of the One, according to which all that exists (or is really true) is a static plenum of Being as such, and nothing exists that stands either in contrast or in contradiction to Being. Thus, all differentiation, motion, and change must be illusory. This monism is also reflected in its view that existence, thought, and expression coalesce into one.

The Eleatic school vis-à-vis rival movements. The Eleatic school was founded by Parmenides, a 5th-century Rationalist, and included two scholars who may have been his pupils, Zeno of Elea, renowned for his paradoxes of motion (see below), and Melissus, an admiral of Samos.

Each member of the Eleatic school espoused a distinctive variety of Eleaticism: Parmenides pursued a direct and logical course of thought and viewed Being as finite and timeless; Zeno concurred in Parmenides' doctrines but employed the indirect methods of *reductio ad absurdum* and infinite regress (see below); and Melissus modified the doctrines, viewing Being as infinitely extensive and eternally temporal. A fourth thinker, the Sicilian Sophist Gorgias of Leontini, though not an adherent to Eleaticism, employed the methods of the Eleatic Zeno to defend its opposite—a nihilism that affirmed Non-Being instead of Being.

Contrasts with other movements

Eleaticism represents a reaction against several tendencies of thought. Methodologically, it spurned the empirical (observational) approach taken by earlier cosmologists, such as the 6th-century Milesians Thales and Anaximenes, who discerned ultimate reality in water and in air (or breath), respectively, for these substances are materializations of Being—analogous to the materialization that occurs in Pythagoreanism in passing from an abstract line or plane or three-dimensional form to a solid perceptible body—rather than Being itself; or, at best (as some scholars hold), the substances are mythological representations of Being. The Eleatics, on the contrary, ignoring perceptual appearances, pursued a rationalistic—*i.e.*, a strictly abstract and logical—approach and thus found reality in the all-encompassing, static unity and fullness of Being and in this alone. Thus Parmenides was the father of pure ontology.

Ontologically—in its view of the nature of Being—the Eleatic school, holding to what Parmenides called the "way of truth" ("what is"), stood opposed to two other "ways of research" that were then current: first, to the "way of opinion" (or Seeming; later developed at length by Plato in the *Sophist*), which held that a being comprises or is defined not only by what it is but also by what it is not—*i.e.*, by its contrast with other things; and, second, to a way recognizable as that of Heracleitus, a caustic and often cryptic philosopher then living in Ephesus, who maintained—still more radically—that the essence of a being lies in part in its involvement in, or even its identity with, its opposite. Finally, as an aspect of Parmenides' opposition to the way of opinion, he was in reaction also against Anaximander, another Milesian scientist and philosopher. Though Anaximander's basic principle, the apeiron ("boundless"), was duly abstract and not a part of the world itself (as were water and air), his philosophy depended, nonetheless, upon the world's contrast with the infinite apeiron, from which all things come and to which they return "in accordance with the ordinance of Time." This contrast—which, in a Pythagorean version, envisioned the world as breathing in voidness from the infinite outer breath in order to keep things apart or discreet—thus spawned "a many" that contradicts the Eleatic One.

Archaeological and literary sources. The sources for the study of Eleaticism are both archaeological and literary. Archaeologists have ascertained that, at the time of Parmenides, Elea was a large town with many temples, a harbour, and a girdle of walls several miles long. They have also unearthed a site presumed to be that of the medical school that Parmenides founded and an inscription bearing Parmenides' name.

The literary sources consist of fragments preserved by later classical authors—19 from Parmenides, 4 from Zeno, and 10 from Melissus—of which all but 3 from Parmenides and 2 from Melissus are 10 lines or less in length. The interpretation is also affected by the weight of scholarly opinion that now holds (as against Karl Reinhardt, an early-20th-century philologist and historian of philosophy) that Parmenides reacted to Heracleitus and not vice versa. Moreover, the biases of the citing authors must be weighed. Heracleitans and Parmenideans of the second generation, for example, saw their masters, simplistically, only as the prophets of movement and immobility; and the ancient Skeptic Sextus Empiricus distorted Parmenides' thinking into problems of epistemology (theory of knowledge), because this is what his Skeptical eye saw in his writings.

The rigorous Ontologism of Parmenides and Melissus. For a long time Xenophanes of Colophon, a religious thinker and rhapsode of the 6th–5th century BC, was con-

sidered the founder of the Eleatic school and Parmenides' mentor. This ancient claim, however, has been successfully criticized by Reinhardt. It is even possible that, on the contrary, Xenophanes was an older pupil of Parmenides. In any case, his monistic view of a cosmic God, whom he may have equated pantheistically with Being itself, was Eleatic in its contention that God is one and ungenerated, that his seeing, thinking, and hearing are equally all-pervading (*i.e.*, he is not a composite), and that he "always remains in the same place, not moving at all."

Parmenides' poem and the two ways of research

Parmenides' poem *Peri physeōs* ("On Nature") is divided into three parts: (1) a proem (preface), in which his chariot ride through the heavens to the very seat of the goddess Alētheia (Truth) is described and their initial conversation is related, in which she announces that he is "to learn all things, both the unshaken heart of well-rounded truth and also what seems to mortals, in which is no true conviction"; (2) the "Way of Truth," the main part, in which the real and unique Being is depicted; and (3) the "Way of Opinion" (or Seeming), in which the empirical world—*i.e.*, the single things as they appear every day to every man—is presented.

Logical and linguistic approach. Thus, at the very heart of Parmenides' philosophy lies the distinction made by the goddess (in Fragment 2) between the two "ways of research." As noted earlier, the first is the antinomy (or paradox) of those who think and say that everything is Being and who shun all assertions of Non-Being; and the second is that of those who think and say that something is in a way and is not in another way—that a book is a book, for example, and not a table. There is, however, also a third way that is far more erroneous and fallacious than the second: that of Heracleitus, who acknowledged, just as Parmenides did, the ontological antinomy of is and is not but reversed it, holding that the real way of understanding things is to grasp their essential contradiction, their intrinsic opposition to everything else. In this view, one must say that to be a table is also not to be just a table and that to be a chair is not to be just a chair but to be also a table, because not only opposite things but also things that are merely different are bound to each other. Thus, life is death to Heracleitus, death is life, and justice would be meaningless if it had no injustice to defeat.

In essence, then, the possible ways are three: (1) that of renouncing all contradictions whatsoever (truth); (2) that of contradicting oneself relatively (seeming); and (3) that of contradicting oneself completely and absolutely (Heracleitus). And Eleaticism chose the first, the absolutely noncontradictory way that says that only what is, Being, is really true.

Coalescence of Being, thought, and expression

Not-Being, in fact, can neither be recognized nor expressed, for, as Parmenides then added, "for the same thing can be thought and can exist." And—if one may guess at the words (now lost) that probably followed—what-is-not you can neither know nor say; thus, to think is indeed the same as to say that what you think is. To this coalescence of existing reality and the intellectual grasping of it, Parmenides also added the linguistic communication of such knowledge. Each way of research, in fact, is at the same time a way of speculation and a way of diction; *i.e.*, both a way of searching for truth with one's mental eyes and of expressing it in words. The primal source of the Eleatic philosophy thus lies in the archaic sense of language, according to which one cannot pronounce "yes" and "no" without deciding about the reality or unreality of the objects of the statements. Thus, "yes," or "is," becomes the name of the truth; and "no," or "it is not," becomes that of its opposite.

This Eleatic principle may be illustrated by a passage from Aeschylus, a leading Greek dramatist, who, in his *Septem contra Thebas* (Eng. trans., *Seven Against Thebes*), judged it very appropriate that Helen would have destroyed Troy, because her name—naïvely derived from *helein* ("destroy") and *naus* ("ship")—marked her as a destroyer of ships. Here *nomen est omen:* the language is not merely a symbol; it corresponds to reality in its very structure. Thus, the Eleatic could not imagine a truth that is only expressible but not thinkable nor one that is only thinkable but not expressible.

Monistic theory of Being. From the premise of the essential coalescence of language and reality follows Parmenides' theory of Being, which comprises the heart of his philosophy. The only true reality is Eōn—pure, eternal, immutable, and indestructible Being, without any other qualification. Its characterizations can be only negative, expressions of exclusions, with no pretense of attributing some special quality to the reality of which one speaks.

Conflict with Melissus on the eternity of Being

In Fragment 8, verse 5, Parmenides said that the absolute Being "neither was nor will be, because it is in its wholeness now, and only now." Thus, its presence lasts untouched by any variation in time; for no one can find a genesis for it, either from another being (for it is itself already the totality of Being) or from a Not-Being (for this does not exist at all).

Obviously, this Parmenidean conception of the eternal presence of the Being conflicts with Melissus' idea of the perpetual continuation of the Being in the past, in the present, and in the future. Thus, if Eleaticism had been founded by Melissus, no one could have really understood its actual doctrine. One could suspect in it only an aspiration to have things capable of being really enduring. But even then the theory would hardly be understandable, because what one wants is not stable things in general; one wants good things to be firm and stable and bad things to be ephemeral. The perpetual continuity of existence as espoused by Melissus was despised by Parmenides just because "will be" and "has been" are not the same as "is." Only "is" is the word of the reality—just because it is the right name for the right thinking of the right Being.

Among the consequences of this Eleatic conception is the rejection of every change (birth, movement, growth, death) as pertaining only to the second-rate reality, which is known and expressed through the second "way of research." Thus, the true and noncontradictory reality is extraneous to all of those happenings, great or small, that make the constant stuff of all history.

Secondly, the real Being has no difference, no lack, no variety whatsoever in itself. Melissus is here the true pupil of Parmenides, who said that the Eōn is so closely connected in itself that "all Being is neighbour of all Being": for Melissus developed this theory by the negation of every form of *kenon* ("void"): the Being is an absolute plenum just because every lack in its plentifulness would amount to a presence of some Not-Being.

The paradoxes of Zeno. The position of the other great pupil of Parmenides, Zeno of Elea, was clearly stated in the first part of Plato's dialogue *Parmenides.* There Zeno himself accepted the definition of Socrates, according to which he did not really propose a philosophy different from that of Parmenides but only tried to support it by the demonstration that the difficulties resulting from the pluralistic presupposition of the *polla* (the multiple beings of man's daily experience) were far more severe than those that seemed to be produced by the Parmenidean reduction of all reality to the single and universal Being.

Paradoxes of plurality

The arguments by which Zeno upheld his master's theory of the unique real Being were aimed at discrediting the opposite beliefs in plurality and motion. There are several arguments against plurality. First, if things are really many, everything must be infinitely small and infinitely great—infinitely small because its least parts must be indivisible and therefore without extension and infinitely great because any part having extension, in order to be separated from any other part, needs the intervention of a third part; but this happens to such a third part, too, and so on ad infinitum.

Very similar is the second argument against plurality: if things are more than one, they must be numerically both finite and infinite—numerically finite because they are as many things as they are, neither more nor less and numerically infinite because, for any two things to be separate, the intervention of a third thing is necessary, ad infinitum. In other words, in order to be two, things

must be three, and, in order to be three, they must be five, and so on. The third argument says: if all-that-is is in space, then space itself must be in space, and so on ad infinitum. And the fourth argument says: if a bushel of corn emptied upon the floor makes a noise, each grain must likewise make a noise, but in fact this does not happen.

Paradoxes of motion

Zeno also developed four arguments against the reality of motion. These arguments may also be understood (probably more correctly) as proofs *per absurdum* of the inconsistency of any presupposed multiplicity of things, in so far as these things may be proved to be both in motion and not in motion. The first argument states that a body in motion can reach a given point only after having traversed half of the distance. But, before traversing half, it must traverse half of this half, and so on ad infinitum. Consequently, the goal can never be reached.

The second argument is that of "Achilles and the tortoise." If in a race the tortoise has a start on Achilles, Achilles can never reach the tortoise; for, while Achilles traverses the distance from his starting point to that of the tortoise, the tortoise will have gone a certain distance, and, while Achilles traverses this distance, the tortoise goes still further, ad infinitum. Consequently, Achilles may run indefinitely without overtaking the tortoise. This argument is fundamentally identical to the previous one, with the only difference being that here two bodies instead of one are moving.

The third argument is the strongest of them all. It says the following: so long as anything is in a space equal to itself, it is at rest. Now, an arrow is in a space equal to itself at every moment of its flight; therefore, even the flying arrow is at rest all of the time. And the final argument says: two bodies moving at equal speed traverse equal spaces in an equal time. But, when two bodies move at equal speed in opposite directions, one passes the other in half of the time that a moving body needs to pass a body that is at rest.

The difficulty with all these arguments is that of really understanding them in their historical frame, which neither Aristotle—who was mainly concerned to confute Zeno—nor many modern scholars—who are concerned with developing new theories for the calculation of infinitesimal quantities—really tried to do. Moreover, the role of the author of the paradoxes in the history of Greek philosophy is itself paradoxical, for many of the same arguments by which Zeno proved the self-contradictory nature of the unity considered as the smallest element of a pluralistic reality (the Many) were later similarly used by Gorgias and Plato to demolish the Parmenidean One-Totality itself.

The decline of Eleaticism. This problem is also connected with that of the correct interpretation of the second part of Plato's *Parmenides*. Here the great dialectical discussion to which Zeno submits the young Socrates is meant as a serious exemplification of the logical training that Socrates still needs if he wants to make progress in philosophy. But the result is simply comic—a "fatiguing joke," according to Plato's *Parmenides*—because Zeno always starts from the mere principles of the pure Being or the One and arrives at absurd conclusions: everything is shown to be true as well as false and deducible and not deducible from everything else.

Gorgias' nihilism and Plato's *Sophist*

Such dialectical futility had been anticipated by the nihilism of Gorgias, presented in a work ironically entitled *Peri tou mē ontos ē peri physeōs* ("On That Which Is Not or Nature"), in which he said (1) that nothing exists; (2) that if anything exists, it is incomprehensible; and (3) that if it is comprehensible, it is incommunicable —and in so doing he applied Parmenides' coalescence of Being and thought and expression to Not-Being instead of to Being and thus signalled the decline of Eleaticism.

The serious discussion and criticism of the Eleatic philosophy, however, and the positive interpretation of every Not-Being as a *heteron* (*i.e.*, as a being characterized only by its difference from "another" being) is neither in Gorgias nor in the *Parmenides* but in the *Sophist* of Plato. There Plato argued that the antinomy between *On* and *Mē-On* (Being and Not-Being) does not really exist, the only real antinomy being that of *Tauton* and *Heteron; i.e.*, only that of a single object of consciousness in its present determination and all other things from which it is distinguished.

The real story of ancient Eleaticism thus ends with Plato and with Democritus, who said that Being exists no more than Not-Being, the thing no more than the no-thing. But many thinkers, and great thinkers at that—from Aristotle to Kant and from Hegel to Marx—have continued to work or to fight with the antinomy of Being and Not-Being.

BIBLIOGRAPHY

Sources: The main edition of the fragments of the Eleatic, as of all the Pre-Socratic, philosophers is still HERMANN DIELS, *Die Fragmente der Vorsokratiker* (1903; 11th ed. rev. by WALTHER KRANZ, 3 vol., 1964), which is a critical edition of the Greek fragments with German translations; for English translations see KATHLEEN FREEMAN, *Ancilla to the Pre-Socratic Philosophers* (1948, reprinted 1962); PILO ALBERTELLI, *Gli Eleati: testimonianze e frammenti* (1939), is a good Italian translation with commentary.

General works: Much of the best material is in general works on ancient Greek or Pre-Socratic philosophy. The most comprehensive treatment is in EDUARD ZELLER, *Die Philosophie der Griechen*, 6–7th ed., 3 vol., ed. by W. NESTLE (1920–23); in the revised Italian trans. of Zeller, ed. with extensive additions by ROLDOLFO MONDOLFO, the portion on the Eleatic school by GIOVANNI REALE (1967) occupies the whole 3rd volume of the 1st section and contains a good selected bibliography; an English translation of Zeller is entitled *A History of Greek Philosophy, from the Earliest Period to the Time of Socrates*, 2 vol. (1881). See also JOHN BURNET, *Early Greek Philosophy*, 4th ed. (1930, reprinted 1963); GEOFFREY KIRK and JOHN E. RAVEN, *The Presocratic Philosophers*, pp. 263–306 (1957); W.K.C. GUTHRIE, *A History of Greek Philosophy*, vol. 2 (1965); and GUIDO CALOGERO, *Storia della logica antica*, vol. 1, pp. 109–208 (1967).

Electoral Processes

Elections are means of making political choices by voting. They are used in the selection of leaders and in the determination of issues. This conception of elections implies that the voters are presented with alternatives, that they can choose among a number of proposals designed to settle an issue of public concern. The presence of alternatives is a necessary condition, for although electoral forms may be employed to demonstrate popular support for incumbent leaders and their policies, the absence of alternatives disqualifies such devices as genuine elections.

Background

ORIGINS IN ANTIQUITY

The origins of election as a means of choosing among alternatives is shrouded in mystery. Literary, rather than genuinely historical evidence from the Greece of Homer and the Germany of Tacitus suggests that acclamation of the victorious leader in tribal wars, by the vanquished and winning sides alike, may have served the important function of re-establishing political peace. Although a practically compulsory form of "choice" only remotely related to what is an election, the losing side's recognition through acclamation of the new state of affairs, served to reduce tension and integrate the community. Taking sides in the selection of leaders or the settlement of controversy seems to have been the next step in the evolution of elections. A 6th-century Athenian law prescribed that in case of civil turmoil all citizens were to join one side or another or lose their status as citizens, for abstention from the conflict by too many would facilitate tyranny.

Elections in Greece

Although elections are nowadays invariably associated with one form or another of representative government, the practice of voting probably preceded the institution of representation, and quite certainly preceded any theoretical understanding of representation. The Greek system of representation was not highly developed and was thought of as limiting rather than extending the participation of citizens in government. Insofar as elections served the purpose of filling public offices, they were used when the duties involved required special knowledge and skill, such as military leadership—a reversal of the modern practice of staffing technical offices through appointment of qualified experts. In general, however, public offices were filled by lot from among tribal demes (units of local government), in a system of short-term rotation, as in the Athenian Council of Five Hundred. Any other procedure was feared to jeopardize the principle of equality and open the door to ambitious men who might seek to exploit their electoral victory for usurping political power.

Voting on measures in the Greek and Roman assemblies was usually open and by show of hands although acclamation by voice was sometimes used. In some voting situations, as in votes of ostracism and lawsuits, decisions were made by use of secret ballots in the form of white and black pebbles, marked and unmarked shells, or carved wooden tablets.

In ancient northern and eastern Europe, acclamation in support of leaders or decisions by the clashing of spears or shields signified unanimity. Unanimous consent was sought because of the prevailing feeling that what could not be done unanimously should not be done at all. As all participants were deemed equal, they all had to take part in making decisions, and the requirement of unanimity guaranteed that they did. All were winners and none were losers. But once the condition of equality gave way to inequality in status and power, as in the medieval Polish diet or the Aragonese cortes, the unanimity rule proved unworkable because it represented, in effect, a form of veto that made collective choice impossible.

THE MEDIEVAL PERIOD

Decline of elections

In the period between the decline of the Roman Empire and the emergence of absolute monarchy in the 16th century, elections probably survived at the local level in towns and regional assemblies. But the medieval social structure was not congenial to electoral practices. In the church election of superiors by their peers was practiced to facilitate and legitimize ascendancy through the hierarchy, but the electorates involved were very small, and to what extent election differed from appointment, it is difficult to say.

Throughout the medieval period the evolution of electoral processes was intimately connected with the tortuous efforts to create workable representative institutions and government by consent. Although relevant solutions, stemming largely from the Roman legal tradition, were proposed by ecclesiastical and constitutional theorists, neither the corporate feudal structures of the early Middle Ages nor the de facto bargaining mechanisms of feudalism in decline were propitious environments for collective decision making. Constitutional development, beginning in 13th-century England, was more in response to rapidly changing political requirements than in pursuit of formal doctrine. The king had a growing need to surround himself with advisers whose voice "counted" (that is, who could be counted), and to solicit the support of the increasingly numerous and densely populated towns on whose consent the success of raising taxes for the royal treasury depended. At the same time, petition for royal favours or the redress of grievances, initially a privilege, came to be regarded as a right. Although it is impossible to trace the history of voting as such, it is possible to see that the need for consent, on the one hand, and the practice of petition, on the other hand, could be readily reconciled in voting.

Throughout the medieval period, in contrast to both antiquity and modern times, the units of counting were not individuals but representatives of landed interests or geographical localities such as towns and boroughs. Although medieval writers, following the Roman tradition, often recognized election as the potential source of popular sovereignty, there was no significant concern with electoral processes. In reality, inheritance of positions and offices became the effective procedure of regulating succession. In the royally convened assemblies voting either called for unanimous consent or involved manipulation by the king's men to overcome recalcitrant opposition. Except in England and Sweden, the age of absolutism in the 16th and 17th centuries represented a period of discontinuity in the evolution both of representative institutions and of those feeble vote mechanisms that may have been used in the medieval period.

EXTENSION OF THE SUFFRAGE

The extension of the suffrage has largely been a consequence of the rapidity of change in a society's social structure and the customary relations among its people. Where social change was relatively slow, as in ancient Rome and in postmedieval England through the 19th century, ruling groups could successfully maintain effective power through gradual extension of the suffrage to would-be opposition groups, thereby co-opting them into the governmental process. On the other hand, where, after a protracted period of social stagnation, changes in social structure went unrecognized, as in many European areas in the postfeudal era through the period of absolutism to the French Revolution, the later battle for the suffrage was not only often violent, but the speed in extending it often found the new electorate unprepared to meet its obligations, thereby contributing to governmental instability.

The need for effective organization

Although the extension of the suffrage to previously disenfranchised population groups is a concomitant of change in a society's social structure, the effectiveness with which the suffrage can be pursued, and the probability of using it successfully once gained, depend on effective organization of the groups demanding the vote. Constitutions often provide for a wide franchise, but the utilization of the right to vote may falter for lack of organization among suddenly enfranchised population groups.

The extension of the suffrage to the working class in 19th-century Europe was anticipated by the formation of workingmen's associations and parties. The extension of the suffrage to women depended on successful prior organization, and intensive, indeed, often shrill, pressure for the vote. By way of contrast, the failure of an effective suffrage for blacks in the American South, following emancipation and formal enfranchisement by the Fifteenth Amendment of the U.S. Constitution, was probably due as much to the organizational weakness and lack of leadership among the former slaves, at it was due to intimidation and biassed administration of the election laws. It was not until almost a century later that the black population could provide sufficient organization and leadership to make the right to vote and other civil rights an effective demand on society.

Early fears about the extension of the suffrage to groups with presumed low stakes in the social order—the propertyless, the enslaved, the uneducated, the itinerant, the disinterested, or the young—appear, in retrospect, as little more than either ill-founded prejudices or strategems to maintain the status quo. Devices invented to offset the effects of extending the suffrage, such as giving property owners or the highly educated more than one vote or highly restrictive residence requirements, failed in their purpose. Social and economic developments hardly to be anticipated at the end of the 18th century so radically transformed modern societies in the next century that few of the arguments advanced in favour of property, income, or educational qualifications could be defended in either logic or fact. Indeed, as it became evident that more and more of the population had a stake in society, the suffrage came to be recognized as an instrument of governance that is both a private right and a public duty.

Although female suffrage was instituted in three or four countries before World War I, it was the new role of women during that war that provided the major impetus for their enfranchisement. Resistance to the demands of the suffragettes crumbled as women, in the course of wartime manpower shortages, entered into a previously male-dominated social and economic order. During the 1918–20 period alone, women achieved the vote in Belgium, the Netherlands, Germany, Poland, Canada, the United States and many other countries. In Great Britain women over 30 years of age were granted the vote in 1918, but not until 1928 was the age requirement equalized at 21 for both men and women. Where women were excluded from voting in the interwar years, as in France, Italy, and Japan, it was their role in World War II that finally led to their inclusion in the electorate. The late 1940s also witnessed the extension of the vote to women in most South American countries. In the Arab nations female suffrage is still subject to numerous qualifications. In the Communist regimes, male and female suffrage has been universal from their inception.

Voting ages

The next stage in the extension of the suffrage has been a movement to reduce the voting age, normally 21, to 18. As large numbers of the young are called upon to do military service and as a large proportion of them receive more and more higher education, the significance of their role in the social order cannot be denied. Eighteen year-olds vote in several countries, including Britain and the United States.

The extension of the vote to women and younger age groups, as well as relaxed residence requirements, has greatly broadened the eligible electorate, although discriminatory practices, such as literacy tests and poll taxes, continue to restrict the franchise.

ELECTIONS AND REPRESENTATIVE GOVERNMENT

The widespread use of elections in the modern world is largely due to the gradual emergence of representative government from the 17th century on. For proper appraisal, however, it is important to distinguish between the form and substance of elections. Electoral forms may be present but the substance may be missing. The substance is, of course, that the voter has a free and genuine choice between at least two alternatives. In a purely formal sense, the great majority of the approximately 130 contemporary nations have what are called "elections," but probably only a third of these have more or less competitive elections; perhaps a fifth have one-party elections; and in some others the electoral situation is highly ambiguous.

The discovery of the individual as the unit to be counted was, from the 17th century on, the critical factor in the emergence of modern electoral processes. The counting of individuals, in turn, was a by-product of the change from the holistic conception of representation in the Middle Ages to an individualistic conception. The British Parliament, for instance, was no longer seen as representing estates, corporations, and vested interests, but as standing for actual human beings. The movement abolishing "rotten boroughs"—boroughs of small population controlled by one person or family—that culminated in the Reform Act of 1832 was a direct consequence of the individualistic conception of representation. Once governments were not only believed to derive their powers from the consent of the governed but were expected to seek consent, the only remaining problem was to decide who was to be included among the governed whose consent was to be sought. The democratic answer was, of course, universal adult suffrage.

Although it is common to equate representative government, elections, and democracy, and although competitive elections under universal suffrage are in many respects a defining characteristic of political democracy, universal suffrage is not a necessary condition of competitive electoral politics. An electorate may be limited by formal legal requirements—as was the case before universal adult suffrage—or it may be limited by citizens' failure to take advantage of the vote, as is often the case in American municipal and other elections. Although such legal or self-imposed exclusion affects the democratic quality of elections and may ultimately affect the legitimacy of government, it does not impede decision-making by election, provided the voter is presented with alternatives among which to choose.

Access to the political arena during the 18th century depended largely on membership in some aristocracy, and participation in elections was regulated mainly by local customs and arrangements. With the American and French revolutions every citizen was declared formally equal to every other citizen, but the vote remained an instrument of political power possessed by very few.

Even with the arrival of universal suffrage, the ideal of one man, one vote was not achieved. Systems of plural voting were maintained in some countries giving certain social groups an electoral advantage. In Great Britain, for example, university graduates and owners of businesses in constituencies other than those in which they lived continued to have an extra vote until 1948. Before World War I, both Austria and Prussia had three classes of weighted votes that effectively kept electoral power in the hands of the upper social strata.

Elections in authoritarian systems

Whereas in the Western nations of the 19th and 20th centuries the increasing use of competitive mass elections in selecting governments had the purpose and the effect of institutionalizing the diversity of modern societies, in the Eastern, one-party, Communist regimes, mass elections came to have quite different purposes and consequences. Elections in these nations were not designed to offer choice of leadership or to influence policy formation. They differ from competitive elections in that only one team of candidates is presented, and the voter has only the choice of voting for the official candidate. They are in the nature of the 19th century Napoleonic plebiscites, intended to demonstrate the unity rather than the diversity of the people, and, above all, they do not make or unmake governments.

Although the Soviet Union's constitution of 1936 provided for elections on the Western model, the election mechanism is manipulated to produce almost universal turnout and unanimous support of the regime. Elections are dramatic occasions for Communist agitation and propaganda to strengthen the citizen's identification with the Soviet way of life.

Because voting is considered a pledge of loyalty, it is easier to vote against the official candidate than to abstain. Although nonparticipation is not a legal offense, it may be socially punished. Although an unmarked ballot is considered a "yes" vote, dissent may be registered by crossing out the name of the candidate on the ballot, as some 2,000,000 Soviet citizens do in each election. These voters are easily identified because they are likely to choose voting booths that make secret voting possible. Perhaps for this reason less than 5 percent of the voters risk public scrutiny by secret voting. It may well be that dissenting votes are cast not so much because of dislike of Communism, but because of grievances involving the conduct of minor officials who stand for election to one of the numerous village, town, republic, or oblast soviets.

Not all elections under authoritarian governments follow the Soviet model. In Poland, for instance, more names appear on the ballot than there are offices to fill, and some degree of electoral choice is possible. Electoral participation is usually over 90 percent, but effective dissent is minimal. It is difficult to appraise election results in the Eastern, one-party, Communist nations because published data are unreliable and cannot be easily compared.

In the non-Communist authoritarian regimes of the world a variety of means is employed to eliminate free electoral choice, ranging from suppression of the opposition to the physical intimidation of voters.

Modern electoral systems

FUNCTIONS OF ELECTIONS

Fundamental to the use of elections is the contribution that they make to democratic government. Where the

members of the body politic cannot themselves govern and must entrust government to representatives, elections serve not only to select leaders acceptable to the voters but also to hold the leaders accountable for their performance in office. Accountability, however, is greatly jeopardized in electoral situations in which elected leaders, for want of ambition, do not care whether or not they are re-elected or in situations in which, for historical or other reasons, one party is so predominant as to preclude effective choice among alternate candidates or policies. Nevertheless, the possibility of controlling leaders by requiring them to submit to regular and periodic elections contributes to solving the problem of succession in leadership and, thereby, to the continuation of democracy. Moreover, where the electoral process is competitive and forces candidates or parties to expose their record of accomplishment and future intentions to popular scrutiny in election campaigns, elections serve as forums for the discussion of public issues, facilitate the expression of public opinion, and, more generally, permit an exchange of influence between governors and governed.

Democratic functions

Elections also serve to reinforce the stability and legitimacy of the political community in which they take place. Like national holidays commemorating common experiences, elections serve to link the members of a body politic to each other and thereby confirm the viability of the political community. By mobilizing masses of voters in a common act of governance, elections lend authority and legitimacy to the acts of those who wield power in the name of the people.

Elections can also confirm the worth and dignity of the individual citizen as a human being. Whatever other needs he may have, participation in an election serves to gratify the voter's sense of self-esteem and self-respect. It gives him an opportunity to have his say, and he can, through expressing partisanship and even through nonvoting, satisfy his sense of belonging to or alienation from the political community. It is for just this reason that the age-long battle for the right to vote and the demand for equality in electoral participation can be seen as the manifestation of a profound human craving for personal fulfillment.

In all forms of government, from the most democratic to the most totalitarian alike, elections have a ritualistic aspect. Elections and the campaigns preceding them are dramatic events which, depending on cultural or historical circumstances, may exude the gay atmosphere of a circus or the sombre atmosphere of a funeral. Rallies, banners, posters, buttons, headlines, and television call attention to the importance of participation in the event. Candidates and parties, from right to left, in addition to propagating their policy objectives through rhetoric and slogans, invoke the symbols of nationalism or patriotism, reform or revolution, past glory or future promise. Whatever the peculiar national, regional, or local variations, elections are events that, by arousing emotions and channelling them toward collective symbols, break the monotony of daily life and focus attention on the common fate.

DECISION RULES

Individual votes are totalled into collective decisions by rules of counting that voters and leaders have accepted as legitimate prior to the election. These decision rules may call for plurality voting, which requires that, among three or more alternatives, the winner need have only the highest number of votes; simple majority voting, which requires that the winner receive more than 50 percent of the vote; extraordinary majority voting, which requires some higher proportion for the winner, such as a two-thirds vote; or unanimity.

Plurality voting

The simplest means of deciding an election is the plurality rule. To win, a candidate need only poll more votes than any other single opponent; he need not, as required by the majority formula, poll more votes than the combined opposition. The more candidates contesting a constituency seat, the greater the probability that the winning candidate will receive less than 50 percent of the vote. The plurality formula is used in the national elections of such countries as Great Britain, Canada, and New Zealand. One half of the West German Bundestag is elected according to the plurality system, while the other half is elected according to a proportional representation formula (see below).

Under the majority rule, the party or candidate winning over 50 percent of the vote in a constituency is awarded the contested seat. The winning party or candidate must poll more votes than the combined opposition. This system thus ensures that the elected representative has the support of the majority of the voters. The majority formula is employed in the election of the Australian House of Representatives, and of the French National Assembly. It is usually applied only within single-member electoral constituencies.

Both the plurality and the majority-decision rules are employed in the election of U.S. presidents. The composition of the electoral college, which actually elects the president, is determined by a plurality vote taken within each state. Voters choose between the names of the presidential candidates, but they are in effect choosing the electors who will elect the president by means of a majority vote in the electoral college. All of a state's electoral votes (which are equal in number to its seats in Congress) are given to the presidential candidate who gains a plurality of the vote in the state election. It is thus possible for a president to be elected on the basis of a minority of the popular vote.

A critical difficulty with the majority formula is that in a multiparty political system, the formula may produce an electoral deadlock if no candidate secures 50 percent of the total vote. In order to break such deadlocks a second round of elections (second ballot) is required, if no candidate obtains a majority on the first round. In Australia, voters rank the candidates on an alternate preference ballot. If a majority is not achieved on the first round of elections, the weakest candidate is eliminated, and the votes he accrued are distributed to the other candidates according to the second preference on the ballot. This redistributive process is repeated until one candidate collects a majority of the votes. If no candidate secures a majority in the first round of the French National Assembly elections, another round of elections is required. In this second round, the candidate securing a plurality of the popular vote is declared winner.

Neither the majority nor the plurality formulas distribute legislative seats in proportion to the share of the popular vote won by the competing parties. Both formulas tend to award the strongest party disproportionately and to handicap the weaker parties. The latter is particularly true if small parties are rooted in ethnic, religious, or social minorities; small parties escape the inequities of the electoral system only if they have a regionally concentrated base. The plurality formula distorts the distribution of seats more than the majority system.

Proportional methods

Proportional representation requires that the distribution of offices be proportional to the distribution of the popular vote among competing political parties or candidates. It seeks to overcome the distribution imbalances that result from majority and plurality formulas, and to create a representative body that reflects the distribution of opinion within the electorate. Because of the use of multimember constituencies in proportional representation, parties with neither a majority nor plurality of the popular vote can still win legislative representation.

Proportional representation is an ideal that is sought after, but only approximated: the size of electoral districts is the critical factor; the larger the electoral district in terms of seats, the more proportional the representation will be. The number of seats assigned to a constituency is in fact a greater determinant of the proportionality of the outcome than is the specific type of proportional formula used. The different formulas of proportional representation are basically similar in their effect on the conversion of votes to political representation.

Developed in the 19th century in Denmark and in Britain, the single transferable vote formula—or Hare system (after one of its English developers, T. Hare)—em-

ploys a ballot that allows the voter to rank the competing candidates in order of preference. When the ballots are counted, any candidate receiving the necessary quota of first preference votes is awarded a seat. In the electoral calculations, votes received by a winning candidate in excess of the quota are transferred to other candidates according to the second preference marked on the ballot. Any candidate who then has the necessary quota is also awarded a seat. This process is repeated, with subsequent surpluses also being transferred, until all the remaining seats have been awarded. Five members constituencies are considered optimal for the working of the Hare system.

The single transferable vote formula, because it involves the aggregation of ranked preferences, necessitates complex electoral computations. This factor, plus the fact that the Hare system limits the influence of political parties, probably accounts for its infrequent use; at present it is used only in Eire and in the selection of the Australian and South African senates. The characteristic of the Hare formula, which distinguishes it from other proportional representation formulas, is its emphasis on candidates, not parties. The party affiliation of the candidates has no bearing on the computations.

The basic difference between the transferable vote formula and the list systems is that, in the latter, voters choose among party-compiled lists of candidates rather than among individual candidates. Although voters may have some limited choice among individual candidates, electoral computations are on the basis of party affiliation; seats are awarded in respect to party rather than candidate totals. The seats that a party wins are allocated to its candidates in the order in which they appear on the party list. Several types of electoral formulas are used, although they fall into two main categories; largest average formulas and greatest remainder formulas. All employ some type of electoral quota.

Largest average formula

In the largest average formula, the number of votes won by each party is divided by the number of seats held by the party, plus one. The first seat is awarded to the party with the highest number of votes, since, no seats yet having been allocated, the initial denominator is 1. When a party wins a seat, its formula denominator is increased by one and hence the party's chances of winning the next seat are reduced. The available seats are awarded one at a time to the party with the greatest average. Party totals, not candidate totals, are used in the calculations. No transfer of ballots takes place. Frequently named after its Belgian inventor, Victor d'Hondt, the largest average formula is used in Austria, Belgium, Finland, and Switzerland, and in the proportional representation half of the West German Bundestag elections.

The d'Hondt formula has a slight tendency to over reward large parties and to reduce the chance of small parties gaining legislative representation. The so-called Lague variation of the d'Hondt formula—used in Denmark, Norway, and Sweden—reduces the reward to large parties but increases further the handicap to small parties. By adjusting the denominator of the d'Hondt formula, the Lague formula increases the cost of both the initial seat of a party and that of additional seats. The Lague formula thus aids middle-size, political parties and reduces the number of legislatively represented small parties.

The greatest remainder method establishes a vote quota for each seat in an electoral district by dividing the total vote in the district by the number of competing parties. The total popular vote won by each party is then divided by the quota, and a seat is awarded as many times as the party total contains the full quota. If all the seats are awarded in this manner, the election is complete. Such an outcome is unlikely, however. Seats that were not won by full quotas are subsequently awarded to the parties with the largest remainder of votes after the quota has been subtracted from each party's total vote for each seat it was awarded. Seats are awarded sequentially to the parties with the largest remainder until all the district's allocated seats have been awarded.

Of all the proportional representation formulas, the greatest remainder formula, given large enough constituencies, yields results closest to the proportional ideal. Small parties fare better when the greatest remainder formula is used than when the largest average formula is employed. The greatest remainder formula is used in Israel, Italy, and Luxembourg and in some elections in Denmark. Italy, however, uses a special variety of the formula, called the Imperiali formula, whereby the electoral quota is established by dividing the total popular vote by the number of parties plus two. This modification increases the legislative representation of small parties, but leads to a greater distortion of the proportional ideal than the unaltered formula.

The choice of majority and plurality or proportional systems is, of course, not simply a matter of pure theory. Different methods of counting, just as different conceptions of representation, usually reflect cultural, social-structural, and political circumstances in a particular jurisdiction. Majority or plural methods of voting are most likely to be acceptable in relatively stable political cultures. In such cultures, fluctuations in electoral support, given to one party or another from one election to the next, reduce polarization and make for political centrism. Thus the "winner take all" implications of the majority or plurality formulas are not experienced as unduly deprivational or restrictive. Proportional representation, on the other hand, is more likely to be found in societies with traditional ethnic, linguistic, and religious cleavages or in societies experiencing pervasive class and ideological conflicts.

TYPES OF ELECTIONS

Elections of officeholders. Rather than deciding public policy, election to public office bestows the right to decide on a small group of elected officials. The elections grant officials the authority to make public policy decisions, and thereby legitimize the decisions that are made. The policy voice of the electorate in these elections may be weak. An electoral mandate results not so much in the implementation of the abstract preferences of the majority of the citizens, but rather in the implementation of the policy of those leaders who come to power in elections.

Role of parties

Most officeholder elections are interpretable only in terms of the role of political parties in the political process. Parties are tied so closely to the democratic functions of elections that their competition for the electorate's support is considered the main criterion by which democratic elections are distinguished from nondemocratic elections. Because of the difficulty in fixing individual responsibility in the complexity and vastness of modern governments, political parties, rather than representatives, have become the vehicle of democratic accountability.

Political parties shape the nature of the electoral decision. The selection and nomination of candidates, a vital first stage of the electoral process, lies in the hands of the political parties; the election serves only as the final process in the recruitment to political office. The party system can thus be regarded in a true sense as an extension of the electoral process. Political parties provide the pool of talent from which candidates are drawn, and they simplify and direct the electoral choice and mobilize the electorate at the registration and election stage. Political parties have transformed elections from a choice of men to a choice of governments.

But the fusion of political parties with the electoral process has not gone unchallenged. In North America a number of modifications have been made in the electoral structure to limit the influence of political parties. Nonpartisan elections (elections in which party affiliations are not formally indicated on ballots) are the norm for some municipalities in the United States and Canada and represent an attempt to remove political parties from the electoral scene. Nonpartisanship started as a reform movement in the early part of the 20th century and was designed to put local government on a more businesslike basis and to isolate local politics from state and national

politics. The exclusion of party labels from the ballot, however, does not guarantee that political parties will be inactive or without influence in nonpartisan elections.

Recall. The practice of recalling officeholders was, like most populist innovations, an attempt to minimize the influence of political parties on representatives. The recall was an electoral modification designed to ensure that an elected representative would act as a spokesman for his constituency rather than for his political party or the dictates of his own conscience or interests. It enabled constituents to recall their elected representative before the end of his term of office if, in their opinion, he was no longer acting in accord with the best interests of the constituency. The actual instrument of recall was often a letter of resignation signed by the elected representative *before* assuming office. During the term of office this letter could be evoked by a quorum of constituents if the representative's legislative performance failed to meet their expectations. In practice the recall is not often or widely used today, even where it is provided for constitutionally.

Referendum. A referendum is an election, held either at the initiative of the governors or the governed, in which the preferences of the community regarding a particular issue are assessed. The use of the referendum reflects a reluctance to entrust full decision-making power to elected representatives. Because of the small voting turnout for referendum elections, and the absence of affixed party labels to the referendum alternatives, voting in referendum elections is more open to leadership and interest group influence than is voting in officeholder elections.

Referenda usually concern the raising and spending of public money, although they are occasionally used to decide moral issues in which the elected bodies are deemed to possess no special competence. They may be legislatively binding, or merely consultative, but even consultative referenda are likely to be considered legislative mandates.

Plebiscites. Plebiscites are elections held to decide two paramount types of political issue: the form of government and the national boundaries adopted by the state. In the first case, the plebiscite is a means of establishing the legitimacy to rule, not a means of providing a choice among alternate governmental teams or legislative proposals. The incumbent government, seeking a popular mandate as a basis for legitimacy, employs a plebiscite to establish its right to speak for the nation. The incumbent rulers seek a single identity with the nation, and thus a vote for the nation is interpreted as a vote for the incumbent regime. Plebiscites of this nature are thought to establish a direct linkage between the rulers and the ruled; intermediaries such as political parties are bypassed in plebiscites, and in this respect they are antithetical to pluralism and competitive politics. Following the Revolution of 1789, the plebiscite had a great appeal in France, rooted as it was in the ideas of nationalism and popular sovereignty. In more recent times totalitarian regimes have employed plebiscites to legitimize their power.

Plebiscites have also been used as a device for establishing the boundaries of political units according to criteria of nationality. After World War I the plebiscite was employed as a means of fitting political boundaries to boundaries of nationality. Eleven plebiscites, based on universal suffrage, were proposed by the League of Nations, the most successful of which was held in 1935 in the Saar (which chose to remain a German territory rather than go to France). The potential of plebiscites for establishing or changing political boundaries is, however, severely limited, because they entail the prior agreement of two governments over what is usually a very contentious issue.

CONSTITUENCIES

The drawing up of constituencies—those subdivisions of the total electorate that send representatives to the local or central assembly—is inextricably linked with questions concerning the nature of representation and methods of voting. Of these questions, that of representation is primary. The problem of electoral representation turns on the question of what is to be represented. In this connection the functions of constituencies and the problem of determining them (districting) become relevant. The central problem is that the constituency, as a geographical area, may contain within its boundaries diverse, and sometimes incompatible, social, economic, religious, or ethnic interests, all of which seek to be represented.

Districting

The solution to this problem has been largely historically determined. Where the interests of electors have not been totally incompatible, and where ethnic, religious, social, and economic differences have been relatively free of passionate conflict, as in the Anglo-American countries, geographical areas (electoral districts) have usually been considered the constituency, and the method of counting has been some system of majority or plurality voting. The elected person represents the geographical unit as a whole, irrespective of internal divisions. In general, the district is a single-member constituency, although multimember constituencies are also possible.

On the other hand, where the electorate is composed of several minorities, none of which can hope to obtain a majority, or perhaps even a plurality sufficiently large to obtain representation, the geographical district can only be regarded as an administrative unit for counting votes. The effective constituency is the group of electors that can be identified as having voted for a given candidate. In this case, election is usually by some method of proportional counting whereby any candidate, party, or group receiving a requisite number of votes is entitled to a proportionate number of representatives.

The drawing up, or delimitation, of electoral districts is inextricably linked with differing conceptions of representation; and conceptions of representation are inextricably linked with alternate methods of vote counting. The virtues and vices of different electoral arrangements are still debated by constitution makers, but the arguments advanced in favour of any one set of arrangements remain inconclusive. Although proportional systems treating electoral districts as merely administrative conveniences and providing for multiple representation are believed to approximate more closely the one man, one vote principle of democratic theory than do single-member geographic constituencies providing for majority or plurality voting, they are probably conducive to governmental instability, and they place an inordinately heavy burden of conflict resolution on representative bodies. This often makes for political stalemate or immobilism, as has been the case at times in France and Italy. But it is doubtful that in nations with many interests seeking representation any other method of electoral districting and vote counting would be satisfactory.

Representation of geographic constituencies with majority or plurality voting, on the other hand, disguises many differences in the electorate's composition and preferences. In single-member, majority vote electoral districts, the minority losing at the polls may feel unrepresented. But it is often a precarious assumption that the majority itself is truly represented, since it is likely to be a loose coalition of diverse interests, and no single representative can usually do justice to the diversity of interests involved. In general, therefore, the representative, in so far as he is responsive, is more likely to play the role of broker among his district's diverse interests, rather than the role of spokesman for the district as a whole.

Whatever the role of representative, and however electoral units are conceived—as geographic areas with stable, compatible interests, or as purely administrative areas for the purpose of vote counting—districting must be distinguished from apportionment. In general, if the district is considered as only an administrative unit for counting votes, its boundaries can be drawn rather arbitrarily without injustice. The district as such has no stakes of its own to be represented. On the other hand, if the district is considered a true constituency, in the sense that it has unique interests that can be geographically and, as a result, socially defined, districting should not be

arbitrary. The area involved should at least be contiguous and compact so that its presumed interests can be fairly recognized.

The difficulty in treating geographic areas as genuine constituencies is, of course, that internal transformations in their economy and social structure may make their historical boundaries obsolete. As a result, historical areas serving as electoral districts (such as provinces, states, or counties), which once served as genuine communities of interest to be represented, may no longer do so. As these districts become increasingly diverse, making it difficult to identify particular constituency interests, representatives find it increasingly impossible to be responsive to constituency wishes or needs.

Apportionment

Problems of apportionment, in contrast to problems of districting, stem from efforts to reconcile the territorial and population bases of representation. If geographic areas, for instance, are assumed to have an equal right to be represented because the area is considered to be a viable constituency, malapportionment in terms of population size is inevitable. New York with a population of nearly 20,000,000 has, in the U.S. Senate, the same number of representatives as Nevada with a population of less than 1,000,000. This kind of "constitutional malapportionment" must not be confused with the kind of "electoral malapportionment" that defies the one man, one vote principle of equal representation. The latter is usually the result of population shifts. Under modern conditions of increasing urbanization, failure to reapportion the number of seats in representative bodies to take account of population changes has largely benefitted rural electoral districts. More recently, the shift of city people to the suburbs has led to possible underrepresentation of suburban vis-à-vis urban populations.

From a political rather than a legal perspective, malapportionment is usually considered "undemocratic" because it results in overrepresentation and underrepresentation of certain sectors of the population and, as a result, may culminate in public policies not acceptable to the true majority.

Apportionment is not a simple matter. In particular, the definition of the population among which a specified number of legislative seats is to be apportioned is not easy to arrive at. Total population, number of citizens of voting age, number of registered voters, or number of actual voters can serve as bases of apportionment. If there were a constant relation between these groupings, apportionment would not be a problem, and any one of them could serve as a basis. In fact, however, the relation is not constant because of variations in registration and voting turnout.

Gerrymandering

Malapportionment, whether of the constitutional or electoral sort, must not be confused with gerrymandering—a form of arbitrary districting used to benefit the party that at a given time controls the apportionment process. Gerrymandering is named after governor of Massachusetts Elbridge Gerry (1744–1814) who recognized the possibility of influencing electoral outcomes by manipulating the boundaries of electoral districts. The practice involves concentrating large percentages of the opposite party's votes into a few districts, and drawing the boundaries of the other districts in such a way that the gerrymandering party wins in them all, even though the majority, or, in three-cornered elections, the plurality, is relatively small.

Gerrymandering comes to politicians easily. Party managers prefer "safe" districts to those that are competitive. By not contesting seriously in the other party's safe districts, by maintaining one's own safe districts, and by carving competitive districts up in such a way that one's own party is favoured, party managers use gerrymandering to create artificial district boundaries that, though advantageous to the parties, may harm other social, economic, and political interests that need representation.

ELECTORAL PRACTICES

There is a direct relation between the size of an electorate and the formalization and standardization of its voting practices. In very small voting groups, in which political encounters are face-to-face and the members are bound together by ties of friendship or common experience, voting is mostly informal and may not even require counting, because the "sense of the meeting" emerges from the group's deliberations. The consensus of the Quaker meeting is of this order. An issue is discussed until a solution emerges to which all participants can agree or, at least, from which any one participant will not dissent.

By way of contrast, in modern mass electorates, in which millions of individual votes are aggregated into the collective choice, formalization and standardization of voting practices and vote counting are the rule. This is necessary in order to guarantee that the outcome can be considered valid, reliable, and legitimate. Validity means that the collective choice in fact expresses the sense of the electorate. Reliability means that each vote is accurately recorded and effectively counted into the total. Legitimacy means that the criteria of validity and reliability have been met; so that the result of the voting is acceptable and provides authoritative guidelines in subsequent political conduct.

The development of routinized and standardized electoral practices in mass electorates is a surprisingly recent phenomenon, not much older than 100 years. It is as much a corollary of the growth of rapid communication through telephone and telegraph as of the growth of the electorate and rational insistence on making electoral processes fair and equitable. Nevertheless, even today electoral practices around the world differ a great deal, depending not just on formal institutional arrangements, but even more on a country's political culture.

Secret voting. Once suffrage rights had been extended to masses of voters who, in theory, were assumed to be equal but who, in fact, were unequal (in order of birth, in intellectual endowment and educational accomplishment, in social status and the possession of property, and so on), open voting was no longer tolerable precisely because it could and often did involve undue influence, ranging from hidden persuasion and bribery to intimidation, coercion, and punishment. Equality, at least in voting, was not something given but something that had to be engineered; the secrecy of the vote was a first and necessary administrative step toward the one man, one vote principle. Equality in voting was possible only if each vote was formally independent of every other vote, and this suggested the need for strict secrecy.

The slow progress made in introducing secret voting, from the French Revolution well into the 20th century, attests to the fact that social engineering, no matter how desirable or lofty in purpose, depends on favourable conditions for success. One need not assume that the obstacles placed in the way of secret voting were the result of some conspiracy on the part of those who recognized, quite accurately, that the mobilization of large numbers of voters fundamentally changed the distribution of political power and who, through opposing the secret vote, hoped to maintain a stranglehold on the newly enfranchised electorates. Rather, the success of secret voting depended on the reduction of illiteracy and, at the cultural level, on the spread of the individualistic norms of privacy and anonymity to certain classes of the population, notably peasants and workers. Traditionally these groups took their cues from those accepted as superior in status, or from their peers. Secret voting required learning to free oneself as a citizen from one's customary associations and from pressures for conformity. The difficulty of introducing and practicing the secret vote in today's politically and economically less developed nations mirrors the tortuous advance of the secret ballot in the Western nations during the 19th and early 20th centuries.

Benefits of secret voting

Secret voting reduces drastically the possibility of undue influence on the voter. Without it, influence can range from outright purchase of votes to social chastisement or economic sanctions. This is not to say that bribery in voting is automatically eliminated by secret voting. Laws prohibiting and punishing the purchase of votes are on

the statute books of many countries and undoubtedly contribute to discouraging the practice.

Although informal social pressures on the voter are probably unavoidable and, in some respects, useful in reducing political rootlessness and contributing to political stability, secrecy in voting permits voters to break away from their social moorings and gives them a considerable degree of independence if they wish to take advantage of this electoral freedom. As a result it becomes ever more difficult for interest groups, whether labour unions, farmers' organizations, commercial or industrial associations, ethnic leadership groups, or even criminal syndicates, to "deliver the vote." The extent to which "deviant voting" occurs depends partly on the degree of rigidity in the social structure. In countries where caste or class barriers are high or where traditional social, economic, religious, or regional cleavages remain strong, deviant voting is less likely than in countries where social mobility is possible and where political conflicts cut across traditional social cleavages. In Western nations the increasing difficulties of labour, farm, religious, or ethnic leaders in influencing the voter attests to the success that secret voting seems to have had on freeing the individual from electoral bondage to his traditional or economic affiliations.

Balloting. The ballot makes secret voting possible. Its initial use seems to have been a means to reduce irregularities and deception in elections. This objective, however, could only be achieved if the ballot was not supplied by the voter himself, as was the case in much early voting by secret ballot, or by political parties, as is still the case in some countries. Ballot procedures differ widely, ranging from marking the names of preferred candidates to crossing out those not preferred or writing in the names of persons who are not formal candidates. Ballots also differ according to the type of voting system employed. Where plurality or majority voting is practiced, most elections employ classified ballots whereby the voter casts his vote for only one candidate or list of candidates. Where proportional methods are used, election is by ballots that enable the voter to rank the candidates according to his preferences.

Though evidence is hard to come by, it is commonly believed that the nature of the ballot influences the voter's choice. In jurisdictions where electors are called upon to vote not only for higher offices but also for a multitude of local positions and where, in addition, the election may include propositions in the nature of referenda, the length of the ballot seems to be a factor affecting vote outcomes. Overwhelmed by the length of the ballot, voters may be discouraged from expressing their preferences for candidates of whom they have not heard, or from deciding on propositions that they do not understand. Breaking up of the single ballot into separate short ballots helps overcome this problem but does not eliminate it. Election data show a rapid decline from votes cast for higher offices to those cast for lower offices and referendum-type propositions.

Ballot position also seems to have an effect on the votes cast for particular candidates, especially in the absence of cues as to party affiliation or other identifications. The first position on the ballot may be favoured, and in the case of a long ballot both first and last names may benefit, with candidates in the middle of the ballot suffering a slight handicap. Ballot position is likely to have its greatest impact in nonpartisan elections, primaries, and elections for minor offices.

Finally, the manner in which candidates are listed—by party column or office bloc—is likely to affect election outcomes. On party-column ballots it is possible to vote a "straight ticket" for all of a party's candidates by entering a single mark, although voting for individual candidates is usually possible. On the other hand, on the office-bloc ballot, voting is for individual candidates grouped by office rather than party. This discourages, though it does not eliminate, voting exclusively for members of one party. This can have important consequences for the structure of government, especially in systems with separated powers and federal territorial organization. If different offices are controlled by different parties, the governmental process may be marked by greater conflict than would otherwise be the case, and governmental decision-making often will be more difficult.

The introduction of voting machines has not substantially changed the balloting process, although it has made it faster, more accurate and economical, and virtually tamper-proof. The voting machine is not without some minor problems of its own, in that it may marginally depress the level of voting. In candidate elections the dampening effect is accounted for by improper use of the machine, a problem that is being overcome through improved machines and voter education.

Compulsory voting. In some nations, notably Australia and Belgium, electoral participation is legally required of all citizens, and nonvoters without legitimate excuses face money fines. The concept of compulsory voting reflects a strain in democratic theory in which voting is considered not merely a right but a duty. Its purpose is to ensure the electoral equality of all social groups. Whether made compulsory in law or through social pressure, it is doubtful that high voter turnout as such is a good indication of an electorate's capability for intelligent social choice. On the other hand, high rates of abstention or differential rates of abstention by different social classes are not necessarily signs of satisfaction with governmental processes and policies and may in fact indicate the contrary.

Electoral abuses. Corruption of electoral practices is, of course, not limited to bribery or intimidation of the individual voter. The possibilities are endless, ranging from the dissemination of scurrilous rumours about candidates, and deliberately false campaign propaganda, to tampering with the election machinery by stuffing the ballot box with fraudulent returns, dishonest counting or reporting of the vote, and total disregard of electoral outcomes by incumbent officeholders. The existence of these practices depends more on a population's adherence to political civility and the democratic ethos than on the prohibitions and sanctions written into the law.

The integrity of the electoral process is maintained by a variety of devices and practices. Permanent and up-to-date registries of voters are maintained to guarantee easy identification of those eligible to participate in elections, and procedures are designed to make the registration process as simple as possible. In most jurisdictions, elections are now held on a single day rather than staggered. Polling hours in all localities are the same, and opening and closing hours are fixed and announced, so that voters have an equal opportunity to participate. Polling stations are manned by presumably disinterested government officials or polling clerks under governmental supervision; and political party agents or party workers are given an opportunity to observe the polling process, enabling them to challenge irregularities and prevent abuses. Efforts are made to maintain order in polling stations, directly through police protection or indirectly through such practices as closing bars and liquor stores. The act of voting itself takes place in voting booths that protect privacy. Votes are counted and often recounted by tellers, watched by party workers to assure an honest count. The transmission of voting results from local polling stations to central election headquarters is safeguarded and checked.

PARTICIPATION IN ELECTIONS

The rate at which individuals participate in the electoral process depends on many factors, including the type of electoral system, the social groupings to which voters belong, the voters' personality and beliefs, their place of residence, and a host of other idiosyncratic factors.

Effect of level and type of election

The level and type of election has a great impact on the rate of electoral participation. Electoral turnout is greater in national than in state or provincial elections, and greater in the latter than in local elections. Because of this, scheduling has an impact on the turnout for local elections. If local elections are held concurrently with provincial or national elections, a higher voter turnout is achieved than for nonconcurrent elections.

Whether an election is partisan or nonpartisan also affects voter turnout—lighter participation occurring in the nonpartisan elections. Participation is also greater in candidate elections than in noncandidate elections such as referenda. There is some evidence that elections based on proportional representation, in which in some cases every vote counts, have higher electoral turnouts than majority or plurality elections. Noncompetitive or safe electoral districts tend to depress the level of voter turnout, whereas marginal elections increase the turnout.

Technicalities in electoral law involuntarily disenfranchise many potential voters. As a result of moving, people may temporarily lose their vote because of residence requirements for voters in their new electoral district. Complicated voter registration procedures, combined with a high level of geographical mobility, significantly reduce the size of the active electorate in the United States, whereas in Canada and Great Britain the size of the electorate is maximized by government-initiated registration immediately prior to elections. Voter registration in the United States is left to the initiative of individuals and political parties.

Group differences

Relatively low levels of electoral participation are associated with rural residence, and also with low levels of education, occupational status, and income. The groups in society that have been most recently enfranchised also tend to vote less. Hence women vote less than men, American blacks less than whites, and working class people less than those of the middle class. Young people who have just turned of age, and have therefore just been enfranchised, are less likely to vote than people who are middle-aged. It is important to note that the nonparticipation of certain groups in elections has important implications; if everyone were to vote, the balance of electoral power would shift toward the recently enfranchised and less privileged members of the society.

Some people are conscientious nonvoters, although such people are rare. Others, perceiving the vote more as an instrument of censure than of support, may not vote because they are satisfied with the present government. This group of voluntary nonvoters is also small, however. In fact, nonvoters have been shown to be generally less satisfied with the political status quo than are voters. The vote is a rather blunt and ineffectual instrument for expressing dissatisfaction, and nonvoting is more likely to be symptomatic of alienation from, than of satisfaction with, the political system.

Supporters of political parties vote more frequently than nonsupporters; to party supporters the vote becomes a pledge of their party loyalty as well as a political instrument.

Those who feel that government policies have some direct relevance to their lives are more likely to vote than those who are disinterested or who sense the government as being more remote.

Finally, a great number of random factors may determine individual participation in specific elections. Election campaigns vary in their intensity. A crisis atmosphere may induce an unusually large number of people to vote, on one occasion, whereas on another the chance to vote for an extremist candidate may increase the participation of the normally disinterested. Even the weather has a substantial impact on election turnout.

INFLUENCES ON THE DIRECTION OF VOTING

The electoral choice of voters is largely influenced by their membership in social groups or by the social groups with which they identify, and, to a much lesser extent, by campaign issues and party promises. The determinants of party membership or party identification are the most crucial factors behind the voting decision. Membership in social and occupational classes, regional, religious or ethnic groupings, and so on, are thus important influences on the direction of the vote.

Because the electoral choice appears to be largely determined by long-standing group and party identifications, the voting decision may appear to be irrational, in that it is not based on a careful calculation of the immediate benefits expected to accrue to the voter from each electoral outcome. Group-determined voting does not preclude rationality, however, for individual self-interest may well be tied to the destiny of the social groups to which the voter belongs.

Independent voting

The independent voter, contrary to much common belief, is likely to be poorly informed politically and relatively uninterested and uninvolved in politics. Paradoxically, however, by switching their support, independent voters represent an important factor in democratic politics.

In most countries the relatively permanent party alignments are based on social and cultural cleavages. But if elections are to be competitive, and if control of the government is to alternate between parties or coalitions of parties, then some voters must switch party support from election to election. New voters and independent voters, therefore, provide a vital source of change in democratic politics.

Electrical and Electronics Engineering

Electrical and electronics engineering originally comprised electrical power, illumination, and the telephone and telegraph but has now expanded into other areas including radio communication, digital computation, automatic control of machines and systems, navigational systems as for radar, sonar, loran and shoran equipment, laser measurements, and the science of information as a basic understanding of the communication process. Frequently included in this field is the analysis of large interacting systems ranging from transportation to biological, ecological, and economic systems. These are logically related to electrical engineering because the mathematical processes employed in the solution of interconnected electrical systems can be applied to other complex interrelated systems.

HISTORY OF THE PROFESSION

Electrical phenomena attracted the attention of European thinkers as early as the 17th century. Beginning as a mathematically oriented science, the field has remained primarily in that form; mathematical prediction often precedes laboratory demonstration. The most noteworthy pioneers included Ludwig Wilhelm Gilbert and Georg Simon Ohm of Germany, Hans Christian Ørsted of Denmark, André-Marie Ampère of France, Alessandro Volta of Italy, Joseph Henry of the U.S., and Michael Faraday of England. Electrical engineering may be said to have emerged as a discipline in 1864 when the Scottish physicist and mathematician James Clerk Maxwell summarized the basic laws of electricity in mathematical form and predicted that radiation of electromagnetic energy would occur in a form that later became known as radio waves. In 1887 Heinrich Hertz experimentally demonstrated the existence of radio waves in his laboratory at Karlsruhe, East Germany.

Early theorists

First practical application

The first practical application of electricity was the telegraph, invented by Samuel F.B. Morse in 1837. The need for electrical engineers was not felt until the inventions of Alexander Graham Bell and Thomas A. Edison some 40 years later; Bell's telephone (1876) and Edison's incandescent lamp (1878) and first central generating plant in New York (1882) overnight created a large demand for men trained to work with electricity.

In the early years of the 20th century a whole new field was opened up for the young profession. Edison's discovery of the "Edison effect," a flow of current through the vacuum of one of his lamps, was the first observation of current in space. Hendrick Anton Lorentz of The Netherlands predicted the electron theory of electrical charge in 1895, and two years later Sir J.J. Thomson of England showed that the Edison effect current was indeed caused by negatively charged particles (electrons). This led to the work of Guglielmo Marconi of Italy, Lee De Forest of the U.S., and many others that laid the foundations of electronics engineering.

ELECTRICAL AND ELECTRONICS ENGINEERING FUNCTIONS

Research. In 1871 the University of Cambridge in England established the Cavendish professorship of experimental physics and built the Cavendish Laboratory, beginning a development that in the 20th century grew into a major trend. With James Clerk Maxwell as its first professor, this laboratory led in research in the 19th century. In the U.S., research and industrial investigation was organized in universities and in industrial research and development laboratories. Many advances, such as ductile tungsten for lamp filaments, practical radio tubes and equipment, long-distance telephony, high-voltage transmission of power, television, the transistor, and satellite communications have come from such organizations. Employing teams of engineers with varied backgrounds and working in well-equipped laboratories, they are able to approach problems fortified with knowledge and equipment not available to the individual inventor.

It is estimated that nearly half of the engineers in the electrical and electronics profession in the early 1970s contribute to research and development activities. Education for such work almost always requires study beyond the usual four-year degree in electrical engineering, mathematics, or physics.

Development. Following the work of the research team is the development and design engineer, who transforms the relatively incomplete models of the research laboratory into marketable products. The developer must plan the product with current production methods and facilities in mind. Often automated production machines are employed, in part to replace expensive hand labour and in part to perform operations beyond the capabilities of human workers. Thus, the design and development engineer must possess a theoretical knowledge sufficient to understand the results of the laboratory, plus a practical understanding of manufacturing operations.

Other functions. Production supervision, monitoring the product, and improving production methods are carried on by technicians, trained in applied electrical engineering. They work with the production force and may modify standard products to meet special needs.

Other engineers work in the field, providing technical guidance to customers, devising systems to meet specialized needs, and, in many cases, emphasizing the advantages of their products in a sales effort.

Opportunities in management constantly arise for those who demonstrate ability to administer, to supervise, to lead other workers in handling technical and corporate problems. Here, additional education in management, finance, and administration adds to the technical skills previously demonstrated by the young engineer.

Consulting or offering one's technical abilities to industries, municipalities, or other governmental bodies on a client–engineer basis is frequently undertaken by power generation and distribution engineers.

SUBDIVISIONS OF ELECTRICAL AND ELECTRONICS ENGINEERING

Expansion of field has been rapid

Electrical and electronics engineering has repeatedly expanded as fresh areas of knowledge were introduced following basic research efforts. Engineering had hardly begun in the field before the relatively simple Edison direct-current system of generation and distribution was challenged by the polyphase alternating-current system. Alternating current possessed considerable economic and industrial advantages but was complex for its day.

Advances in power-system design continued to the mid-1920s. Then radio broadcasting began, along with high-frequency radio transmission; engineers' knowledge was extended to cover the mysteries of the vacuum tube. Television, ready for commercialization after World War II, brought new electron-optical devices such as the kinescope and the scanning camera tube into use and required further broadening of knowledge and skills.

Advances in World War II

During World War II electronics engineers worked with still higher frequencies, such as radar and microwave radio. These systems, in which electromagnetic energy is transmitted through metal pipes, called wave guides, required engineers to extend their knowledge of electric fields and mathematics. As other detection systems were developed, such as sonar for underwater ranging with acoustic waves, electrical engineers became sound experts. Infrared light was used for invisible illumination of night scenes, calling for at least peripheral knowledge and skills in this area. Also developed were loran and shoran, systems for long- and short-range navigation. Equipment developed for these systems was later used in telephone and television microwave relay systems.

Even more sensational was the revolution brought about by the development of the transistor, first announced in 1948. This device led in the early 1970s to the era of integrated circuits or microcircuits, in which transistors, resistors, capacitors, and connectors are deposited by metallic evaporation or by diffusion of one material into another on silicon chips, often using only a fraction of a square millimetre per circuit. New techniques emerged, with whole circuits deposited in a monolithic array visible only with a microscope.

In the 1950s the development of the electronic digital computer brought a revival of the on–off coded signals, first used in telegraph, in a wholly new application. The computer does its work with small electrical circuits, carrying out the "and," "or," "not" operations of conventional logic. Besides use in scientific computation and in business systems, computer elements and functions appear in navigational equipment, such as that used to measure distances and calculate course in airliners and to provide inertial guidance for submarines and spaceships.

Able to build a circuit of almost any complexity, often with the help of a computer, the electrical engineer has now turned his attention to the overall performance of his systems more than to a study of the individual components. His ability to analyze complex interconnected systems has broad potential for application to social, environmental, and economic problems in the important field of systems engineering.

Power systems, a backbone element of all modern industry, continue as an area of importance. Power engi-

neers, planning the huge systems of modern metropolitan areas, must constantly bear in mind the numerous related social and environmental problems.

ELECTRICAL AND ELECTRONICS ENGINEERING EDUCATION

University education in electrical engineering began soon after the development of incandescent lighting and central power generation in 1882. During the 1890s engineering schools all over the world added studies in electrical engineering, often as optional courses within the mechanical engineering field. Academic departments of electrical engineering emerged around the turn of the century; over 190 departments of electrical engineering now exist in the U.S. In the U.K. the formal electrical education usually began within the physics area. In Germany, the field was often divided into "heavy current" and "light current," for power and electronics, respectively, and some schools established separate academic departments. This was also undertaken in India and Japan. In the U.S., there were educational leaders who felt that a fundamental electrical science background was needed for both areas and that specific applicational study should follow entrance into an industrial position. Splitting of academic departments thus did not occur widely, and most U.S. schools offer electrical education based on electrical theory, bolstered by considerable mathematics. Specialization follows at the postgraduate level or after acceptance of a post in industry.

Heavy- and light-current education

Departments usually offer work in the basic areas of circuit theory, electronic circuits, transistor and semiconductor theory, electromagnetic field theory, communication or information theory, and automatic control. This basic technical core is supported by extensive mathematical study and by work in economics, management science, social science, and the humanities.

It may safely be predicted that electrical and electronics study will continue to stress the mathematical and physical background of the field. Use of the computer in circuit and system design will grow. Graduate study will be undertaken by larger numbers. Interdisciplinary knowledge and skills will attain increased importance.

Modern electrical industries customarily offer opportunities for continued study, either in technical or management areas, after employment of the graduate, usually financing part or all of the expenses.

Technical institutes or community colleges offer programs of two-year duration, leading to Associate degrees. These programs are directed toward application, involve more direct use of equipment than do college degree programs, and usually employ somewhat less mathematics. Technician graduates directly or indirectly support engineers in developing, designing, testing, and installing equipment; they serve in a liaison function between engineers and skilled craftsmen. The Associate often moves into supervisory positions in production management or into technical sales work.

PROFESSIONAL ORGANIZATIONS IN THE FIELD

Early electrical industrial activities in England led to organization of the Institution of Electrical Engineers (IEE) in 1871. The American Institute of Electrical Engineers (AIEE) was founded in 1884. It undertook the dissemination of technical information concerning electrical power, illumination, and telephony through meetings and publications. The early wireless operators and engineers organized the Institute of Radio Engineers (IRE) in New York in 1912.

The expansion of the electronics field that occurred during and after World War II caused the IRE to grow phenomenally in size and importance.

The power field of electrical engineering and the radio and electronics fields overlap in electronic control of equipment in industry and in many military and aerospace fields. Leaders in the field long recognized that the members of the profession would gain if one organization represented all, and in 1962 the AIEE and the IRE merged into the Institute of Electrical and Electronics Engineers (IEEE). With headquarters in New York City, the organization serves members throughout the world. It fosters the development of electrical and electronics engineering and the allied sciences and operates an extensive publishing program with over 30 journals.

In Japan, Australia, and India there are additional organizations serving members in electrical power and in telecommunications. National organizations serve members in the countries of Europe as well. In the U.S.S.R. the radio and electronic interests of the profession are advanced by the A.S. Popov Scientific and Engineering Society of Radio Engineering and Electrical Communications, Moscow, so named to commemorate the achievements of Aleksandr Stepanovich Popov (1859–1905) in early radio research. The IEEE, in its worldwide activities, cooperates with all these national organizations.

Other societies covering portions of the field include the Illuminating Engineering Society (IES) and the Audio Engineering Society (AES), both in New York City.

THE FUTURE

With continuing new developments in the semiconductor field, with the computer industry having many opportunities for further expansion of use, with global communication by satellite now expanding, and with the power industry facing challenges raised by rapid growth in demand coupled with environmental encroachment, the electrical field does not lack unsolved problems. In the future it will continue in the development of solutions for its problems by application of well-founded theory.

Electricity

Electricity is the phenomenon associated with positively and negatively charged particles of matter at rest and in motion, individually or in great numbers. The properties of electrical charges, of moving charges that constitute currents, and of complex circuits of currents are understood in two complementary ways. The older view is in terms of theories and laws that have developed from experiments during the past two centuries in a steadily evolving knowledge. The other view is concerned with the space around the charged particle called the electric field, and knowledge of fields flowered in the latter half of the 19th century. Because every atom contains both positive and negative charged particles, electricity cannot be divorced from the physical properties of matter, which include such diverse phenomena as magnetism, conductivity, and crystal structure; from chemical reaction; or from the waves of electromagnetic radiation, which include visible light. The study of electricity thus involves the structure of matter and is intimately related to the apparatus with which electricity is studied. No one has ever seen an electrical charge; and until this century it was impossible to isolate single fundamental charges and study their behaviour in certain ways that take account of the charges on the probing instrument. Some of the information subsumed under electricity, therefore, was obtained through thought experiments; *i.e.*, through questions such as "What is the magnitude of the force acting between two charges?"

Electric and magnetic phenomena are inextricably connected with each other; moreover, most, though not all, of the devices employed daily rely on a combination of electric and magnetic effects. Thus, although this article is concerned principally with the subject of electricity, a complete and satisfactory treatment must also include topics on magnetism (*q.v.*).

The main reasoning of the article will be conducted in verbal terms, using only elementary mathematical no-

tions and a minimum of the differential and integral calculus; this will, however, be augmented by using vectors (quantities having direction and magnitude) whenever necessary and appropriate.

The most readily observable electrical phenomenon in a modern household is likely to be the illumination that follows the activation of a light switch. The simplest, or the most easily described, phenomenon of electrical origin is, however, static electrification, which occurs in a dry atmosphere when one walks across a carpet or removes clothing. The phenomena that accompany static electrification are diverse: the occurrence of sparks, minor sensory shocks, and, occasionally, the smell of ozone; but from the point of view of the fundamental properties of electricity, the most significant is the attractive force between two bodies electrified by friction. The whole science of electrostatics is founded on a quantitative investigation of this force and will be covered in the sections *Development of concepts and theories* and *Static electricity*. It will suffice here to note that static electrification is now interpreted as resulting from the transfer, by abrasion, of charged particles from one physical body to another. If the bodies are initially electrically neutral, they acquire equal and opposite charges and attract each other. As the two bodies are pulled apart, the work done against the attractive force increases their potential, or stored, energy; in some circumstances, this may be released later as a spark or an electric shock. This process works on a grand scale in the atmosphere, and the resulting discharge of electricity and dissipation of potential energy is manifest in lightning. It is possible, though some ingenuity is required, to devise machines to accumulate static electric charge and raise it to a high enough potential energy to produce other more useful and different electrical effects such as heating, chemical change, or magnetism. Before these effects are dealt with, however, there is one further aspect of static electricity that requires mention. If two bodies are electrified by friction, then placing other bodies between them alters and generally reduces the force that they exert on each other. In particular, if they are joined by a metal wire, a column of water or any wet object, a filament of graphite, or human tissue, by simultaneously touching each body with the fingers, the two bodies soon lose their electrification and no longer exert forces on each other. In the last case, an electric shock is experienced and the sensation is confined to the part of the body in the direct path between the two electrified bodies. This suggests that something flows between the two electrified bodies. The flow is now identified with the flow of electric charge.

Flow of charge between two electrified bodies

Charge can be transferred from a point A to a point B by moving a charged body initially at A to B; but the charge also can flow through a material body from a charged body at A to another body at B without any apparent motion of any of the bodies. Material media that have this property of transferring electrical charge are called electrical conductors, or, more usually, when spoken of in the context of electricity, simply conductors. All metals are conductors, and so are a number of nonmetallic media; *e.g.*, silicon, graphite but not diamond, water and a few other liquids, a number of organic and inorganic compounds (*e.g.*, lead sulfide), and, by virtue of their water content, most animal and plant tissues. Media that do not conduct electricity are known as insulators. Diamond, glass, dry paper, most hydrocarbons and stable inorganic and simple organic compounds, and, up to a point, most gases, are insulators. In the sections *Direct electrical currents* and *The conduction of electricity* below, the quantitative characterization of conductors and insulators is expounded by means of the resistance they offer to the flow of electricity. Resistance is described by their specific resistivity and, in the units used here, is expressed in ohm-metres. The specific resistivity of a superconducting metal is zero, that of a normal metal at room temperature about 10^{-7} ohm-metre and that of a good insulator 10^{17} ohm-metres. The enormous range of 10^{24} ohm-metres between a metal and a good insulator, or even the range of 10^{16} or so between a poor conductor and a good insulator makes it rather easy to classify media simply as conductors, perfect, good, fair, or bad and as insulators good, fair, or bad.

Other aspects of electrical phenomena are those associated with the flow of electric charge or currents. The familiar phenomena here are the production of heat as in an electric oven, the production of light either by heating a filament or through an electric discharge in a gas, the production of chemical change as in electrolysis, the production of mechanical work, either by the motion of an armature in a relay or in an electric motor, or the production of magnetic effects. All of these effects have converse effects, but whereas the conversion of heat or light directly to electrical energy in a thermocouple or photocell is usually not a practical process for producing electricity, the various forms of chemical battery and electromagnetic dynamo are prime means for generating electrical effects.

By not going too deeply into the fundamental nature of the processes involved, all of these phenomena can be described without reference to electrostatics. Setting aside the electromagnetic effects for now, the other effects can all be described in terms of the motion of an electric fluid, possibly against viscous friction from a region of higher potential energy to a region of lower potential energy. The name electric charge, or charge, is now given to this fluid; but it is a matter for experimental verification that charge in this context has the same properties and nature as charge in an electrostatic context. The verification rests on the observation that the same media conduct electricity in both contexts, and the same media are insulators in both contexts. It can then be demonstrated experimentally that electrostatic charge produces all the effects attributed to this electric fluid and that similarly the fluid produces all the effects attributed to electrostatic charge.

Magnetism was originally discovered as a phenomenon quite apart from electricity. One of the great turning points in the development of the physical sciences was the experimental discovery that electrical currents produce magnetic effects and that changing magnetic fields produce electrical effects. The whole structure of theoretical physics and most of modern electrotechnology rests on these observations. The magnetic effects of electric currents are seen at their simplest in the electromagnet. The forces exerted on conductors carrying currents, for example, drive the electric motor and the cone of a loudspeaker; the electric effects of changing magnetic fields comprise the basis for the operation of many types of dynamo; and both the magnetic effects of currents and the electric effects of changing magnetic fields are responsible for the operation of the transformer. The propagation of radio waves, radiant heat, light, X-rays, and gamma rays alike depends on this connection between magnetism and electricity.

Although electricity is generally associated with manmade devices such as electric motors, radio receivers, and so forth, electrical and electromagnetic effects play an important role throughout physics, chemistry, and biology. Two of the senses, sight and the perception of heat, depend either entirely or in part on the interaction of the eyes or skin with electromagnetic waves. Thus, much personal knowledge of the outside world is mediated by electromagnetic phenomena. The range and delicacy of perception can be increased by the use of optical or electronic instruments such as the microscope, telescope, radio telescope, infrared detector, gamma ray counter, and the simple galvanometer, thus extending man's knowledge of external phenomena. Electromagnetic laws also play an important role in observed phenomena. The behaviour of astronomic objects and the laws that determine cosmic structure depend to some extent on electric and magnetic fields. Biological processes (*e.g.*, muscle action, nerve transmission, and the activity of the brain) are accompanied by electrical effects; and these can often, as in electroencephalography, be detected directly and furnish useful information about the processes themselves. The nature and stability of the Earth's atmosphere, too, depend crucially on electric and magnetic effects, especially in the upper layers.

Sensory perception of electromagnetic waves

There is, however, a more fundamental way in which electromagnetism influences the whole of the material world. It is now known that matter consists of positively charged heavy nuclei and negatively charged electrons of small mass bound together as atoms. In some circumstances—*e.g.*, in a metal, a semiconductor, or an ionized gas—electrons are detached from atoms, leaving positive ions. These latter may either remain fixed in the material structure, as in a metal, or be free to move, as in a gas. The conduction of electricity in metals is caused by the motion of free electrons and in a gas by the motion of both electrons and ions. In some liquids (*e.g.*, water) one or more of the atoms in a molecule may lose an electron to another part of the molecule, yielding a mobile positive and a mobile negative ion.

Electrons detached from atoms can, in some circumstances, be drawn out of a material medium into vacuum and their motion controlled by electric or magnetic forces; the whole technology of electron tubes is based on this phenomenon, and much knowledge of the structure of matter is based on observations of the behaviour of free electrons in vacuum. The motion of electrons can also be controlled within matter. Technically, this control is easiest in a semiconductor such as silicon; a whole family of electronic devices from the simple rectifier to the most complex integrated circuits used in computers is based on this principle.

The force that binds electrons to nuclei in atoms is the electrostatic attraction manifest between two oppositely charged particles. Electrostatic force also plays some part in determining the structure of nuclei; but its most significant role is in the structure of the outer electronic part of atoms. The way the electrostatic force determines this structure is governed by the laws of quantum mechanics, which are used in working out much of theoretical atomic physics and theoretical chemistry. In the end, however, the crucial fact is that most of the physical properties and the whole of the chemical behaviour of atoms depend on the simple laws of electrostatic force acting between charged particles.

Electric effects determine the structure of matter, and, to an almost equally significant degree, electromagnetic theory determines thinking about the physical universe. The perfection and apparently almost universal validity of the electromagnetic laws and equations leads to theories of other phenomena by analogy with the theory of electromagnetism. Thus, for example, when Enrico Fermi, a physicist, came to consider the laws governing the beta decay of nuclei—*i.e.*, the emission of electrons from atomic nuclei—he set them up in a form as close as possible to the laws governing the emission of gamma rays, or electromagnetic radiation, by nuclei. There is one further way in which the highly developed theoretical structure of electromagnetism has influenced thinking and this is through the theory of relativity that first arose from the theoretical electromagnetic studies of physicists Henri Poincaré in France and Hendrik Antoon Lorentz in The Netherlands and the experimental observations of electromagnetic phenomena of numerous investigators around the turn of the century, of which the most important was the work of A.A. Michelson, a physicist, and Edward Williams Morley, a chemist. Both theory and experiment indicated that the velocity of light, an electromagnetic phenomenon, is a universal constant independent of any velocity possessed by either the observer or the source. Lorentz and Poincaré worked out many of the consequences of these facts, but it was left to Einstein to enunciate the special theory of relativity in a general form independent of electromagnetism. The fact that the velocity of light plays a unique and central role in the theory of relativity, which applies to all phenomena, indicates either that electromagnetism plays a crucial role in the structure of the universe or, at the very least, that electromagnetic phenomena reflect this structure in a particularly simple and direct fashion. Speculations about the nature of this connection extending well back beyond the formulation of the relativity theory have played, and still play, a dominant part in determining the development of fundamental physics.

Electromagnetism and cosmic structure

Of the sections of this article, the first is concerned qualitatively and nonmathematically with the general background to the study of electricity. The middle sections—II, III, IV, and V—develop the basic theoretical structure of electricity, beginning with the fundamental laws of electrostatics, and the final sections VI and VII, deal again in a mainly qualitative way with the most important electric effects. The middle sections necessarily involve a certain amount of mathematical manipulation and a knowledge of elementary algebra, and some familiarity with the basic notions of calculus will be required to assimilate parts of these sections. Vector notation is used in sections II and VI. The article as a whole is complementary to that on MAGNETISM, and the reader will find it useful to consult that article at several points. Because electricity is a subject with applications in almost every branch of science and technology, ELECTRICITY covers only a fraction of the topics that could be included under this subject heading. Only material that sets out or illustrates general principles has been included.

The article is divided as follows:

I. Development of concepts and theories
- Origin of concepts
- The rise of electrical theory
- Development of electrical technology
- Modern views of the nature of electricity and magnetism

II. Electrostatics
- Static electricity
- Dielectrics
- Electrostatic potential

III. Direct electrical currents
- Basic principles
- Steady currents, magnetic fields, and electromagnetic units
- Electromotive force
- Direct-current circuits

IV. The conduction of electricity
- The motion of charged particles in an electric field
- Conduction in vacuum
- Conduction in gases
- Electrolytic conduction
- Conduction in metals
- Conduction in semiconductors
- Contact potential and thermoelectricity
- Electron emissions

V. Alternating electric currents
- Faraday's law of electromagnetic induction
- The mathematical and graphical representation of sinusoidal phenomena
- The basic alternating-current circuit laws
- The detection and measurement of alternating currents and voltages
- Resonant circuits
- Alternating current bridges
- Nonlinear elements
- Electric waves in cables
- Filters
- Transient phenomena
- Eddy currents and the skin effect
- Power generation and distribution

VI. The primary effects and properties of electric fields and currents
- Magnetic effects of steady currents
- Magnetic effects of changing currents
- Force, energy, and power associated with fields
- Electromagnetic radiation

VII. The effects of electricity on matter
- Piezoelectricity
- Electro-optic phenomena
- Thermal effects
- Electrical production of light
- Chemical effects
- Bioelectric effects

I. Development of concepts and theories

ORIGIN OF CONCEPTS

Electrical, magnetic, and optical effects were known to the ancients, though little systematic investigation of them occurred until the late Middle Ages. Curiously enough, because electrostatics tends to be regarded as both the simplest and most fundamental branch of the whole subject, the first important investigations were made in magnetism, no doubt stimulated by the useful

and curious properties of the magnetic compass. There is some doubt as to where this device originated. It was known in England in the 12th century and was not, apparently, regarded at that time as a novelty. The first observation that has any bearing on modern notions of magnetism was made in the 13th century by Petrus Peregrinus de Maricourt, a French crusader, in Picardie who took a natural magnet, or lodestone, rounded into globular form and laid on it a magnetic needle and marked on the globule the line along which the needle set itself as it was placed on different parts of the globule. He found that when the whole stone had thus been marked the lines formed a set of meridians of longitude passing through two points at opposite ends of the stone, just as meridians of longitude on the Earth's surface pass through its north and south poles. De Maricourt called these points the magnetic poles and observed that the way a magnetic needle set itself when brought near the body depended only on the position relative to these poles. Thus, he is given credit for the notions of poles and polarization that were to dominate magnetic and electric theories for 700 years, and still play an important role in electromagnetism.

Lodestone investigation in the 13th century

The father of the modern subject of electromagnetism was William Gilbert of England. In his book *De Magnete magneticisque corporibus et de magno magnete tellure*, published in 1600, three years before his death, he not only gave a systematic discussion of magnetism, especially the magnetism of the Earth, but also considered the force between two objects charged by friction. To this force he gave the name electric. He showed that frictional electricity occurs in many common materials and he also noted what is still regarded as one of the primary distinctions between magnetism and electricity: the force between magnetic objects tends to align the objects relative to each other and is little affected by most intervening objects; the force between electrified objects is primarily a force of attraction or repulsion between the objects and is grossly affected by intervening matter.

Gilbert attributed the electrification of a body by friction to the removal of a fluid, or "humour," which then left an "effluvium," or atmosphere, around the body. The language is quaint but if the "humour" is renamed "charge" and the "effluvium" renamed "electric field," Gilbert's notions closely approach modern ideas. The 17th and early 18th centuries saw an increased interest in electrostatic effects. Electrical conductors were discovered by Stephen Gray in England in 1729, and in 1733, Charles François de Cisternay Dufay, gardener to the king of France, announced the existence of two types of electric force: an attractive force, already known, and a repulsive force. These observations were organized and systematized by Benjamin Franklin, who essentially attributed the plus sign (+) and the minus sign (—) to the two types of electricity and enunciated the law now known as the conservation of charge (the net sum of the charges within a region is always constant). Sir Isaac Newton's work on gravity had surprisingly little influence on the development of electrical theory before the middle of the 18th century. There had been some speculation as to the law of force between charged bodies, but this was not elucidated until 1767, when Joseph Priestley, an English chemist, acting on a suggestion of Franklin's, showed that when a hollow metal (conducting) vessel is electrified no electric force acts on objects in its interior. He inferred that "the attraction of electricity is subject to the same laws with that of gravitation and is therefore according to the (inverse) squares of the distances." With this discovery, subsequently verified in other ways by many experimenters, the laws of electrostatics were complete and have not further been changed to this day, although the years between Priestley's discovery and the middle of the 19th century saw a great clarification of the expression of the laws and substantial mathematical advances in handling them. The advances are mainly associated with two physicists, Henry Cavendish and Charles-Augustin Coulomb, and a mathematician, Poisson, during the 18th and early part of the 19th centuries. Poisson's equation, published in 1813, and the law of charge conservation virtually contain in two lines the whole of the laws of electrostatics.

While the science of electrostatics had been progressing and its fundamental laws were becoming clear and codified, the study of current electricity, or "galvanism," had begun. Though Luigi Galvani was a professor of anatomy in Bologna, he also had an interest in electrical (*i.e.*, electrostatic) phenomena and acquired several electrical machines that apparently he kept and investigated in his dissection room. The sequence of events that followed from this coincidence is not entirely clear, but certainly Galvani noticed that electrical sparks produced by a nearby machine caused muscular contraction in a dissected frog. He went on to investigate this effect and at first considered that it was the result of atmospheric electricity because similar effects could be observed during lightning storms. In this he was almost certainly correct, but a second happy chance led him to an altogether more important discovery—that whenever a connection was made by a metal connector between the frog's muscle and the frog's nerve the same muscular contraction was observed, although some metals appeared to be more effective than others. Galvani concluded that a fluid that he identified with electric charge was transported by the metal from the nerve to the muscle and caused the contraction. Galvani's results, published in 1791, excited considerable controversy and speculation.

Galvani's experiment with frogs

A more serious attitude to Galvani's discoveries was taken by a physicist, Alessandro Volta of Pavia, who in 1792 correctly conjectured that the effect was caused by the contact between metal and a moist body. By 1800, Volta, pursuing this line of thought, had constructed what is now known as a voltaic pile consisting of layers of copper, moist pasteboard, and zinc (repeated in that order) and had discovered that, with an extended pile, he could obtain an electric shock by touching the first copper plate and the last zinc plate. Volta confirmed that the effects of his pile were in every way equivalent to those of static electricity. Within 20 years, galvanism had been unequivocally related to static electricity.

Heating effects caused by electrostatic discharges had been known for some time, and there had even been sporadic reports of iron objects becoming magnetized when struck by lightning. But the advent of a sustained and reliable source of electric current made more systematic investigation possible.

THE RISE OF ELECTRICAL THEORY

In 1820 a Danish physicist named Hans Christian Ørsted announced his discovery that a magnetic compass needle was influenced by currents in neighbouring conductors; and by the end of the year a French physicist, André-Marie Ampère, had shown that two parallel wires carrying current attracted each other if the currents flowed in the same direction and repelled each other if the currents were opposed. The first quantitative analysis of Ørsted's results was made by two French physicists, Jean-Baptiste Biot and Félix Savart, also in 1820, and in 1825 Ampère essentially formulated in mathematical terms the laws that govern the interaction of steady currents with static magnetic fields. The final simplification of these laws and their expression in the form now used, however, was not achieved until much later in the century.

The power of a material to conduct static electricity had been investigated earlier (1775) by Cavendish, but the final clarification of the laws was effected by a physicist in Germany, Georg Simon Ohm, and Ohm's law (see below), published in 1827, still forms part of the conceptual structure—and perhaps the most widely used part—employed in practical electrical design. The relation between electric currents and heat, although known to earlier investigators, was not investigated quantitatively until somewhat later (1841) by James Prescott Joule, a physicist who formulated in more or less its final form the theory of the heating effects accompanying the flow of electricity in conductors.

In 1813 the chemist Sir Humphry Davy appointed Michael Faraday as his assistant at the Royal Institution

of Great Britain, London. Faraday is primarily remembered for his discovery of electromagnetic induction and the introduction of the concept of a line of electric force or magnetic force. The discovery of electromagnetic induction (the production of a transient current in a conductor when the current in a nearby conductor is changed) was announced in 1831. But the concept of lines of force that permeated Faraday's thinking has influenced physics since Faraday's time and profoundly impressed the Scot James Clerk Maxwell, born the same year (1831), when he began his researches that culminated in 1864 with the formulation of his electromagnetic equations.

Discovery of electromagnetic induction

While Faraday was engaged in his experimental researches, a parallel development in the mathematical theory of electricity and magnetism was proceeding on the continent of Europe, mainly in Germany. To this period belongs the work of the German physicists Franz Ernst Neumann, Wilhelm Eduard Weber, and H.F.E. Lenz. At the same time, Joule and two other physicists, Sir William Thomson (later Lord Kelvin) of England and Hermann von Helmholtz of Germany, were clarifying and developing the theory of the relation between electricity and other forms of energy; and Helmholtz, Thomson, Joseph Henry, a United States physicist, Gustav Kirchhoff, a German physicist, and Sir George Gabriel Stokes, a British physicist, were extending the theory of the conduction and propagation of electrical effects in conductors. In 1856, Weber and his German colleague, Rudolf Kohlrausch, determined the ratio of the electric and magnetic units and found that it is almost exactly equal to the velocity of light and of the same dimensions. In 1857, Kirchhoff used this result to demonstrate that electrical disturbances propagated on a perfectly conducting wire with the speed of light. Thus by 1860 the connection between electromagnetism and optics was apparent. The final steps in establishing the connection between light and electromagnetism were made by Maxwell and, with the formulation of his celebrated equations, the history of classical electromagnetism comes to an end. Maxwell's equations have not yet been superseded, and subsequent developments in electromagnetic theory have either been concerned with the relation between electromagnetism and the atomic, or submicroscopic structure, of matter or with exploring the practical and theoretical consequences of Maxwell's equations.

Maxwell's greatest distinction is that he finally synthesized electricity, magnetism, and optics into one coherent whole. His electromagnetic equations will be treated in detail below, and it need only be noted here that whereas Faraday had discovered experimentally that a changing magnetic field produces an electric field, Maxwell hypothesized that a changing electric field will produce a magnetic field. With this hypothesis, Maxwell rounded out the structure of electromagnetism and brought optics and radiant heat within its purview. More recent developments, such as relativity and quantum mechanics, have done little to upset the fundamental correctness of Maxwell's formulation. Indeed, as experiments confirm the predictions of quantum electrodynamics based on Maxwell's equations with ever-increasing accuracy, confidence in their validity increases rather than diminishes. The notion of a field, introduced by Faraday and expressed succinctly in mathematical form by Maxwell, continues to dominate 20th-century thinking.

With the formulation of Maxwell's equations, physicists were equipped with a complete description of the electromagnetic field, although, as might be expected, Maxwell's ideas did not win general acceptance until the end of the 19th century. The primary focus of interest in physics shifted from electromagnetic effects to their origin in the structure of matter.

Electrical discharge in gases

By the middle of the 18th century, luminous electrical discharges in rarefied gases had been observed; but little notice of the phenomenon was taken until, in 1838, Faraday gave the first exact description of the effects that occurred and noted a dark space between the glowing negative electrode and the main bulk of the discharge. Faraday remarked on the significance of the difference between negative and positive electricity, but little further work was done on the subject until the invention of a mercurial air pump made low pressure investigations easier. Between 1850 and 1895 the properties of cathode ray discharge were subjected to almost continuous investigation, and a mass of apparently contradictory and obscure evidence accumulated. Between 1896 and 1898 two English physicists, Sir J.J. Thomson and Sir J.S.E. Townsend, identified a cathode ray as a stream of negatively charged particles now called electrons, much lighter than the lightest atoms of chemistry.

From the discovery of the electron to the present day the theory of electromagnetism has been inextricably entangled with theories of the atomic, subatomic, and subnuclear structure of matter, one theory influencing the other and vice versa.

The thermodynamics of thermal radiation had been investigated in Germany by the physicist Wilhelm Wien between 1890 and 1900. Wien had virtually exhausted the resources of thermodynamics in dealing with this problem. Two British scientists, Lord Rayleigh (John William Strutt) and Sir James Hopwood Jeans, had by 1900 applied the newly developed science of statistical mechanics to the same problem. They obtained results that, though in agreement with Wien's thermodynamic conclusions (as distinct from his speculative extensions of thermodynamics), were only in partial agreement with experimental observations. The problem had also attracted the attention of Max Planck, a German physicist, who attempted to combine both the statistical approach and a thermodynamic approach. By concentrating on the necessity of fitting together the experimental data he was led to the formulation of an empirical law that satisfied Wien's thermodynamic criteria and fitted the data. When Planck interpreted this law in terms of Rayleigh's statistical concepts, he came to the conclusion that radiation of frequency (ν) exists only in quanta of energy, $nh\nu$, in which n is a whole number and h is a new universal constant. Planck's result, announced in December 1900, marked the foundation of quantum mechanics and initiated a change in the basic structure of physical theory that was as profound as anything that had happened in the previous century.

By 1900 it was apparent that Thomson's electrons were a universal constituent of matter, and in the early years of the century many physicists attempted to construct theories of the electromagnetic properties of metals, insulators, and magnetic materials in terms of electrons. The most notable landmark in this period was the publication of *The Theory of Electrons and its Applications to the Phenomena of Light and Radiant Heat* by Lorentz in 1909 (based on his lectures in 1906). Some of Lorentz's ideas have been modified in the light of quantum theory, and some of his ideas have been put into more precise form in the decades that have elapsed since 1909; but just as Maxwell unified the theories of electricity, magnetism, and optics, Lorentz unified their interpretation in atomic terms.

The one other major conceptual advance in electromagnetic theory that remains to be discussed is the theory of special relativity. In Maxwell's time a mechanistic view of the universe was popular; and just as sound was interpreted as an undulatory motion of the air, light and other electromagnetic waves were regarded as an undulatory motion of an intangible medium, the ether. The question then arose as to the velocity of the Earth through the ether and whether or not the velocity of light measured by an observer moving relative to the ether would be affected by his motion. Michelson and Morley in 1887 had shown that no such effect occurred, and Lorentz and Poincaré in the period 1900–04 had shown that this was consistent with Maxwell's equations. On this basis they built a theoretical construct, the theory of relativity, in which the absolute motion of a body relative to a hypothetical ether is no longer significant. The theory was first given the name the Principle of Relativity by Poincaré in a lecture at St. Louis, Missouri, in September 1904; in 1906, Planck gave the first formulation of relativistic dynamics. The most general formulation of the principle of

Relativity

relativity was, however, given by Einstein in 1905; and it is with his name that the principle is usually associated.

Maxwell's equations, the special theory of relativity, the discovery of the electronic structure of matter, and the formulation of quantum mechanics had all occurred by 1930. The triumphs of quantum electrodynamics in the era 1945–55 and later added little to a fundamental understanding even if they immeasurably increased confidence in the general validity of electromagnetic, atomic, quantum, and relativity theory.

DEVELOPMENT OF ELECTRICAL TECHNOLOGY

Some attention must now be given to the development of electrical technology. This period may be said to have begun with Faraday's discovery of electromagnetic induction, which gave a possible means of turning mechanical energy into electrical energy on a large scale.

The first moderately efficient battery (the Daniell cell) dates from 1836; and the forerunner of the modern dry battery (the Leclanché cell) was first announced in 1866. The lead–acid accumulator did not appear until 1881, six years after arc lighting energized by a motor generator had been installed in the Gare du Nord.

Within a year of Faraday's discovery a small hand generator was demonstrated in Paris, and by 1850 generators were being manufactured in several countries and experiments with carbon arc lights for lighthouses were afoot in England and France. The first dynamos were little more than an assembly of coils and permanent magnets that could be maintained in relative motion. The slotted armature appeared only in 1880, although between 1860 and 1870 the principle of the self-excited generator was discovered. The early years of the electrical industry were thus dominated by the problems of generation, and the only serious use of electric power considered was the arc light. Faraday's discovery of the transformer was not put to practical use until the 1880s, and at about this time the question of whether alternating current (ac) or direct current (dc) should be used for power transmission became a live issue.

The carbon arc lamp was never suitable for domestic use and required regular attention, so that it could hardly ever have led to a large scale demand for electricity. The incandescent filament lamp, originating in the 1840s, became a practical device (1878) with a carbon filament lamp invented by an English physicist, Sir Joseph Wilson Swan, and was independently discovered within the year by Thomas A. Edison of the United States. (Litigation between Swan and Edison was finally resolved by the formation of a joint company.) The tungsten filament lamp introduced in 1905 has become the main form of electric lamp, although in the last 20 years it has gradually begun to give way to the more efficient and longer-lived, but more expensive, fluorescent gas discharge lamp.

Simple and robust instruments for measuring electric charge, current voltage, and power have been in an almost continuous state of development since Faraday's time. At the present time a considerable fraction of the output of the electrical industry, and especially of the scientific instrument industry, is concerned with the production of electrical measuring instruments of ever-decreasing size and ever-increasing reliability and accuracy. Most major countries maintain a central standards institute, one of the major activities of which is the maintenance and establishing of electrical standards.

Apart from lighting and, in some countries, space heating, the other major use of electric power is in electric motors. The electric motor is the standard domestic prime mover in hand tools, cleaners, kitchen equipment, fans, boiler pumps, in some modes of transportation, and the like; in manufacturing, it has virtually eliminated all other forms of prime mover.

First commercial electric motors

The principle of the electric motor was devised by Faraday in 1821, but no motor of commercial significance was produced until 1873; and the first important ac motor, the creation of a United States inventor, Nikola Tesla, was not demonstrated in the United States until 1888. Tesla produced his first motors in association with the Westinghouse Electric Company (now Westinghouse Corporation) a few years after direct current motors had been installed in trains in Germany and Ireland. By the end of the 19th century the electric motor had taken a recognizably modern form. Subsequent improvements have rarely involved radically new ideas; but as design experience has accumulated and new and better bearing, armature, magnetic, and contact materials have become available, motors have become smaller, cheaper, more efficient, and more reliable.

The Leclanché cell of 1866 and the lead–acid accumulator of 1881 still dominate the battery market, although improved out of all recognition both in size, efficiency, and convenience. Other chemical cells are used for special purposes, and in recent years there has been some resurgence of interest in batteries. It has been prompted partly by the increased use of portable electronic equipment and partly by the search for a fuel cell that will convert the chemical energy of a readily available fuel, such as oil, directly to electricity without going through an intermediate, and necessarily inefficient, steam-raising thermal process.

Although not necessarily a major user of electric power in terms of quantity, the electronics and communications industries and services are perhaps one of the most spectacular products of the electrical age. By 1866 telegraphy over wires—using simple electrochemical or electromechanical receivers—was a well-established technique, and in 1850 a submarine cable was laid across the English Channel. This became unserviceable in a matter of weeks, and not until 1865 was a further and successful attempt made. Alexander Graham Bell's telephone was patented in the United States in 1876, and within a few years the first public telephone services began to take root. In 1895 Sir Ernest Rutherford, a British physicist, transmitted radio signals for three-quarters of a mile at Cambridge, England, and by 1901 Guglielmo Marconi had established communication across the Atlantic. Radio telephony, the electrical recording and reproduction of sound, and television had to await the development of the thermionic valve, or electron tube; and public radio transmissions were not established before the 1920s.

In a remarkably short time the electron tube had grown from Thomson's discovery of the electron. An English physicist, Sir John Ambrose Fleming, invented the electron diode in 1904 and Lee De Forest, an inventor in the United States, the triode in 1907, with which weak electrical signals could be amplified. By the end of World War I electronics based on the triode was an established industry. The first radio telephony transmission—from Arlington, Virginia, to the Eiffel Tower in Paris—was made in 1915; and a commercial radio telephone service opened between New York City and London in 1927. The years between the wars were mainly concerned with the expansion of the radio and the phonograph entertainment industries and the sound film industry; but, especially in England, rapid progress was being made toward the transmission of moving pictures; and just before the outbreak of World War II the British Broadcasting Corporation inaugurated the first public television service.

Until 1939 the electronics industry had been almost solely concerned with communications and broadcast entertainment, but during the 1930s work had started in England on a device for detecting aircraft now known as radar. Although the system is important in itself, for both its military and its civil uses, it also marked the beginning of an electronics industry not entirely dependent on communications and entertainment. During the war and in the years that followed, the electronics industry made strides paralleled only by those of the chemical industry. Television has become a commonplace; and new electronic gadgets and systems, of which the most significant is the electronic digital computer, have appeared. For many purposes the transistor or semiconductor triode, invented in the 1940s at Bell Telephone Laboratories, has replaced the electron tube and has led to a notable diminution in the size, cost, and failure rate of electronic equipment.

In the next section, the historical approach is abandoned and a brief summary is given of the modern view of electricity, outlining some of the ideas to be developed at greater length in later sections.

MODERN VIEWS OF THE NATURE OF ELECTRICITY AND MAGNETISM

The question "What is electricity?" like the question "What is matter?" really lies outside the realm of physics and belongs to that of metaphysics; but the questions "How does electricity fit into the general understanding of the physical universe?" or "How is electricity related to other physical phenomena?" are proper in the context of physics and must be considered.

Importance of the notion of a moving electric charge

Electromagnetism. Electromagnetism, the theory dealing with electric and magnetic fields, is based on the concept of a moving electric charge. The way this arises is as follows: If a charged macroscopic body is moved, the charge is transferred from one point in space to another, and the motion leads to a current. Conductors can also transfer charge without apparent bodily motion. It is logically possible for charge to flow without mass motion, but the study of processes on an atomic or sub-atomic scale shows that charge transfer is always accompanied by the motion of particles of finite mass. Thus, charge transfer is associated with the motion of electrons, protons, nuclei, ions, or a variety of unstable particles such as mesons. A charge may therefore be assigned to these particles. Experimentally, each particular type of particle is always associated with the same charge; and this charge is always an exact integral multiple of a fundamental unit e, about 1.6×10^{-19} coulomb (the unit of electrical charge). The only two unconditionally stable elementary particles with a finite mass are a proton with charge $+e$ and an electron of charge $-e$. Neutrons (elementary particles of about the same mass as protons but with zero charge) are unstable except when bound in nuclei. Composite systems of neutrons (*i.e.*, nuclei, atoms, and ions) may have charges that are other multiples of e. Thus, for example, the oxygen nucleus has a charge $+8e$, the chloride ion a charge $-e$, and the phosphate ion (PO_4) a charge $-3e$. The general dimensions of nuclei, electrons, and protons are 10^{-13} centimetre; but atoms and ions are usually 100,000 times larger (10^{15} times greater volume) and about 10^{-8} centimetre in linear dimensions.

Today the flow of an electric current is considered to be caused by the motion of one or another of these types of charged particles. Because the electron, of mass about 10^{-30} kilogram, is 2,000 times lighter than any ion, it responds more rapidly to electric fields; and most of the phenomena grouped together as conduction are caused primarily by the motion of electrons. In metals and semiconductors this is exclusively the case; but in a gas discharge both electrons and ions are important, and in an electrolyte (an electrically conducting compound) such as water only ions are responsible for conduction. Both electrons and ions also lead to important effects in insulators, and electronic motion is entirely responsible for the phenomenon of magnetism.

A conductor always contains mobile charges, usually electrons, but in an insulator the charges are bound to fixed positions in the lattice (the atomic sites in a crystal) if it is a solid, or in exactly neutral groups, atoms, or molecules, if the insulator is a liquid or gas. Thus, in air, each oxygen molecule contains 16 protons and 16 electrons and has no net charge, whereas in a sodium chloride crystal, although the individual sodium (Na^+) and chlorine (Cl^-) ions are charged, they are tightly bound in position in the crystal lattice. When a charge is brought near an insulator and its electric field exerts a force on the charges in the insulator, the most these charges can do is to perform minute excursions of less than atomic dimensions from their equilibrium positions. Thus, if the external charge is positive, the electrons in atoms will move slightly toward it and the positive nuclei will move away from it. In sodium chloride the motion of the ions as units is superimposed on this effect. The displacements may be small, but the large number of displaceable charges in unit volume leads to gross and easily observable effects. In the theory of dielectrics, to be dealt with in more detail in a section below, these displacements lead to an effect called polarization of the medium, so that if two charges of opposite sign are placed on either side of an insulating body, the net effect is a reduction in the force acting between the two charges. The general theory that emerges from this picture of the behaviour of insulating bodies is in accord with facts.

Originally, magnetism was regarded as an effect completely distinct from electricity, but the discoveries of Ørsted, Ampère, and Faraday showed that in fact the two effects are closely connected. Further, all the effects associated with magnetized bodies can be reproduced exactly by systems containing circulating electric currents. Thus, there is no need to postulate a separate magnetic source. This is the modern view, and all magnetic effects are now attributed either to actual macroscopic currents in circuits or to microscopic currents circulating within atoms. In its most naïve form this theory would identify the atomic currents with the effects of electrons in atoms rotating in their orbits about the nuclei. Neither this picture nor its simple transposition into quantum mechanical terms leads to complete agreement with experiment, and, in the early days of quantum mechanics, this was evaded by introducing the concept of the spinning electron. The electron itself was given an internal degree of freedom associated with internal rotation, angular momentum, and a circulation of internal current. This led to exactly the additional magnetic properties actually observed. The origin of electron spin became apparent when P.A.M. Dirac, an English physicist, gave the first complete relativistic and quantum mechanical treatment of the electron.

Relation of electric and magnetic effects

Charged particles and Maxwell's equations. If the phenomena of electromagnetism are explained as the consequences of the motion of atomic or sub-atomic charged particles, it is appropriate to look briefly at the nature of the charged particles themselves.

The electron is characterized by its electric charge and mass, which are regarded as its most significant properties. Its spin about its own axis and magnetic moment, the same magnetic property possessed by a bar magnet, are connected with these properties; but that they are not its only properties can be seen by considering the basic reaction of beta decay in which a neutron (n) of zero charge decays, or transforms, to a proton (p), an electron (e), and an antineutrino ($\bar{\nu}$), a massless particle that moves with the speed of light, symbolized $n \rightarrow p + e + \bar{\nu}$. The electron, by virtue of its negative charge, generally interacts with a positively charged proton; but here it interacts in a quite different way, with not only a proton but with two uncharged particles, the neutron and the massless antineutrino. This is not the only additional interaction in which electrons engage, and the proton has a whole series of even more complex interactions. Thus, although electric charge fits into a general scheme of fundamental interactions, the relation is unlikely to be simple. At present, the nature of this scheme is somewhat of a mystery. The only hard facts are that nature provides a multitude of charged and uncharged particles, some of which have a finite mass and others of which are, like the neutrino, both chargeless and massless. There are only two stable particles with mass, the proton and the electron; and these both have the same spin, one-half Planck's constant divided by 2π (symbolized $\frac{1}{2}\hbar$), and charges plus and minus e ($\pm e$). The proton, however, has some 2,000 times the mass of the electron.

It is known with enormous precision that the proton and electron charges are numerically equal, for otherwise normal matter could not be electrically neutral, but no more fundamental reason why this should be so is known; nor, despite almost continuous speculation for the last 50 years, is it known why the fundamental unit of charge should have exactly the value it does. Thus, although electromagnetic phenomena fit into the same general scheme as the structure of matter, the ultimate laws that determine this scheme are as yet undiscovered.

Maxwell's equations of the electromagnetic field relate

two vectors (quantities characterized by both magnitude and direction), the electric field E and the magnetic field B, to electric charges and currents, which act as the sources of the field much as a running tap acts as a source of flow lines in a bathtub, or an open drain acts as a sink of flow lines. Theorists typically seek symmetrical theories, and in recent years there has been some discussion as to whether magnetic charges and currents could not also appear in the field equations. Dirac, the founder of elementary particle theory, originated the idea in 1931, and certainly it has considerable aesthetic appeal. Calculations have indicated that if free magnetic charges are to exist they must be associated with massive particles and could be created only in particle reactions at energies well above anything at present available. Thus, to date, there is no experimental evidence whatsoever that supports the inclusion of magnetic charge in the field equations. As far as is now known, Maxwell's equations are a complete description of the electromagnetic field and its interaction with matter. There are problems in combining the field equations with the laws of relativistic quantum mechanics. Contemporary quantum electrodynamics is a scheme that allows the calculation of many experimentally measurable effects with extreme accuracy but leaves the general problem of combining a continuous field theory with particle mechanics unresolved.

Significance of Maxwell's equations

II. Electrostatics

Electrostatics is concerned with the relation between three quantities: electric field, charge, and force. One of these quantities, charge, has magnitude but no direction associated with it; the other two involve both magnitude and direction and are called vectors, being represented by boldface characters (*e.g.*, E for electric field and F for force). Vector notation is a compact, simple language that expresses important physical results in a form brief enough to be memorable and also taken in at a glance. As an example, an important electromagnetic law, Faraday's law of electromagnetic induction, states that the total electromotive force (potential difference) acting around any closed path in space is equal to the rate of decrease of the magnetic flux (a measure of the magnetic field taken as lines per unit area) linking the path. This law can be expressed in mathematical terms without using vectors. A simple formulation is one that relates the partial derivatives (symbolized by the delta sign: ∂) of the Cartesian components (a component is the value of a quantity along one of three possible axes, usually denoted x, y, or z) E_x, E_y, and E_z of the electric field to the time derivatives of the Cartesian components B_x, B_y, and B_z of the magnetic field. This gives the three equations, each having three partial derivative terms:

Law of electromagnetic induction

$$\frac{\partial E_z}{\partial y} - \frac{\partial E_y}{\partial z} = -\frac{\partial B_x}{\partial t}$$

$$\frac{\partial E_x}{\partial z} - \frac{\partial E_z}{\partial x} = -\frac{\partial B_y}{\partial t}$$

and

$$\frac{\partial E_y}{\partial x} - \frac{\partial E_x}{\partial y} = -\frac{\partial B_z}{\partial t}.$$

In vector notation, however, the law is completely expressed by the equation

$$\nabla \times E = -\frac{\partial B}{\partial t}.$$

In this equation, $\nabla\times$ represents a mathematical operator, called the curl, which, when acting on the vector E, produces the three partial differential equations above. Clearly, this vector notation, called curl E, is both memorable and more easily recognizable. It is also more useful than the purely verbal statement because it can be manipulated, using mathematical techniques, and can be used in conjunction with vector statements of the other electromagnetic laws to derive useful practical results.

STATIC ELECTRICITY

The basic phenomena and laws. If two objects are rubbed together and then drawn apart it sometimes happens, especially in a dry atmosphere and with dissimilar materials, that the bodies appear to exert an attractive force on each other. They are said to be electrified. The force between the bodies decreases rapidly as they are pulled apart and generally appears to decay with the passage of time. Further, if two similar bodies (*e.g.*, two plastic rods) are electrified by rubbing against the same body (*e.g.*, a dry silk handkerchief) both rods attract the handkerchief but the two rods repel each other. Electrification leads to both attractive and repulsive forces. The electrification of a body can be transferred to another body by contact, and two bodies electrified by contact with the same body repel each other. A further important qualitative observation is that electrification can be transferred from an electrified to an unelectrified body by connecting the bodies by a metal wire. By themselves, these observations are not enough to lead to a quantitative theory but they suggest that, in frictional electrification, a "fluid" can either be transferred by actual contact or can flow through metals. Historically the elucidation of the laws of electrostatics, the interaction of charged bodies at rest, was achieved indirectly, and following the historical path does not help to explain these laws as well as might be hoped. The basic laws are therefore better stated in terms of a set of hypothetical experimental observations. These observations can be made with reasonable precision, though ultimately the validity of the electrostatic laws rests on the precision with which they predict the results of less direct experiments. The experimental facts may be set out in the form of five laws.

Electrification

1. If A and B are two electrified bodies, the force acting between A and B is along the line joining A and B, and its magnitude varies inversely with the square of the distance between A and B.
2. Action and reaction balance. Body A exerts a force on body B equal in magnitude to the force B exerts on A but in the opposite direction.
3. If body A exerts a force F_{AC} and body B exerts a force F_{BC} on a test body C at the same distance from A or B, and F_{AD} and F_{BD} are the forces exerted on a second test body D at the same distance, then $F_{AC}/F_{BC} = F_{AD}/F_{BD}$. These three observations make it possible to assign to each body a numerical measure of electrification, the charge q, which determines both the force exerted on, and the force experienced by, a body. If repulsive forces are defined as positive and attractive forces as negative, the force (F) acting between bodies of charge $q(A)$ and $q(B)$ at a distance r apart, in accordance with experimental fact (1) above, can be written as equal to a universal constant k times the product of the two charges divided by the square of their separation distance, or,

$$F = k\frac{q(A)q(B)}{r^2}.$$

If the charges have the same sign the force is repulsive ($+F$ in the convention used here). The interaction of two bodies with a third leads to a definition of equality of charge. The force between two bodies of the same charge is equal to the constant k times the ratio of the charge squared to the separation squared, or, $F = k\,q^2/r^2$. If r is expressed in metres and F in newtons, the unit of force, the choice of the constant k determines a unit for charge q. In the mks (metre-kilogram-second) or SI (International System of Units) scheme of units the constant k is equal to $\frac{1}{4\pi\epsilon_0}$ in which the constant ϵ_0 is defined as $\frac{10^7}{4\pi c^2}$, and the constant c is the experimental value for the speed of light. Further, ϵ_0, called the dielectric constant *in vacuo*, is regarded as having dimensions (*i.e.*, not a pure number but is expressed in units). The reason for this choice of constant k is connected with the desirability of defining the units of charge q in terms of precise magnetic measurements rather than less precise electrostatic measurements. As for other systems of units, in electrostatic units (esu), or Gaussian units (named after

Other systems of units

a German mathematician, Carl Friedrich Gauss) the constant k is equal to unity (one), with r and F of the force equation in centimetres and dynes. In Heaviside–Lorentz units $k = \frac{1}{4\pi}$, and in electromagnetic units (emu) $k = \frac{1}{c^2}$ with r in centimetres and F in dynes (a unit of force, 10^{-5} newton).

Force, because it is a directed quantity, by definition is a vector. If there is a charge $q(1)$ at a point specified by the vector $\boldsymbol{r}(1)$ and another, $q(2)$ at point $\boldsymbol{r}(2)$ (see Figure 1), the force $\boldsymbol{F}(1,2)$ acting on $q(1)$ and arising from $q(2)$

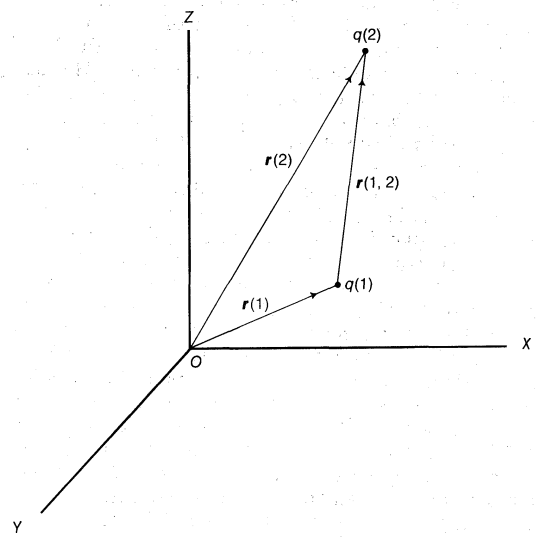

Figure 1: Vector addition $\boldsymbol{r}(2) = \boldsymbol{r}(1) + \boldsymbol{r}(1, 2)$ in Cartesian coordinate system OX–OY–OZ, showing that vector $\boldsymbol{r}(2)$ is the resultant of the sum of vectors $\boldsymbol{r}(1)$ and $\boldsymbol{r}(1, 2)$ (see text).

can be expressed in terms of the vector separation $\boldsymbol{r}(1,2) = \boldsymbol{r}(2) - \boldsymbol{r}(1)$ of the charges as the equation

$$\boldsymbol{F}(1,2) = \frac{q(1)q(2)}{4\pi\epsilon_0 r^3(1,2)}\, r(1,2),$$

in which $r(1,2)$ is the magnitude, or length, of the vector $\boldsymbol{r}(1,2)$. (In this case, length r in the denominator is cubed because it is also introduced into the numerator as a first power in order to make a vector equation.)

4. All forces acting on a single charge are additive. If charges $q(1)$ at $\boldsymbol{r}(1)$, $q(2)$ at $\boldsymbol{r}(2)$ etc., up to $q(n)$ at $\boldsymbol{r}(n)$, act on a charge $q(0)$ at $\boldsymbol{r}(0)$ the force on this charge is

$$\boldsymbol{F}(0) = \boldsymbol{F}(0,1) + \boldsymbol{F}(0,2) + \text{etc.}$$

and this can be expressed as

$$\boldsymbol{F}(0) = q(0) \sum_n \frac{q(n)\boldsymbol{r}(0,n)}{4\pi\epsilon_0 r^3(0,n)}, \qquad (1)$$

in which $\sum_n$ means the sum of terms, each of which has n equal to a whole number 1,2,3, etc. The results so far give a means of defining and measuring charge.

5. The final law of electrostatics is that charge is conserved. Before investigating this law it will be convenient to develop a little further the ideas implicit in equation (1) and to examine the way in which electrical conductors fit into the scheme of electrostatics.

As a beginning, the electric field $\boldsymbol{E}$, work, and electrostatic potential will be defined. The sum on the right hand side of equation (1) is a vector. If the electric field $\boldsymbol{E}$ at the point $\boldsymbol{r}(0)$ occupied by the charge $q(0)$ is defined so that the force is equal to the product of charge and field, $\boldsymbol{F}(0) = q(0)\boldsymbol{E}(0)$, then the electric field $\boldsymbol{E}(0)$ at $\boldsymbol{r}(0)$ generated by the other charges $q(n)$ at points $\boldsymbol{r}(n)$ is equal to the sum

$$\boldsymbol{E}(0) = \sum_n \frac{q(n)\boldsymbol{r}(0,n)}{4\pi\epsilon_0 r^3(0,n)}$$

If there is only one charge q and it is at the origin, $\boldsymbol{r} = 0$, the field at a general point specified by $\boldsymbol{r}$ will be

$$\boldsymbol{E}(\boldsymbol{r}) = \frac{q\boldsymbol{r}}{4\pi\epsilon_0 r^3}. \qquad (2)$$

It can be shown that the work $W(1,2)$ done in this field *against* the force $q(0)\boldsymbol{E}(\boldsymbol{r})$ in taking a test charge $q(0)$ from $\boldsymbol{r}(1)$ to $\boldsymbol{r}(2)$ is

$$W(1,2) = q(0)\frac{q}{4\pi\epsilon_0}\left(\frac{1}{r(2)} - \frac{1}{r(1)}\right).$$

This result has two important consequences. First the work done depends only on the initial and final positions $\boldsymbol{r}(1)$ and $\boldsymbol{r}(2)$ and is independent of the path (*i.e.*, work is not a vector quantity; it is called a scalar quantity because it has only magnitude), and secondly the work $W(1,2)$ can be expressed as $q(0)$ times the change in the function $\phi(\boldsymbol{r})$, *i.e.*, $q(0)\phi(\boldsymbol{r})$, in which

$$\phi(\boldsymbol{r}) = \frac{q}{4\pi\epsilon_0 r}.$$

This equation defines the electrostatic potential.

Because the work is independent of the path, the work done against or by the electrostatic field in taking a charge round a closed path is zero. This is in conformity with the conservation of energy on the assumption that the motion of the charge does not, of itself, cause work to be done elsewhere in the universe, true only if the motion of the charge is slow (*i.e.*, quasistatic). It also means that the vector, curl $\boldsymbol{E}$, or $\nabla \times \boldsymbol{E}$, must be zero. Thus, the electrostatic field $\boldsymbol{E}$ may also be defined as the gradient (symbolized ∇ and called del) of a scalar potential; *i.e.*, expressed in vector notation as

$$\boldsymbol{E} = -\nabla\phi, \qquad (3)$$

another way of writing equation (2), a most important vector relationship. Because the effects of several charges are additive the potential of several charges is the summation

$$\phi(\boldsymbol{r}[0]) = \sum_n \frac{q(n)}{4\pi\epsilon_0 r(0,n)}. \qquad (4)$$

Definition of conservative field

Writing the properties of the vector electrostatic field in terms of a simple additive scalar potential is an enormous simplification. A field of any kind with this relationship to potential is known as a conservative field.

The electric field $\boldsymbol{E}$ has another important property. If the electric field $\boldsymbol{E}$ is designated E_n when it is perpendicular to a closed surface S, and E_n is known (*i.e.*, can be calculated) for each point of the surface, then the expression $\oint_S E_n dS$ is a surface integral, meaning that E_n is summed over the whole surface. Gauss's theorem states that such a surface integral is proportional to the sum of the electric charges that lie within the closed surface, which can be expressed in equation form as

$$\oint_S E_n dS = q/\epsilon_0, \qquad (5)$$

in which q is the total charge inside S and ϵ_0 is the dielectric constant *in vacuo*.

The results above can be generalized to the case in which the charge is continuously distributed in space with a density ρ (*e.g.*, in the space between the cathode and anode of a vacuum tube). In this case the total charge q is found by integrating over the volume (V) enclosed by surface S: $q = \int_V \rho dV$. Substituting this value of q in equation (5) gives the relation

$$\oint_S E_n dS = \frac{1}{\epsilon_0}\oint_V \rho dV.$$

If V and S are allowed to become infinitesimal in this equation, then upon integration, the result

$$\frac{1}{V}\oint_S E_n dS = \rho/\epsilon_0$$

follows. The expression on the left side of the equation has an equivalent form, namely, the divergence of E (div E), denoted $\nabla \cdot E$; so that

$$\nabla \cdot E = \rho/\epsilon_0. \tag{6}$$

In non-vector form, the divergence of E is a partial differential equation in terms of the components E_x, E_y, and E_z of the field E:

$$\frac{\partial E_x}{\partial x} + \frac{\partial E_y}{\partial y} + \frac{\partial E_z}{\partial z} = \rho/\epsilon_0. \tag{7}$$

This is generally regarded as the basic equation of electrostatics and is sometimes called Poisson's equation although this name is usually reserved for the equation that results from the combination of equations (3) and (6):

$$\nabla^2\phi = -\rho/\epsilon_0,$$

Stated explicitly in terms of the coordinates x, y, and z, it is

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2} = -\rho/\epsilon_0. \tag{8}$$

As may be seen, both of these equations are expressed in terms of the scalar potential ϕ.

If in the equation (4) the charges are replaced by a continuous density $\rho(r[1])$ in a volume element dV at $r(1)$, it yields the relation

$$\phi(r[0]) = \int_V \frac{\rho(r[1])\, dV(r[1])}{4\pi\epsilon_0 r(0,1)}. \tag{9}$$

If the potential ϕ is given as a function of position, equation (8) yields the charge density ρ directly. On the other hand, if the charge density is given, equation (9) yields the potential ϕ and thus the electrostatic field E.

A conductor contains mobile electric charges, usually electrons, and, in the presence of a field E, these charges move. The motion continues until the redistribution of charge in the conductor produces a field that just cancels E in the conductor. Thus in electrostatics a conductor is a body that cannot support (contain) an electric field. Because the total field in the conductor is zero the gradient of the potential is zero by equation (3), $\nabla\phi = 0$. For the gradient of a quantity to be zero the quantity itself must be zero or a constant. Thus the potential must be constant in a conductor. In particular, the surface of a conductor must be everywhere at equal potential, an equipotential surface. If there is no electric field E inside the conductor, its components E_x, E_y, and E_z do not change and therefore the left side of equation (7) is zero and (7) reduces to $\rho = 0$. Charge density zero means there is no volume charge within the conductor. Thus all the charge associated with a conducting body must reside on its surface. Surface charge per unit area is symbolized by the Greek letter σ (sigma). Furthermore, at the surface of a conductor E must be normal (*i.e.*, perpendicular) to the surface, and the intensity of the normal component of E is related to surface charge σ by $\sigma = \epsilon_0 E_n$. The original observations that led to the law of charge conservation were made by Benjamin Franklin who performed the following experiment. One person A standing on an insulated block rubs a glass tube with silk. A second person B, also on an insulated block, touches the glass tube and receives a shock. If now either A or B touches a third person C standing on the floor, C will receive a shock. If, however, A and B first touch each other they receive a shock and subsequently, when either A or B touches C, C will feel no effect. Franklin interpreted this as follows. A initially, by friction, removed negative electricity from the glass leaving it with a net positive charge. B, on touching the glass, transfers negative electricity to it and is left with a net positive charge. When A touches C he (C) receives a negative shock and when B touches C he (C) receives a positive shock; but if A touches B first their opposite charges are cancelled and therefore neither one can affect C. In the whole series of processes the algebraic sum of the charges present remains zero.

Franklin's charge conservation experiment

The first quantitative investigation of electric charge was carried out by Michael Faraday in his famous ice pail experiment. He began by charging a metal ball suspended on an insulating silk thread. He then connected a metal ice pail resting on an insulating block to a gold leaf electroscope (for the operating principle of this device see below, *Electrostatic induction*), and lowered the charged ball into the pail. The electroscope reading increased as the ball was lowered into the pail, finally reaching a steady reading once the ball was within the pail. If the ball was withdrawn without touching the pail the electroscope reading fell to zero but if the ball touched the bottom of the pail the reading remained at its steady value and the ball on removal was found to be completely discharged. Faraday concluded that the electric charge induced on the outside of the pail, when the ball was inside the pail (but not in contact with it) was exactly equal to the charge initially on the ball. He then inserted other bodies in the pail, such as a set of concentric pails insulated from one another, space between these pails being filled with various insulating media; *e.g.*, sulfur. In each case, the electroscope reading was the same once the ball was completely within the pail. From this he concluded that the total charge of the system was an invariable quantity equal to the initial charge of the ball. In other words, charge is a conserved quantity. As remarked above, this belief that conservation is a fundamental property of charge rests not only on Franklin's and Faraday's experiments but on its complete agreement with all the observations in electrical engineering, quantum electrodynamics, and experimental electricity. It might be expressed as follows: "In an isolated system the algebraic sum of all the charges present remains constant." If an isolated system with a closed surface is divided into an inner part A and an outer part B by a second closed surface S, any charge transferred from region A to region B must cross S and its rate of flow is the outward current I through S. If q is the charge in S and dq/dt its rate of increase, then $dq/dt + I = 0$. If ρ is the charge density in the volume V enclosed by S, and J is the vector current density, it can be expressed as the sum of two integrals,

$$\int_V (d\rho/dt)dV + \oint_S J_n dS = 0,$$

in which J_n is the outward normal component of J at the surface S. This holds for any volume, however small, and letting V become infinitesimal this gives

$$\frac{d\rho}{dt} + \frac{1}{V}\oint_S J_n dS = 0,$$

which can be expressed in vector notation using the divergence (symbolized $\nabla\cdot$) of the vector J as

$$\frac{d\rho}{dt} + \nabla\cdot J = 0.$$

This equation without doubt can be regarded as the simplest and most economical statement of the conservation law.

Recapitulation of the basic laws

The basic laws of electrostatics have now been stated, but it is convenient to collect these laws and to express them in a number of different forms.

The most basic statement is concerned with the definition of charge.

1. To any electrified body can be assigned a numerical quantity, capable of taking either sign, its charge q. The forces experienced and exerted by the body are proportional to q.

2. The sum of all the charges in an isolated system is constant.

3. If a body of charge q at r experiences a force F the electric field (E) at r is equal to F/q.

4. The field at a point located at r relative to a body of charge q is

$$E = \frac{qr}{4\pi\epsilon_0 r^3}.$$

5. The effects of several charged bodies are linearly

additive. From these five laws a number of subsidiary laws can be derived.

6. The line integral of the electrostatic field $\boldsymbol{E}$ around any closed path is zero. This is a mathematical way of saying that although an electric charge may do work in moving through an electric field, or work may be done on it, the net work will be zero if the charge is returned to its starting position. In vector notation

$$\nabla \times \boldsymbol{E} = 0.$$

7. The field $\boldsymbol{E}$ can be derived as the negative gradient of a scalar potential by

$$\boldsymbol{E} = -\nabla\phi.$$

8. The scalar potential at $\boldsymbol{R}$ resulting from charges $q(n)$ at $\boldsymbol{r}(n)$ can be expressed as

$$\phi(\boldsymbol{R}) = \sum_n \frac{q(n)}{4\pi\epsilon_0|\boldsymbol{R} - \boldsymbol{r}(n)|}$$

(here the magnitude of a vector sum is expressed by parallel brackets); or, if the charge distribution is continuous with density $\rho(\boldsymbol{r})$, as

$$\phi(\boldsymbol{R}) = \int_V \frac{\rho(\boldsymbol{r})dV(\boldsymbol{r})}{4\pi\epsilon_0|\boldsymbol{R} - \boldsymbol{r}|}.$$

9. If S is the closed surface of a volume V in which there is a net charge q,

$$\oint_S E_n dS = q/\epsilon_0.$$

If the charge distribution is continuous this leads to

$$\nabla \cdot E = \rho/\epsilon_0.$$

10. As a result the electrostatic potential ϕ satisfies Poisson's equation

$$\nabla^2\phi = -\rho/\epsilon_0,$$

and in empty space, Laplace's equation, which is

$$\nabla^2\phi = 0.$$

11. If $\boldsymbol{J}$ is the current density vector, the conservation of charge law is expressed by

$$\nabla \cdot \boldsymbol{J} + \frac{\partial\rho}{\partial t} = 0.$$

12. Lines of electric field are normal to equipotential surfaces.

To these laws some special laws relating to conductors can be added. Of these the most basic is:

13. The electrostatic field within a conductor is zero. From this it follows that

14. The surface of a conductor is an equipotential.

15. Charge resides only on the surface of conductors.

16. The electric field just outside a conductor is normal to its surface, and

17. If E_n is the normal electric field away from a conducting surface the surface charge density on the conductor is $\sigma = \epsilon_0 E_n$. Of all these, the basic laws are (1), (2), (4), (5), and (13). The result (3) is a definition and the remaining laws are restatements or consequences of the basic laws.

Given definitions of q, ρ, $\boldsymbol{E}$, and $\boldsymbol{J}$ the simplest statement of the laws, in vector notation, is the set of equations

$$\begin{aligned} \boldsymbol{F} &= q\boldsymbol{E} \\ \nabla \times \boldsymbol{E} &= 0 \\ \nabla \cdot \boldsymbol{E} &= \rho/\epsilon_0 \\ \nabla \cdot \boldsymbol{J} + \frac{\partial\rho}{\partial t} &= 0. \end{aligned}$$

Except for the third equation, which is valid only in vacuum, these laws are universally valid in any medium. Alternatively, the third and fourth laws are universally valid in vacuum, but as will be seen, the first and second have to be modified when considering magnetic forces and electromagnetic induction. With these reservations the above set of four equations summarizes the theoretical structure of electrostatics. The complete scheme of electrostatics also includes a treatment of the effects of insulating bodies, or dielectrics, which is detailed below.

Properties of the electrostatic field. The force acting on unit charge in a field $\boldsymbol{E}$ is equal to $q\boldsymbol{E}$ (from the equation $\boldsymbol{F} = q\boldsymbol{E}$) and lines of force are traced by starting at one point in space and proceeding along the direction of $\boldsymbol{E}$ following any changes in $\boldsymbol{E}$. In this process equipotential surfaces are crossed and the path is normal to these surfaces. An example is given in Figure 2

From (top) W.R. Smyth, *Static and Dynamic Electricity* copyright 1939; used with permission of McGraw-Hill Book Co.

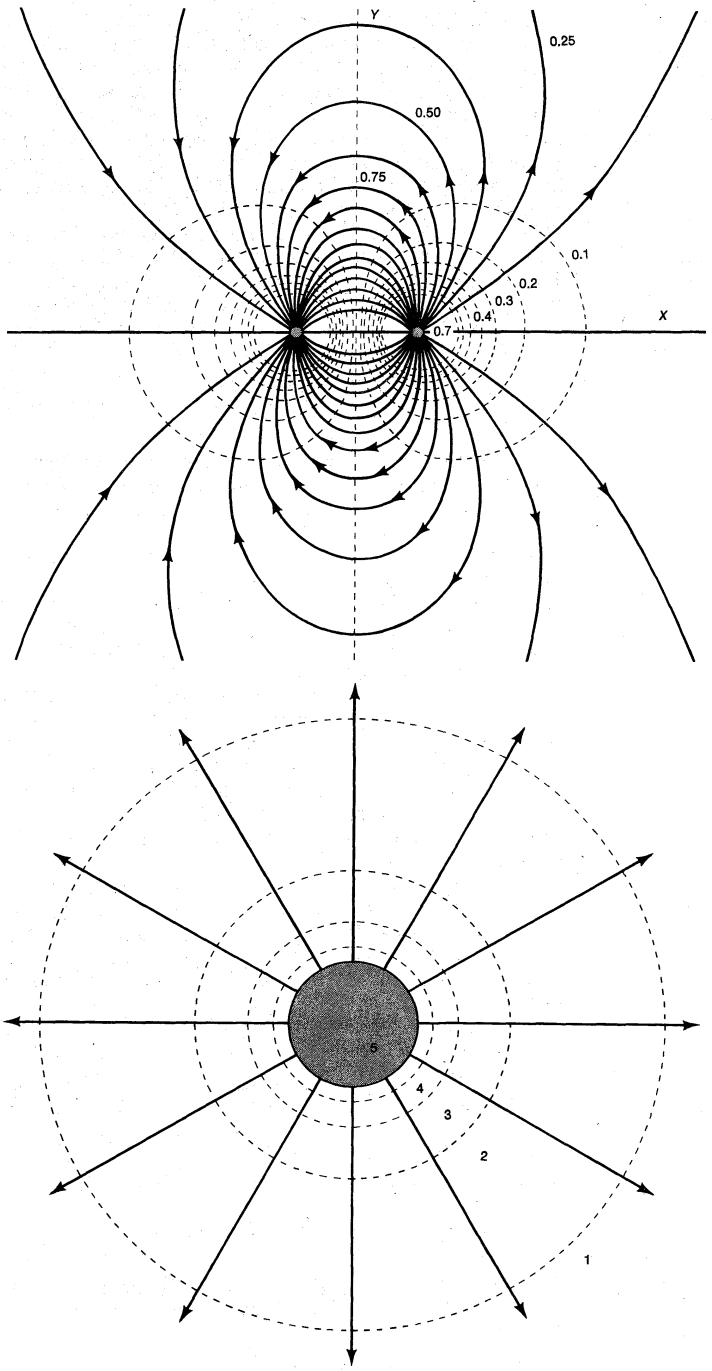

Figure 2: Lines of force (solid lines) and equipotentials (broken lines). (Top) Near two equal charges of opposite sign; (bottom) near a charged sphere (see text).

(top) which shows the lines of force and equipotentials (*i.e.*, equipotential lines) in the vicinity of two charges of opposite sign. Lines of force are seen crowded together near the charges where the field is most intense, and where the field is strongest the equipotentials are closest. Figure 2 (bottom) shows the lines of force and equi-

Lines of force and equipotentials

potential associated with a uniformly charged conducting sphere. These equipotentials get further apart with distance according to the law

$$\phi = \frac{q}{4\pi\epsilon_0 r}.$$

The density of lines of force decreases quadratically with distance (as $1/r^2$), exemplifying the inverse square law; but the total number crossing each spherical surface remains constant, as required by Gauss's law

$$\oint E_n dS = q/\epsilon_0.$$

A diagram such as this powerfully suggests that lines of force emanate from charge, and explains why charge is often referred to as the source of the electric field. In some cases general notions of symmetry and an intuitive idea of the behaviour of field lines based on this approach allow the solution of electrostatic problems without engaging in mathematical calculations. In other cases, Gauss's law often provides enough insight to lead to a numerical solution.

The presence of an electric field in space is associated with the presence of charge or charges, which suggests that work must have been expended to bring them together. It can be shown with the help of Gauss's law that the work (W) is expressed by the integral equation

$$W = \frac{1}{2}\epsilon_0 \int_{V\to\infty} E^2 dV, \qquad (10)$$

in which the range of integration is extended to include the whole volume V. This equation expresses the energy of the system entirely in terms of the electrostatic field.

The energy stored per unit volume in a compressed gas or a distorted solid is proportional to the square of the stress and equation (10) suggests that in some ways the "ether" is analogous to an elastic medium. This idea was pursued with great vigour by the theoretical electricians of the 19th century and, although the search for mechanical explanations of electrical phenomena is now regarded as pointless, the theoretical structure developed by Maxwell on this basis remains an important component of electromagnetic theory. The presence of an electric field in a region of space does, in fact, confer on it many of the properties of an elastic medium even if the concept of an elastic ether is no longer used.

Electrostatic induction. Both Cavendish's and Faraday's experiments showed that when a charged body is placed inside a hollow conductor the outside of the conductor acquires a charge equal to that of the body. This is an important example of the phenomenon of electrostatic induction, and it is instructive to see how it comes about in terms of the laws of electrostatics that have just been formulated.

Figure 3 shows a body with a charge q inside a spherical conducting vessel. Inside the conductor on the surface S, shown as a broken line, the electric field is zero. Thus $\oint_S E_n dS$ over the surface S is zero. Gauss's theorem therefore reveals that there is no net charge inside S. There must therefore be a surface charge density σ' induced on the inner surface S' of the vessel so that

$$q + \oint_{S'} \sigma' \, dS' = 0.$$

But the vessel was originally electrically neutral and so there must be an opposite surface charge σ'' on the outer surface S'' and hence

$$\oint_{S''} \sigma'' \, dS'' = -\oint_{S'} \sigma' dS' = q.$$

In the absence of any outside disturbing influence this charge will be evenly distributed over S''. If the radius of the outer surface is a, then integration of this equation gives $4\pi a^2\sigma'' = q$. Lines of electric field will leave the outer sphere radially and the field at the surface of the sphere is $\frac{\sigma''}{\epsilon_0}$. The application of Gauss's theorem over any spherical surface at a radius r, r being greater than a, $r > a$, leads to

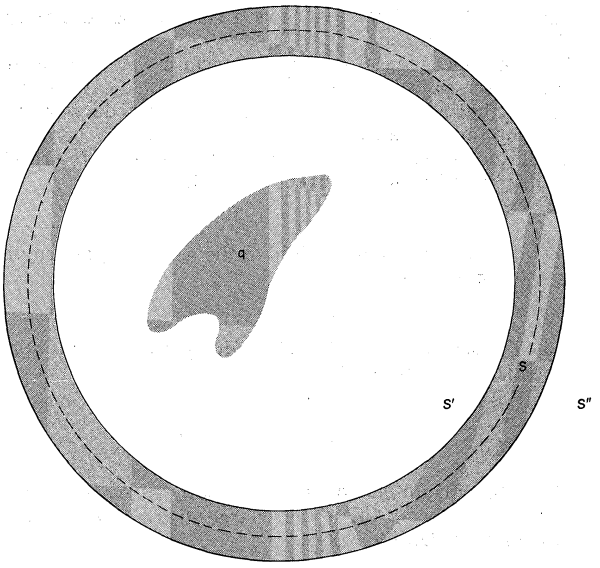

Figure 3: A charged body q inside a spherical conducting vessel S with walls S' and S'' (see text).

$$E = \frac{q}{4\pi\epsilon_0 r^2},$$

and the whole system behaves externally as though there were a point charge q at the centre. If the charged body is allowed to touch the interior of the sphere it neutralizes the inner surface charge but does not affect the outer charge. When the body is removed it is uncharged and the sphere has a net charge q on its outer surface.

The spherical capacitor

Next to be considered is a spherical capacitor, a device for storing electric charge, consisting of two concentric metal spheres. The inner conducting sphere initially has a charge q that must reside on its outer surface. If the outer conducting sphere is initially uncharged and isolated there will be an induced charge $-q$ spread over its inner surface and therefore $+q$ on its outer surface. Next the outside of this sphere is connected to ground or earth, so that the outer charge leaks away, and the contact is then broken. If later the inner sphere is removed (*e.g.*, by imagining the outer sphere cut in two) without touching the outer sphere, the outer sphere will be left with a net charge $-q$. This charge could be transferred to a third body and the process repeated. Thus starting with a single charge q after n steps a charge $-nq$ is transferred to the third body and $+nq$ to ground (the total charge $+q$ being conserved at all times). Many continuously acting electrostatic machines work on essentially this principle.

Again, when the outer sphere is still grounded, the inner sphere has a plus charge $(+q)$ on its outer surface and the outer sphere a negative charge $(-q)$ on its inner surface. If now the radii of both spheres are increased keeping their separation constant, then the surfaces flatten out and local conditions approach more and more closely to the geometry of a capacitor consisting of two plane plates parallel to each other. Therefore, if a plate carrying a charge q is placed above and near a grounded plate, the charge will concentrate on the inner surface and a charge $-q$ will be induced on the upper surface of the grounded (earthed) plate. If the earthed contact is broken and the lower plate moved away it will have a net charge $-q$.

The first and most obvious use to which these induction effects can be put is in electrostatic shielding. Many pieces of laboratory apparatus, and some pieces of domestic equipment (*e.g.*, piezoelectric phonograph pickups, transistor amplifiers, and electrostatic microphones) are adversely affected by stray electric fields. These can be shielded completely from stray fields simply by placing them inside a metallic enclosure usually referred to as a screen or screening can.

A second application of induction is the measurement of charge. In Faraday's time the most usual indicator of the electrical state of a body was the gold leaf electroscope, which consists of two thin leaves of gold hanging from an insulated metal rod, and mounted inside a metal box. When the rod is charged the leaves repel each other and the deflection indicates the size of the charge. Faraday's ice pail experiment

Faraday's electroscope incorporated an ice pail or metal vessel (also conducting) standing on a plate attached to the insulated metal rod. When a charged body was placed in the pail, even if it did not touch the pail, induction (see below) insured that the electroscope indicated the charge on the body. Further, once the charge was measured the body could be removed with charge unchanged. A modern experiment would retain the pail, or something like it called a Faraday cage, with a more sophisticated indicator than a gold leaf electroscope.

In the same paper in which Faraday described the phenomenon of electrostatic induction he speculated on its possible connection with atmospheric electricity and lightning. The modern view would probably be that although induction may play a limited role in the production of charged volumes of air or clouds the main mechanisms involve the mechanical separation of positive and electrical charge much as in a Van de Graaff machine used in generating a high potential (named after the inventor, Robert J. Van de Graaff, a physicist in the United States). For a more detailed account see the articles on LIGHTNING and THUNDERSTORMS.

The electric dipole. To obtain a general understanding of electrostatics it is not necessary to study in detail the fields caused by particular arrangements of charges, with one exception, that of the so-called dipole. An electric dipole is a system of two equal but opposite charges $+q$ and $-q$ at a fixed separation l from each other, which can be specified as a vector moment as shown in Figure 4A. The vector moment (p) of the dipole is defined as a vector quantity directed from the negative charge to the positive charge and equal in magnitude to the product of charge and separation distance:

$$p = ql.$$

Importance of the dipole

The dipole is important because it is the simplest system of overall electrical neutrality (*i.e.*, has no net charge) that produces external effects. Aspects of interest in connection with the dipole are: the form of the potential and field distribution it generates, the effect of an impressed field on a dipole, and the generalization of the concept in connection with atomic physics.

The energy of a dipole in a field E may be derived from a potential ϕ in which the electric field is equal to minus its gradient, $E = -\nabla\phi$. As may be shown, the energy of a charge situated in an electric field is equal to the product of charge times electric potential. The energy of the dipole thus is equal to the sum of its energies, that is, $+q$ of the positive charge times its potential $\phi(r + l)$ at position $r + l$ and $-q$ of the negative charge times its potential $\phi(r)$ at r:

$$U = q\phi(r + l) - q\phi(r),$$

r being the position of the negative charge. If it is assumed that l is small or that ϕ varies only slowly over the length of the dipole the energy (U) can be approximated by minus the scalar product of dipole moment (p) and electric field (E), or $U = -p \cdot E$. It can be shown that if E is a constant field and θ the angle between the dipole moment (p) and (E), the dipole energy (U) becomes $U = -pE \cos\theta$.

In a constant field the dipole energy (U) is independent of the position of the dipole but depends on its orientation. There is therefore no net force on the dipole, but a twisting force that tends to turn p towards the direction of E (*i.e.*, align the two charges along the field direction). The magnitude (Γ) of this couple is

$$\Gamma = -\frac{\partial U}{\partial\theta} = pE \sin\theta;$$

or, in vector notation, the vector product of the dipole moment (p) and the electric field (E),

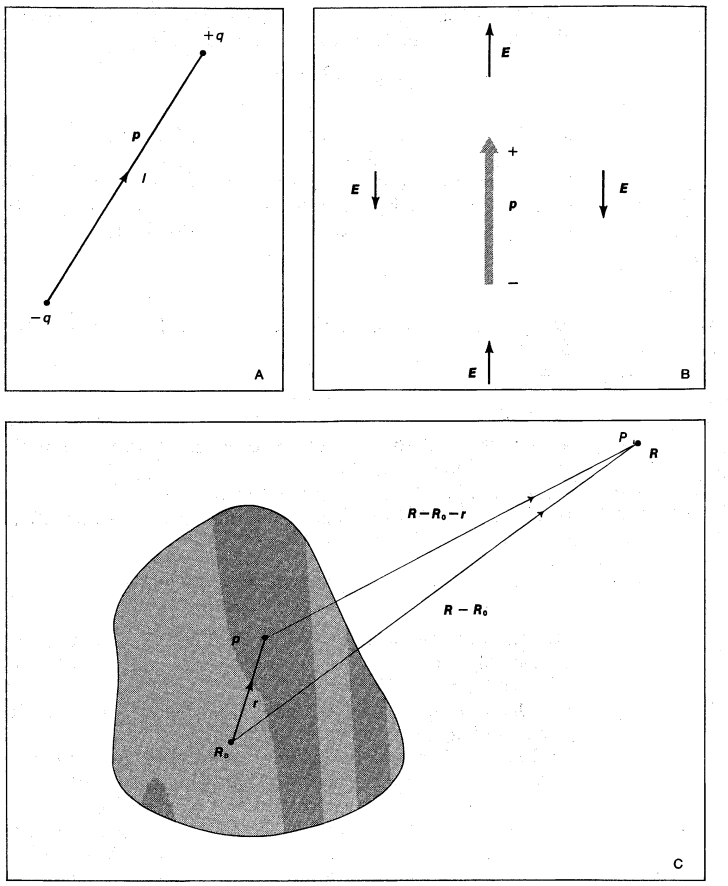

Figure 4: *Electric dipole.*
(A) Dipole of two equal and opposite charges $-q$ and $+q$, separated by distance l. The dipole moment $p = ql$ is directed from $-q$ to $+q$. (B) Fields E near a dipole p. (C) Vector notation for the position (R) of a point (P) in the vicinity of a dipole (p).

$$\Gamma = p \times E.$$

If E is non-uniform, the force acting on the dipole is $-\nabla U$, and so

$$F = -\nabla U = \nabla(p \cdot E).$$

If p is a constant vector both in magnitude and direction this result can be simplified to

$$F = (p \cdot \nabla)E; \qquad (11)$$

i.e., the x component of the force is

$$F_x = p_x\frac{\partial E_x}{\partial x} + p_y\frac{\partial E_x}{\partial y} + p_z\frac{\partial E_x}{\partial z}.$$

It can be shown that (11) is also the correct expression even when dipole moment (p) is not constant but is related to E. This is important because all atoms and molecules acquire a dipole moment in an electric field and in most cases $p = \alpha\epsilon_0 E$, in which α is a positive constant (of the order of the volume of the atom). In this case,

$$F = \alpha\epsilon_0(E \cdot \nabla)E,$$

and this may be shown to be

$$F = \tfrac{1}{2}\alpha\epsilon_0\nabla(E^2).$$

This means that neutral atoms and molecules are attracted towards regions in which the electric field is the strongest. The potential $\phi(R)$ at point R resulting from a dipole p at the origin may be expressed by the equation

$$\phi(R) = \frac{p \cdot R}{4\pi\epsilon_0 R^3}.$$

As may be seen from this equation, the potential decreases quadratically with distance, whereas, as was seen above, the potential for a point charge decreases with the first power. The corresponding electric field pro-

duced by the dipole is $E = -\nabla\phi$ and the final result obtained after much vector manipulation is

$$E(R) = \frac{3(p \cdot R)R - R^2 p}{4\pi\epsilon_0 R^5},$$

and decays as the cube of the distance. Some insight into the form of the field lines can be gained by considering the value of E along the axis of the dipole in which $p \cdot R = pR$, and in the equatorial plane in which $p \cdot R$ is equal to zero. Along the axis, the dipole field is

$$E = \frac{2p}{4\pi\epsilon_0 R^3}$$

and is parallel to p. In the equatorial plane, the dipole field is

$$E = -\frac{p}{4\pi\epsilon_0 R^3}$$

and is opposed to p. These results are shown schematically in Figure 4B.

Energy of interaction between two dipoles

The energy of interaction between a dipole p_1 at the origin and a dipole p_2 at R is obtained from the above expression for $E(R)$ and $U = -p \cdot E$ as

$$U = -\frac{3(p_1 \cdot R)(p_2 \cdot R) - R^2 p_1 \cdot p_2}{4\pi\epsilon_0 R^5}$$

and falls off as the cube of the distance R. Because the energy of interaction of two charges q_1 and q_2 falls off only as $1/R$, dipole interactions between systems that also have a net charge are negligible at any appreciable distance. On the other hand, because most of the systems studied in physics (*e.g.*, atoms, molecules, piezoelectric crystals, or complete systems of batteries and conductors) are usually neutral when considered as a whole, the distant interaction between these systems is often solely caused by their dipole moments. In magnetism, in which no free "poles" exist, the dipole effects are always dominant.

If there is a distribution of charge, of density ρ, confined to a small volume V of linear dimensions l, the potential at a great distance ($R \gg l$), which is

$$\phi(R) = \int_V \frac{\rho(r)dV(r)}{4\pi\epsilon_0|R - r|}$$

can be approximated as follows. An origin at R_0 is taken somewhere in the charge distribution and r is defined relative to R_0 as shown in Figure 4C; the denominator of the quantity being integrated is then expressed as

$$\frac{1}{|R - R_0 - r|} = \frac{1}{|R - R_0|} - r \cdot \nabla\left(\frac{1}{|R - R_0|}\right) + \text{etc.};$$

so that

$$\phi(R) = \frac{1}{4\pi\epsilon_0}\frac{1}{|R - R_0|}\int_V \rho dV - \frac{1}{4\pi\epsilon_0}\nabla\left(\frac{1}{|R - R_0|}\right) \cdot \int_V \rho r dV.$$

But $\int_V \rho dV = q$ is the total charge and, if the dipole moment is defined as

$$p = \int_V \rho r dV, \tag{12}$$

it produces a potential $\phi(R)$ according to

$$\phi(R) = \frac{q}{4\pi\epsilon_0|R - R_0|} - p \cdot \nabla\left(\frac{1}{4\pi\epsilon_0|R - R_0|}\right).$$

Thus the effects of the charge distribution have been approximated in terms of a point charge q at R_0 and a dipole p at R_0. If it happens that q equals zero, this approximation is unique and the choice of R_0 is arbitrary as long as it is within or near the distribution. If, however, q is not equal to zero, the choice of R_0 is critical and determines the correct value of p. Changing R_0 to R'_0 changes p by $-q(R'_0 - R_0)$. When equation (12) is applied to atoms, R_0 is always taken to be at the nucleus and no ambiguity arises. When nuclei are considered, R_0 is usually taken as the centre of mass. In a general consideration of media that are continuous on a macroscopic scale, no unique origin is specified and the location of R_0 becomes quite complicated, leading to false conclusions if R_0 is defined incorrectly (see the section below dealing with dielectrics).

The definition of the dipole moment by equation (12) is a simple generalization of the original definition (see Figure 4C) and is an important concept in atomic physics. Many important phenomena (*e.g.*, dielectric behaviour, radiation and absorption of spectral lines, and intermolecular forces) are directly related to atomic dipole moments.

The electron. The science of electrostatics, so far presented, is the study of fields, potentials, and charges that have been indifferently treated as charges on material bodies, point charges, or continuous volume distributions of charge. The discovery of the essentially electrical constitution of matter in the early years of the 20th century clearly forces a reconsideration of some of these notions. This reassessment has two effects, one clearly beneficial: a new insight is gained into the nature of electrical phenomena, and the other less welcome: everything tends to be interpreted in terms of electrons even before the basic laws of electricity and the nature of the gross phenomena that they describe have been grasped. The electron is treated separately in another article (see ELECTRON) and only its most basic properties and their consequences for the study of electricity need be of concern here.

Millikan's oil drop experiment

The first reasonably precise determination of the charge of the electron ($-e$) was made by Robert A. Millikan, a physicist in the United States, in 1912. Although his method is not now used for precise measurements his result was a landmark in physics. Millikan observed the rate of fall of oil drops between two plates across which he could maintain a known potential difference. In the absence of any field the rate of fall of a drop is determined by gravity, the size of the drop, and the viscosity of air. Because the gravity and the viscosity are known, the rate of fall gives the size and mass of the drop. If a drop acquires a charge q, then the force acting on it is no longer the mass (m) times the acceleration of gravity (g), but $mg + qE$, and its velocity is changed in the ratio $(mg + qE)/qE$. In the circumstances of Millikan's experiment, in which the air was slightly ionized, he found that charge q was always a multiple, generally -1 times a basic unit $e = 1.60 \times 10^{-19}$ coulomb, which he identified as the electronic charge.

The important determinations were (*i*) the order of magnitude of the charge and (*ii*) the fact that the product of Avogadro's number (N, the number of atoms in a gram atom of a substance, 6.02×10^{23}) and the electronic charge, Ne, is 9.6×10^4 coulombs, which is just one Faraday; *i.e.*, the charge required to liberate one gram (one gram atom) of hydrogen. Further, because the value of e/m for electrons measured by Thomson, and with increased precision by later workers, is 1.76×10^8 coulomb per gram, the mass of the electron is 9.11×10^{-28} gram or 9.11×10^{-31} kilogram. (A good round number for the mass is 10^{-30} kilogram.) These numbers give some idea about the numbers of electrons that actually take part in macroscopic electrostatic phenomena. A few examples are:

The normal density of solid matter is around five grams per cubic centimetre or 5,000 kilograms per cubic metre and a gram molecule of a simple compound occupies something between five and 100 cubic centimetres. Thus the number of atoms per cubic centimetre is in the region of 10^{22} to 10^{23}. The number of electrons per atom varies from one to more than 92 in the periodic table, but the number of relatively loosely bound valence electrons per atom that can be appreciably influenced by electric fields is usually small, in many cases there is only one per atom. As a general rule these are of the order of 10^{23} effective

electrons per cubic centimetre or 10^{29} per cubic metre. The total charge associated with these electrons is thus some 10^{10} coulombs per cubic metre. The number of electrons lying within one atomic diameter of the surface of a solid is $(10^{29})^{2/3}$ per square metre (*i.e.*, about 10^{20}) and so the available charge per square metre is of the order of 10 coulombs per square metre. Now a surface charge density of 10 coulombs per square metre is associated with an electric field normal to the surface of $10/\epsilon_0 \simeq 10^{12}$ volts per metre. Even in extreme cases fields rarely exceed 10^8 volts per metre, and so, in general, the surface charges that appear in electrostatics correspond to fractional changes in the internal charge distribution. Furthermore, a field of 10^{12} volts per metre corresponds to a field of 100 volts per angstrom (the angstrom is 10^{-10} metre and is the typical radial dimension of atoms). A field of this strength would be sufficient to disrupt and destroy the surface atoms, and certainly at this magnitude the simple notions about conductors and insulators would be useless.

A conducting sphere of radius a metres with a charge q has a potential (ϕ): $\phi = q/4\pi\epsilon_0 a \simeq 10^{10} q/a$ so that $q \simeq 10^{-10}\, a\phi$. The displaceable electronic charge (Q) is of the order of

$$Q \simeq 10^{10} \frac{4}{3}\pi a^3 \simeq 4 \times 10^{10} a^3;$$

and so,

$$q/Q \simeq 2.5 \times 10^{-21} \phi/a^2.$$

If, for example, $\phi = 10^4$ volts and $a = 10^{-6}$ metre this ratio is only 2.5×10^{-5}; in most practical cases it is much smaller. It may be concluded that when a body of normal dimensions is charged there is an utterly negligible change in the number of electrons it contains. Only in the most extreme cases (the channel in a field effect transistor is an important example) is the change in electronic content enough to change the properties of the material appreciably.

If it were possible to give a conducting sphere of one metre radius a charge of 10^{10} coulombs, certainly the addition of the required electrons would change its mass by less than one part in 2,000. Because in practice it would be difficult to give the sphere a charge of much more than $\frac{1}{100}$ coulomb, the fractional change in mass would be more like one part in 10^{15} and quite unobservable. From the point of view of practical electricity, the electric charge behaves like a massless fluid. It is only in electronic devices, and especially vacuum electronic devices in which electrons are detached from matter, that the finite mass of the charge carriers is significant.

Flow rate of electrons in one ampere

A current of one ampere corresponds to a flow of about 10^{19} electrons per second. In a metal with some 10^{29} mobile electrons per cubic metre a current density of one ampere per square metre corresponds to a mean electronic velocity of 10^{-10} metre per second; *i.e.*, electrons cover about one atomic diameter per second. Even at 10^{10} amperes per square metre, which is about the maximum safe current density in a conductor, the velocity is only one metre per second. Electrons in metals have random velocities as a result of thermal energy of about 10^6 metres per second, and thus the effects of an electric field driving a current produce only a minuscule change in the motion of the electrons. Although the discovery of the electron gives a new understanding of electricity, for most practical purposes it makes no difference to the description of macroscopic phenomena. Electricity in this context can be regarded as a massless and continuous fluid. It is only in microscopic physics (*i.e.*, atomic physics) and in electronics in which the motion of rather small numbers of electrons is controlled, that the mass and discrete charge of the electron become significant.

From the point of view of macroscopic practical electricity, one of the most important consequences of the discovery of the electron and the electronic structure of matter is that it relates the electrical properties of a medium to its structure. Thus, for example, it can be understood why carbon in the form of diamond is an insulator and in the form of graphite is a conductor, or why the relatively few insulating elements tend to be clustered towards the top right-hand corner of the chemists' periodic table. Another important practical consequence of this knowledge is, of course, the whole technology of electronics.

DIELECTRICS

Capacitors. If two conductors are placed in proximity with each other and one conductor is charged, the other acquires a surface charge by induction. If, however, the conductors are connected to the terminals of a battery to maintain a potential difference between the two separated conductors, the overall effect will be that one conductor will acquire a net positive charge and the other conductor an equal negative charge. The charge (q) will be proportional to the potential difference (ϕ), the coefficient of proportionality—*i.e.*, C—in the equation relating them, $q = C\,\phi$, is called the capacitance of the system. The system itself is referred to as a capacitor or condenser. The unit of capacitance in the International System of Units (SI), or metre–kilogram–second (mks) system, is the farad (F). It has the dimensions of coulomb per volt. The electrostatic unit of capacitance has no particular name and is usually written esu. One farad is equal to nearly 9×10^{11} esu. In practical electronics the μF, or microfarad, which is 10^{-6} F, and the picofarad, or pF, which is 10^{-12} F, are normally used. A useful order of magnitude conversion is 1 esu is approximately equal to 1 pF.

The potential (ϕ) associated with a point charge q at a distance r is $q/4\pi\epsilon_0 r$; and so

$$\epsilon_0 = \frac{1}{4\pi}\frac{q}{\phi}\frac{1}{r}.$$

The dimensions (physical units) of the fundamental electrical constant ϵ_0, the dielectric constant for empty space, are therefore most easily expressed in practical terms as farads per metre, or Fm^{-1}. The corresponding magnetic fundamental constant μ_0 in the expression for the magnetic field dB resulting from a current element Idl is

$$dB = \mu_0 Idl \times r/4\pi r^3,$$

and is arbitrarily given the exact value $4\pi \times 10^{-7}$ henry per metre, in which one henry (H) is the unit of inductance, in order to define the unit of current, ampere (A). This is connected with the practical use of the magnetic current balance for maintaining an exact standard of current related to mechanical forces. Maxwell's field equations lead to an expression for the velocity of light (c) in vacuum as $(\mu_0\epsilon_0)^{-1/2}$. Inasmuch as c can be measured with great accuracy and μ_0 is defined, ϵ_0 is defined by the relation

Velocity of light defined by Maxwell's equations

$$\epsilon_0 = \frac{1}{\mu_0 c^2} = \frac{10^7}{4\pi c^2},$$

in which c is the agreed experimental value of the velocity of light. This expression leads to the result

$$\epsilon_0 = 8.854\ldots \times 10^{-12}\mathrm{Fm}^{-1}.$$

For order of magnitude calculations, ϵ_0 may be taken to be approximately equal to $10^{-11}\mathrm{Fm}^{-1}$.

The charge q on a conductor can be expressed as the surface integral of its surface charge density, and, since by Gauss's theorem the surface charge density (σ) is equal to the product of the dielectric constant and the outward normal component of the electric field (E_n) at the surface, or $\sigma = \epsilon_0 E_n$, the capacitance (C) can be expressed as

$$C = \epsilon_0 \frac{\int E_n dS}{\phi}.$$

This relationship gives a formal method of calculating capacitance from the geometry of the system. It is, however, often simpler to proceed by a more direct method, as shown in the following three examples.

The first example to be considered is a spherical capacitor consisting of two concentric spheres of radii a and b. For simplicity the outer sphere of radius b is taken to be at zero potential and the inner at $\phi(a)$ with a charge q. By symmetry the electric field is radial (outward from

centre), and Gauss's theorem yields, for E at radius r,

$$4\pi r^2\epsilon_0 E(r) = q.$$

Thus,

$$E(r) = q/4\pi\epsilon_0 r^2.$$

The potential at r is obtained by integrating this expression with respect to r:

$$\phi(r) = \phi(a) - \int_a^r E(r)dr,$$

and this gives

$$\phi(r) = \phi(a) - \frac{q}{4\pi\epsilon_0}\left(\frac{1}{a} - \frac{1}{r}\right);$$

but where r equals b, the potential $\phi(b)$ must be zero and so from the preceding equations,

$$\phi(a) = \frac{q}{4\pi\epsilon_0}\left(\frac{1}{a} - \frac{1}{b}\right).$$

Thus, the capacitance of the system is

$$C = \frac{q}{\phi(a)} = 4\pi\epsilon_0\frac{ab}{b-a}.$$

If b is much greater than a, this is approximately

$$C \simeq 4\pi\epsilon_0 a.$$

The result, therefore, is the capacitance of an isolated sphere. If the radius a is one centimetre, the capacitance is roughly 10^{-12} F, or one picofarad; in fact, it is also exactly one esu.

The second example is a long coaxial cylindrical capacitor consisting of two cylinders of radii a and b ($b > a$). In this case τ is taken to be the charge per unit length on the inner cylinder. Again the field is radial, but now Gauss's theorem yields

$$2\pi r\epsilon_0 E(r) = \tau,$$

and

$$E(r) = \frac{\tau}{2\pi\epsilon_0 r},$$

which gives

$$\phi(r) = \phi(a) - \frac{\tau}{2\pi\epsilon_0}\log\frac{r}{a}.$$

Because $\phi = 0$ when $r = b$, this yields

$$\phi(a) = \frac{\tau}{2\pi\epsilon_0}\log\frac{b}{a},$$

and the capacitance per unit length is

$$C' = \frac{2\pi\epsilon_0}{\log\frac{b}{a}} \text{ farad m}^{-1}.$$

In this case if b becomes infinitely large, C' approaches zero, but this has no physical meaning unless the length of the system is infinite; otherwise the calculation is based on a fallacy, that the field is radial over most of the length.

The final example is that of the plane parallel plate capacitor composed of two large parallel conducting plates separated by a distance d. Near the middle of the plates the field E between them is uniform and normal to the plane of the plates. The surface charge (σ) is $\epsilon_0 E$ and the potential difference is Ed; thus the capacitance per unit area (C'') in this region is $C'' = \sigma/\phi = \epsilon_0/d$. Near the edges of the plates there is a fringing effect of the fields, and the calculation is more complicated; but if the transverse linear dimensions of the system are large in comparison with d, it is easy to see that the total capacity (C) for plates of area A is approximately $C \simeq \epsilon_0 A/d$. The fringing fields or edge effects make C slightly larger. If the plate separation is one millimetre and the area is 100 square metres, the formula gives for the capacitance approximately 10^{-6} farad, or one microfarad. Because radio capacitors of up to $10^4\mu$F are readily available it can be concluded that they are plates of large area (folded) and small separation. This can be confirmed rather easily by taking a capacitor apart.

Fringing fields

If a capacitor of capacitance C is already charged to a potential difference ϕ, and an element of charge dq is added to the system, external sources (*e.g.*, batteries, electrostatic machines, etc.) will have to do an amount of work ϕdq to place the charge on the plates. The stored energy (W) can thus be calculated as

$$W = \int_0^q \phi dq = \frac{1}{C}\int_0^q q dq = \frac{1}{2C}q^2.$$

This work can also be written as

$$W = \tfrac{1}{2}C\phi^2 = \tfrac{1}{2}q\phi.$$

Neglecting edge effects, in a parallel plate capacitor this gives $q = A\epsilon_0 E$ and $\phi = Ed$; so that $W = \frac{1}{2}Ad\epsilon_0 E^2$.

In a parallel plate condenser the energy can be written either as

$$W = \frac{q^2}{2C} = \frac{q^2 d}{2\epsilon_0 A}, \tag{13}$$

or as

$$W = \tfrac{1}{2}C\phi^2 = \frac{\epsilon_0\phi^2 A}{2d}. \tag{14}$$

The force (F) pulling the plates together can be obtained from either result using the definition of work, change of potential energy with change of distance:

$$F = \frac{\partial W}{\partial d}.$$

Taking the partial differential, equation (13) gives

$$F = \frac{q^2}{2\epsilon_0 A},$$

whereas (14) gives

$$F = -\frac{\epsilon_0\phi^2 A}{2d^2} = -\frac{q^2}{2\epsilon_0 A},$$

which has the opposite sign. Only one result can be correct. Now the relation $F = \partial W/\partial d$ is only correct if, as d changes, no other external source does work on the system. This is the case if the plates are isolated and charge q is a constant, but is not the case if the plates remain connected to a battery and ϕ is held constant as the plates are moved. In this case, q decreases as the plates move apart and charge is forced back into the battery, increasing its internal energy. The correct expression for the force (F) is therefore

$$F = \frac{\partial W}{\partial d} - \phi\frac{\partial q}{\partial d},$$

because $-\phi\delta q$ is the work done on the battery for a change of d. Also, because

$$q = \frac{\epsilon_0 A\phi}{d}$$

and

$$-\phi\frac{\partial q}{\partial d} = +\frac{\epsilon_0 A\phi^2}{d^2} = \frac{q^2}{\epsilon_0 A},$$

this gives

$$F = -\frac{1}{2}\frac{q^2}{\epsilon_0 A} + \frac{q^2}{\epsilon_0 A} = +\frac{1}{2}\frac{q^2}{\epsilon_0 A}$$

as before.

This is not the only puzzling feature of this result. The charge on the surface of the positive plate is q, and a field (E) equal to ϕ/d acts on this plate. At first inspection it would seem that the force ought to be $Eq = \frac{q\phi}{d} = \frac{q^2}{\epsilon_0 A}$ and not $\frac{1}{2}\frac{q}{\epsilon_0 A}$. To see why this is not so, the conditions at one plate surface must be considered in more detail. At this surface the field E changes from zero in

the bulk of the metal to E_0 in vacuum on passing through the (thin) layer of surface charge. This layer has an actual charge density (ρ) per unit volume so that the charge density (σ) per unit area is

$$\sigma = \int_{layer} \rho dx.$$

The force (f) per unit area is

$$f = \int_{layer} \rho E dx;$$

but, from either Gauss's theorem or $\nabla \cdot \boldsymbol{E} = \rho/\epsilon_0$, the equation $\rho = \epsilon_0 \frac{\partial E}{\partial x}$ is obtained, and so

$$f = \epsilon_0 \int_{layer} E \frac{\partial E}{\partial x} dx = \epsilon_0 \int_0^{E_0} E \, dE = \frac{1}{2}\epsilon_0 E^2.$$

Thus, the force (F) for the total area (A) is

$$F = Af = \frac{1}{2}A\epsilon_0 E^2 = \frac{1}{2}\frac{q^2}{\epsilon_0 A}.$$

The factor ½ arises because, however thin the surface layer of charge is, the field drops to zero on passing into the metal through the layer and the charge in the layer experiences only the average field $\frac{1}{2}(E_0 + 0) = \frac{1}{2}E_0$.

Capacitors connected together

Capacitors are important circuit elements in electronics, and they are dealt with below in the section on alternating current circuits. This section treats only one related result, series and parallel connections. Two capacitors C_1 and C_2 are connected in parallel when two plates of each are connected together as in Figure 5 (left). For a

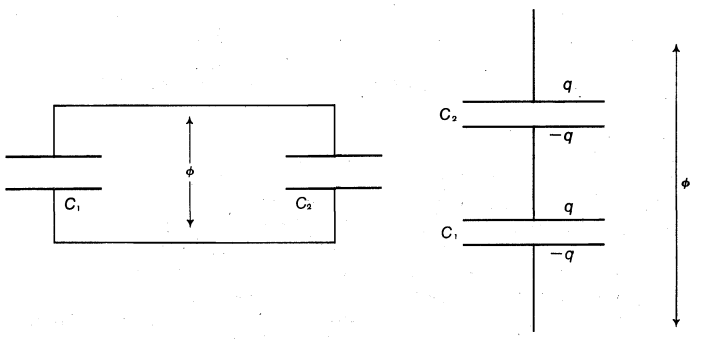

Figure 5: Two ways of connecting capacitors: (left) two capacitors C_1 and C_2 in parallel; (right) two capacitors C_1 and C_2 in series (see text).

given potential difference the total charge is $C_1\phi + C_2\phi$, and so the effective capacitance is $C_1 + C_2$. Two capacitors are connected in series when alternate plates are connected together (Figure 5 right). The charges are both the same and the total potential difference (ϕ) is the sum of the potential of each

$$\phi = \frac{q}{C_1} + \frac{q}{C_2},$$

and thus

$$\frac{1}{C} = \frac{\phi}{q} = \frac{1}{C_1} + \frac{1}{C_2}$$

or

$$C = \frac{C_1 C_2}{C_1 + C_2}.$$

The capacitance of the series combination is less than the capacitance of either capacitor alone.

Although only the capacitance of systems of conductors of especially simple geometry has been considered, any two conductors of any shape will have some capacitance, and, in addition, any isolated conductor will also behave as a capacitor; its capacitance will be of the order $4\pi\epsilon_0 l$, l being its linear dimension. The human body, for example, has dimensions of the order of one metre and therefore a capacitance of the order of 10^{-10} farad, or 100 picofarads. It is notable that the capacitance between two conductors of 100 metres of standard power cable is of the order of 5,000 picofarads.

Dielectric concepts. *Dielectric media.* Only one type of material body (*i.e.*, the electrical conductor) has been considered so far in relation to the electrostatic field. All other materials have been classified in a contrary way as insulators—*i.e.*, nonconductors. Here other kinds of materials will be investigated.

If any material body is inserted between the plates of a capacitor the potential difference (ϕ) between the plates will drop, even if the material is an insulator. Equally, if the potential difference is held constant the charge (q) increases. In both cases, then, the capacitance (C) is increased, and it becomes immediately apparent that insulators have electrical properties that are not completely specified simply by saying that they do not permit the passage of an electric current.

Experimentally, it is found that when a capacitor *in vacuo* is immersed in an insulating medium, the capacitance is increased by a numerical factor ϵ that is characteristic of the medium. The constant ϵ is referred to as the dielectric constant of the medium or, more precisely, the relative dielectric constant (relative to vacuum for which $\epsilon = 1$, symbolized ϵ_0). It is found that ϵ for a particular medium (*e.g.*, oil or mica), except in extremely high fields, is almost independent of the electric field and varies slightly with temperature and the state of strain of the medium. The value of ϵ, however, can vary considerably with the frequency of the electric field. For example, the dielectric constant of glass is about seven in static fields but falls to 2.3 in fields with frequencies in the range of 10^{14} hertz (abbreviated Hz; cycles per second); *i.e.*, the fields associated with optical phenomena. If the material is a single crystal, it is also found that the factor ϵ depends quite appreciably on the relative directions of the electric field $\boldsymbol{E}$ and the crystal axis. Materials that have this property are said to be electrically anisotropic. If the anisotropy also occurs at optical frequencies it leads to birefringence, or double refraction, the phenomenon in which the velocity of light in some media depends on the vibration plane of the light waves. The effects of anisotropy are usually small, but in some cases the value of ϵ varies with direction by a ratio of more than 2:1.

Two fundamental laws of electrostatics

The expression for the capacitance C of a plane parallel capacitor ($C = \epsilon_0 A/d$) depends on two fundamental laws of electrostatics. One of these is essentially that potential ϕ and electric field $\boldsymbol{E}$ are related by $\boldsymbol{E} = -\nabla\phi$; the other is that the surface charge σ on the plates is equal to $\epsilon_0 E_n$, and this is an expression of Gauss's theorem or equivalently of $\nabla \cdot \boldsymbol{E} = \rho/\epsilon_0$. The capacitance C is larger than predicted by this formula when the space between the plates is filled with a dielectric medium, and so one at least of these laws must be modified. Because both these laws originate in the expression for the force between charges, namely,

$$\boldsymbol{F} = \frac{q_1 q_2 \boldsymbol{r}}{4\pi\epsilon_0 r^3},$$

this law also needs modification. Indeed, starting with this law it might be claimed that it is an experimental fact that when two charges are immersed in a medium the force $\boldsymbol{F}$ is reduced by a factor $1/\epsilon$. Such an experimental fact is hard to verify if the medium is a liquid and impossible if it is a solid. It is simpler to proceed in a rather less direct way and maintain the validity of $\boldsymbol{E} = -\nabla\phi$ and the defining equation $\boldsymbol{F} = q\boldsymbol{E}$, but alter the equation $\nabla \cdot \boldsymbol{E} = \rho/\epsilon_0$. This expression is replaced by a completely new equation involving a new vector $\boldsymbol{D}$, called Maxwell's displacement vector and written $\nabla \cdot \boldsymbol{D} = \rho$. The displacement $\boldsymbol{D}$ is then related to $\boldsymbol{E}$ by $\boldsymbol{D} = \epsilon\epsilon_0\boldsymbol{E}$, in which ϵ is unity in a vacuum but characteristic of the medium in a dielectric. The electric field $\boldsymbol{E}$ now satisfies the equation $\nabla \cdot (\epsilon\epsilon_0\boldsymbol{E}) = \rho$, but not, be it noted, $\epsilon\epsilon_0(\nabla \cdot \boldsymbol{E}) = \rho$, which has quite different conse-

quences in a region in which ϵ varies with position (*e.g.*, at the surface of a dielectric).

Gauss's theorem now becomes $\oint_S D_n dS = \int_V \rho dV$, and, in a homogeneous uniform dielectric,

$$\boldsymbol{D}(r) = \frac{q\boldsymbol{r}}{4\pi r^3},$$

$$\boldsymbol{E}(r) = \frac{q\boldsymbol{r}}{4\pi\epsilon\epsilon_0 r^3}$$

$$\phi(r) = \frac{q}{4\pi\epsilon\epsilon_0 r}.$$

The dielectric constant of a medium can be measured simply by constructing a capacitor using the medium as the insulator and comparing its capacitance with a similar vacuum-spaced capacitor. Maxwell's equations and the theory of electromagnetic waves, however, lead to the result that the inverse ratio of the velocity c' in a dielectric medium to the velocity c of the waves in vacuum is equal to the quantity n and the square root of ϵ; *i.e.*, $n = c/c' = \sqrt{\epsilon}$.

The ratio n is the refractive index of the medium, and so ϵ can be obtained by measuring n. Because refractive index is a function of wavelength, the measurement gives ϵ for a particular frequency.

Numerical values for the dielectric constant

The quantity $\epsilon - 1$ depends on the density of the medium. In gases, ϵ is close to unity—for air at standard temperature and pressure, for example, $\epsilon = 1.0006$—and for many purposes almost any gas can be regarded as very nearly equivalent to vacuum. In solids ($\epsilon - 1$) usually exceeds unity. In most cases ϵ lies in the range 2–10, but several solids have static dielectric constants over 1,000. Dielectric constants in the optical frequency range are usually between two and three. A few media—*e.g.*, rutile (TiO_2)—have values as large as eight and correspondingly high refractive indices.

The following list briefly summarizes the effects of a medium with a dielectric constant ϵ greater than unity:

1. The electric field $\boldsymbol{E}$ from a charge within the medium, and also the potential ϕ, are reduced by $1/\epsilon$.
2. The capacitance of a system of conductors immersed in the medium is increased by ϵ.
3. The velocity of propagation of electromagnetic waves is reduced by $\sqrt{1/\epsilon}$.
4. The field $\boldsymbol{E}$ no longer satisfies the relation $\nabla \cdot \boldsymbol{E} = \rho/\epsilon_0$, but instead $\nabla \cdot (\epsilon\epsilon_0\boldsymbol{E}) = \rho$, which may also be written as $\nabla \cdot \boldsymbol{D} = \rho$.

Because a dielectric medium increases the capacitance, most practical capacitors employ dielectrics. This usage has a further advantage in that the breakdown strength of solid and liquid dielectrics is much higher than that of air. The plate separation for a given voltage can therefore be reduced, and this in turn leads to more capacitance for a given overall size.

Dielectric polarization. It is necessary now to examine how these effects arise, and, in particular, why in a dielectric the field $\boldsymbol{E}$ no longer satisfies the same equations. This amounts, in effect, to determining why $\epsilon - 1$ is not zero, and suggests that the significant vector is not the displacement $\boldsymbol{D}$ but the difference between $\boldsymbol{D}$ and $\epsilon_0\boldsymbol{E}$ that vanishes in vacuum. A new vector $\boldsymbol{P}$ is therefore defined so that

$$\boldsymbol{D} = \epsilon_0\boldsymbol{E} + \boldsymbol{P}.$$

For reasons that will eventually become clear, this quantity $\boldsymbol{P}$ is called the polarization. Since $\nabla \cdot \boldsymbol{D} = \rho$, the result follows,

$$\nabla \cdot \boldsymbol{E} = \frac{\rho}{\epsilon_0} - \frac{1}{\epsilon_0}\nabla \cdot \boldsymbol{P}.$$

It would, then, appear that variations in polarization from point to point act as sources of electric field in exactly the same way as charge.

It is known that the mobile charges in conductors, and the charges that are transferred in frictional electrification, are described by ρ. It is therefore reasonable to suspect that polarization in some way describes the effects of the immobile or bound charges in insulators. A closer insight into this notion may be derived by considering a long, uniform, cylindrical rod of a dielectric in which there are no free charges and the polarization $\boldsymbol{P}$ is uniform and parallel to the axis of the rod. Because $\boldsymbol{P}$ in the rod is uniform, the divergence $\nabla \cdot \boldsymbol{P}$ is zero inside the rod but not zero at its end faces. If the notation $\rho_b = -\nabla \cdot \boldsymbol{P}$ is introduced so that $\nabla \cdot \boldsymbol{E} = \rho_b/\epsilon_0$, then the field $\boldsymbol{E}$ that arises from the effect of $\boldsymbol{P}$ will be the same as the field that arises from a charge density ρ_b. Now ρ_b is zero except at the end of the rod; so that the field $\boldsymbol{E}$ is the same as a field resulting from two charges, one at each end of the rod. In Figure 6 a coordinate system is defined for the problem, below which are two plots, the variation of $\boldsymbol{P}$ with x and the variation of the divergence $\nabla \cdot \boldsymbol{P} = \frac{\partial \boldsymbol{P}}{\partial x}$ with x. The total "charge" at each end of the rod is obtained by integrating $-A\frac{\partial \boldsymbol{P}}{\partial x}$ through a thin layer δx including the end faces of the rod. At the left end this gives $-AP$ and at the right end $+AP$. The electric field $\boldsymbol{E}$ from this polarized rod is therefore the same as the electric field of two charges $+AP$ and $-AP$ separated by a distance l; *i.e.*, a dipole of moment AlP. But Al is the volume of the rod. This suggests that $\boldsymbol{P}$ might be interpreted as the dipole moment per unit volume of the rod resulting from bound charges.

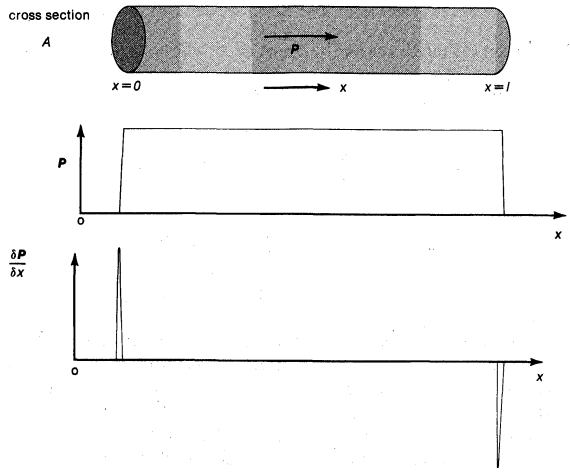

Figure 6: Polarized cylinder and graphs of the variation of $\boldsymbol{P}$ and $\delta\boldsymbol{P}/\delta x$ with distance (see text).

Polarization from the atomic point of view

It is instructive to look at the problem from an atomic point of view. If an electric field is applied to an insulator (*e.g.*, diamond or sulfur), the electrons in the atoms will be pulled in one direction by the field and the nuclei in the other. The centre of gravity of the negative electronic charge and the positive nuclear charge will no longer coincide; in other words, the atoms will have acquired a small electric dipole moment. If the field $\boldsymbol{E}$ points in the direction of increasing x, the positive nuclei will move toward increasing x and the induced moment $\boldsymbol{p}$ is parallel to $\boldsymbol{E}$. The relation between $\boldsymbol{p}$ and $\boldsymbol{E}$ is dealt with below; here it can be assumed that $\boldsymbol{p}$ is proportional to $\boldsymbol{E}$ and is written as $\boldsymbol{p} = \epsilon_0\alpha\boldsymbol{E}$.

The quantity α, called the atomic polarizability, has the dimensions of volume. If there are N atoms in unit volume, the dipole moment density (*i.e.*, the total dipole moment per unit volume) is $N\boldsymbol{p} = \epsilon_0 N\alpha\boldsymbol{E}$. If this were identified with the polarization vector $\boldsymbol{P}$ it would give

$$\boldsymbol{D} = \epsilon_0\boldsymbol{E} + \epsilon_0 N\alpha\boldsymbol{E}$$

and the relative dielectric constant would be

$$\epsilon = 1 + N\alpha.$$

The reasoning is plausible, but the question still remains why, if $\boldsymbol{P} = \epsilon_0 N\alpha\boldsymbol{E}$, or $\boldsymbol{P} = N\boldsymbol{p}$, the quantity $-\nabla \cdot \boldsymbol{P}$ behaves as though it were a source of electric field, just as a charge is a source of the field. To understand this, a simple one-dimensional example can be considered, but first it is necessary to make a clear distinction between

macroscopic and microscopic quantities. The fields and vectors considered here are quantities related to macroscopic—*i.e.*, laboratory-size—bodies. The atomic structure of a medium is a microscopic feature of the medium and on a macroscopic scale (or even on the scale of light waves) is unobservable. Thus, any reference to macroscopic quantities or macroscopic volume elements implies defining neither their position nor their extent with microscopic (*i.e.*, atomic) accuracy. The quantities $\boldsymbol{D}$, $\boldsymbol{E}$, $\boldsymbol{P}$, ρ, and $\rho_b = -\nabla \cdot \boldsymbol{P}$ are, on a microscopic scale, averages over rather vaguely defined regions containing many atoms. It may be assumed that a medium has a polarization $\boldsymbol{P}$, which is increasing with increasing x. In this case, it can be represented in atomic detail by a row of dipoles, increasing in size toward the right. For this representation, the divergence of the polarization,

$$\nabla \cdot \boldsymbol{P} = \frac{\partial \boldsymbol{P}}{\partial x}$$

is positive. Next, the net charge is determined somewhere along this row for a region of macroscopic length L the exact position of which is vague on an atomic scale. If the left end of L is at x and the right end at $x + L$ it must be assumed that x is chosen randomly. If the individual dipole charges are plus and minus q, the dipole lengths are $l(x)$, and the separation between dipoles is d, there will be zero charge in L whenever both ends of L lie between dipoles. The probability of this happening, if x is chosen randomly, is

$$\left(\frac{d - l(x)}{d}\right)\left(\frac{d - l(x + L)}{d}\right).$$

The charge will be $+q$ if the left end at x falls inside a dipole and the right end does not. This probability is

$$\frac{l(x)}{d}\left(\frac{d - l(x + L)}{d}\right).$$

The charge will be $-q$ if the right end intersects a dipole and the left does not. This has a probability

$$\frac{l(x + L)}{d}\left(\frac{d - l(x)}{d}\right).$$

The expected value (Q) of the charge in L is therefore

$$Q = q\left\{\frac{l(x)}{d}\left(\frac{d - l(x + L)}{d}\right) - \frac{l(x + L)}{d}\left(\frac{d - l(x)}{d}\right)\right\},$$

which simplifies to

$$Q = -\frac{q}{d}\{l(x + L) - l(x)\}.$$

Now if L, though large on an atomic scale, is not so large that $l(x + L)$ is appreciably different from $l(x)$, this can be approximated by

$$Q = -L\frac{\partial}{\partial x}\left(\frac{ql(x)}{d}\right).$$

But $\frac{ql(x)}{d}$ is just the dipole moment per unit length and Q/L is the expected macroscopic charge per unit length; so,

$$Q/L = -\delta P/\delta x.$$

This equation is the one-dimensional form of $\rho_b = -\nabla \cdot \boldsymbol{P}$. This treatment is not wholly satisfactory, but it at least avoids the contradictions implicit in the usual elementary accounts. A detailed and general mathematical proof that, if $\boldsymbol{P}$ is defined as the average dipole moment density, then $-\nabla \cdot \boldsymbol{P}$ acts as a source term for the macroscopically observable electric field (in exactly the same way as the free or mobile charge density), is not simple; indeed it has been given only quite recently. The result itself has been known and used since the beginning of the 20th century.

It can be seen, then, that if $\boldsymbol{D}$ is written as $\epsilon_0\boldsymbol{E} + \boldsymbol{P}$, the vector $\boldsymbol{P}$ has a simple relation to the structure and properties of the medium. It is important to realize that, in identifying $\boldsymbol{P}$ with the electric dipole moment density, caused by bound charges in the medium, it is not necessary to invoke any special properties of these charges nor to assume that $\boldsymbol{P}$ is proportional to $\boldsymbol{E}$. The interpretation of $\boldsymbol{P}$ in the equation $\boldsymbol{D} = \epsilon\boldsymbol{E} + \boldsymbol{P}$ is valid, either if $\boldsymbol{P}$ is not proportional to $\boldsymbol{E}$ or if $\boldsymbol{P}$ is not solely the result of the relative displacement of electrons and nuclei. In particular, in a medium such as sodium chloride (NaCl), part of the dipole moment density may be caused by the relative displacement of sodium (Na^+) and chlorine (Cl^-) ions.

In most media the polarization $\boldsymbol{P}$ is in fact almost exactly proportional to electric field $\boldsymbol{E}$. If $\boldsymbol{P} = \epsilon_0\chi\boldsymbol{E}$ the dimensionless constant χ is known as the dielectric or electric susceptibility or, if the context is clearly electric (as distinct from magnetic), as the susceptibility. From the expression $\boldsymbol{D} = \epsilon_0\boldsymbol{E} + \boldsymbol{P}$ and $\boldsymbol{D} = \epsilon\epsilon_0\boldsymbol{E}$ it is seen that $\epsilon = 1 + \chi$.

Electric susceptibility

By far the vast majority of gases, liquids, and solids have a linear constitutive relation; *i.e.*, $\boldsymbol{P}$ is proportional to $\boldsymbol{E}$. In these cases only $\boldsymbol{P} = \epsilon_0\chi\boldsymbol{E}$.

The polarization does not usually follow instantaneously on the application of a field $\boldsymbol{E}$; in a few cases the time lag (t) may be several seconds, although in the majority of media it is much shorter. Values ranging from 10^{-2} second down to 10^{-15} second occur in different types of media. Long times tend to be associated with viscous and highly polarizable liquids, short times with most other media. If the frequency of the electric field is $\omega/2\pi$ and the product ωt is small, the polarization is virtually instantaneous.

At high (optical) frequencies the relation between $\boldsymbol{P}$ and $\boldsymbol{E}$ can be anisotropic (*i.e.*, is dependent on direction) even in gases and liquids, and anisotropy is associated with the phenomenon of natural optical activity (*i.e.*, the rotation of the plane of polarization of light); but in static fields all gases, liquids, amorphous solids, glasses, and cubic crystals are isotropic—that is, the relation between $\boldsymbol{P}$ and $\boldsymbol{E}$ is independent of the direction of $\boldsymbol{E}$ in the medium. In crystals having other than cubic symmetry the relation is almost always direction-dependent.

In a few media (*i.e.*, crystals belonging to symmetry classes that lack a centre of symmetry) the constitutive relation may contain a small quadratic (squared) term. If for simplicity the vector character of $\boldsymbol{P}$ and $\boldsymbol{E}$ is omitted, then the relation is

$$P = \epsilon_0\chi E + \epsilon_0 dE^2.$$

Some media called ferroelectrics, such as barium titanate, exhibit a spontaneous polarization even in zero field. Other media, the pyroelectric crystals with polar symmetry, also have this property, but it is usually masked by other effects; *e.g.*, the accumulation of surface charge. Many crystals acquire a polarization $\boldsymbol{P}$ in zero field when they are subjected to strain. These media are known as piezoelectrics. The nature and origin of these effects are dealt with below. Here, it is enough to know that a medium can have a non-zero value of $\boldsymbol{P}$ even when $\boldsymbol{E} = 0$. The relation $\boldsymbol{P} = \epsilon_0\chi\boldsymbol{E}$, although extremely common, is not a basic law of electricity.

Fields in dielectrics. The basic equations that govern the behaviour of electric fields in dielectrics are four in number:

1. The electric field ($\boldsymbol{E}$) is equal to minus the gradient of the electric potential (ϕ):

$$\boldsymbol{E} = -\nabla\phi. \tag{15}$$

2. The curl of the electric field is zero:

$$\nabla \times \boldsymbol{E} = 0. \tag{16}$$

3. The electric displacement ($\boldsymbol{D}$) is equal to the dielectric constant (ϵ_0) times the electric field, plus the electric polarization ($\boldsymbol{P}$):

$$\boldsymbol{D} = \epsilon_0\boldsymbol{E} + \boldsymbol{P}.$$

4. The divergence of the electric displacement is equal to the density of electric charge (ρ):

$$\nabla \cdot \boldsymbol{D} = \rho. \tag{17}$$

If attention is restricted to regions free from mobile or free charge, then $\rho = 0$ and $\nabla \cdot \boldsymbol{D} = 0$. In simple linear dielectrics $\boldsymbol{P} = \epsilon_0 \chi \boldsymbol{E}$ and $\boldsymbol{D} = \epsilon_0(1 + \chi)\boldsymbol{E} = \epsilon_0 \epsilon \boldsymbol{E}$, but this cannot always be assumed to be the case. Equations (15) and (16) are both equivalent to the statement that the line integral of $\boldsymbol{E}$ around any closed path is zero. When this is applied to a path in Figure 7 (left), with two

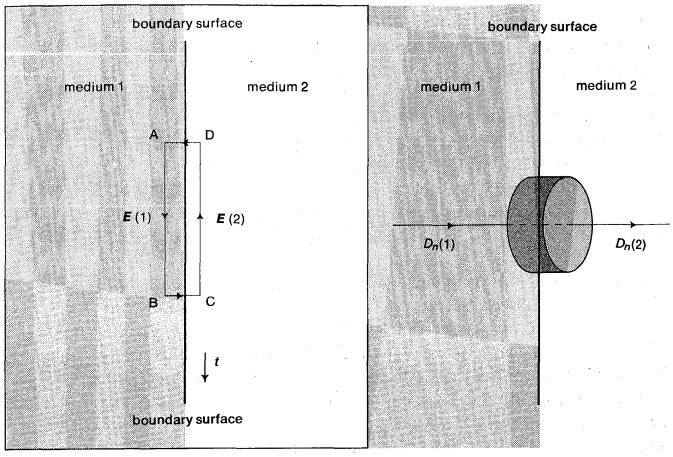

Figure 7: Components of field $\boldsymbol{E}$ and displacement $\boldsymbol{D}$ across a boundary surface. (Left) Tangential component of the electric field is continuous; (right) normal component (D_n) of the displacement vector is continuous (see text).

finite segments of either side of a surface separating two different media (1 and 2) and two infinitesimal segments crossing the surface, and if E_t is the component of $\boldsymbol{E}$ tangential to the surface, the vanishing of the line integral implies that

$$E_t(1) = E_t(2). \tag{18}$$

As the surface of a dielectric is crossed, the tangential component of the electric field is continuous. This implies that ϕ is also continuous.

Similarly, equation (17) implies that the surface integral of the normal component D_n of $\boldsymbol{D}$ over any closed surface in which there is no free charge is zero. If this is applied to the flat "pillbox" shown in Figure 7 (right), with faces in each medium, it may be seen that this requires $D_n(1) = D_n(2)$; for as the sides of the "pillbox" shrink to zero, all the contributions to the surface integral come from the faces, and this condition leads to the conclusion that at the boundary between two different dielectric media the normal component of $\boldsymbol{D}$ is continuous. Therefore,

$$D_n(1) = D_n(2). \tag{19}$$

Equations (18) and (19) are the key to the treatment of problems involving dielectric bodies. Before these relations are applied, two further results that follow from the basic equations can be written, namely,

$$\nabla \cdot \boldsymbol{E} = -\frac{1}{\epsilon_0} \nabla \cdot \boldsymbol{P} \tag{20}$$

and

$$\nabla \times \boldsymbol{D} = \nabla \times \boldsymbol{P}. \tag{21}$$

The significance of equation (20) has been referred to above and will be used below. Equation (21) is of no real use; it is given here only because its omission could suggest that the curl of $\boldsymbol{D}$ is always zero, which could lead to confusion.

A particularly simple problem, that of the field surrounding a dielectric sphere with a definite spontaneous uniform polarization $\boldsymbol{P}$, may now be analyzed. Because the system has a spherical surface of discontinuity, Cartesian coordinates are not really suitable, and it is useful to introduce a spherical polar coordinate system. The azimuthal or longitudinal angular coordinate in this set of coordinates is irrelevant, since the system has axial symmetry about the polar axis parallel to $\boldsymbol{P}$. If ϕ_i is the potential inside the sphere and ϕ_0 that outside the sphere, both potentials satisfy Laplace's equation (proposed by the French mathematician, Pierre-Simon Laplace), since $\nabla^2 \phi = -\nabla \cdot \boldsymbol{E} = \frac{1}{\epsilon_0} \nabla \cdot \boldsymbol{P}$ is zero in both regions ($\boldsymbol{P}$ is zero outside and constant inside). Further, the solutions of the equation must have axial symmetry and, in addition, $\phi(r, \theta = 0) = -\phi(r, \theta = \pi)$. There are only two such solutions of Laplace's equation, $\phi = Ar \cos\theta$ and $\phi = B \cos\theta / r^2$. The first solution is inapplicable outside the sphere (for $\phi \to \infty$ as $r \to \infty$). The second is inapplicable inside (for $\phi \to \infty$ as $r \to 0$). The appropriate solutions are, therefore, $\phi_i = Ar \cos\theta$ and $\phi_0 = B \cos\theta / r^2$, in which A and B are constants. The potential is to be continuous (because E_t is continuous) at the surface of the sphere (arbitrary radius r equal to sphere radius b) and so

$$Aa \cos\theta = B \cos\theta / a^2, \text{ or } B = a^3 A.$$

The further condition $D_n(i) = D_n(0)$ must also be satisfied. Now

$$E_n = E_r = -\frac{\partial \phi}{\partial r}, \text{ and so}$$

$$E_n(i) = -A \cos\theta$$

$$E_n(0) = \frac{2B \cos\theta}{r^3} = \frac{2B \cos\theta}{a^3} = 2A \cos\theta.$$

But also $D_n(i) = \epsilon_0 E_n(i) + P \cos\theta$

and $D_n(0) = \epsilon_0 E_n(0)$;

so that $\epsilon_0 A \cos\theta = \epsilon_0 A \cos\theta + P \cos\theta A$

which gives $A = \frac{P}{\epsilon_0}$.

This leads to $\phi_0 = \frac{1}{3} a^3 \frac{P \cos\theta}{\epsilon_0 r^3}$

and $\phi_i = \frac{1}{3\epsilon_0} Pr \cos\theta.$

In vector notation, if $\boldsymbol{r}$ is a vector displacement from the centre of the sphere, these results are

$$\phi_0 = \frac{4\pi}{3} a^3 \frac{\boldsymbol{P} \cdot \boldsymbol{r}}{4\pi \epsilon_0 r^3}$$

$$\phi_i = \frac{1}{3\epsilon_0} \boldsymbol{P} \cdot \boldsymbol{r}.$$

Thus ϕ_0 is the potential arising from a dipole of moment $\frac{4\pi}{3} a^3 \boldsymbol{P}$, but more interestingly, the internal field $\boldsymbol{E}(i)$ derived from ϕ is $-\frac{1}{3\epsilon_0} \boldsymbol{P}$. The field inside the sphere is opposed to $\boldsymbol{P}$ and therefore

$$\boldsymbol{D}(i) = \epsilon_0 \boldsymbol{E}(i) + \boldsymbol{P} = \frac{2}{3} \boldsymbol{P} = -2\epsilon_0 \boldsymbol{E}(i).$$

If now, in addition to the effects of $\boldsymbol{P}$, there is an external impressed field $\boldsymbol{E}(ext)$ parallel to $\boldsymbol{P}$, then fields are linearly additive

$$\boldsymbol{E}(i) \to \boldsymbol{E}(ext) - \frac{1}{3\epsilon_0} \boldsymbol{P}.$$

Further, if instead of there being a spontaneous polarization $\boldsymbol{P}$, the polarization is given by the linear relation $\boldsymbol{P} = \epsilon_0 \chi \boldsymbol{E}(i)$, there results the relation

$$\boldsymbol{P} = \epsilon_0 \chi \left(\boldsymbol{E}[ext] - \frac{1}{3\epsilon_0} \boldsymbol{P} \right),$$

$$\boldsymbol{P} = \frac{\chi}{1 + \frac{1}{3}\chi} \epsilon_0 \boldsymbol{E}(ext).$$

Even if χ is extremely large, $\boldsymbol{P}$ cannot exceed $3\epsilon_0 \boldsymbol{E}(ext)$. Also, it will be noticed that

$$\boldsymbol{E}(i) = \frac{\boldsymbol{E}(ext)}{1 + \frac{1}{3}\chi}$$

Spherical coordinates

and is less than $E(ext)$. Calculations such as this can be performed only for a limited class of bodies in which the polarization and the electric field are uniform and the surface of the body is an ellipsoid; *i.e.*, the Cartesian equation of the surface is

$$\frac{x^2}{a^2}+\frac{y^2}{b^2}+\frac{z^2}{c^2}=1.$$

If the field is applied along a principal axis (*i.e.*, x, y, or z), the general result is that $E(i)=E(ext)-\frac{1}{\epsilon_0}\gamma_\alpha P$, in which γ_α is a dimensionless shape factor appropriate to the axis α (α stands for x, y, or z). These shape factors are generally known as demagnetizing factors because they are of rather greater importance in practical magnetism. The three principal shape factors, γ_x, γ_y, and γ_z, satisfy the equation $\gamma_x+\gamma_y+\gamma_z=1$.

Demagnetizing factors

If the body has axial symmetry about the z-axis ($\gamma_x=\gamma_y$), the shape factors γ_x and γ_y will each be equal to $\frac{1}{2}(1-\gamma_z)$. For a sphere in which x, y, z are equivalent, then $\gamma_x=\gamma_y=\gamma_z=\frac{1}{3}$, as was just seen. A long thin needle parallel to the z-axis approximates an ellipsoid. If E is parallel to the axis the condition E_t is continuous applied to the side of the needle and ensures that $E(i)=E(ext)$. Thus $\gamma_z=0$ and $\gamma_x=\gamma_y=\frac{1}{2}$. For a thin flat disk normal to the z-axis, with E parallel to the z-axis, the condition that D_n is continuous applies to the flat faces and ensures that $D(i)=\epsilon_0 E(ext)$; thus $E(i)=\frac{1}{\epsilon_0}(D[i]-P[i])=E(ext)-\frac{P_i}{\epsilon_0}$ and $\gamma_z=1$ so that $\gamma_x=\gamma_y=0$.

If a long dielectric needle is placed parallel to a uniform external field, E inside the needle is equal to the external field. If a flat disk is placed normal to a field, D, inside the disk, is $\epsilon_0 E(ext)$. In this case if $D=\epsilon\epsilon_0 E$ the result is $E(int)=\frac{1}{\epsilon}E(ext)$.

These results can, so to speak, be turned inside out to give the field inside a hollow cavity in a medium, where the electric field well away from the cavity is E and the polarization is P. If γ is the appropriate shape factor for the cavity then

$$E(cavity)=E+\frac{1}{\epsilon_0}\gamma P.$$

If the cavity is a sphere $\gamma=\frac{1}{3}$ and

$$E(cavity)=E+\frac{1}{3\epsilon_0}P. \tag{22}$$

If it is a long, needle-shaped cavity parallel to E the result is

$$E(cavity)=E; \tag{23}$$

and if it is a disk normal to E,

$$E(cavity)=E+\frac{1}{\epsilon_0}P$$

or

$$E(cavity)=\frac{1}{\epsilon_0}D. \tag{24}$$

In some older texts the results (23) and (24) are taken to explain the significance of the vectors E and D in a dielectric. There is, however, no simple physical case in which they are applicable. The result (22) for a spherical cavity is, however, of some importance. If the field acting on an atom in a dielectric medium is regarded as the field in a spherical cavity surrounding the atom, and if the atom has an atomic polarizability α, the induced dipole moment will not be $\epsilon_0 E$ but $p=\epsilon_0\alpha(E+\frac{1}{3\epsilon_0}P)$.

But because the polarization P is equal to N, the number of atoms per unit volume, times the induced dipole moment p, or $P=Np$, there results

$$P=\epsilon_0 N\alpha\left(E+\frac{1}{3\epsilon_0}P\right);$$

so that

$$P=\epsilon_0\frac{N\alpha}{1-\frac{1}{3}N\alpha}E.$$

Also,

$$\chi=P/\epsilon_0 E,$$

giving

$$\chi=\frac{N\alpha}{1-\frac{1}{3}N\alpha}. \tag{25}$$

Substituting $\chi=\epsilon-1$ in the last equation, the following relationship is found:

$$\frac{\epsilon-1}{\epsilon+2}=\frac{1}{3}N\alpha, \tag{26}$$

a result known as the Clausius-Mossotti equation. The argument leading to equations (25) and (26) has been expressed in much more cogent form and treated almost continuously under the general heading of "local field corrections" since around 1920. It is probably fair to say that there is still no general agreement about the range of validity of these results.

If equation (26) is believed to be correct and α to be a constant atomic parameter, then, in a gas in which N can be varied by varying the pressure, $\frac{\epsilon-1}{\epsilon+2}$ should be proportional to pressure. This is found to be the case experimentally. On the other hand, $\epsilon-1$ is small for gases and $\frac{\epsilon-1}{\epsilon+2}\simeq\frac{1}{3}(\epsilon-1)$, and in practice the simple expression $\epsilon-1=N\alpha$ gives almost as good a fit to the experimental data.

The next step is to consider the energy associated with the field in a dielectric. The work done to change a distribution of free charge ρ by an increment $d\rho$ is

$$dW=\int(\phi d\rho)dV;$$

but now $d\rho=\nabla\cdot(dD)$, and so

$$\phi d\rho=\phi\nabla\cdot(dD)=\nabla(\phi dD)-dD\cdot\nabla\phi.$$

The term $\nabla\cdot(\phi dD)$, when integrated over a volume V with a closed surface S, gives a surface integral that vanishes as S recedes to infinity, and therefore

$$dW=-\int_V dD\cdot\nabla\phi dV=\int_V E\cdot(dD)\,dV.$$

It will be noticed, however, that the volume of integration is the whole of space, and so dW includes contributions from outside the dielectric when $D=\epsilon_0 E$. If the dielectric is linear and $D=\epsilon\epsilon_0 E$ in the body, dW can be integrated and gives $W=\frac{1}{2}\int E\cdot D\,dV$, so that it is possible to regard the scalar product $\frac{1}{2}E\cdot D$ as the field energy density. In a dielectric with $\epsilon=10$ and a breakdown strength of 5×10^7 volts per metre, the maximum energy density is about 10^8 joules per cubic metre. This amount is negligible compared with the thermal energy density of a solid, about 10^8 joules per cubic metre at room temperature, or the energy of combustion of fuel oil, about 10^{10} joules per cubic metre. Energy storage in dielectrics is not an attractive practical proposition for most purposes. Further consideration of energy in dielectrics will be found below under *Force, energy, and power associated with fields.*

Storage capacities compared for heat and electrical energy in a capacitor

Polarization. *Dielectric properties and the structure of matter.* There are essentially six ways in which a material body can acquire a dielectric polarization. In some solids—for example, beryllium oxide (BeO)—the positively charged beryllium (Be) atoms and negatively charged oxygen (O) atoms are arranged in a crystal lattice in such a way that the medium as a whole has a built-in polarization that cannot be appreciably changed without completely disrupting the crystal structure. Media of this type may be referred to as pyroelectric media because, as noted below, the only easily observable effects of the built-in polarization occur when the medium is heated. In other solids—*e.g.*, barium titanate ($BaTiO_3$)—the crystal structure also leads to a built-in polariza-

tion, but, in some temperature ranges at least, a sufficiently strongly applied electric field can reverse the polarization without disrupting the crystal. A medium with this property is known as a ferroelectric. Many media, although normally unpolarized, when mechanically strained (which displaces the atoms in the structure) acquire a polarization even in zero field. Media with this property are called piezoelectric. The effect is of some practical importance, especially in electronics.

Many simple molecules—*e.g.*, those of hydrogen chloride (HCl)—have a permanent molecular dipole moment resulting from the positive charge on the hydrogen atom and the negative charge on the chlorine atom. In a gas or liquid the forces of thermal disorder result in a completely random orientation of the individual dipoles, and no net polarization of the medium as a whole is observed. If, however, a field is applied, the dipoles tend to align themselves parallel to the field, and there results a polarization $\boldsymbol{P}$ parallel to $\boldsymbol{E}$, which is proportional to $\boldsymbol{E}$ for moderate fields. This leads to linear dielectric behaviour, but, because the degree of alignment is controlled by thermal disorder, the effects of $\boldsymbol{E}$ are strongly temperature dependent.

When a compound such as hydrogen chloride is condensed to form a solid crystal, the free rotation of the molecules will cease. When a field is applied to the crystal, instead of the molecules being rotated to align their moments parallel to the field, the only effect will be an elastic displacement of the positive and negative ions away from their position of equilibrium. This will result in an induced ionic dipole polarization. In sodium chloride (NaCl), for example, the lattice of alternating, equally spaced Na^+ and Cl^- atoms in each of the cubic directions leads to no net polarization; but if a field is applied, the distortion of the arrangement will lead to a nonvanishing value of polarization parallel and proportional to $\boldsymbol{E}$, the electric field.

In all matter, gaseous, liquid, or solid, ionic or nonionic, the application of a field displaces the atomic electrons relative to the atomic nuclei, and each atom acquires a dipole moment parallel to the field. This universal mechanism is known as electronic polarization. Because it involves only the displacement of electrons, whereas all the other mechanisms involve the displacement of relatively heavy atoms or ions, it gives the fastest response of polarization to electric field. The time delay involved is typically less than 10^{-15} second, whereas all other mechanisms have delays of 10^{-13} second or longer. Thus electronic polarization is the only mechanism operative at frequencies above 10^{14} hertz, the so-called optical frequencies.

Electronic polarization

Pyroelectricity, ferroelectricity, piezoelectricity, and related effects are dealt with in the following section. The next three sections deal in more detail with the three basic mechanisms, electronic polarization, ionic polarization, and polarization by dipole alignment, which lead to linear dielectric behaviour. Electronic polarization is presented first because it is present in all matter and often masks other effects.

Electronic polarization. In an electric field $\boldsymbol{E}$ an atom acquires a dipole moment $\boldsymbol{p} = \epsilon_0\alpha\boldsymbol{E}$ proportional to $\boldsymbol{E}$, because the field tends to pull the nucleus in one direction and the electrons in the other. The force binding the electrons to the nucleus is their ordinary electrostatic attraction. The effects of this attraction are modified by the fact that the atom is a dynamical system obeying the laws of quantum mechanics, but it is still meaningful to talk about the order of magnitude of the binding force in terms of the nuclear electric field acting on the electrons. An electron has a charge (e) equal to 1.6×10^{-19} coulomb, and its field E_a at a distance r_0 is of the order of

$$E_a \simeq \frac{e}{4\pi\epsilon_0 r_0^2}.$$

But in an atom, r_0 is of the order of atomic dimensions, roughly one angstrom, or 10^{-10} metre. This distance gives an E_a equal to 10^{11} volts per metre, or 10 volts per angstrom. The fields (E) normally dealt with in the laboratory are of the order of 10^8 volts per metre at most and, thus, produce only small effect on the actual electronic distribution in atoms. It is not unreasonable to guess that the resulting charge displacement r for a field $\boldsymbol{E}$ is of the order $r_0\boldsymbol{E}/E_a$, and the acquired dipole moment (p), which is the product of the charge times the distance of separation (*i.e.*, er), is therefore

$$er_0\frac{4\pi\epsilon_0 r_0^2}{e}\boldsymbol{E} \simeq 4\pi r_0^3\epsilon_0\boldsymbol{E}.$$

It may be supposed that in a solid the atoms are packed with their centres at the corners of cubes. The number of atoms N per unit volume will be $N \simeq \left(\frac{1}{2r_0}\right)^3$. Thus $\boldsymbol{P} = N\boldsymbol{p}$ is given by $\boldsymbol{P} = \frac{\pi}{2}\epsilon_0\boldsymbol{E}$.

This crude model therefore yields a susceptibility χ of the order of $\frac{\pi}{2} \simeq 1.5$. It follows that the dielectric constant ϵ is $1 + \chi \simeq 2.5$ and the refractive index n is $\epsilon^{1/2} \simeq 1.6$. In fact, the vast majority of simple, transparent, solid media have refractive indices (n) between 1.4 and 1.8; thus this crude model has at least some relation to reality. A quantum mechanical calculation of α yields an expression $\alpha = \eta 4\pi r_0^3$, in which η is a numerical factor not far from but usually less than unity, so that the result also has a more sophisticated theoretical interpretation.

The atoms in liquids are packed less tightly than those in solids, and as a result the quantities χ, ϵ, and n tend to be somewhat smaller. In a gas at standard temperature and pressure the density is typically 1,000 times less than that in a solid. This suggests that ϵ will be of the order of 1.0015. The actual values of ϵ for air and hydrogen are 1.0006 and 1.00026—*i.e.*, rather smaller than expected, because the quantum mechanical factor η is less than unity. The results for solids are better than those for liquids because in a solid, the product $N\alpha$ is of the order of unity and the local field correction cannot be neglected. This gives

Atomic packing in liquids

$$\chi \simeq \frac{N\alpha}{1 - \frac{1}{3}N\alpha},$$

and if, for example, $N\alpha = 1$, χ is increased to 1.5. The second reason is that r_0, the radius that determines α, is not the same as the radius that determines the packing. In many media—especially, for example, diamond and silicon—the electron clouds of neighbouring atoms overlap and r_0 is greater than the packing radius. This tends to increase χ.

It may be suspected that a more elaborate and accurate calculation of α would give better results. This is only partly right, for two reasons. It is remarkably difficult, except in rather trivial cases (*e.g.*, gaseous helium), to calculate α to better than two-figure accuracy; and, in addition, even if α is known to high accuracy, the general uncertainty attached to the local field theory, which replaces the field acting on atoms by $\boldsymbol{E} + \frac{1}{3\epsilon_0}\boldsymbol{P}$, would make the final result rather uncertain. The atomic theory of dielectric properties, especially of solids, is most usefully regarded as a descriptive theory rather than as an exact quantitative theory.

If the displacement of charge in atoms is proportional to the field, it then follows that the force binding electrons in atoms can be approximately treated as harmonic; *i.e.*, the restoring force is proportional to displacement. This means that the approximate classical equation of motion for a bound electron in a field $\boldsymbol{E}$ is $m\frac{d^2\boldsymbol{r}}{dt^2} + k\boldsymbol{r} = -e\boldsymbol{E}$, where m is the electron mass, k the force constant, $-e$ the electron charge, and $\frac{d^2\boldsymbol{r}}{dt^2}$ the acceleration along $\boldsymbol{r}$. (It is assumed that the much heavier nuclei remain almost stationary.) The restoring force is not exactly harmonic, and the residual effects of anharmonic terms in the force are, to a first approximation, equivalent to frictional or viscous damping. Atomic

vibrations and also atomic collisions also contribute to this term. This gives an equation of motion that can be expressed as

$$\frac{d^2r}{dt^2} + \omega_0\eta\frac{dr}{dt} + \omega_0^2 r = -\frac{e}{m}E, \tag{27}$$

in which $\omega_0 = \left(\frac{k}{m}\right)^{\frac{1}{2}}$

is the natural frequency of oscillation of the electronic system (strictly this is $\omega_0/2\pi$) and η measures the strength of the damping term.

If the applied field has a frequency $\omega/2\pi$ and varies as $E_0 \cos \omega t$, and equation (27) is solved for r and P is expressed as Ner, then the result is

$$P = \frac{Ne^2}{m}\frac{(\omega_0^2 - \omega^2)E\cos\omega t + \omega\omega_0\eta E\sin\omega t}{(\omega_0^2 - \omega^2)^2 + (\omega\omega_0\eta)^2}. \tag{28}$$

The polarization contains a term in phase with E and a term lagging by $\pi/2$, or 90°, which, as will be seen below, corresponds to power absorption and generates heat through the frictional term η. Not surprisingly, quantum mechanics leads to a similar expression and identifies ω_0 as the absorption frequency of the atoms. The in-phase part of (28) yields a susceptibility

$$\chi = \frac{Ne^2}{\epsilon_0 m}\frac{\omega_0^2 - \omega^2}{(\omega_0^2 - \omega^2)^2 + (\omega\omega_0\eta)^2},$$

which when plotted rises to a positive peak when ω is about $\omega_0(1 - \frac{1}{2}\eta)$ and falls to a negative peak when ω is about $\omega_0(1 + \frac{1}{2}\eta)$. When $\omega > \omega_0$ χ is negative and therefore

$$\chi \to -\frac{Ne^2}{\epsilon_0 m}\frac{1}{\omega^2} \to 0$$

as ω gets very large. At frequencies below ω_0 and well away from the resonance,

$$\chi = \frac{\frac{Ne^2}{\epsilon_0 m}}{\omega_0^2 - \omega^2} \tag{29}$$

and the static susceptibility is

$$\chi_0 = \frac{Ne^2}{\epsilon_0 m\omega_0^2}.$$

Thus χ at frequencies less than ω_0 can be expressed as

$$\chi(\omega) = \chi_0\frac{\omega_0^2}{\omega_0^2 - \omega^2}.$$

This result is in good agreement with the observed frequency dependence of the refractive index $\eta(\omega) = (1 + \chi[\omega])^{\frac{1}{2}}$. When the refractive index varies appreciably with frequency (wavelength) a medium is said to be dispersive. Equation (29), which gives a useful description of dispersion, is known as Sellmeier's equation.

Sellmeier's equation

Because electronic resonance frequencies generally lie in the visible or ultraviolet region of the spectrum (*i.e.*, above 10^{14} hertz), at ordinary radio frequencies (below 10^{12} hertz) the electronic contribution to the susceptibility of matter is almost constant and equal to the static value.

Ionic polarization. The forces that hold ions in place in a crystal lattice are primarily electrostatic. The reasoning about the electronic susceptibility that leads to the approximate result $\chi \simeq \frac{\pi}{2} \simeq 1.5$ can be repeated almost word for word. This would suggest that in a simple ionic crystal such as sodium chloride (NaCl) the susceptibility χ is approximately 3 with more or less equal electronic and ionic contributions. In practice the ionic term is usually somewhat larger.

If in unit volume there are N ions, each contributing α_i to the ionic susceptibility and α_e to the electronic susceptibility, and the local field polarizing the ions is $E + \frac{1}{\epsilon_0}\gamma P$ in which γ is the shape factor (*i.e.*, about $\frac{1}{3}$) for the particular crystal lattice, then

$$P = \frac{N(\alpha_i + \alpha_e)}{1 - \gamma N(\alpha_i + \alpha_e)}\epsilon_0 E$$

or

$$\chi = \frac{N(\alpha_i + \alpha_e)}{1 - \gamma N(\alpha_i + \alpha_e)}.$$

If $\gamma N(\alpha_i + \alpha_e)$ approaches unity, χ will be extremely large, even though $N(\alpha_i + \alpha_e)$ itself may not be large. Thus it is not astonishing that values of χ as high as 10^4 can be observed in some solids. If, however, $\gamma N(\alpha_i + \alpha_e)$ is greater than, or equal to, unity, the system is unstable and P is nonzero even in zero field. This can be put more logically by saying that any arrangement of the ions that leads to $\gamma N(\alpha_i + \alpha_e) \geq 1$ is unstable and will not occur. The crystal or solid will only be stable in some other crystal structure, which may or may not correspond to P not equal to zero in zero field. Clearly, however, if a structure leads to values of $\gamma N(\alpha_i + \alpha_e)$ nearly equal to unity, small changes in γ or N will lead to instability. Thus crystals with high values of χ are likely to transform to a ferroelectric structure as the temperature is varied.

The forces that bind ions to their equilibrium positions in a crystal lattice are of the same magnitude as the forces that bind electrons in atoms, but the masses of ions are in general 10^4 to 10^5 times greater. The resonance frequencies associated with ionic polarization therefore occur at frequencies 100 to 1,000 times lower and correspond to infrared or even, in some cases, microwave wavelengths. At frequencies well above a resonance the contribution of ionic processes to χ is negligible. Thus at visible wavelengths χ is represented almost entirely by the electronic term and the refractive index $n = \epsilon^{\frac{1}{2}} = (1 + \chi_e)^{\frac{1}{2}}$. This relationship can be used experimentally to sort out the relative importance of electronic and ionic effects.

Dipolar polarization. A molecule such as hydrogen chloride contains charges of order $+e$ and $-e$ separated by a distance of about one angstrom (10^{-10} metre). Its dipole moment is therefore of the order of 1.6×10^{-29} coulomb-metre. The unit used in almost all discussions of molecular dipole moments is the debye (named after a Dutch chemist, Peter Debye). This is 10^{-18} electrostatic unit and is equivalent to 3.3×10^{-30} coulomb-metre. Typically, molecules have either zero dipole moment—*e.g.*, oxygen (O_2)—or a moment of a few debyes. In an electric field E, the energy of a dipole (p) is $-p \cdot E$; thus, in a field of 10^6 volts per metre, the energy of a molecular dipole is of the order of 10^{-24} to 10^{-23} joule. Boltzmann's constant k is 1.38×10^{-23} joule per degree Kelvin, and at room temperature the mean thermal energy of molecules, kT, in which T is the Kelvin temperature, is about 4×10^{-21} joule. Thus, even in strong electric fields, the energy of interaction of a molecular dipole with the field is a small fraction of its thermal energy. It might be expected that the degree of alignment of the dipoles would be proportional to the ratio pE/kT, and, if there are N dipoles per unit volume, the polarization parallel to E would be given by $Np\frac{pE}{kT}$. An exact classical or quantum mechanical calculation gives

$$P = \frac{1}{3}Np\frac{pE}{kT};$$

and so

$$\chi = \frac{Np^2}{3\epsilon_0 kT}. \tag{30}$$

This equation, known as the Langevin–Debye law, shows that χ varies inversely with T. The law has the same form as Curie's law in magnetism. In a gas at standard temperature and pressure, with a dipole moment (p) equal to one debye, this gives $\chi \simeq 2 \times 10^{-3}$. Local field corrections are relatively unimportant, and both the temperature and pressure dependence are found experimentally to fit the Langevin–Debye equation. At high pressures, in which the number N of dipoles is increased, the local field correction becomes more important; and at densities corresponding to densities in the liquid and solid state, χ—predicted by equation (30)—exceeds three;

The Langevin–Debye law

and the simple Lorentz local field calculation (see equation 25) then gives

$$\chi = \frac{\frac{Np^2}{3\epsilon_0 kT}}{1 - \frac{1}{3}\frac{Np^2}{3\epsilon_0 kT}},$$

which is negative. These divergent results are not found experimentally; *e.g.*, for water, which is a dipolar liquid. The proper method of calculating the local field correction is uncertain, but an improvement on the Lorentz calculation by Lars Onsager has at least the merit that it yields a finite value of χ.

Pyroelectricity, piezoelectricity, and ferroelectricity. Many crystals—*e.g.*, zinc oxide (ZnO)—have structures that contain alternate positively and negatively charged layers of atoms. As a result the crystal has a built-in dielectric polarization P that can easily be of the order of one coulomb per square metre. The electric field within the crystal is then of the order of P/ϵ_0; *i.e.*, up to 10^{11} volts per metre. As a result any stray mobile charge within the crystal, on its surface, or in its surroundings migrates to the ends of the crystal in such a way as to neutralize the field and the external effects of P. If, however, the crystal temperature is changed, the resulting change in atomic positions alters P, and transient external effects can be observed in the interval between the change in P and the redistribution of the surface charge. This effect is known as pyroelectricity. It can be used to detect small temperature changes by their electrical effects and is the basis of some forms of detector for infrared radiation. It can occur only in crystals of particular symmetries, the polar classes, and is used by crystallographers to identify crystals as belonging to these classes.

Piezoelectricity

If a crystal with this type of structure is strained (*i.e.*, deformed by an external force) the change can lead to a change in polarization and external electric charge effects. This relationship between an applied force and an external charge is known as piezoelectricity. Piezoelectric effects resulting from simple compression are limited to the polar crystal classes, but piezoelectric effects resulting from more general types of strain (*e.g.*, shear) can occur in a much wider class of crystals, those that lack a centre of symmetry. Again, the presence of a piezoelectric effect is taken by crystallographers to be evidence for the absence of a centre of symmetry in a crystal structure. In the converse piezoelectric effect the application of an electric field produces strain. The two effects are important practically in electromechanical transducers. The crystal microphone, the crystal pickup, and the ultrasonic transducer are important examples. Perhaps the most important application of piezoelectricity is in the quartz crystal resonator, a device in which electrodes attached to a quartz crystal both produce strain in the crystal and detect the electrical effects of strain. If the voltage applied to the crystal coincides in frequency with a natural mechanical resonance of the crystal, the effects on an external circuit attached to the electrodes are large. Because mechanical resonances in quartz are sharp (*i.e.*, limited to a small frequency range) and lightly damped, quartz crystals are much used in electronics as frequency selective elements. The quality factor (see below *Alternating electric currents*) of a quartz crystal can be as high as 10^5 to 10^6 compared with 10^2 to 10^3 for electrical tuned circuits.

In some crystals the interaction between ionic and electronic polarization through the internal or local electric field makes the structure unstable if the atoms are stationary at their mean positions in the crystal lattice. At sufficiently high temperatures, however, the thermal vibration of the atoms about their mean positions tends to average out the internal fields, thus stabilizing the structure in a state of zero net polarization. The interaction is not simple in any real crystal, and the highly simplified and idealized treatment of the behaviour that follows is based on barium titanate ($BaTiO_3$). At high temperatures above 120° C the structure is cubic and unpolarized and the atomic arrangement is based on a repeat of a structure with one barium atom at the body centre of a cube, eight titanium atoms at the corners (each shared with eight cells), and 12 oxygen atoms (each shared with four cells). Thermal vibration stabilizes the structure so that the mean position of the negatively charged oxygen atoms is at the centre of a cube edge. Each cell and each atomic plane is neutral on the average, and the crystal is unpolarized. When the temperature is lowered below 120° C, the thermal vibration can no longer stabilize the structure and the oxygen atoms move spontaneously along one of the cube edge directions. There are six equivalent distortions possible along the $\pm x$, $\pm y$, or $\pm z$ axes. The new form of the crystal no longer has perfect cubic symmetry and exhibits a spontaneous polarization. At temperatures not too far below the ferroelectric transition temperature, or Curie point, the crystal can be switched from one state of polarization to another by an electric field which, though strong, is not strong enough to destroy the crystal structure. The actual behaviour of real crystals, including those of $BaTiO_3$, is far from being as simple as this, partly because the crystal splits up into oppositely polarized domains (see MAGNETISM) and partly because changes in polarization involve mechanical changes in the crystal structure. In general, ferroelectricity is not well understood, and explanations developed for one particular type of crystal (*e.g.*, $BaTiO_3$) fail when applied to another (*e.g.*, potassium dihydrogen phosphate, KH_2PO_4).

The effect is of some practical importance, in part because ferroelectric crystals can be used as memory elements in computers and in part because ferroelectric media generally display large values of linear dielectric susceptibility both above and below the Curie point.

Except for hysteresis effects in ferroelectric media (*i.e.*, the polarization P and electric field E are not in phase for rapid changes), in ferroelectricity the dielectric relation between P and E is almost exactly linear (*i.e.*, proportional to the first power). A few media, crystals that lack a centre of symmetry, do, however, also have a small quadratic dependence of P on E (*i.e.*, P is proportional to the second power of E), which arises from the fact that the forces binding ions in lattices, and especially electrons in atoms, are not exactly harmonic. This has interesting consequences of some technical importance. If, for example, $P = \epsilon_0\chi E + \epsilon_0 dE^2$, then in a field $E\cos\omega t$, because $\cos^2\omega t = \frac{1}{2}(1 + \cos 2\omega t)$, the polarization P will contain a component at the double frequency 2ω. This is known as second harmonic generation. It can, for example, be used to convert infrared radiation of wavelength 10^{-6} metre to visible radiation of wavelength $\frac{1}{2} \times 10^{-6}$ metre. If two fields $E\cos\omega t$ and a static field E_0 are applied, the polarization is $P = \epsilon_0(\chi + 2dE_0)E\cos\omega t +$ etc. The crystal now appears to have a linear polarizability, $\chi + 2dE_0$, which depends on the static field. If ω is an optical frequency, this gives a field-dependent refractive index and is known as the Pockels effect, or the linear electro-optic effect. It can be used to modulate or deflect a beam of light by the application of an electric field. It should not be confused with the much weaker quadratic electro-optic effect, or Kerr effect, which is mentioned briefly in a section below.

Second harmonic generation

Electrets. The built-in polarization that occurs in crystals of polar symmetry is little altered by external influences. Certain materials, especially waxes containing polar molecules, can be made to exhibit similar but smaller and more controllable effects and are known as electrets. If a molten dipolar wax is subjected to a strong electric field it acquires a net polarization as described above. If the wax is cooled well below the melting point in the presence of the field, this polarization can be "frozen in." If, in addition, the wax is a good insulator and hydrophobic, so that it does not collect surface moisture, this relatively weak frozen-in polarization will not only persist but will remain unmasked by surface changes and leakage. This is one form of electret, the electrical equivalent of a permanent magnet; it is not the only, or even the most important, mechanism that produces electrets. In carnauba wax, a common electret material, the polarization is almost certainly also due to separation of

ionic charge in the field applied during solidification. The electret gives a useful method of maintaining a static electric field over long periods. Electrostatic microphones using plastic electrets are commercially available, and there has been some work done on the use of electret membranes in medicine.

ELECTROSTATIC POTENTIAL

High-voltage phenomena. If two electrodes (*i.e.*, conductor terminals) in vacuum are maintained at a high potential difference, a current flows in the gap between them when the electric field at the surface of the negative electrode exceeds a certain threshold value, characteristic of the material of this electrode. The current in the conductors rises rapidly with increasing field, and, at high enough fields, the ordinary resistive heating of the electrode associated with the current can melt or vaporize the electrode. The emission of electrons from a negative electrode subject to a strong field is known as field emission, and is basically a quantum mechanical phenomenon. The essential features of the process are as follows: In Figure 8 the potential energy of an electron is plotted

Field emission

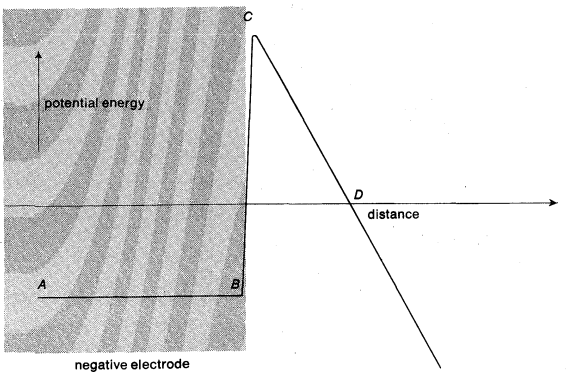

Figure 8: The potential energy of an electron at a metal surface subjected to a strong electric field (see text).

against distance near a metal surface. The potential energy within the metal (region AB of the negative electrode) is negative and rises abruptly at the metal surface. Electrons in the metal lack sufficient kinetic energy to surmount the barrier and thus remain bound in the metal. Outside the metal in the region CD and beyond, the potential energy falls rapidly because of applied field. The slope of the line CD, representing the change of energy with distance, is eE. As E is increased, the distance from D to a point on the metal surface decreases (if the electrons have a negative potential energy) and eventually becomes so small that quantum mechanical tunnelling can take the electrons through the potential barrier and out of the metal. This field emission current depends exponentially on the distance of D from the surface and, as the field increases and the distance decreases, the current rises rapidly.

Though field emission is an unwanted effect in many high-voltage vacuum tubes, it can also be put to good use. If the negative electrode surface has a radius of curvature r and the applied voltage between the electrodes is V, the field at the electrode surface, which is approximately V/r, can be made large, even if V is rather small, by decreasing r. It is possible to draw appreciable field emission currents, even when V is only 100 volts or less, if the electrodes are pointed. The field emission cathode is used as a source of electrons in many practical devices. The effect is also used in the field emission microscope and in a somewhat more complicated way in the field ion microscope, which is capable of resolving single atoms on a metal surface.

In a liquid or solid insulator a field of the order of one volt per angstrom, or 10^{10} volts per metre, is enough to disrupt individual atoms and usually leads to a catastrophic breakdown of the medium. In practice, breakdown usually occurs at fields a factor of 10 lower because microscopic non-uniformities (voids, dislocations, impurity atoms, etc.) cause local field concentrations. The reason that liquids (*e.g.*, oil) are generally used as insulators in high-voltage applications is that they are self-healing, but solids, in general, tend to have somewhat higher intrinsic breakdown fields. The most varied and interesting phenomena associated with breakdown occur in gases and are dealt with in the section *The conduction of electricity*, below.

Fields and potential distributions. *Solutions to Laplace's equation.* Given a definite charge distribution $\rho(\boldsymbol{r})$, the resulting potentials $\phi(\boldsymbol{R})$ and field $\boldsymbol{E}$ can be obtained directly from the relation

$$\phi(\boldsymbol{R}) = \int_V \frac{\rho(\boldsymbol{r})dV(\boldsymbol{r})}{4\pi\epsilon_0|\boldsymbol{R}-\boldsymbol{r}|}.$$

Electrostatic problems do not, however, usually take quite this simple form. More often a set of electrodes at definite potentials is given, and the potential near the electrodes is required; or both a set of electrodes and a specified set of charges are given. Although there are formal mathematical procedures for solving these problems, the techniques required are cumbersome and the results are involved. Instead, the results of a number of special problems are used to construct the desired solution of a new problem. Thus, much of the study of formal electrostatic problems consists of the laborious process of acquiring a series of known solutions; *e.g.*, solutions to Laplace's equation $\nabla^2\phi = 0$.

Method of images. A rather different method of solving electrostatic problems is the so-called method of images. It may be used, for example, where there is a point charge q at a distance $x = h$ above a conducting plane at zero potential, and it is necessary to find the potential at any point x in the region above the plane. This at first appears to be a difficult problem because the potential ϕ is zero in the plane where x is zero and thus $\nabla^2\phi = 0$ for $x > 0$, except at the point $(h,0,0)$, where the charge is located. If, however, an imaginary, or image, charge (denoted by $-q$) were placed at the same distance h *behind* the plane, this would mean that each point on the plane would be equidistant from q and $-q$ and the plane would be at zero potential as required. The potential at any position x,y,z—*i.e.*, $\phi(x,y,z)$—would then be

$$\phi(x, y, z) = \frac{q}{4\pi\epsilon_0}\left(\frac{1}{([x-h])^2+y^2+z^2)^{1/2}} - \frac{1}{([x+h^2])+y^2+z^2)^{1/2}}\right).$$

This equation satisfies the condition $\phi = 0$ on the plane; and for $x > 0$, $\nabla^2\phi = 0$, except at the point $(h,0,0,)$ where a detailed investigation shows that $\nabla^2\phi$ has a singularity corresponding to a charge q. Thus ϕ given by this expression is the solution that is sought. It is not valid below the plane where $\phi = 0$ simply because there is no real charge where x is equal to $-h$. A negative charge $(-q)$, however, actually resides on the surface of the plane.

This is the simplest of image problems, but similar techniques can be applied to more complicated situations and the image method is of considerable practical use.

Other methods. Two completely different techniques for solving electrostatic problems will now be considered, in which the fields are actually measured.

In a homogeneous conducting liquid the current density $(\boldsymbol{J})$ is related to the electric field $\boldsymbol{E} = -\nabla\phi$ by $\boldsymbol{J} = \sigma\boldsymbol{E}$, in which σ is the electrical conductivity of the liquid. The current density $\boldsymbol{J}$ satisfies the equation of charge conservation, $\nabla \cdot \boldsymbol{J} + \partial\rho/\partial t = 0$ ($\partial\rho/\partial t$ is the time rate of change of ρ), and, in a static situation, $\partial\rho/\partial t = 0$ so that $\nabla \cdot \boldsymbol{J} = 0$. Thus $\sigma\,\nabla \cdot \boldsymbol{E} = 0$ and $\nabla^2\phi = 0$. Further, if electrodes of much higher conductivity are inserted in the liquid they will provide equipotential surfaces. Thus the potential distribution in vacuum due to a set of electrodes held at potentials ϕ_1, ϕ_2, etc., can be found by immersing the whole electrode system in a liquid of low but finite conductivity (*e.g.*, saltwater) and picking up the potential point by using a wire probe insulated except at the point. This is known as the electrolytic trough method, and it and related methods are widely used, especially in

Electrolytic trough method

electron optics, to design electrode systems to produce a desired potential distribution.

A second method for determining an electric field is also based on the similarity between Laplace's equation and an equation that describes a different physical system—in this case, a uniformly stretched thin rubber sheet. This method is, however, applicable only to symmetrical systems in which ϕ is known to be independent of coordinate z so that the problem is essentially two-dimensional.

In a horizontal elastic sheet in uniform tension (T) the net downward force on an element of area $dx\,dy$ at a variable height h off the sheet is

$$T\left(\frac{\partial^2 h}{\partial x^2}+\frac{\partial^2 h}{\partial y^2}\right)dx\,dy.$$

If the sheet is to remain stationary this force must vanish. The transverse displacement h of the sheet thus satisfies Laplace's equation in two dimensions

$$\frac{\partial^2 h}{\partial x^2}+\frac{\partial^2 h}{\partial y^2}=0.$$

If the sheet is clamped in a horizontal frame and objects representing positive electrodes are pushed against it from underneath, they physically raise the sheet a distance proportional to their potentials, whereas objects representing negative electrodes push the sheet down; the contours of constant h on the sheet will be the equipotentials of the original problem. Further, if the positive and negative electrodes are interchanged with positive on top and negative below, a small ball rolled on the sheet will experience the same forces in the gravitational field as an electron moving in a corresponding electrostatic field. The rubber sheet model can therefore be used to investigate not only equipotentials but also electron trajectories in practical devices. Many vacuum devices, especially secondary emission multipliers, were originally designed in this way.

Electrostatic problems can be programmed for computer solution. The results so obtained, though possibly accurate, are seldom as useful in practical work or general theoretical work as either an approximate analytic solution in closed form or an analogue solution. Both analytic and analogue solutions give a "feel" for the nature of the problem that is lacking in a purely numerical solution.

III. Direct electrical currents

Although the study of electrostatics provides a basic conceptual structure on which to base the solution of electrical problems, it is, of itself and in practical terms, a relatively insignificant part of the whole subject of electricity.

BASIC PRINCIPLES

In electrostatics, charge, potential difference, or voltage, and current are defined and related to phenomena associated with forces acting on or in electrified bodies. Current is regarded as the rate of flow of charge associated with the motion of charged bodies, which may be generalized to include the flow of charge in conductors. Electrostatics is not concerned with processes that go on while charges are in motion, however, but only with the properties of the equilibrium charge configurations that result when the flow has ceased. The notion of potential is essentially described in terms of the work that would have to be done to produce this final equilibrium configuration by the mechanical transport of charge. When electric currents are dealt with, the electromotive forces (emf) that maintain the flow of charges are of much more concern than the potential concept. These electromotive forces are associated with the steady supply of energy to the system by external agencies; *e.g.*, batteries, electrostatic machines, thermocouples, and electromagnetic generators (dynamos). Most of the common laboratory sources of electromotive force are complex devices involving chemical reactions, rotating machinery, and so on. About the only feature they have in common is the existence of two conducting terminals across which the device maintains a potential difference even when current is drawn from the terminals. Because of this disparity it is sensible to try to relate the study of steady currents to electrostatic concepts by describing a possible, though impracticable, source of a steady electromotive force that involves only the simplest of electrostatic principles. Figure 9 shows a metal case in which a vertical

Sources of electromotive forces

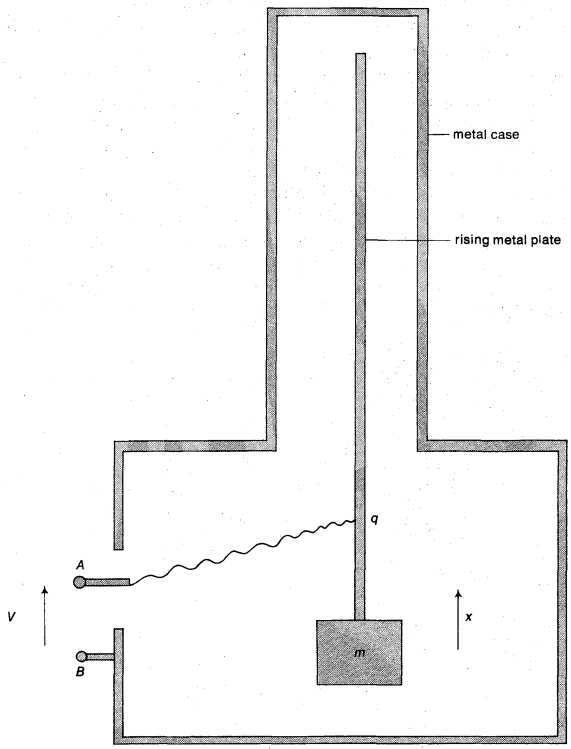

Figure 9: Electrostatic voltage source involving a movable charged plate inside a metal box or case (see text).

plate supporting a mass (m) moves freely in a vertical direction. The metallic case forms one terminal (B) of the device, and the other terminal (A) is connected by a flexible conducting lead to the movable plate. The capacitance C between the plate and the case can be expressed as $C=C_0+\gamma x$, in which C_0 and γ are constants and x is the height of the mass above some fixed reference point. If the movable plate carries a charge q, the electrostatic stored energy of the system is $\frac{1}{2}\frac{q^2}{C_0+\gamma x}$, and the mechanical stored energy is mgx. The total stored (*i.e.*, potential) energy is

$$U=mgx+\frac{1}{2}\frac{q^2}{C_0+\gamma x}.$$

According to the general laws of mechanics, the position of equilibrium of the plate (*i.e.*, the value of x) is the value that minimizes the potential energy, and is found by setting the differential dU/dx of the above equation for U equal to zero; so that

$$mg-\frac{1}{2}\frac{\gamma q^2}{(C_0+\gamma x)^2}=0.$$

Thus

$$C_0+\gamma x=q\left(\frac{\gamma}{2mg}\right)^{1/2}.$$

The potential difference between A and B is $\frac{q}{C_0+\gamma x}$, and if this is denoted by V, then, $V=\left(\frac{2mg}{\gamma}\right)^{1/2}$, which is independent of charge q. This device maintains a constant potential difference between A and B independent of q (until, of course, it is completely discharged

and the movable plate drops to the bottom of the case). When a current I is drawn from the terminals, the charge q decreases at a time rate dq/dt equal to $-I$ and the plate falls at a velocity (dx/dt), in which

$$\frac{dx}{dt} = -I\left(\frac{1}{2mg\gamma}\right)^{1/2}.$$

The mechanical potential energy decreases at a rate $mg(dx/dt)$, which is

$$mg\frac{dx}{dt} = -I\left(\frac{mg}{2\gamma}\right)^{1/2} = -\frac{1}{2}IV,$$

and at the same time the stored electrostatic energy decreases at a rate

$$\frac{1}{2}\frac{d}{dt}\left(\frac{q^2}{C_0 + \gamma x}\right) = \frac{1}{2}\frac{d}{dt}(qV) = \frac{1}{2}V\frac{dq}{dt} = -\frac{1}{2}IV.$$

Thus the total stored energy decreases at a rate $-IV$, and IV is the rate at which energy is delivered to whatever system is drawing current from the terminals.

This thoroughly impracticable device illustrates the basic property of a source of electromotive force. It has two terminals, A and B, across which it maintains a constant voltage or potential difference, and if current I is drawn from these terminals the device delivers energy at a rate IV.

Current measurement

Currents flowing in conductors can be measured by their magnetic or chemical effects, and in general it is found that (except in superconductors at low temperatures) if a current I flows in a conductor the potential V drops with distance along the conductor in the direction in which I is flowing. Thus if a voltage generator is connected to a load (a device that uses electrical energy) the potential difference V_L at the terminals of the load will be less than V_0 at the source. The power, defined as voltage times current, $V_L I$, delivered to the load will be less than the power $V_0 I$ delivered by the source. The difference in power $(V_0 - V_L)I$ has disappeared into the conductors. If the conductors are fixed material, such as wires, plates, or bars that cannot do external mechanical work by motion, the lost energy will be dissipated as heat. The rate of heat production (dH/dt) in the conductors is $dH/dt = I(V_0 - V_L)$, or

$$\frac{dH}{dt} = IV, \tag{31}$$

in which V represents the voltage drop $(V_0 - V)$ in the conductors.

For many conductors (*e.g.*, metals maintained at constant temperature) the voltage drop V is proportional to I. This is Ohm's law. It is written $V = RI$, in which the constant of proportionality, R, is the resistance of the conductor. Although few media other than metals obey Ohm's law exactly over appreciable ranges of I, nevertheless, the voltage drop is often almost linearly proportional to I. Inasmuch as $V = RI$, heat production as given by equation (31) can be expressed as $dH/dt = RI^2$, or, if preferred, as $dH/dt = V^2/R$.

In a conductor of uniform cross-sectional area A and length l, the resistance R of the conductor is found experimentally to be proportional to l and inversely proportional to A. The constant of proportionality, by convention written as ρ, is a property of the material known as its specific resistivity or just its resistivity. The resistance is $R = \rho l/A$. It is often convenient to describe a material in terms of its conductivity, $\sigma = 1/\rho$. In terms of σ this expression gives

$$R = \frac{l}{\sigma A}, \text{ or } G = \frac{1}{R} = \frac{\sigma A}{l}.$$

The quantity $G = 1/R$ is known as the conductance of the conductor.

In a conductor of cross section A carrying a current I the current density is $J = I/A$, and the voltage drop per unit length V/l gives the electric field E; therefore,

$$J = \frac{I}{A} = \frac{V}{RA} = \frac{V}{l}\frac{l}{RA} = \frac{V}{l}\sigma.$$

Thus $J = \sigma E$, or $E = \rho J$. This last statement can be generalized by considering filaments or tubes of current within a conductor parallel to the direction of current and expressed as a law in vector notation:

$$\boldsymbol{J} = \sigma \boldsymbol{E},$$

or

$$\boldsymbol{E} = \rho \boldsymbol{J}.$$

These equations are the most complete and general statement of Ohm's law. The general expression for the heat generated per unit volume then becomes

$$\frac{dH}{dt} = \boldsymbol{E} \cdot \boldsymbol{J} = \sigma E^2 = \rho J^2.$$

If a generator of electromotive force V_0 delivers current I and power $I V_0$, part of this power may be dissipated as ohmic (resistance) heating in a conductor, but part of it may be used to do mechanical work by causing the conductors to move against external forces (*e.g.*, the electric motor), part may be used to store energy in capacitors, or part may be used to store energy in chemical form (*e.g.*, electrolysis). Thus, in general, the power of a system is represented by

$$I V_0 = dH/dt + \sum_n (dW_n/dt),$$

in which $\sum_n (dW_n/dt)$ is the sum of all the various work and energy storage rates.

STEADY CURRENTS, MAGNETIC FIELDS, AND ELECTROMAGNETIC UNITS

Although, historically, magnetism (*q.v.*) developed independently and before the study of electricity as the science describing the behaviour of magnetized bodies, the laws relating magnetism to electricity are now regarded as the fundamental magnetic laws. Magnetized bodies stand in the same relation to these laws as polarized dielectrics to the fundamental laws of electrostatics. In these terms the most fundamental fact about magnetism is that conductors carrying electric currents in the vicinity of magnetized bodies or other conductors experience a force at right angles to the direction of current flow, being proportional to the current. This result is expressed in terms of a magnetic field acting on the current. The equation for the force (dF) acting on an element (dl) of a conductor carrying a current (I), when written in the form

Relation of magnetism to electric currents

$$d\boldsymbol{F} = I d\boldsymbol{l} \times \boldsymbol{B}, \tag{32}$$

serves as a definition of the magnetic field $(\boldsymbol{B})$ in much the same way as the expression $\boldsymbol{F} = q\boldsymbol{E}$ for the force acting on a charge q serves as a definition of the electrostatic field $\boldsymbol{E}$. The vector $\boldsymbol{B}$ will be referred to as the magnetic field, although some texts use magnetic induction for $\boldsymbol{B}$ and reserve the term field for a subsidiary magnetic vector $\boldsymbol{H}$.

In electrostatics the basic law that relates the field $\boldsymbol{E}(\boldsymbol{r})$ at $\boldsymbol{r}$ associated with a charge q at the origin is

$$\boldsymbol{E}(\boldsymbol{r}) = \frac{q\boldsymbol{r}}{4\pi\epsilon_0 r^3},$$

and this expresses the fact that $\boldsymbol{E}$ acts along the line joining the charge to the point $\boldsymbol{r}$ and obeys an inverse square law. The corresponding magnetic result is more complicated. In magnitude, the field also obeys an inverse square law; but in direction, the element $d\boldsymbol{B}(\boldsymbol{r})$ of magnetic field caused by a current I in a line element $d\boldsymbol{l}$ at the origin is at right angles to both $\boldsymbol{r}$ and $d\boldsymbol{l}$. Thus the basic law is

$$d\boldsymbol{B}(\boldsymbol{r}) = \mu_0 \frac{I d\boldsymbol{l} \times \boldsymbol{r}}{4\pi r^3}. \tag{33}$$

Furthermore, the law must be expressed in differential form because no real conductor carrying a current can be straight in entirety; eventually, the conductor has to form a closed loop.

If there are two complete circuits (1) and (2), equations (32) and (33) can be used to express the force $(\boldsymbol{F}_{12})$ acting between the two circuits as

$$F_{12} = \frac{\mu_0}{4\pi} I_1 I_2 \int_1 \int_2 \frac{dl_1 \times (dl_2 \times r_{12})}{r_{12}^3},$$

in which the line integrals run over both circuits and r_{12} is the vector distance from the element dl_1 to the element dl_2. Given the geometric specification of the circuits, the integral can be evaluated with arbitrary accuracy. If, by connecting the circuits in series, the same current I flows in both circuits, then

$$F_{12} = \frac{\mu_0}{4\pi} I^2 G, \tag{34}$$

in which G is a precisely known geometric factor. Equation (34) now forms the basis for the international system of electric units, because, given the constant of proportionality μ_0, a definite value for a current I can always be expressed in terms of the force it exerts. If F is expressed in newtons (one newton is the force required to give one kilogram an acceleration of one metre per second per second) and μ_0 is given the value $\mu_0 = \frac{4\pi}{10^7} = 4\pi \times 10^{-7}$, the corresponding unit of current is the ampere (A). The unit of charge is the coulomb (C), or ampere-second, and the unit of potential is the volt (V), defined so that one ampere flowing for one second across a potential difference of one volt corresponds to an energy of one joule (J). All systems of electromagnetic units are now based on these definitions, but, in the SI or mks system of units the constants μ_0 and ϵ_0 are retained in all the equations. In SI and mks units all electrical quantities are expressed in terms of amperes, coulombs, and volts and all mechanical units in terms of metres, kilograms, and seconds.

The international system of electrical units

Once the constant μ_0 has been defined, the quantity ϵ_0 that appears in electrostatic equations must be obtained by experiment. Direct measurements of electrostatic forces are too difficult and inaccurate to serve for this purpose; however, Maxwell's equations relate the velocity of light in vacuum c to μ_0 and ϵ_0 by

$$c = (\mu_0 \epsilon_0)^{-1/2}; \tag{35}$$

and, because c can be measured with great accuracy, ϵ_0 is taken to be defined by

$$\epsilon_0 = \frac{1}{\mu_0 c^2} = \frac{10^7}{4\pi c^2}.$$

It is clear from equation (35) that μ_0, or ϵ_0, or both, must have dimensions. The conventional choice of dimensions is such that μ_0 is expressed in kilogram-metre-second^{-2}-ampere^{-2} and ϵ_0 in kilogram^{-1}-metre^{-3}-second^4-ampere^2. This gives $(\mu_0\epsilon_0)^{-1/2}$ in metre-second^{-1}, the units of velocity. The most usual expression of these dimensions is through the subsidiary quantities used to measure self-inductance, the henry (H), and capacitance, the farad (F). In these units,

$$\mu_0 = 4\pi \times 10^{-7} \text{ henry metre}^{-1}$$

and

$$\epsilon_0 = \frac{10^7}{4\pi c^2} \text{ farad metre}^{-1}.$$

The farad is the capacitance that stores one coulomb with a potential difference of one volt. The henry, considered in more detail below, is the inductance of a coil that produces a back electromotive force of one volt when the current increases at a rate of one ampere per second.

These definitions give a self-consistent and absolute set of electromagnetic units. The commonest laboratory instrument for measuring electrical quantities, the moving coil meter, relates rather directly to these definitions, for it indicates the value of a current by the force exerted on a conductor in a standardized magnetic field B produced by a permanent magnet system.

In terms of a current density (J), the two magnetic laws can be expressed in a slightly more general form. In a region in which the field is (B), the magnetic force (f_m) acting per unit volume is equal to the vector product of current density and magnetic field,

$$f_m = J \times B,$$

and the field $dB(r_1)$ resulting from currents in a volume element $dV(r_2)$ at r_2 is

$$dB(r_1) = \mu_0 \frac{J(r_2) \times r_{12}}{4\pi r_{12}^3} dV(r_2), \tag{36}$$

with vector $r_{12} = r_1 - r_2$.

If the current density J is produced by a charge of density ρ in motion with a velocity v, then $J = \rho v$ and

$$f_m = \rho v \times B.$$

When this is applied to a volume element containing a charge q, the magnetic force on the moving charge is

$$F_m = qv \times B.$$

If an electric field E is also present, the total force (F) is equal to the sum

$$F = q(E + v \times B).$$

This is Lorentz' force equation, and it finds widespread application in discussing the motion of electrons. If in some region a particle continues in rectilinear (straight-line) motion or experiences no net force, then

Lorentz' force equation

$$E + v \times B = 0,$$

and E must be at right angles to v and B and of magnitude vB.

Just as the equation

$$E = \frac{qr}{4\pi\epsilon_0 r^3}$$

yields the two electrostatic field equations

$$\nabla \times E = 0$$

and

$$\nabla \cdot E = \rho/\epsilon_0,$$

so equation (36) yields two magnetic field equations,

$$\nabla \cdot B = 0$$

and

$$\nabla \times B = \mu_0 J.$$

The equation $\nabla \times E = 0$ applies only to static fields, and similarly the equation $\nabla \times B = \mu_0 J$ applies only to steady fields produced by steady currents. How these equations are modified in time-dependent situations will be explained below.

ELECTROMOTIVE FORCE

A key concept in dealing with the flow of currents in conductors is clearly the idea of an electromotive force that drives the current round the circuit against the frictional forces associated with resistance. This section treats some of the possible sources of electromotive force.

Electrostatic electromotive force. The section on *Basic principles*, above, presented one possible way in which an electrostatic system could be used to obtain a steady potential difference between two terminals. This system, though easy to analyze, is not a practical source of electromotive force. On the other hand, a continuously operating machine such as the Van de Graaff generator can obviously be regarded as a source of electromotive force. This machine can deliver a continuous current in a circuit connected between the lower charging electrodes and the high-voltage terminal as long as the charge on the high-voltage terminal is continuously replenished by charge from the belt. The electrical energy available in the circuit is derived from the mechanical energy expended in driving the belt. In practice, electrostatic sources of emf are not much used, as their operation tends to be somewhat erratic.

Piezoelectric electromotive force. If a piezoelectric (see below *Piezoelectricity*) crystal is equipped with metal electrodes and then strained, a potential difference develops between the electrodes. This device can be regarded as the source of an electromotive force; but it should be noted that a constant current can be drawn from the electrodes, thus keeping a constant potential difference, only if the strain is continuously increased. This procedure is clearly likely to have catastrophic consequences for the crystal. In general, piezoelectric systems

can be used to produce only alternating emf's as the result of oscillating strain.

Thermionic electromotive force. If a conductor is heated, the mobile electrons within the conductor eventually acquire enough thermal kinetic energy to escape from the conductor into vacuum. For most conductors, however, the temperature required to produce any appreciable thermionic emission of electrons is so high that the conductor would be vaporized. A few materials, notably tungsten and barium oxide, are copious emitters of electrons well below the temperature at which the material evaporates. A tungsten cathode heated to about 2,300° K essentially boils off electrons, and these electrons have appreciable kinetic energies. The average energy associated with motion directed away from the metal surface is kT, in which k, Boltzmann's constant, is 1.38×10^{-23} joule-degree^{-1}, and the average energy per electron for the temperature is about 3.2×10^{-20} joule. The charge on an electron being 1.6×10^{-19} coulomb, its energy can be expressed as 0.2 electron volts (eV; one eV is the energy acquired by an electron in moving through a potential difference of one volt). The electrons from the cathode therefore have enough kinetic energy to move against a potential gradient and reach an electrode negative with respect to the hot cathode by an appreciable fraction of a volt. A vacuum diode consisting of a hot filament and negative electrode therefore can be used as a source of emf, converting heat to electrical energy.

Thermoelectric electromotive force. The thermionic electromotive force described in the preceding section is really a thermoelectric emf, and similar effects occur when charge carriers can move from one medium to another at a different temperature. If two different metals are in contact at the same temperature, electrons cross freely from one metal to the other in both directions. If the potential energy of the electrons in one metal, A, happens to be lower than in the other, B, there will be a net transfer of electrons from B to A, and A will acquire a negative charge and potential relative to B until the potential energies in A and B are equalized. This phenomenon is known as contact potential. If a closed circuit consists of a succession of metals $A, B, C, \ldots X, Y, Z, A$, the sum of all the contact potential differences $AB, BC, CD, \ldots YZ, ZA$ is zero, and no net emf operates in the circuit. If, however, the temperature of one junction, say BC, is changed, this will change the contact potential at this junction because it will alter conditions inside B and C; and this will give a net emf that can drive a current around the circuit. Thermoelectric effects are discussed in more detail in the section below, *Contact potential and thermoelectricity*.

Photoelectric electromotive forces. When light or ultraviolet radiation falls on a material body, and especially on a conductor, all the energy $h\nu$ (h is Planck's universal constant) in each incident photon of frequency ν may be transferred to single electrons in the material. These electrons may then have more than enough energy to escape from the conductor, and if they happen to start off near the surface they may, in fact, do so before their energy has been dissipated in collisions. If the conductor is placed in vacuum there will be a current of electrons leaving its surface, and in many cases the electrons may have kinetic energies corresponding to several electron volts. They can therefore move against a potential gradient and reach a negative electrode.

The solar cell

It is also possible to produce a photoelectric effect at the junction between two dissimilar conductors. The solar cell uses a junction between two different semiconductors. In this case, relatively high energy conversion efficiencies from light to electrical energy can be achieved. Again these effects are considered in more detail in the section *The conduction of electricity* below.

Chemical electromotive force. The effects discussed in the above sections on *Direct electrical currents*, though interesting and occasionally useful, are not, with the possible exception of the solar cell, of much practical importance as sources of electromotive force. The two effects described in this and the next section (*i.e.*, chemical batteries and dynamos) are by contrast the main practical devices for producing sustained electromotive forces. The chemical reaction $2HCl + Zn \rightarrow H_2 + ZnCl_2$, hydrogen chloride plus zinc produces hydrogen plus zinc chloride, releases energy. The total energy of the materials on the right-hand side of the reaction is less than that on the left. Normally this energy would be released as heat, but, if the reaction occurs in aqueous solution, it proceeds through stages, some involving charged ions.

The emf available from chemical batteries rarely exceeds 2.5 volts. If n batteries of emf V_0, however, are connected in series (*i.e.*, positive and negative terminals are connected successively), the total emf is increased to nV_0. The batteries used in the laboratory, home, or automobile usually have from two to 100 unit cells connected in series.

Electromagnetic electromotive force. If a material body moves at right angles to a magnetic field $\boldsymbol{B}$ the charged particles (electrons and nuclei) in the body experience a force at right angles to both $\boldsymbol{B}$ and the velocity $\boldsymbol{v}$. If the body is an insulator the charges will not move far under the influence of this force because they are bound to each other and held tightly in position in the body. If, however, the body contains mobile charge and is a conductor, the force will cause a bulk movement of the charge that will continue until the separation of negative and positive charge sets up a field $\boldsymbol{E}$ opposing the magnetic force. The charges then move in a new configuration fixed in the body with the velocity of the body. According to Lorentz' force equation, the field $\boldsymbol{E}$ is given by $\boldsymbol{E} = -\boldsymbol{v} \times \boldsymbol{B}$. This result may be applied to a straight wire of length l, shown in Figure 10 moving

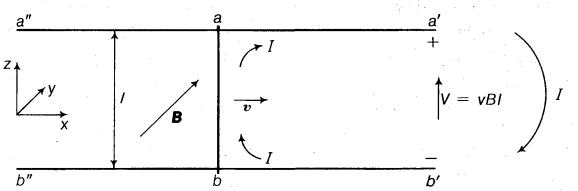

Figure 10: Generation of an electromagnetic emf. The wire ab moves along the rails $a''a'$ and $b''b'$ in the x-direction. The field $\boldsymbol{B}$ is directed into the page in the y-direction (see text).

in a field $\boldsymbol{B}$ that is directed along the y-axis (into the plane of the diagram). If the wire moves with velocity $\boldsymbol{v}$ in the xz plane parallel to the x-axis, then positive mobile charges will be driven by a force F_m toward a and negative charges toward b, and their presence sets up the field $\boldsymbol{E}$, having a magnitude vB and directed from a to b. Furthermore, if the moving wire is forced to slide along two stationary contact wires parallel to $\boldsymbol{v}$, as shown in Figure 10, then there will be a potential difference $V = El = vBl$ between the two wires. This difference can act as an electromotive force in a circuit connected between the terminal points a' and b'. If a current I flows in the external circuit, which therefore absorbs energy at a rate $IV = IvBl$, then the same current I can be said to flow also in the moving wire, and a force IBl will act on the wire in the direction opposite to $\boldsymbol{v}$. To continue in motion, the wire must be driven by an external force $\boldsymbol{F}$ of this magnitude (IBl) parallel to $\boldsymbol{v}$. The force does mechanical work on the system at a rate $\boldsymbol{F} \cdot \boldsymbol{v}$, which is equal to $IBlv = IV$. Thus the device converts mechanical energy to electrical energy. It is a simple dynamo.

The circuit of a simple dynamo

From Figure 10 it can be seen that the expression $V = vBl$ can be expressed as $-B(dA/dt)$, in which $-(dA/dt)$ is the rate at which the area (A) of the loop $b'\ b\ a\ a'\ b'$ is decreasing. This result can be generalized as follows: if there is a conducting loop in a steady magnetic field $\boldsymbol{B}$, and the configuration of the loop changes, either because the loop is rotating, being distorted, or simply translated as a rigid whole, and if the magnetic flux threading the area A of the loop is

$$\psi = \int_A B_n dS,$$

then the emf acting in the loop is

$$V = -\frac{d\psi}{dt}.$$

It is to be noted that the flux ψ can change either because the area of the loop normal to $\boldsymbol{B}$ is changing or because the loop is moving from one region to another where $\boldsymbol{B}$ has a different value. It should be noted also that this is *not* Faraday's law of electromagnetic induction: Faraday's law is concerned with the emf induced in a stationary loop by a changing magnetic field.

The equation $V = -(d\psi/dt)$ is useful in explaining the basic principle of a dynamo. A rectangular wire loop of area A can be imagined rotating with angular velocity ω about an axis perpendicular to the magnetic field $\boldsymbol{B}$. At any instant (t) the flux (ψ) linking the loop is $AB \cos \omega t$, and the emf available at the terminals of the loop is

$$V = -\frac{d\psi}{dt} = -\frac{\partial}{\partial t}(AB \cos \omega t) = \omega AB \sin \omega t.$$

If instead of a single loop there are n turns, the emf is

$$V = n\omega AB \sin \omega t.$$

(The value of sin ωt oscillates between $+1$ and -1.) This device therefore gives an alternating emf, and, by choosing n appropriately, the peak voltage can be raised to any reasonable amount.

Electromotive force and internal resistance. All practical generators of electromotive force involve real conductors of nonzero resistance. For example, in a battery the resistance to the flow of electric current is offered by both the chemical components of the cell (electrolyte) and the electrodes themselves. In a dynamo the windings have a finite resistance. As a result, when a current is drawn from a generator the electromotive force available at the actual physical terminals is equal to the difference between the emf when there is no load and the voltage drop in the internal resistance. The properties of a source of emf are specified in terms of (1) its output emf with no load (open-circuit voltage) and (2) its internal resistance. Thus, if these quantities are denoted by V_0 and R_i, the available emf when a current I is being drawn is $V_0 - IR_i$.

If a load attached to the terminals of a source of emf draws a current I, the power delivered to the load is $IV = I(V_0 - R_iI)$. This has a maximum value $V_0^2/4R_i$ when I is chosen to be $V_0/2R$. The available output power (P_{max}) of a generator is thus $P_{max} = V_0^2/4R_i$. The load that extracts this maximum power has $V/I = R_i$ and is thus equivalent to a resistance equal to the internal resistance of the generator. A typical dry cell used in a flashlight has V_0 equals 1.5 volts and $R_i \simeq \frac{1}{4}$ ohm; thus $P_{max} \simeq 2.25$ watts. As the cell ages, the value of R_i increases and usually reaches an unsatisfactorily high value before the value of V_0 has dropped appreciably. An open-circuit test of V_0 shows little about the state of a battery unless it is completely discharged.

DIRECT-CURRENT CIRCUITS

Ohm's law and the definition of resistance. Ohm's law states that the potential difference V across a conducting body is proportional to the current I flowing through the body; *i.e.*, $V = RI$. Though it is not an invariable law, it is true in enough cases to be useful. Because I has an absolute definition and is measured in an internationally maintained standard unit, whereas the product VI, being power (a mechanical quantity), leads to an equally absolute unit of V, it appears that the unit of R, the standard ohm, would be of little interest. This is not so. The measurement of electrical power with high enough accuracy for use in defining the standard volt is not practicable. The secondary electrical standard is instead the farad, and the standard ohm is obtained by comparing the impedance (see the section *Alternating electric currents*) of a standard capacitor for alternating current with a resistance. Because a resistance is physically easily reproduced whereas a standard capacitor, the capacitance of which can be calculated in geometric terms, is cumbersome and delicate, the ohm, so standardized, is in practice treated as the secondary standard. The volt is then defined as the potential difference across a standard ohm resistance carrying an absolute ampere. This standard is then used to calibrate a standard cell so that its open-circuit electromotive force becomes once removed from the secondary standard, a tertiary standard. Most laboratories base their electrical measurements on a standardized cell and a standard resistance, so that, in practice, currents are measured in terms of the potential difference they cause in a standard resistance. Absolute electrical measurements are undertaken at only a few national standards institutions such as the National Bureau of Standards in Washington, D.C., or the National Physical Laboratory in London. Instruments designed for normal laboratory use have an accuracy of much less than ten parts per million, which is expected of instruments in a standards institution (see CONSTANTS, PHYSICAL).

The standard ohm

The galvanometer, the ammeter, and voltmeter. Apart from a source of electromotive force, the next most important device needed in the experimental investigation of electrical currents is some sort of indicator of the presence of a current or a potential difference, and preferably one that gives a quantitative measure of current or potential difference. Although the device can be quite crude (*e.g.*, a lamp bulb) or can be a sophisticated digital electronic instrument, the commonest and most generally useful instrument is a moving coil galvanometer modified for use as either an ammeter or a voltmeter.

As its name implies, the moving coil galvanometer contains a coil that rotates on an axis that is perpendicular to a magnetic field, and it is the displacement of this coil against a mechanical restoring force, when a current flows through the coil, that indicates the presence, polarity, and strength of a current. The magnetic field is provided by a permanent magnet and is shaped so that the field acting on the coil is as nearly as possible the same for all positions of the coil. The magnet produces a radial magnetic field $\boldsymbol{B}$ in the air gap between the concave poles of a permanent magnet and a cylindrical soft iron core that is inside the coil. A rectangular coil is mounted so that it is free to pivot about the axis of this core, as shown in Figure 11. If the coil carries a current

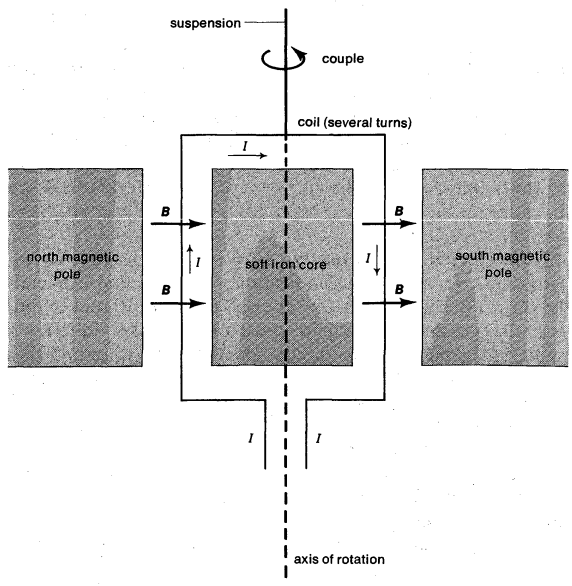

Figure 11: Galvanometer movement; coil with current I is suspended between two magnetic poles of field $\boldsymbol{B}$ (see text).

I in each of n turns, the forces acting on the two vertical sides of the coil produce a couple, which tends to turn the coil about the axis. The magnitude of the couple (Γ) is approximately given by $\Gamma = BAnI$, in which A is the area of the coil. In the most sensitive instruments the coil is suspended by conducting torsion fibres, which both act as current leads and produce a weak couple proportional to angular displacement to restore the coil to its rest position. In less sensitive and more robust instruments, the coil is mounted on pivots, and hair springs provide the restoring couple and act as leads. As long

as the magnetic field remains constant, the deflection is proportional to the current. In a well-designed instrument the deflection is linear with current to about one part in 1,000, and the instrument will maintain its absolute accuracy to a few parts in 1,000. The multimeters found in most laboratories usually have an overall accuracy of 1 or 2 percent. A sensitive torsion galvanometer will give a full-scale deflection for 10^{-8} ampere, but the most usual instruments have full-scale sensitivities of from 50×10^{-6}A to 10^{-2}A.

The ballistic galvanometer

The response of a galvanometer to transient current pulses depends critically on the moment of inertia of the coil and the damping of the motion caused by both the air and currents induced by the motion in the coil and its supporting frame. In the ballistic galvanometer these effects are used to produce an instrument having a maximum transient deflection proportional to the total charge in a current pulse. Today, transient currents are largely measured by electronic instruments.

The coil of a galvanometer necessarily has a finite resistance R_0 and so, if the deflection for a current I is kI, the coil deflection for an applied voltage V is kV/R_0. A galvanometer can be used as either an ammeter or a voltmeter if it will respond to the current or voltage it is to measure. Usually the resistance is small, and so most ammeters and voltmeters consist of a galvanometer with additional resistances.

For example, a galvanometer has an internal resistance R_0 and gives a full-scale deflection with a current I; then by connecting a suitable resistance R in series it will give a full-scale deflection with a voltage V provided $(R + R_0)I = V$. In a typical case, I is 50×10^{-6}A, R_0 is 500 ohms (symbolized by Ω), and if R is $(10^6 - 500)\Omega$ the meter will read full scale when V is 50V. In practice the accuracy of the meter is usually such that it will be adequate if $R = 10^6\Omega$, $\pm$ 0.5 percent.

To convert a galvanometer reading I full scale to an ammeter reading I_0 full scale, a resistance R is added in parallel. The current through R must be $I_0 - I$ and the potential difference across R is $R(I_0 - I)$, which must equal the potential difference, IR_0, across the meter. Thus $R = R_0I/(I_0 - I)$ is the correct value to use.

Standard ammeters and voltmeters of better than 1 percent accuracy are delicate and expensive instruments, and therefore it is often necessary to check the accuracy of a simpler instrument. The procedure using a potentiometer and a standard cell is outlined below under *The potentiometer*. The general theory of direct-current networks will now be developed.

Kirchhoff's laws and direct-current circuits. Kirchhoff's two circuit laws are essentially restatements of two basic electrostatic laws, the conservation of charge and the vanishing of any closed line integral of electric field. If in a complex circuit a number of conductors connected to the same point, or node, carry currents I_1, I_2, etc., toward the node, then charge (q) must be accumulating at the node at a rate (dq/dt) equal to the algebraic sum of the currents.

$$dq/dt = \sum_n I_n = I_1 + I_2 + I_3 + \text{, etc.}$$

But if the system is not changing with time, the potential at the node and the charge located at the node (if any) are constant. This gives the first of Kirchhoff's laws. In a direct-current circuit the sum of all the currents leading to a node is zero

$$\sum_n I_n = 0.$$

If any closed loop is taken in a complex circuit, the line integral of electric field round this loop must be zero.

The formula for the resistance total R of a set of resistances R_1, R_2, etc., in parallel (*i.e.*, a current branches into each resistance), $\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} +$ etc., can, of course, also be derived using Kirchhoff's laws. The idea of a voltage generator and a current generator can be obtained by imagining a circuit in which there is a complex source of electromotive force giving a voltage V across its terminals when the current in the external load R_L is I. Because the circuit equations that result from the application of Kirchhoff's laws are linear, V must be related to I by a linear equation $V = A + BI$, in which A and B are constant. If the load R_L is removed, V is the open-circuit voltage (V_{oc}) of the system; thus A is equal to V_{oc}. If R_L is replaced by a short circuit ($V = 0$) and I is the short-circuit current (I_{sc}), then the equation becomes $0 = V_{oc} + BI_{sc}$ and $B = -\frac{V_{oc}}{I_{sc}}$. The whole circuit can therefore be replaced by a generator of open-circuit voltage V_{oc} with an internal resistance R equal to V_{oc}/I_{sc}, called a voltage generator, and in which the resistance (R) is obtained experimentally by measuring V_{oc} and I_{sc}.

The notion of a voltage generator arises naturally from a consideration of the nature of physical sources of emf. An electrode in a vacuum tube collecting a beam of energetic electrons, however, is a different case. The current I in the external lead will be more or less independent of the electrode voltage. This leads to the concept of a current generator, which forces a current I through the external circuit across its terminals whatever the voltage across them. If the terminals are connected by a resistance R, the voltage developed is RI. An ideal current generator cannot actually exist and any current source must have some parallel leakage conductance (G) from one terminal to the other. Such a circuit is equivalent in every respect to having a voltage generator with open-circuit voltage $V = I/G$ and internal resistance $R = 1/G$. The available maximum power (P_{max}) from each network is

The current generator

$$P_{max} = \frac{1}{4}\frac{V^2}{R} = \frac{1}{4}\frac{I^2}{G}.$$

The direct application of Kirchhoff's laws to complex networks generally leads to a large number of simultaneous equations. Over the years a number of techniques for organizing the work and minimizing the number of equations have been developed. These techniques are not considered here, but it should be clear that the numerical solution of a large set of linear simultaneous equations is an ideal task for a digital computer. Most computer facilities have ready-made programs for just this task.

The potentiometer. If V is the potential difference between terminals E and G in Figure 12 (top), the potential difference between F and G is $V\frac{R_2}{R_1 + R_2}$; thus if V is known, voltages that are a known variable fraction of V can be produced by altering the values of R_1 and R_2. The circuit of Figure 12 (top) is the basic potentiometer circuit. The potentiometers used in radio as volume controls usually consist of a fixed resistor R with variable tapping point; *i.e.*, $R = R_1 + R_2$. Laboratory potentiometers can be constructed either with switched resistors or with a continuous variable tap on a slide wire. If the potentiometer is constructed with enough care, it is possible to measure the ratio of two voltages within an accuracy of a few parts per million. A typical potentiometer circuit used in the laboratory is shown in Figure 12 (bottom). A standard cell and a galvanometer (G_1) are connected across a fixed length (SS') of the slide wire, and the current (I) through the slide wire is varied using R until the galvanometer reads zero. The potential difference (V_S) between SS' is now equal to the standard cell electromotive force on no load. The unknown voltage (V) is then found by moving the slider (Y) until the galvanometer (G_2) reads zero. The source of V is now under no load, and V is obtained in terms of V_S by the ratio of the lengths XY and SS'; thus, $V = (XY/SS')V_S$.

To calibrate a voltmeter, the meter is placed across terminals PQ and, with an auxiliary circuit, the meter reading is set at, say, one volt and this is compared with the potentiometer reading. The potentiometer is a basic instrument in any electrical laboratory, and the foregoing method is useful for checking a meter whenever one is required to an accuracy of better than a few percent.

If the null reading galvanometer in a potentiometer cir-

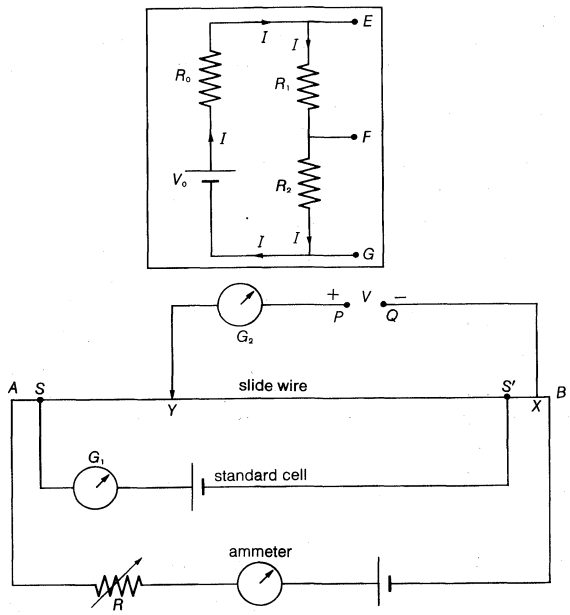

Figure 12: *Potentiometer.*
(Top) Schematic diagram; (bottom) potentiometer with a calibrated slide wire (see text).

cuit is replaced by an electronic amplifier, the output of this amplifier can be used to drive a servomotor that will automatically set the potentiometer tap at the null point. Self-nulling, direct-reading potentiometers are widely used in the laboratory. They are particularly convenient when a number of routine measurements have to be made.

The Wheatstone bridge. Figure 13 shows two potentiometers connected to form a Wheatstone bridge. The galvanometer reads zero when the ratio of resistances is such that

$$\frac{R_1}{R_2} = \frac{R_1'}{R_2'}.$$

If R_2 and the ratio R_1'/R_2' are known, this can be used to find the value of R_1. In one form of the instrument R_2 is a fixed resistance chosen to have a value near to R_1, and R_1' and R_2' are selected by switches or by plugging in fixed resistors. The Wheatstone bridge is a valuable instrument because its accuracy does not depend on the use of standard cells or even on having a steady source of electromotive force.

During the latter part of the 19th century a number of bridge circuits were designed for special applications. A typical example is the Kelvin double bridge used to compare two very low resistances. These special bridges are usually complicated to analyze and to operate, and their use has generally been replaced by simpler potentiometric methods. The simple Wheatstone bridge remains useful largely because it is cheap, easy to construct, and accurate enough for most laboratory purposes. In a section below a modification of this circuit is considered for use with alternating currents.

Kelvin double bridge

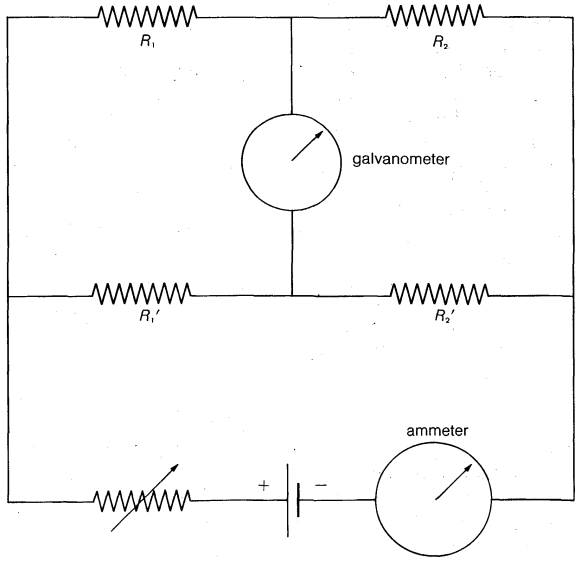

Figure 13: Wheatstone bridge (see text).

Nonlinear direct-current circuits. Only circuits in which Ohm's law is obeyed (*i.e.*, the potential difference across an element of a circuit is proportional to the current) have been dealt with so far. Many practical devices exhibit a more complicated behaviour. Most nonlinear devices are primarily of interest in connection with alternating currents and electronic circuits, but one familiar direct-current device, the electric lamp, displays such exceedingly nonlinear behaviour that it seems appropriate to end this section on direct-current circuits by considering the lamp's behaviour.

The common electric lamp bulb consists of a fine tungsten filament in an evacuated glass envelope. At the rated voltage, this filament will be at a temperature of some 2,800° C, and at this temperature the specific resistivity of tungsten is some 20 times its room temperature value. Thus if a standard 100-watt, 100-volt lamp, at 2,800° C carries one ampere, its resistance is 100 ohms (cold, its resistance is only five ohms). If, on the other hand, only 10 volts is applied to the lamp, the filament will barely heat up, the resistance will be slightly over five ohms, and the current will be greater than 0.1 ampere as it would be for a resistance of 100 ohms. Thus, if the current through the lamp is plotted against the applied voltage, the resulting curve will be nonlinear and bear little relation to Ohm's law.

A number of materials have specific resistivities that change rapidly with temperature, and these are frequently used to control or stabilize currents in, for example, electric motors. Although Ohm's law is so simple and so useful, it does not follow that it is obeyed by all media. Even if the temperature is held constant, the relation between I and V in some semiconductors, for example, is far from linear.

IV. The conduction of electricity

This section deals with electrical conduction in terms of the flow of charged particles and begins with a general treatment of the motion of charged particles in an electrical field. It then examines the principal types of electrical conductor, paying special attention to metals and semiconductors. In the two final sections of this part, other phenomena are considered (*e.g.*, thermoelectricity and photoelectricity) that are readily explicable in terms of the electron theory of conduction.

THE MOTION OF CHARGED PARTICLES IN AN ELECTRIC FIELD

If v is the velocity of a particle of mass m and charge q in an electrical field $\mathbf{E}$, the equation of motion is

$$m\frac{dv}{dt} = q\mathbf{E}.$$

The acceleration is parallel to the field, and, except in the presence of magnetic fields, there is little need to retain a three-dimensional vector description. For the time being, vector notation is omitted and it is assumed that E is parallel to the x-axis and all motion takes place in this direction. Thus the above equation becomes

$$m\frac{dv}{dt} = qE.$$

The three-dimensional equation $E = -\nabla\phi$ simplifies to $E = \frac{\partial\phi}{\partial x}$. Also, since $\frac{dv}{dt} = \frac{dv}{dx}\frac{dx}{dt} = v\frac{dv}{dx} = \frac{d}{dx}\left(\frac{1}{2}v^2\right)$,

the equation of motion can be written as

$$\frac{d}{dx}\left(\frac{1}{2}mv^2 + q\phi\right) = 0.$$

This is of course, a statement of the conservation of energy and gives

$$\frac{1}{2}mv^2 + q\phi = W_0,$$

in which W_0 is the total energy of the particle, a constant. These results are sufficient for an understanding of the behaviour of the motion of charged particles in vacuum. If, however, as in a metal, a gas discharge, or an electrolyte the particles of mass m move through a background of other particles they will be continually undergoing collisions, and this will obviously seriously affect the equations of motion. Some of these collisions will be violent and completely change the path and energy of the particle; others will be less violent and will result in only small changes; but both types of collision are likely to have sufficient effect to make it impossible to calculate the details of the motion of a simple particle. Instead, only the average motion of a large number of particles can be described. The general problem of setting up an approximate average equation of motion poses difficult and subtle questions in statistical mechanics which would be inappropriate to consider here. It is possible, however, to proceed in a more intuitive, and essentially correct, fashion as follows. The net effect of collisions is a change in the path of a particle and the average effect can be represented in terms of an average force F acting on the average particle. Thus the average equation of motion for the average velocity v becomes

Collision effects in the equation of motion

$$m\frac{dv}{dt} = qE + F.$$

It is reasonable to suppose that, as the average particle velocity increases, collisions will damp the motion and tend to limit the velocity. In other words, the effect of collisions is similar to friction. This effect could be represented by writing F as $-kv$, but it will be more convenient to write the relation as

$$F = -\frac{m}{\tau}v$$

so that the quantity τ has the dimensions of time. The equation of motion now becomes

$$\frac{dv}{dt} + \frac{v}{\tau} = \frac{q}{m}E.$$

If at time zero, the velocity equals zero, then the solution of this equation is

$$v = \frac{q\tau}{m}E(1 - e^{-t/\tau});$$

and as t increases v tends to a limiting value $(q/m)\tau E$. If τ is short this will happen almost instantaneously. If there are N charged particles per unit volume the current density is $J = Nqv$; and so

$$J = \frac{Nq^2\tau}{m}E.$$

Thus the current density J is proportional to E and the conductivity (σ) of the medium is

$$\sigma = \frac{Nq^2\tau}{m}. \qquad (37)$$

If, instead, $E = 0$, and at time $t = 0$ the velocity is v_0, then

$$v = v_0e^{-t/\tau};$$

so that τ can be interpreted as a relaxation time—*i.e.*, as the time it takes currents to decay from any specified value once the field has been turned off.

Instead of considering how the force F depends on velocity v it is possible to proceed in a different way. If the particles of mass m make collisions at a mean rate $1/\tau'$ per second so that τ' is the mean time between collisions and after each collision the velocity of the particle is reduced to zero, then between one collision at time $t = 0$ and the next, the velocity of the particle is qEt/m; and by the time it makes its collision at $t = \tau'$ it has travelled a distance $qE\tau'^2/2m$. Its mean velocity is

$$v = \frac{1}{2}\frac{q}{m}E\tau'; \qquad (38)$$

and, with N particles in unit volume, this gives a current density

$$J = Nqv = \frac{1}{2}\frac{Nq^2\tau'}{m}E$$

and a conductivity

$$\sigma = \frac{1}{2}\frac{Nq^2\tau'}{m}.$$

This equation will coincide with (37) if the mean collision time τ' is twice the relaxation time τ.

In most cases the particles have in addition to their mean drifting velocity v a random spread of velocities caused by thermal energy, etc.; and, in the case of electrons in metals, ions in an electrolyte, or electrons and ions in a high-pressure gas discharge, the random velocities are usually much bigger than the drift velocity. Thus, if the particles with which the drifting charged particles collide are on an average a distance l apart, it is plausible that τ', the collision time, should be of the order of l/u, in which u is the mean random velocity. This interval of time is not quite correct because the drifting charged particles do not necessarily collide violently with every particle that they encounter. This discrepancy can be accounted for by attributing to the particles a collision cross section s, such that, if particles coming within a distance r of each other undergo a violent collision, $s = \pi r^2$. If there are ν target particles per unit volume, a drifting particle makes, on the average, νs collisions per unit length of path. The mean free path (λ) between collisions is $\lambda = 1/\nu s$, and is inversely proportional to the density of target particles or collision centres.

Collision cross sections

The average charged particle drifts with a mean velocity given by equation (38), but now $\tau' = \lambda/u$, and so

$$\sigma = \frac{Nq^2\lambda}{2mu}.$$

Therefore, if the mean free path is relatively constant, σ decreases with increasing u, and, because the random velocity is expected to increase with temperature, σ will decrease with temperature. This expectation is, on the whole, fulfilled in metals, but in other cases the variation of N or λ with temperature is more important.

The treatment given above is, in all essentials, the standard approach used in understanding electrical conduction. It relates the bulk motion of the charge carriers to parameters such as N, q, m^* (effective mass), u, τ, τ', and λ, which might reasonably be expected to be characteristic of the medium and the charge carriers. A quantum mechanical approach makes little difference to the overall picture, but it does relate the parameters listed above to other, perhaps more fundamental, features of the structure of the medium.

In some cases (*e.g.*, conduction in an ionized gas) the simple picture thus developed is inadequate. The processes that go on are now too complicated to be described solely in terms of drift velocities, mean free paths, and the like. Almost equally complex phenomena can also occur in semiconductors, although fortunately most of the important practical applications of semiconductors involve relatively simple conduction processes.

The theory given above expresses the electrical conductivity in a form that may be written as

$$\sigma = Nq\mu,$$

in which N is the number of carriers of charge q per unit volume and μ would be the average velocity acquired by a carrier in unit field. The quantity μ is usually referred to as the mobility of the carriers and is much used in dealing with all types of conducting media, especially with semiconductors.

CONDUCTION IN VACUUM

A current can flow between two electrodes in vacuum only when at least one of the electrodes emits charged particles. Although radioactive materials may emit posi-

trons (positive electrons) or α-particles (positively charged helium nuclei) the emission expressed as a current is negligible (one curie yields about 5×10^{-9} ampere) and the only important cases are photoelectric, thermionic, or field emission of electrons. Because electrons have a negative charge, current will flow only when the emitter is the cathode (*i.e.*, negative electrode). If the rate of emission of electrons is small and the anode, or positive electrode, is at a high positive potential and near the cathode, all the emitted electrons will be collected by the anode and the current will be controlled by the rate of emission. If the emission is caused by the photoelectric effect the current will depend on the light intensity, whereas if the emission is thermionic it will be controlled by the cathode temperature. A diode operating because of thermal emission is said to be temperature limited when the current is controlled by the cathode temperature. Field emission can occur only when there is a strong field, usually in excess of 10^6 volts per metre at the cathode surface. In this case the emission depends critically on the field and is controlled by the anode potential. Neither photoelectric emission nor field emission usually leads to appreciable charge densities or space charge in the vacuum space between the electrodes. In the photoelectric case, this is because the emission current is usually small; in the field emission case, it is because the field required to cause emission sweeps the electrons rapidly away from the cathode toward the anode. The case is quite different with a thermionic cathode. If the cathode temperature is high enough, the emission can easily exceed 10^4 ampere per square metre (one ampere per square centimetre), and, if the anode to cathode potential difference is not too large, an appreciable negative electronic space charge can accumulate between the cathode and the anode. Because the space charge is negative it reduces the field at the cathode surface, and eventually the field drops to zero.

Dependence of field emission on field

Any additional electrons emitted by the cathode are then returned to the cathode, and the total current is controlled by the space charge. The diode is said to be space-charge limited. This is the usual case in practical devices such as the thermionic diode or triode. It is possible to calculate the maximum current that can flow between a plane cathode of area A with a plane anode at a positive potential V in front of the cathode and a distance d away from it. If d is much less than the transverse dimensions of the system, edge effects can be neglected and the problem is essentially one-dimensional. At a point at a distance x from the cathode, where the potential is ϕ, the velocity of the electrons is obtained from $\frac{1}{2}mv^2 = e\phi$ as $v = (2e\phi/m)^{1/2}$; and so, if the current density is J, the space charge is

$$\rho = -\frac{J}{v} = -\frac{J}{\left(\frac{2e\phi}{m}\right)^{1/2}}.$$

The potential (ϕ) satisfies Poisson's equation $\nabla^2\phi = -\rho/\epsilon_0$, and in one dimension this becomes

$$\frac{\partial^2\phi}{\partial x^2} = -\rho/\epsilon_0 = \frac{J}{\epsilon_0\left(\frac{2e\phi}{m}\right)^{1/2}}.$$

The desired solution of this equation gives $\phi = 0$ at the cathode surface, where $x = 0$, and also gives

$$\frac{\partial\phi}{\partial x} = -E = 0 \text{ at } x = 0$$

because the limiting current flows when the field E at the cathode surface is zero. It may be verified that the correct solution is

$$\phi = \left(\frac{9J}{4\epsilon_0\left[\frac{2e}{m}\right]^{1/2}}\right)^{2/3} x^{4/3}.$$

The potential, instead of increasing linearly with x, as it would do in the absence of space charge, increases as $x^{4/3}$. At x equal to d, however, the potential $\phi = V$. The resulting equation determines the limiting value of the current density as

$$J = \frac{4\epsilon_0\left(\frac{2e}{m}\right)^{1/2}}{9}\frac{V^{3/2}}{d^2}, \tag{39}$$

and so the total current is

$$I = AJ = 2.33 \times 10^{-6} V^{3/2}\frac{A}{d^2}$$

ampere, in which the numerical values of ϵ_0, e, and m have been used. This result, known as Child's law, states that the current I is proportional to the 3/2 power of the anode-to-cathode potential difference V. For example, if $A = 1$ square centimetre and $d = 1$ millimetre so that $A/d^2 = 10^2$, and if $V = 100$ volts, then $I = 0.233$ ampere (233 milliamperes). The 3/2 power law is not restricted to plane diodes but is a general result.

Child's law

This treatment has been idealized in one respect because it ignores the thermal energy of the electrons emitted from a hot cathode. If the cathode temperature is 1,000° K, the electrons will be emitted with a mean kinetic energy directed away from the cathode of the order of 1/10 electron volt. This additional electron energy does not make an appreciable difference to the result if the anode voltage exceeds about one volt, but at lower voltages the current is somewhat greater than predicted by equation (39). The effects of the initial thermal velocities are of significance mainly in determining the fluctuations or noise in the electron current. The transverse components of the thermal velocities also limit the maximum current density of an electron beam that can be focussed on the screen of a cathode-ray tube.

The current that flows between two electrodes in vacuum is transported by electrons, and it is of interest to consider the current that flows in the external circuit connected to the electrodes while the electrons are in transit in the vacuum space. Two electrodes, one at zero potential and the other maintained by a battery at a potential V, will produce a field $\boldsymbol{E}$ in the space between the electrodes; and, if there is an electron of charge $q = -e$ in the space with a velocity v, the field will do work on it at a rate $q\boldsymbol{E} \cdot \boldsymbol{v}$. This work must be done by the battery, and so the current I in the battery lead, while the electron is in transit, satisfies the equation $VI = q\boldsymbol{v} \cdot \boldsymbol{E}$, or $I = (q/V)\boldsymbol{v} \cdot \boldsymbol{E}$. If an electron starts at the zero potential electrode and proceeds to the positive electrode, charge will flow in the external circuit only while the electrons are in transit and not at the instant when they leave the cathode or the instant when they arrive at the anode. If, for example, the cathode and anode are one centimetre apart and the potential difference is 25 volts, the time of flight is approximately 10^{-8} second and the transit of each electron produces a pulse lasting 10^{-8} second (10 nanoseconds) in the external circuit.

This result is of fundamental importance in any consideration of high-frequency effects in thermionic devices, but it also has applications to semiconductor devices. Exactly the same argument applies to the currents in the external leads attached to a p–n junction diode and leads to the conclusion that the external current flows only while electrons (or holes) are in transit across the depletion layer at the junction.

In some systems (*e.g.*, a cathode-ray tube or an electron microscope) there is less interest in the current than there is in the trajectories of the electrons. Electron optics, or the study of electron trajectories, is a highly developed subject with an extensive literature and is dealt with in the articles ELECTRON; ELECTRON TUBE; MAGNETISM; PHOTOELECTRIC EFFECT; TELEVISION; and THERMIONIC DEVICES.

CONDUCTION IN GASES

Two essentially different types of electrical discharge in a gas can be distinguished: self-sustaining discharges in which, once the discharge has been initiated, enough electrons and ions are generated in the discharge to keep it going; and non-self-sustaining discharges in which the

electrons or ions must be continuously introduced from outside. The space-charge limited diode mentioned in the section above is a typical non-self-sustaining discharge. A somewhat more complicated type of non-self-sustaining discharge occurs in an electron tube having a hot emitting cathode and containing gas at low pressure.

At low anode-to-cathode voltages the current is reduced by collisions in the gas, which slow down the electrons and increase the space charge for a given current. As the anode voltage is increased, however, electrons eventually acquire enough kinetic energy to ionize gas atoms on impact. This ionization increases the number of electrons available and also forms positive ions that tend to neutralize the electronic space charge. Ions do this rather effectively because they have much larger mass and therefore move more slowly than electrons. At this stage, the current begins to increase rapidly with voltage. A condition is eventually reached in which the electronic space charge is almost entirely neutralized throughout the space between the cathode and anode, except near to the cathode where (1) the electrons are moving rather slowly and (2) the ions are being swept toward the cathode. If the voltage is increased still further, the current rises enormously and the number of collisions is so high that atoms can be ionized by multiple electronic collisions. At this time it is no longer necessary for the electrons to acquire enough kinetic energy to produce ions in a single collision. Thus, once this low-voltage arc phase has been initiated, the applied voltage can be reduced without putting out the discharge. The effect is used in the mercury-vapour thermionic rectifier, because it allows high currents of many amperes to flow even when the anode-to-cathode voltage is only 10 volts or so. Somewhat similar effects also occur in the mercury and tungsten arc lamps, the carbon arc, and the mercury pool rectifier. In these cases the electrons are supplied, either by thermionic emission from the electrodes heated by the energy dissipated in the arc or by field emission (see above) caused by the high potential gradients that can occur at the cathode surface.

The Townsend discharge

The simplest self-sustaining discharge is probably the Townsend discharge in a gas between two parallel metal plates. This is a low-current (a few microamperes) discharge at moderately high voltage in a gas at reduced pressure. Before this discharge is treated, a general remark about the stability of gas discharges is needed. In almost every case the voltage required to initiate a discharge is higher than the voltage needed to sustain it, and, in addition, the sustaining voltage decreases with increasing current. Thus to observe the Townsend discharge the current must be limited by a resistance (R) in series with the discharge tube.

In the Townsend discharge the primary ionizing event is accidental and attributable to stray X-rays, cosmic rays, and so on. The electron-ion pair formed in this event is pulled apart by the field, and the electron, colliding with gas molecules, then produces further ions and electrons. The number of pairs formed in this avalanche depends on the voltage and the pressure of the gas. The higher the voltage, the more energy the electrons pick up between collisions and the greater the ionization; on the other hand, the higher the pressure, the greater the number of atoms per unit volume, and as a result collisions are more frequent and the electron picks up less energy between collisions. If this were the only process then, once the avalanche was over, the discharge would go out; however, the ions formed in the discharge will hit the cathode and release further electrons. If the ions formed in a single avalanche release on the average more than one electron the discharge is self-sustaining.

In elastic collisions between electrons of mass m and atoms or ions of mass M approximately equal to $10^4\ m$, the average energy loss of the electrons per collision is the small fraction $2m/M$ approximately equal to 2×10^{-4}. Electrons formed at the cathode therefore drift toward the anode, acquiring energy from the field and losing little energy in collisions until they have enough energy, 10–20 electron volts, to excite or ionize atoms. The excited atoms emit light as they lose energy, and a luminous layer thus forms at a short distance from the cathode. The electrons lose most of their kinetic energy in this layer by inelastic collisions and then drift on toward the anode until again they have enough energy to excite atoms and another layer forms. These so-called Holst and Oosterhuis layers extend from the cathode to the anode.

At low currents, space charge is negligible; but if the external resistance (R) is reduced, allowing the current to increase from a few microamperes to a few milliamperes, space charge begins to be significant and, as in the thermionic arc, the potential drop in the discharge begins to concentrate in the region near the cathode. This phenomenon is called a glow discharge (see Figure 14). Electrons in a region near the cathode (the Crookes dark space) pick up energy from the field until they can excite and ionize atoms and form a luminous layer, the negative glow. By contrast with the Townsend discharge, there is sufficient ionization in this region to supply a neutral plasma (of electrons and ions of low velocity) to fill the tube out to the anode. The Holst and Oosterhuis layers disappear and, beyond the negative glow, there is a dark space extending out to the anode.

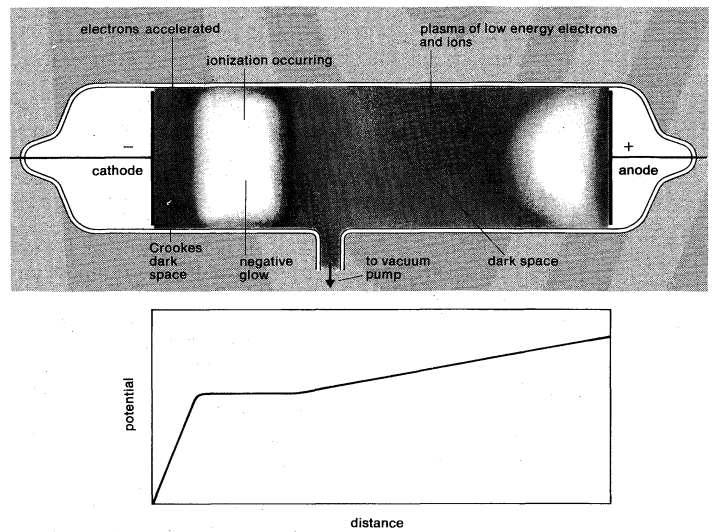

Figure 14: Conditions in a moderately intense discharge (see text).

The positive column

If the anode is moved farther away from the cathode, a new luminous region, the positive column, forms in front of the anode. In this region the electric field is small, but, if the field acts over a long enough distance, it can give electrons sufficient kinetic energy to ionize and excite atoms and produce a luminous region. Additional electrons and ions formed in the positive column are lost from the surface of the discharge to the walls of the vessel where they recombine.

The discharge configuration described above is stable only for a particular current density, determined by the nature of the gas, its pressure, and the configuration and material of the electrodes. Thus, variation of the current leads to a change in the area of the electrodes covered by the discharge and not to a change in current density and potential distribution. The voltage across the tube is almost independent of current as long as the whole cathode is not covered. This property of the glow discharge is important in the voltage stabilizing tubes used in electronics.

Once the current has reached a point at which the entire cathode is covered by the discharge, any further increase in current must result in a change in the potential distribution in the discharge. The field near the cathode increases, and, eventually, positive ions in this region acquire enough energy to excite atoms near the cathode surface. A luminous region then appears at the cathode surface. If a hole is made in the cathode the ions passing through the hole (canal rays) cause the cathode glow to extend behind the cathode.

As the current is further increased and the cathode fall in potential increases, ionization caused by positive ion collisions becomes significant; also the impact of energetic ions on the cathode may eject not only electrons but even atoms of the cathode material. This latter behaviour is known as sputtering. The ejected atoms themselves become ionized, and the cathode glow contains spectral lines characteristic of the cathode material rather than just the gas. Finally, as the current increases still further, the heating of the cathode from ion bombardment leads to thermionic emission, and the discharge takes, more and more, the form of an arc. The voltage across the electrodes collapses to a low value and eventually gives a typical low-voltage arc.

The form taken by the discharge in any particular practical case depends on the nature of the gas and the electrodes, the applied voltage, and the current density. It also depends on the pressure of the gas. Temperature does not of itself have much direct effect, except insofar as it alters the gas pressure and possibly facilitates thermionic emission. The effects of changes in pressure are rather more dramatic. At low currents, and therefore in the initiation of a discharge, the primary controlling parameter is the energy picked up by electrons between collisions, compared to the ionization potential ϕ_i of the gas. The ratio $E\lambda/\phi_i$, in which E is the electric field and λ the free path of electrons, is an important dimensionless parameter (a quantity without units). Because λ is inversely proportional to pressure (p), the ratio E/p is roughly constant. If, for a given electrode spacing, the gas pressure is doubled, the breakdown voltage more or less doubles. At high pressures in high fields, however, once the discharge has started, the energy density is much higher and the discharge tends to be altogether more violent. Simple and easily controlled discharges are, on the whole, confined to gases at pressures well below atmospheric.

The study of gas discharges is an important and flourishing branch of modern physics and generally considered under the heading of plasma physics. The reader will find relevant material in the articles on LIGHTING AND LIGHTING DEVICES; LIGHTNING; ELECTRON TUBE; THERMIONIC DEVICES; LASER AND MASER; and PLASMA STATE.

ELECTROLYTIC CONDUCTION

Apart from liquid metals, a few other pure liquids, notably molten salts, also conduct electricity. The flow is usually accompanied by chemical change. The most important case of this type of conduction, however, occurs in aqueous solutions. The purest water has a rather low electrical conductivity, about 10^{-4} mho per metre (reciprocal ohms per metre). Thus conductivity may be compared with metals for which a typical value is 10^7 to 10^8 mho per metre. The flow of electricity in water is usually accompanied by the evolution of hydrogen at the negative terminal and oxygen at the positive terminal. The addition of a salt such as potassium chloride increases the conductivity; thus, a normal solution (74.6 grams per litre) has a conductivity of 10 mho per metre.

Range of conductivity in materials

Electrolytic conduction is due to the motion of charged ions; *e.g.*, a hydrogen ion (H^+) or bare hydrogen nucleus, a positively charged potassium ion (K^+), a neutral potassium atom that has lost its single valence electron, a negatively charged chlorine ion (Cl^-), an atom with an extra valence electron, or a complex ion such as the phosphate ion (PO_4^{3-}). The conductivity is small for a number of reasons. First of all, the ionic concentration is small, usually less than 10^{20} per cubic centimetre, compared with the electron concentration in metals, about 10^{23} per cubic centimetre. Second, the ions move through a disordered background, with which they interact strongly, thus slowing down the drift of ionic charge. Third, the ions are massive compared with electrons and so do not acquire much velocity from the field between collisions.

The chemical aspects of electrolysis are treated in the articles on ELECTROCHEMICAL REACTIONS and ELECTROPLATING. The articles on LIQUID STATE and SOLUTIONS AND SOLUBILITY are relevant. This article concentrates on the basic features of the conduction process.

The atoms in an isolated water (H_2O) molecule are held together by electrostatic forces. The energy of the molecule is less than that of two hydrogen (H) atoms and one oxygen (O) atom because in the molecule the two valence electrons of the H atoms and the six valence electrons of the O atom can share the attractive potential of three positive nuclei. Repulsion between the nuclei and between the electrons, and quantum mechanical dynamic effects, somewhat reduces the binding energy and also determines the (triangular) shape of the molecule. The binding energy is so large that, in water vapour, hardly any molecules are thermally dissociated at normal temperatures.

The work required to remove a positive ion from a water molecule to produce H^+ and OH^- ions is of the order of $e^2/4\pi\epsilon_0 r$, in which r is a typical linear dimension of the water molecule. If r is taken to be 2Å (2×10^{-10} metre), the energy (W) is about five electron volts (5 eV) and the probability, $e^{-W/kT}$ ($k \simeq 10^{-4}$eV per degree is Boltzmann's constant), that a molecule will be dissociated at a temperature T is negligible. At 127° C, or 400° K, the probability is about e^{-120}, or 10^{-50}.

The work required in liquid water is entirely different. Once the hydrogen ion has been removed a small distance, it is in a medium with a high dielectric constant, $\epsilon = 80$, and the work required to remove it completely is reduced by a factor related to $1/\epsilon$. In fact, in pure water at room temperature, roughly one molecule in 10^9 dissociates; thus the work W must have been reduced to about 0.5 electron volt by dielectric effects.

In a potassium chloride crystal the potassium atoms are already present as K^+ ions and the chlorine atoms as Cl^- ions. The energy required to extract an electron from a potassium atom and attach it to a chlorine atom is positive, but it is more than counterbalanced by the strong attraction between the resulting ions in the crystal lattice. When potassium chloride (KCl) is dissolved in water, the attractive force between the ions is reduced, because of the high dielectric constant of water, and the salt goes into solution as free K^+ and Cl^- ions. In general, ionic crystals dissolve appreciably only in solvents of high dielectric constant, which means that usually the solvent molecules themselves have intrinsic, permanent, electric dipole moments and for this reason are classified as polar solvents.

Conduction with free ions in solution

With free ions in solution, the mechanism of conduction is obvious. In an electric field, positive ions drift toward the negative electrode and negative ions toward the positive electrode. Both processes conduct electricity from the positive to the negative electrode. It may happen that one ion has a higher mobility than the other, and in this case charge transport can be ascribed predominantly to the more mobile ion. This is especially the case when H^+ ions, which have some six times the mobility of the other common ions, are present.

As a conduction process, electrolytic conduction is rather uninteresting. There are no spectacular or even useful associated phenomena. Its importance is almost wholly in the realms of chemistry and biology. It does, however, have a profound historical significance for the physicist. J.J. Thomson's discovery of the electron really began with Faraday's discovery that, in electrolysis, the charge required to release one gram atom of a substance is always a small integral multiple of a basic unit. As atomic theory developed, this led to the obvious conclusion that electric charge itself might have a discrete structure.

CONDUCTION IN METALS

This section gives the classical theory of metallic conduction; it is followed by a look at how the theory is modified by quantum mechanics (see METALS, THEORY OF).

The classical theory of metallic conduction. There are two fundamental characteristics of metals. First, all metals have similar, and high, values of electrical conductivity, σ, in the range 10^6 to 10^8 ohm^{-1} (or mho) per metre; second, metals tend to occur in groups in the periodic table, toward the left of the table, where there

are relatively easily detached valence electrons. The first characteristic suggests that the mechanism of conduction is the same in all metals; the second suggests that the charge carriers are detached valence electrons. The classical theory of conduction is based on this hypothesis, and, because it leads to reasonable agreement with experiment, it is believed to be essentially correct.

The periodic potential

The classical model of a metal assumes that a cloud, or atmosphere, of mobile electrons moves against a background provided by the ionic cores of the atoms. These are arranged on a more or less rigid and regular crystal lattice. As the electrons move through the metal, they move through a periodic electric potential produced by the ions. In the classical theory the effects of this periodic potential are neglected and the electrons are regarded as moving in a region of constant positive (with respect to the outside world) potential. This potential, denoted by ϕ, binds the electrons in the metal. The work (W) required to move an electron from the influences of the lattice is the product of the electron charge (e) and the potential, or $e\phi$. Thus W is the work function of the metal expressed in electron volts. In quantum mechanics the periodic potential is dealt with more carefully. It is pointless to do so in classical theory, because if a more accurate theory is required it must include quantum effects as well. Despite this drawback, classical theory nonetheless gives a useful understanding of the basic processes of conduction.

It is reasonable to suppose that the number of mobile electrons contributed by each metal is, on average, about one. Each electron removed from a metal atom leaves it with an additional positive ionic charge e. Thus, even though aluminum (Al) has three valence electrons, it would be unlikely, on the classical model, that all three electrons would be released from each ion. For most metals the gram molar volume is between six and 25 cubic centimetres. Thus the number (N) of electrons, on the basis of one electron per atom and Avogadro's number (6×10^{23} molecules per gram mole), is of the order of 10^{22} to 10^{23} per cubic centimetre, or $N \simeq 10^{28}$ to 10^{29} per cubic metre. In a section above (see equation [37]) the conductivity was expressed as (setting $q = e$)

$$\sigma = N\frac{e^2\tau}{m}. \tag{40}$$

If $\sigma \simeq 10^7$ mho per metre and the numerical values of e and m are inserted, the result is $\tau \simeq 10^{-14}$ second. Because this time is so short, it is easy to understand why transient effects are not observed in metals as the electrons get moving. They reach their terminal drift velocity almost immediately.

If v is the drift velocity of the electrons, the current density is $J = Nqv = -Nev$. If J has the rather high value of 1,000 amperes per square centimetre, or 10^7 amperes per square metre, the numerical values of N and e give a velocity of one centimetre per second. Thus, at all usual current densities the drift velocity of electrons in a metal is small, at most a few centimetres per second.

The electrons in a metal are in thermal equilibrium, and classical kinetic theory predicts that their mean kinetic energy (in one dimension) would be $\frac{1}{2}mu^2 = \frac{1}{2}kT$, in which u is the average speed. If the temperature equals 300° K (27° C), then with the numerical values of m and k (Boltzmann's constant) the result is $u \simeq 10^5$ metres per second, which is much greater than any possible drift velocity. Because the relaxation time (τ) obtained from equation (40) is, to within a factor 2, the mean time between collisions, the mean free path (λ) between collisions is proportional to ut and approximately equal to 10^{-9} metre. In addition, if there are 2.7×10^{28} atoms per cubic metre, the separation of the atoms is

$$(2.7 \times 10^{28})^{-1/3} = \tfrac{1}{3} \times 10^{-9} \text{ metre}.$$

Thus the electrons on an average get past about three atoms before they make a collision. This figure is not unreasonable, although it should not be taken too seriously, for if the temperature of copper is lowered from room temperature (300° K) to liquid helium temperature (4° K), its conductivity increases roughly 1,000 times. At 4° K electrons make a collision only after passing several hundred atoms.

The Hall effect

If a magnetic field (B) is applied to a metal carrying a current density J at right angles to B, so that (by convention) the electrons are moving with a velocity v in the direction of $-J$, there will be a force at right angles to both v and B given by $-ev \times B$ acting on the electrons. This will deflect the electrons until enough charge has accumulated to set up an electric field $E = -v \times B$, which cancels the effect of B. Thus, if a metal bar carries current normal to B, there will be an electromotive force between points on opposite sides of the bar. This phenomenon, known as the Hall effect, is named for a U.S. physicist, Edwin Herbert Hall, who discovered it. For conduction by electrons with a charge $-e$ the Hall coefficient (R_H) in the expression

$$E = -R_H(J \times B) \tag{41}$$

is seen to be

$$R_H = -\frac{1}{Ne}. \tag{42}$$

For the alkali metals and copper and silver the value of R_H obtained experimentally is negative and the value of N deduced from (42) corresponds to one mobile electron per atom. In other cases (*e.g.*, zinc and cadmium) the numerical agreement is reasonable but R_H has the wrong sign. This anomalous Hall effect can only be explained quantum mechanically. Metals are noticeably better conductors of heat than most nonmetals are, and it is reasonable to attribute this characteristic to the transport of heat by the mobile electrons. If there are mobile particles with an average random velocity u and a mean free path λ that contribute a term C to the thermal capacity per unit volume, the general expression for the thermal conductivity (K) is

$$K = \tfrac{1}{3}u\lambda C.$$

If this expression is compared with the one for electrical conductivity,

$$\sigma = \frac{1}{2}N\frac{e^2}{mu}\lambda,$$

it is seen that their ratio is

$$\frac{K}{\sigma} = \frac{2}{3}\frac{mu^2C}{Ne^2}.$$

If the electrons behave as a classical gas, this ratio gives

$$\frac{1}{2}mu^2 = \frac{3}{2}kT$$

and

$$C = \frac{3}{2}Nk,$$

in which k is Boltzmann's constant and T is the absolute temperature. Thus, the ratio becomes

$$\frac{K}{\sigma} = 3\frac{k^2T}{e^2}. \tag{43}$$

The ratio of the thermal and electrical conductivities should therefore be the same for all metals and proportional to the temperature. This is indeed the case, and equation (43) expresses a well-known empirical rule discovered by two German physicists, Gustav Heinrich Wiedemann and Rudolph Franz, in the 19th century. There are appreciable deviations from this rule at low temperatures, but it is reasonably well obeyed near room temperature.

If, as has been assumed, the electrons have a molar specific heat $(3/2)R$, in which R is the gas constant, this should be observable directly, as an addition to the molar specific heat $3R$ expected as a consequence of thermal energy stored in lattice vibrations. This is not observed experimentally, and most metals have molar specific heats at room temperature that are quite close to $3R$. This result, like the anomalous Hall effect in some metals, has no classical explanation and is essentially a quantum mechanical effect. Therefore, although classical theory

gives a reasonable interpretation of much of the behaviour of metals, there are some phenomena to which it gives completely wrong answers.

Quantum theory of metallic conduction. In classical mechanics, electrons are regarded as point particles of mass m and charge q equal to $-e$ pursuing definite trajectories calculable from the equations of motion and the initial position and momentum of the particle. In quantum mechanics the uncertainty principle makes it impossible to assign precise values simultaneously to the position and momentum of a particle, and only approximate trajectories can be considered. These are described in terms of wave functions ψ (the Greek letter psi), which have the property that the product $\psi^2 dV$ is the probability of finding the particle described by ψ in a volume element dV. The classical equations of motion are replaced by a differential equation for ψ, called Schrödinger's equation (after Erwin Schrödinger, an Austrian physicist, who first proposed it), which is

Schrödinger's equation

$$\frac{\hbar^2}{2m}\nabla^2\psi + (U - q\phi)\psi = 0.$$

In this equation, U is the total energy of the particle, $q\phi = -e\phi$ is its potential energy in the electrostatic potential ϕ, m its mass, and $\hbar = h/2\pi$. When this equation is solved, the solutions must fit the prescribed physical conditions of the problem; thus in a metal ψ^2, and therefore ψ, must vanish at the surface of the metal. Prescribed boundary conditions such as this lead to the result that Schrödinger's equation has solutions for only particular values of the total energy U. The possible values of U are known as the eigenvalues of the problem and the corresponding wave function as the eigenstates of the problem. The eigenvalues and eigenstates are uniquely determined by the boundary conditions and the form of the potential ϕ. These in turn are determined by the atomic structure of the metal. Each electron in the metal must be assigned to a definite eigenstate, and Pauli's exclusion principle states that not more than two electrons, with opposite spins, can be assigned to each eigenstate.

In a metal there are huge numbers of electrons (10^{20} or so in a cubic millimetre), and the trajectories of individual electrons would be of no interest even in the classical case. Only the average behaviour of all the electrons is significant. In quantum mechanics the individual states of the electrons are not of interest but only the average distribution of the electrons among the possible states. Because the number of electrons is so large, the average properties derived from this average distribution are an excellent approximation to the actual behaviour. The process of finding this average distribution and using it to derive average properties is the subject matter of statistical mechanics; and so a treatment of electronic conduction in metals is necessarily a problem in quantum statistical mechanics. Fortunately, although the details of any calculation are exceedingly complicated, the results are simple, and virtually all the information of any use is available once the average distribution of the electrons among the various states has been found.

The first step in the calculation is to find the way the states themselves are distributed in energy—that is, to find a function (G) of the energy (U)—*i.e.*, $G(U)$—such that the product $G(U)\,dU$ is the number of available states in an energy range dU. The next step is to find the probability $F(U)$ that states in the energy range dU at U are actually occupied by electrons. Once both these steps have been performed, the number of electrons dN in states of energy between U and $U + dU$ can be written as

$$dn = F(U)\,G(U)\,dU.$$

Each state that is an allowed solution of Schrödinger's equation can accommodate two electrons according to Pauli, and in describing the states obtained in this way of calculating $G(U)$ it is convenient to incorporate this factor of two in the definition of $G(U)$, so that $F(U)$ becomes the probability of a state of energy U being occupied subject to the restriction that no state can contain more than *one* electron. The derivation of the probability $F(U)$ is purely a problem in statistics and the answer is that

$$F(U) = \frac{1}{e^{(U-W)/kT} + 1}, \qquad (44)$$

in which T is the temperature, k Boltzmann's constant, and W a constant energy. Equation (44) is the Fermi–Dirac formula (named for the physicists Enrico Fermi and P.A.M. Dirac), W is the Fermi energy, and particles described by this equation are said to obey Fermi–Dirac statistics.

Figure 15A shows the probability function F against U for three values of temperature T; one curve corresponds to absolute zero ($T = 0$), the second to a low temperature $kT << W$, (in which $<<$ symbolizes much less than), and the third to a temperature $kT > W$. At absolute zero, F equals one when U is less than W, and F equals zero when U is greater than W. All states of en-

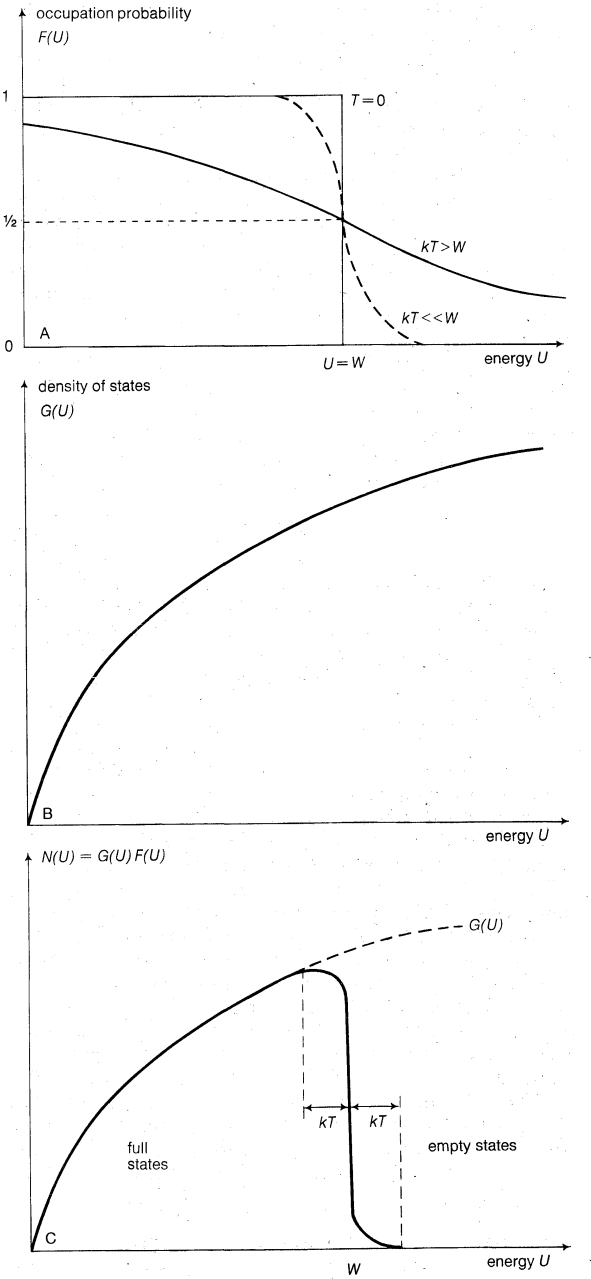

Figure 15: *Fermi–Dirac statistics.*
(A) Fermi–Dirac probability function at three different temperatures; (B) density of states available to electrons in an idealized metal; (C) electron distribution as a function of energy at a finite temperature (see text).

ergy less than W are occupied and all states of higher energy are empty. When kT is small a few states of energy just less than W will be empty and a few states of energy just greater than W will be occupied. When T is large the distribution is much more spread out, but in every case the probability that a state of energy U equals W is occupied is ½.

In metals and semiconductors, only the case in which kT is much smaller than W is important; then the Fermi level effectively divides the full low-energy states from the empty high-energy states.

The probability function F is determined by the general laws of statistical mechanics and is the same for every material; the density of states function $G(U)$, however, depends on the form of the allowed solutions of Schrödinger's equation. These in turn depend on the form of the potential ϕ, and this is a feature of the structure of the material. Before $G(U)$ can be investigated some sort of model for the material has to be adopted.

The classical theory simply assumed that $q\phi$ is constant inside a metal and increases suddenly at the surface. If this model is used in quantum theory, the resulting equations can be solved directly. The allowed wave functions are standing, or stationary, waves (*e.g.*, a vibrating rope attached at one end gives standing waves), with nodes at the surface of the metal, and the function $G(U)$ is given by

$$G(U)dU = \frac{\pi}{2}V\left(\frac{8m}{\hbar^2}\right)^{3/2}U^{1/2}dU,$$

in which V is the volume of the metal. In the treatment below, since the primary concern is with the number of electrons per unit volume, V may be taken as unity and omitted from the equations. The density of states function G for this model is plotted in Figure 15B. At absolute zero, all states up to W are filled, and the actual distribution of electrons in energy is given by the function $G(U)\,F(U)$, in which $F(U)$ is one for $U < W$ and zero for $U > W$. The total number of electrons (per unit volume) is

Distribution of electron energies

$$N = \int_{U=0}^{U=\infty} dN(U) = \int_0^\infty F(U)G(U)dU$$

$$= \int_0^W G(U)dU = \frac{\pi}{3}\left(\frac{8m}{\hbar^2}\right)^{3/2}W^{3/2}.$$

Because the value of N is fixed (there is one electron per atom), the result determines the value of the Fermi energy W. This gives

$$W = \frac{\hbar^2}{8m}\left(\frac{3N}{\pi}\right)^{2/3},$$

and using the numerical values of Planck's constant h and mass m and taking N equal to 27×10^{27} electrons per cubic metre, it leads to $W \simeq 5 \times 10^{-19}$ joule $\simeq 3$ electron volts $\simeq k \times 3 \times 10^4$ degrees. Thus, at temperatures up to the melting points of most metals, the equation yields a kT much less than W. In this case the distribution of the electrons in energy is as shown in Figure 15C. The value of W is little changed from the value appropriate to T equal to zero. Only the occupation of those states with an energy range kT about W is appreciably changed. It is now possible to see why the electrons do not contribute to the specific heat of the metal. As the temperature of the metal is increased, only a fraction, kT/W, of all the electrons change their energy states. Thus the electronic specific heat per mol, instead of being $\frac{3}{2}R$, is nearer to $\frac{3}{2}R\frac{kT}{W}$. At room temperature $kT/W \simeq 0.01$ and so this contribution is small and unimportant.

So far the wave functions, which are solutions of Schrödinger's equation, have been regarded as corresponding to standing waves in the interior of the metal, and in order to understand conduction (*i.e.*, the motion of electrons) this concept must be modified. A standing wave in quantum mechanics can never correspond to a net motion of a particle. Moving particles are described only by running waves. A typical standing wave describing an electron in a definite state in the metal is of the form $\cos \beta x \cos \omega t$, in which $\hbar^2\beta^2$ is the mean square momentum of the electron in its oscillatory motion and $\hbar\omega$ is its energy. It can, however, always be written as a combination of running waves in opposite directions; thus, for example,

$$\cos \beta x \cos \omega t = \frac{1}{2}(\cos [\omega t - \beta x] + \cos [\omega t + \beta x]),$$

which is the sum of two waves travelling in the positive and negative directions with velocities ω/β and $-\omega/\beta$. The allowed electronic states could equally well have been described in terms of pairs of running waves rather than standing waves.

In the presence of an electric field ($\boldsymbol{E}$), electrons in running-wave states that correspond to motion "downhill" in the field pick up energy from the field and, as a result, electrons occupying these states need to acquire less thermal energy from collisions with other electrons and the lattice of ionic cores. Thus these states tend to be preferentially occupied by electrons at the expense of states corresponding to "uphill" motion. If an electron spends a time τ between collisions in a state corresponding to a velocity v, the thermal energy required to get it into that state is reduced by $q\boldsymbol{E} \cdot \boldsymbol{v}\tau$. Thus, if U is the initial energy of the state in zero field, the probability that the state is occupied in a field $\boldsymbol{E}$ is no longer given by equation (44) but by the same equation with U replaced by $U - q\boldsymbol{E} \cdot \boldsymbol{v}\tau$. This makes no difference to the states with U much less than W, because these are occupied in any case; nor does it make any difference to the states with U much greater than W, which remain empty. It does, however, alter the distribution in states within the region where U approaches W and tends to increase the number of electrons in states that correspond to motion with the field. The effect can be estimated as follows: near the Fermi level, the exponential factor $(U - W - q\boldsymbol{E} \cdot \boldsymbol{v}\tau)/kT$ in the Fermi–Dirac formula, equation (44) is near unity and is, for small values of $\boldsymbol{E}$, approximately $1 - q\boldsymbol{E} \cdot \boldsymbol{v}\tau/kT$. Thus the Fermi–Dirac factor can be approximated, and a brief calculation leads to the expression

The Fermi–Dirac factor

$$J = \frac{1}{3}N\frac{q^2\tau}{m}\boldsymbol{E}.$$

A more accurate evaluation gives a different numerical factor. If this equation is compared with the classical result,

$$J = \frac{1}{2}N\frac{q^2\tau}{m}\boldsymbol{E},$$

it is seen to be virtually the same. Thus this particular quantum mechanical model leads to the same result as the classical model for the conductivity and can also be shown to yield the Wiedemann–Franz law. It has the advantage, however, that it explains the absence of any appreciable electronic specific heat. It does not, on the other hand, explain the anomalous Hall effect. To deal with this it is necessary to drop the assumption that the electrons move in a constant potential inside the metal.

In a real metal (or semiconductor) electrons move in a periodic potential caused by the ionic cores of the metal atoms. This appreciably modifies the solutions of Schrödinger's equation, and the density of states, instead of increasing steadily with energy, has the form shown in Figure 16A. There are regions of allowed energy (energy bands) and forbidden zones in which there are no solutions of Schrödinger's equation. Furthermore, a general theorem about the solutions of Schrödinger's equation ensures that total number of states per unit volume in each allowed band is always a small, even-integral multiple of the number of atoms per unit volume. If, as in diamond, the number of electrons is just sufficient to fill all the states in a band, then the Fermi level, which

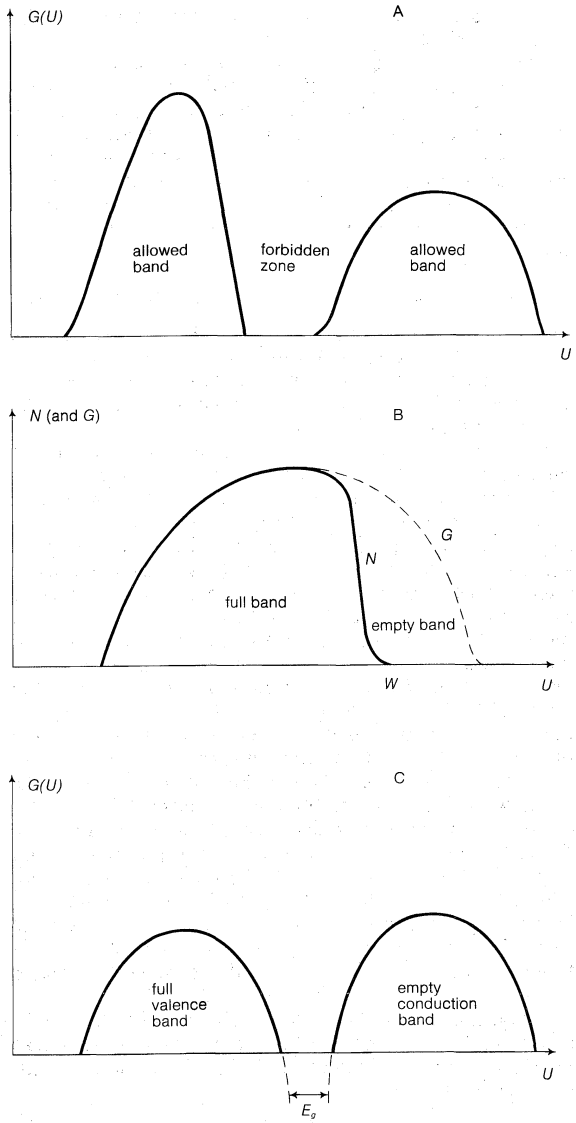

Figure 16: *Electron states in a solid.*
(A) General form of the density of states as a function of energy; (B) occupation of the available states in a partially filled (conduction) band; (C) density of states as a function of energy in a semiconductor (see text).

divides the full states from the empty states, lies in a forbidden zone. The electrical conduction results only from electrons with energies near the Fermi level, and in this case there are no electrons in this region of energy. Thus a material with a completely filled band and no electrons left over is an insulator. In the section that follows, it is seen how this mechanism is modified in semiconductors.

A metal must be a material in which one band of allowed states is only partially filled. This band is known as the conduction band, and the Fermi level lies within it. Figure 16B shows both the conduction band and the distribution of electrons in a typical metal.

In considering the motion of electrons in a constant potential, quantum mechanics does not lead to results essentially different from those of classical mechanics. The case, however, is quite different with a periodic potential. Then, according to classical mechanics, an electron situated where energy is less than the maximum potential energy cannot travel through the medium but will be trapped in one of the potential wells. In quantum mechanics, an electron with less energy than the maximum can still travel from one potential well to the next one.

Thus, the motion of electrons in real metals and semiconductors leads to mechanical behaviour not explicable in purely classical terms. On the other hand, in order to be able to visualize the response of electrons to periodic fields, it is useful when possible to employ equations that show some similarity to the equations of classical mechanics. In particular, if p is the momentum of an electron and a force F acts on the electron, it would be convenient to retain Newton's law,

Motion of electrons in periodic potentials

$$\frac{dp}{dt} = F, \tag{45}$$

and at the same time, if the electron has an equivalent classical velocity v, to be able to express the rate of change of the electron energy (U) when it responds to a force (F) as

$$\frac{dU}{dt} = Fv.$$

These equations are, of course, satisfied by free electrons, for which the electron energy is the same as its kinetic energy, $U = \frac{1}{2}mv^2$. The equations, however, are also satisfied in a more general way if the velocity is expressed as

$$v = \frac{\partial U}{\partial p}. \tag{46}$$

This gives, according to the laws of classical mechanics, the following:

$$\frac{dU}{dt} = \frac{\partial U}{\partial p}\frac{dp}{dt} = \frac{\partial U}{\partial p}F = vF.$$

For a classical particle the energy is the sum of a potential energy term (zero in this case) and a kinetic energy term $p^2/2m$, and equation (46) leads immediately to $p = mv$, which could be used to define the momentum of a classical particle. This equivalence is also true for a free quantum particle moving in a constant potential; but for a quantum particle moving in a periodic potential, if p is to obey equation (45), the energy can no longer depend on p simply through a term $p^2/2m$. Indeed, one of the important properties of solutions of the Schrödinger equation for a particle in a periodic potential is that the energy U is a periodic or oscillatory function of p. This means that for some values of p the energy actually decreases with increasing p. When this happens the velocity v is negative and the equivalent classical velocity is in the opposite direction to the momentum p. Clearly the behaviour of a particle with these properties would be strange. It is necessary to investigate this behaviour because, in many metals and semiconductors, the Fermi level falls in a region where it occurs, and, since it is just those electrons with an energy near the Fermi level that determine the electrical properties, the anomalous behaviour has important consequences.

No matter how energy depends on p, it cannot depend on the sign of p, for then the energy would be lower for one sign of p and there would be more electrons with this sign of p even in zero field. The electrons in the crystal would then have a net total momentum, which is clearly unacceptable. Thus U must be a function of p^2 to make it sign-independent. The actual dependence of U on p^2 is often quite complicated in real metals and semiconductors, but for many purposes a good approximation to U at the bottom of an energy band of allowed states is

$$U \simeq \frac{1}{2}Kp^2;$$

and near the top of a band of allowed states it is

$$U = U_0 - \frac{1}{2}K'p^2,$$

in which U_0, K, and K' are positive constants.

With v defined by equation (46) the rate of change of v is

$$\frac{dv}{dt} = \frac{d}{dt}\left(\frac{\partial U}{\partial p}\right) = \frac{\partial^2 U}{\partial p^2}\frac{dp}{dt} = F\frac{\partial^2 U}{\partial p^2},$$

and so, to present the motion in completely classical

terms using Newton's law in the form $\frac{dv}{dt} = \frac{1}{m}F$, the factor $\frac{1}{m}$ must be replaced by

$$\frac{1}{m^*} = \frac{\partial^2 U}{\partial p^2}.$$

The effective mass

This quantity m^* is known as the effective mass. For electrons near the bottom of a band, it is equal to $1/K$ and is positive, but for electrons near the top of a band it equals $-1/K'$ and is negative. If there is an electron near the top of a band with p positive and a force F (electric field) is applied that increases p, then according to equation (45) the energy of the electron decreases and work is done against the source of the force F. This is not what happens in a real metal, for it would imply that the current caused by an applied field is in the wrong direction. The reason this does not occur is that in real metals, if there are any electrons near the top of an energy band, then all the lower energy states in the band are already filled. Since there is never an occasion in which conduction is due solely to a few negative effective mass electrons near the top of a band, the only cases to be considered are that of either a few electrons in states near the bottom of a band, in which case they have positive effective masses and behave normally, or of an almost full band with a few vacant states, or holes, near the top of the band. The problem is to find a reasonable way of describing the latter situation.

In a completely filled band, for every electron with a velocity v there is another electron with a velocity $-v$, and so the total current resulting from a full band of electrons is zero. If one electron of charge $-e$ and velocity v is missing, a contribution $-ev$ to the current density is missing (considering unit volume of material). The net current density is then $+ev$. The total current density can be expressed either by summing $-ev$ over all the full states or by summing $+ev$ over all the vacant states or holes. In an electric field (E), electrons with momentum p (written here as a vector because momentum is a directed quantity) in the direction of the force $-eE$ will increase in momentum but decrease in energy. In the process, they do work against the source of the field. More thermal energy would have to be supplied by collisions to maintain electrons in states in which p is in the direction of the force. This will not happen, and at the first collision these electrons are likely to drop into states with smaller values of p or with p opposed to the force. Because v is opposed to p, this gives a net flow of electrons in the direction of the force; and a current of the normal sign (*i.e.*, J) could, however, equally be described in terms of holes. In a field E the number of holes in states corresponding to electrons with momenta parallel to the force $-eE$ increases. The electron velocity in these states obeys the law

$$\frac{dv}{dt} = \frac{F}{m^*} = \frac{1}{m^*}(-eE) = +e\left(-\frac{E}{m^*}\right),$$

and this is therefore the equation of motion for the hole. It is the equation of motion of a particle of charge $+e$ and effective mass $-m^*$, which is also positive, because effective mass m^* is negative. Because it is a hole that also contributes $+e$ of charge to the current density, the dynamics of the system can be treated entirely in terms of holes of positive charge and positive effective mass. This is so convenient, compared with treating negatively charged electrons with a negative mass and an esoteric relation between energy and momentum, that whenever electrons near the top of a band are involved, their behaviour is always considered in terms of holes.

The concept of hole

Because the energy levels that influence the electrical properties of a metal are those lying near the Fermi level, the factor that decides whether electrons or holes are appropriate is the position of the Fermi level in the band. If there are few electrons in the band and the Fermi level is near the bottom of the band, an analysis in terms of electrons is appropriate. If, on the other hand, the band is almost full and the Fermi level is near the top of the band, then the useful concept is hole conduction.

It is now possible to consider the anomalous sign of the Hall coefficient. According to equation (41), when a magnetic field B is applied perpendicular to current flow J in a conductor, an electric field E, perpendicular to both J and B, is produced and is given by

$$E = -R_H(J \times B) = \frac{1}{Ne}(J \times B).$$

In some metals (*e.g.*, sodium) this agrees with experiment, but in other cases (*e.g.*, zinc) the observed field has the opposite sign. The reason for this is that in zinc the conductors must be holes and the effective charge of the carriers is $+e$, not $-e$. This interpretation is strengthened by the fact that Hall effects of anomalous sign occur only in metals in which there are other grounds (chemical, crystallographic, etc.) for believing that the conduction band is almost full.

In a perfectly regular lattice, which produces a perfectly regular periodic potential, quantum mechanics would predict that there should be no collisions and no transitions between different electronic states or energy levels, which would lead to an infinite conductivity. If an electric field were applied to such a perfect medium, the electrons would acquire so much energy from the field that they might either ionize the atoms still further or perhaps emerge from the positive end of the medium. A real medium does not behave like this. One reason is that even single crystals of metals are not perfect. The periodicity of the lattice is disturbed by dislocations and impurity atoms. An impurity of as little as one part per million gives an impurity atom on an average once every hundred atoms in each direction. Impurities and lattice imperfections make an important contribution to electron collisions and, at low temperatures in many metals, are the dominant cause of a residual resistivity. Experimentally, however, the resistivity of most metals rises appreciably as the temperature T increases. Because the number of conduction electrons (if it changes at all) increases with T, this means that collisions become more frequent, the reason being that, as T increases, the vibration of the ionic cores about their mean lattice positions becomes more violent. Also, as T is raised, the lattice becomes less and less a perfect periodic structure until, at the melting point, it disintegrates entirely.

The atoms in a crystal are strongly bound together; as a result, the vibrations of the atoms are tightly coupled and one atom does not vibrate alone without influencing its neighbours. Thus the fundamental modes of vibration are much more like waves propagating through the lattice. These waves have the same nature as sound waves, although they are usually of much higher frequency, and are known as phonons, by analogy with photons or light waves. Just as a light wave or photon can be scattered by electrons, electrons in a metal can be scattered by phonons. In a normal metal, individual electrons are scattered by phonons and impurities, and this scattering is what gives them a finite mean free path. Under some circumstances, however, the interaction between electrons and the lattice waves, or phonons, has a quite different effect and leads to an interaction between the electrons themselves. This action couples together electrons with energies near the Fermi level; at temperatures near absolute zero, its effects are sufficient to cause these electrons to move as a coherent group through the medium. Thus, once a current has been set up, the lattice vibrations, or phonons, instead of being able to scatter individual electrons, must produce a change in the motion of the whole of this coherent group of coupled electrons. Neither the relatively weak, thermally excited phonons nor impurities are able to disturb the motion of such a large number of coupled electrons and so, once this type of interaction has taken hold of the electrons, they can move through the lattice without scattering. A current once set up in the material persists indefinitely, and the metal becomes what is called a superconductor of zero resistance. The effect normally sets in abruptly as the special metal is lowered through a critical temperature

Phonons

T_c, the superconducting transition temperature. Below T_c the metal has zero resistance, unless the current is made too large, in which case the coupling between electrons is strained to a breaking point and the coherent superconducting state is destroyed. As far as is known experimentally and as far as the detailed theory can be interpreted, the resistance in the superconducting state is not only very small but is identically zero.

A magnetic field in a metal appreciably raises the energy of electrons in the superconducting state and, as a result, if it is strong enough, can make the state unstable and cause the metal to revert to a normal conductivity. If, however, the field is not that strong a much more interesting effect—the Meissner effect (proposed in 1933 by the German physicists, W. Meissner and R. Ochsenfeld)—occurs. The electrons now set up coherent circulating currents, the net effect of which is just sufficient to cancel the field in the metal. Thus, when a metal is cooled through its superconducting transition temperature in a magnetic field, the field is expelled from the metal as it passes through the transition temperature. For further details see SUPERCONDUCTIVITY.

CONDUCTION IN SEMICONDUCTORS

Semiconductors are materials that have a low concentration of mobile charge carriers (electrons or holes) and a correspondingly low conductivity. They display many properties that can be put to practical use in electronic devices such as the transistor. The elements carbon (C), silicon (Si), germanium (Ge), and the gray allotrope of tin (Sn), together with a large number of compounds, have two things in common: they all contain an average of four valence electrons per atom, and they all crystallize in the diamond structure in which each atom is at the centre of a regular tetrahedron of neighbouring atoms. All these materials have a band of electronic levels, the valence band, which can just accommodate four electrons per atom and a second band of levels, the conduction band, the lowest level of which is separated from the highest valence-band level by a forbidden zone with no allowed levels. The width of this zone (E') represents the energy gap. It varies in width from a fraction of an electron volt in tin to several volts in diamond and cuprous chloride. The density of states available to electrons in these materials is shown in Figure 16C. According to the theory explained in the last section, all these materials, which contain one full band and one empty band, ought to be insulators. They have, however, one peculiarity in that the energy gap (E') is not large, which has a profound influence on their properties.

The conduction band

According to the general principles of statistical mechanics, the probability that an electron will pick up enough thermal energy to be excited from a state at the top of the valence band is very nearly $e^{-E'/kT}$. The energy represented by kT at room temperature is 1/40 electron volt and so this probability, with E' expressed in electron volts, is $e^{-40E'}$. There are about 10^{28} electrons per cubic metre in the valence band; as a result the probable number of electrons in the conduction band is of the general order of $10^{28}\ e^{-40E'}$ per cubic metre. This factor can also be expressed as $10^{(28-18E')}$. If, as in silicon, E' equals 1.1 electron volts, this gives about 10^8 conduction electrons per cubic metre of silicon (a better estimate is given below); but if, as in diamond, E' equals 3.5 eV, the number is virtually zero. Thus quite small changes in the energy gap (E') lead to a large difference in the number of electrons. Diamond may thus be considered to be an insulator, but silicon, with a few electrons in the otherwise empty conduction band and a few holes in the otherwise full valence band, is a poor conductor or semiconductor. Gray tin with a smaller energy gap is almost metallic.

The various elements mentioned above, as well as others of the same general type, are all regarded as semiconductors even though, as in the case of diamond, the semiconducting properties can occur only at high temperatures. A few elements of different structure—*e.g.*, tellurium—are also semiconductors; but, of them, only silicon is considered, partly because it is the most familiar and technologically important material and partly because it illustrates all the main features of semiconductor behaviour.

In silicon there are a few electrons in the conduction band and a few electrons missing from the valence band. The probability of a state in the conduction band being occupied is small and the probability of one being vacant in the valence band is also small. It follows that the Fermi level (W) must lie somewhere between the two bands—*i.e.*, in the energy gap. In fact, the Fermi level lies more or less in the middle of the forbidden energy gap, and the intrinsic hole and electron concentrations N_c and H_v are equal and given by

$$N_c = H_v = Ke^{-E'/2kT},$$

in which K is a constant. Because both holes and electrons contribute to the conductivity, the conductivity can be expressed as $\sigma = eN_c\mu_e + eH_v\mu_H$, in which μ_e and μ_H are the mobilities of electrons at the bottom of the conduction band and holes at the top of the valence band. (Here μ_e is taken as positive, although many textbooks take $-e\mu_e$ to be positive instead.) It follows then that the conductivity is

$$\sigma = Ae^{-E'/2kT}.$$

With E' equal to 1.1 electron volts, the conductivity changes by a factor of 10 as T changes from 300° K (27° C) to 340° K. This rapid exponential rise of conductivity with temperature is characteristic of semiconductors. Silicon, in common with most semiconductors, has two other important features. First, the mean free path and mobility of the charge carriers are high compared with those of metals, and, second, by introducing impurities, all the holes can be eliminated to produce many more electrons in the conduction band, or vice versa. The significance of the long mean free paths and high mobility is that silicon is a better conductor than might be expected with so few carriers and also that carriers in silicon can reach quite high velocities at relatively small current densities.

Silicon belongs to Group IV of the periodic table and has four valence electrons. Elements from neighbouring groups—*e.g.*, boron with three valence electrons and phosphorus with five valence electrons—can be introduced in small quantities as impurities and fit into the crystal lattice without appreciably disturbing the structure of the electronic energy levels. If boron is introduced (called doping), however, there will be one electron too few per boron atom to fill the levels of the valence band, and if phosphorus is introduced, there will be one too many. Thus, in boron-doped silicon, there are additional holes in the valence band, and in phosphorus-doped silicon there are additional electrons in the conduction band.

The number of electrons and holes in pure silicon at room temperature is about 10^{16} per cubic metre, and because there are some 10^{28} silicon atoms per cubic metre, the addition of one part per million of phosphorus—*i.e.*, 10^{22} atoms per cubic metre—increases the number of electrons available for the conduction band by a factor of $10^{(22-16)} = 10^6$. A few of these electrons are used to fill the holes in the valence band, but the remainder are available for conduction. Boron has the opposite effect. It "soaks" up all the conduction-band electrons and greatly increases the number of holes. Thus, whereas in pure, or intrinsic, silicon the conduction process involves equal numbers of holes and electrons, in phosphorus-doped silicon the process involves only electrons and in boron-doped silicon only holes. Silicon doped with a donor element from Group V, such as phosphorus, is known as *n*-type silicon because the conductivity is caused by negative carriers. Silicon doped with an acceptor element from Group III, such as boron, is known as *p*-type silicon because the conductivity results from positive carriers (holes). Adding electrons to a system always raises the Fermi level, and removing them lowers it. As a result, in *n*-type silicon the Fermi level lies near the bottom of the conduction band, and in *p*-type silicon it lies near the top of the valence band. If a sample of

n-type and *p*-type silicon

n-type silicon is placed in contact with a sample of p-type silicon some of the excess electrons in the n-type material flow into the p-type material and fill a few of the holes. This charges the p-material negatively and raises the potential energy of all the electrons in the material. According to statistical mechanics the process continues until the Fermi levels in the two materials coincide. This can be illustrated as shown in Figure 17. There is now a

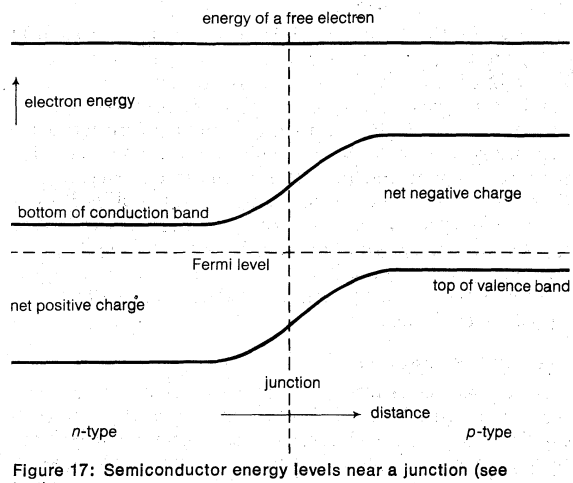

Figure 17: Semiconductor energy levels near a junction (see text).

contact potential difference between the two regions. If the Fermi levels actually coincided with the band edges, the contact potential ϕ_c would be given by $e\phi_c = E'$; *i.e.*, $\phi_c \simeq 1.1$ volts, with the p-material negative. This process is the origin of all forms of contact potential.

There are many interesting phenomena that occur at a p-junction, details of which may be found in SEMICONDUCTOR DEVICES. Electrical conduction in semiconductors differs in many ways from conduction in metals. For example, it will suffice to consider n-type silicon with 10^{22} conduction electrons per unit volume compared with 10^{29} in a metal. It follows immediately that, for a given current density, the velocity of the carriers must be much greater. Because the mobility of carriers in silicon (about 0.1 metre per second per volt metre^{-1} in SI units) is some 100 times larger than in metals, quite high current densities can be achieved in silicon. If the current density ($J = nev$) is 10^6 amperes per square metre, there are n equal to 10^{22} electrons per cubic metre, and because e is equal to 1.6×10^{-19} coulomb, the velocity will be 10^3 metres per second. This is comparable with the velocity of the lattice waves, or phonons, that scatter the electrons. Detailed analysis shows that the scattering becomes more effective as v approaches this velocity. In high fields, J is no longer proportional to E and there is a breakdown in Ohm's law. The limiting drift velocity is of the order of 5×10^4 metres per second. At still higher fields the drift velocity increases again and eventually electrons acquire enough energy from the field to create new pairs of charge carriers—*i.e.*, electrons and holes—in collisions. The fields in many semiconductor devices are strong enough to make all these nonlinear phenomena significant.

CONTACT POTENTIAL AND THERMOELECTRICITY

The atomic structure of a metal or semiconductor determines the position of its allowed energy levels relative to the energy of an electron at rest outside the metal. The number of electrons in the metal then determines, at any particular temperature (T), the energy of the Fermi level (W). The position of the Fermi level, relative to the standard energy zero, is a characteristic property of each metal and varies appreciably from metal to metal or metal to semiconductor. When two metals, a metal and a semiconductor, or two semiconductors are placed in electrical contact, electrons flow out of the material with the higher value of W. This continues until the resulting change in electrostatic potential brings the Fermi levels into coincidence (see Figure 17). If W_1 and W_2 are the two Fermi-level energies relative to an external electron at rest, the contact potential developed (ϕ_{12}) is given by

$$e\phi_{12} = W_1 - W_2.$$

In a chain of different metals (1, 2, 3 $\cdots$ n), the potential difference between (1) and (n) is $\phi_{12} + \phi_{23} + \cdots \phi_{n-1,n}$ or is equal to ϕ_{1n} because $e\phi_{1n} = (W_1 - W_2) + (W_2 - W_3) + \cdots (W_{n-1} - W_n)$. In a closed loop, therefore, there will be no net electromotive force and no current. If, however, in a closed loop of two metals, A and B, the two contacts are maintained at different temperatures T_1 and T_2, then, if the positions of the Fermi levels of A and B vary in a different way with temperature, the contact potential $\phi_{AB}^{(1)}$ at T_1 will no longer be equal to $\phi_{AB}^{(2)}$ at T_2. There is now a net emf acting around the loop and a current will flow. The current could be used to do mechanical work, and the laws of thermodynamics then require that heat should be taken in at the hot junction and given out at the cold junction. The production of a thermal emf is known as the Seebeck effect (after the Estonian-born German physicist Thomas Johann Seebeck), and the absorption and rejection of heat at the junctions when a current flows is known as the Peltier effect (after French physicist Jean-Charles Peltier).

The Seebeck effect

There is a third thermoelectric effect, the Thomson effect (discovered by William Thomson, later known as Lord Kelvin), which occurs in the interior of a single, homogeneous piece of metal in which there is a temperature gradient. This effect has two aspects. In an isolated piece of metal the presence of a temperature gradient means that the distribution of the electrons among the available energy levels will vary slightly from point to point in the metal. As a result there will be a redistribution of the negatively charged electrons in the metal, and this will cause a potential gradient to appear. If, on the other hand, a current flows in the metal from the cold end to the hot end so that electrons travel from the hot to the cold end, electrons arriving at any point in the metal will have thermal energy to spare. There will, therefore, be a local generation of heat proportional to both the temperature gradient and the electron flux. It is usual to express the heat generated per unit volume in terms of the conventional current density J and the temperature gradient as $-\sigma J dT/dx$. When J and dT/dx are positive, current flows from cold to hot and electrons from hot to cold. The Thomson coefficient σ is therefore expected to be negative. In those metals in which the conduction is caused by the positive holes (and also in p-type semiconductors) the coefficient will be positive. These expectations are not fulfilled in practice; thus, although sodium has a negative coefficient, as expected, lithium, a similar metal, has a positive coefficient. The reason for this is described next.

The only electrons that take part in the conduction process are those with energies within a few multiples of kT (the thermal energy) of the Fermi level, and further, if the mean free path of the electrons varies appreciably with energy, the electrons within this group that have the largest free paths will preponderate in the current. In general, the mean free paths near the Fermi level vary with energy in a way that depends critically on the atomic structure of the metal and it is quite possible for the mean free path to decrease rapidly with energy, in which case most of the electrons constituting the current will have thermal energies below, rather than above, the Fermi level. If the temperature is raised, electrons farther from the Fermi level in both directions can take part in conduction, but now the main increase will come from electrons considerably below the Fermi level. Thus, as the temperature is increased, the main thermal energy of those electrons that actually constitute the current will decrease, rather than increase, and this will reverse the sign of the Thomson coefficient σ.

Figure 18 shows two conductors labelled (1) and (2) and the various thermoelectric effects that occur. The Peltier coefficient $\Pi_{12}(T)$ is defined so that the heat ab-

The Peltier coefficient

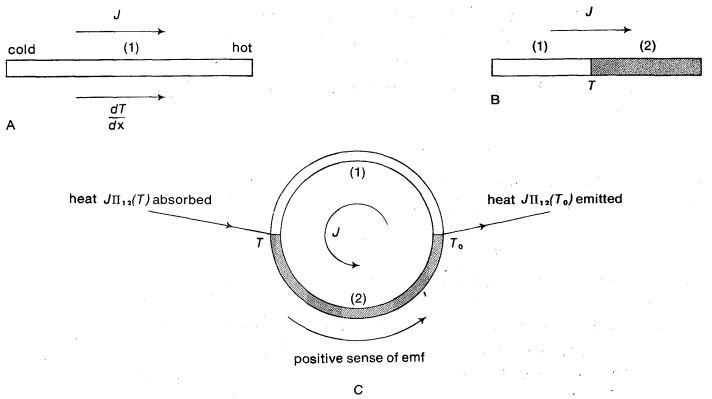

Figure 18: *The thermoelectric effects.*
(A) Heat generated at a rate $-\sigma_1 J\, dT/dx$ per unit volume; (B) heat absorbed at the junction at a rate $J\Pi_{12}(T)$ per unit area of cross section. (C) Seebeck electromotive force in a complete circuit (see text).

sorbed per unit area of cross section at the junction between (1) and (2)—when current I of density J flows from (1) to (2)—is $J\Pi_{12}(T)$. The Seebeck electromotive force acting round the complete circuit is V with the sense shown in the figure. The Seebeck coefficient S_{12}, or thermoelectric power of the junction, is defined with the result that

$$S_{12} = \underset{T \to T_0}{limit} \frac{V}{T - T_0} = \frac{dV}{dT}.$$

Thermodynamics yields two relations,

$$S_{12} = \Pi_{12}/T$$

and

$$\sigma_1 - \sigma_2 = -T\, dS_{12}/dT = -T\, d^2V/dT^2,$$

between the thermoelectric parameters.

The Thomson coefficients σ_1 and σ_2 for the two metals occur only as the difference $\sigma_1 - \sigma_2$, and the Peltier coefficient can be expressed as a difference between coefficients for each metal $\Pi_{12}(T) = \Pi_1(T) - \Pi_2(T)$ and the thermoelectric power as

$$S_{12} = S_1 - S_2.$$

Thus each metal can be characterized by three parameters S, σ, and Π, which are related by the Thomson equations, $\sigma = -T\, dS/dT$ and $\Pi = TS$. The third law of thermodynamics requires all thermoelectric effects to vanish at absolute zero, and so integration of the expression for dS/dT yields

$$\frac{\pi}{T} = S = -\int_0^T \frac{\sigma dT}{T}.$$

Experimentally, the Thomson coefficient σ is found to be zero in a superconductor; therefore, the absolute thermoelectric power of any metal can be measured by incorporating it in a loop with a superconductor. This is rather inconvenient, and, in practice, thermoelectric powers are usually expressed relative to the element lead which is known to have a low value.

From an experimental point of view the easiest thermoelectric parameter to measure is the electromotive force in a circuit containing two metals at different temperatures—*i.e.*, the thermoelectric power of the couple S_{12}. If S_{12} is known over a range of temperatures for a range of different pairs of metals, the other thermoelectric parameters can be obtained using the Thomson relations.

In practice, thermoelectric effects are significant in a number of ways. First of all, the possible presence of unwanted thermal electromotive forces in direct current circuits is a source of error in dc measurements. It is a prime cause of drift in dc bridges, for example. Second, thermal emf's can be used to measure temperature differences. Third, the Peltier effect may be used to produce refrigeration.

A typical pair of metals used in thermometry is the copper–constantan (alloy of 60 percent copper, 40 percent nickel) couple. Near room temperature the thermal emf is about 40 microvolts per degree temperature difference. This is too small to be easily measured and so a thermopile is usually used—*i.e.*, a circuit consisting of a set of alternating copper and constantan wires with alternate junctions at the reference temperature T_0 and the unknown temperature T. With 25 junctions at each temperature, the emf's add in series to give one millivolt per degree.

In metals, the Peltier cooling at a junction is usually completely masked by the irreversible joule heating in the bulk of the metal and is of no practical use. Semiconductors, however, have Fermi levels the exact energy of which is much more critically dependent on temperature than in metals; as a result, metal–semiconductor junctions exhibit much larger thermoelectric effects. The thermoelectric power is typically a few millivolts per degree compared with microvolts for metals. The Peltier coefficient is correspondingly larger and as a result practical refrigerating junctions can be constructed. The low thermal conductivity of semiconductors also helps to insulate the cold junctions.

ELECTRON EMISSIONS

Thermionic emission. A metal contains mobile electrons in a partially filled band of energy levels—the conduction band. These electrons, though mobile within the metal, are rather tightly bound to the metal. The energy required to release a mobile electron from the metal varies from about 1.5 electron volts to about six electron volts, depending on the metal. The electrons can acquire enough energy to escape in a number of ways. A few electrons, for example, can pick up enough thermal energy in collisions. This leads to thermionic emission. The number of emitted electrons, and therefore the thermionic emission current, depends critically on the temperature. If energetic electrons are injected into the metal from outside, some of their excess energy can be transferred directly to other electrons which may then escape from the metal. This process is known as secondary emission. In some cases one extra energetic electron incident on the metal may lead to three or four secondary electrons. Finally, if light of high enough frequency falls on the metal so that the photon energy $h\nu$ (Planck's constant h times frequency ν) exceeds the binding energy of the electrons, electrons are released from the surface, resulting in a photoelectric emission current. These are the three primary effects that will be of concern below, in addition to photoelectric effects in semiconductors. Light incident on a semiconductor leads normally not to the release of electrons but rather to the production of additional charge carriers within the semiconductor. This internal photoelectric effect has a number of interesting consequences. In a homogeneous semiconductor it leads to an increase in electrical conductivity, the photoconductive effect; but if the semiconductor contains a rectifying p–n-junction (permitting current to flow in only one direction), it can also generate an electromotive force. This is known as the photovoltaic effect. In a metal the conduction band levels are filled up to the Fermi level, which lies at an energy $-e\phi_w$ relative to a free electron outside the metal. The typical energy required to release an electron is $e\phi_w$ and this is known as the work function. At a temperature T, the number of electrons with enough energy to escape is proportional to $\exp(-e\phi_w/kT)$, in which k is Boltzmann's constant. If, for example, ϕ is two volts and T equals 1,000° K, this proportionality factor is about 10^{-10}, and thus only this small fraction of the mobile electrons will have sufficient energy to escape. Those electrons that can escape are moving so fast in the metal and have such high kinetic energies that they are little affected by the periodic potential caused by atoms of the metallic lattice. In other words, they behave like electrons trapped in a region of constant potential. Because of this, when the rate at which electrons escape from the metal is calculated, the detailed structure of the metal has little influence on the final result, and so a universal formula is valid for all

Secondary emission

metals. This result is known as Richardson's law (first proposed by English physicist Owen Williams Richardson). It is usually expressed in terms of the emission current (J) for unit area as

$$J = AT^2\exp(-e\phi_w/kT),$$

in which the universal constant A is 120 ampere degree^{-2} centimetre^{-2}, or 1.2×10^6 ampere degree^{-2} metre^{-2}, and T is in degrees Kelvin. If, for example, T equals 1,000° K and ϕ_w equals 2 volts the result is a J equal to 1.2×10^{-2} ampere per square centimetre. The rapid rise with temperature should, however, be noted. If T is increased to 1,200° K, J rises to ½ ampere per square centimetre. In most practical vacuum tubes, the cathode is coated with a mixture of barium and strontium oxides, and at 1,000° K this not only has a work function somewhat less than two electron volts but also acts as a reasonably good conductor. Typically, currents of several amperes per square centimetre can be drawn from oxide cathodes but, in practice, the current density is usually less than 0.2 ampere per square centimetre because higher densities lead to rapid degradation of the oxide layer. Tungsten has the potential ϕ_w equal to about 4.5 volts and does not emit appreciably below about 2,000° K. According to Richardson's law, at 2,800° K the emission should be about 10 amperes per square centimetre, which is roughly in agreement with experiment.

Secondary emission. If energetic electrons—*i.e.*, electrons of 10 to 1,000 electron-volt energies—strike a metal surface in vacuum, their energy is lost in collisions in a region near the surface and mainly transferred to other electrons in the metal. Because this occurs near the surface, some of these electrons may be ejected from the metal and form a secondary emission current. The ratio of the number of secondary electrons to the number of incident electrons is known as the secondary-emission coefficient. For low-incident energies (below about one electron volt) the primary electrons tend to be reflected, and the secondary emission coefficient is near unity. With increasing primary energy, the coefficient at first falls and then at about 10 electron volts begins to rise again, usually reaching a peak of from two to four at energies of a few hundred electron volts. At higher energies the primary electrons penetrate so far below the surface before losing energy that the excited electrons have little chance of reaching the surface and escaping. Thus at higher energies the secondary emission coefficients fall, and, when the electrons have a few thousand volts primary energy, are usually well below unity. If the incident primary particles are massive ions rather than electrons, they are stopped much nearer the surface. The increase in the secondary emission coefficient then persists to rather higher incident energies, and the peak value is somewhat larger. Secondary emission is not confined to metals but can also occur in insulators. Because many insulators have rather high secondary emission coefficients, it is often useful to coat a metal electrode with a thin layer of an insulator a few atoms thick when high secondary emission yields are required.

Secondary-emission coefficient

The principal use of secondary emission is in the multiplier tube, generally in association with a photo-emitting cathode. Light falling on the cathode generates photoelectrons, which are then accelerated to energies of a few hundred electron volts. The electrons strike a secondary emitting cathode and produce perhaps three secondaries per electron. These secondaries are then accelerated and strike a second electrode producing nine electrons and so on. With 10 stages of secondary emission the current gain is about 10^5, and a single photoelectron produces a current pulse large enough to operate electronic equipment. The main advantage of the secondary emission process as a gain mechanism is that it is largely free from noise.

Photoelectric effect. If light, the frequency of which is such that the photon energy $h\nu$ exceeds the work function $e\phi_w$, falls on a metal surface, some of the incident photons will transfer their energy to electrons, which will then be ejected from the metal. This is the primary photoelectric effect. If $h\nu$ is greater than $e\phi_w$, the excess energy $h\nu - e\phi_w$ transferred to the electrons will be observed as their kinetic energy outside the metal. The relation between electron energy E and ν ($E = h\nu - e\phi_w$) is known as the Einstein relation (after Albert Einstein, who first proposed it), and its experimental verification helped to establish the validity of quantum theory. It should be noted that the energy of the electrons depends on the frequency of the light, not its intensity. The intensity determines the rate of photoelectric emission. With quantum theory these relations seem almost obvious but are completely inexplicable in classical terms.

In practical devices based on photoelectric emission that are used to detect light and produce electrical signals from light signals, the photocathode is usually combined with a secondary-emission multiplier. This gives a large amount of low-noise amplification before the signal is processed by the normal techniques of electronic amplification. The internal photoelectric effect in semiconductors can now be explained. In a semiconductor the lower valence band of energy levels is almost completely full and the upper conduction band almost empty. The conductivity of the material derives from the few holes present in the valence band and the few electrons in the conduction band. Electrons can be excited from the valence to the conduction band by light for which $h\nu$ exceeds the energy gap E_g between the bands. The value of E_g depends on the particular semiconductor; for lead sulfide the threshold frequency occurs in the infrared, whereas for zinc oxide it is in the ultraviolet. For silicon, E_g equals 1.1 electron volts, and the threshold wavelength is about 9000 angstroms—*i.e.*, just in the infrared. Visible radiation produces electron transitions with almost unity quantum efficiency in silicon. Each transition gives a hole–electron pair—*i.e.*, two carriers—which contributes to the electrical conductivity. If photons arrive at a rate n per second in a volume V, and the excess carriers have a lifetime τ before they recombine, the net increase in the carrier density is $2n\tau/V$. A sample of pure silicon may be considered, in which there are some 3×10^{10} carriers per cubic centimetre at room temperature in the form of a thin plate one square centimetre and 0.03 centimetre thick, which is thick enough to absorb all incident light. If the incident radiation is 5×10^{15} quanta per second (about one milliwatt) and τ is approximately 2×10^{-4} second, the resultant density is 6×10^{13} carriers per cubic centimetre, with the result that the resistance of the plate will be decreased by a factor of about 2,000. In practice, photoconductive effects are not usually as noteworthy as this, but this example indicates that appreciable changes in conductivity can occur even with much less intense illumination. Photoconductive devices are simple to construct and are used to detect visible, infrared, and ultraviolet radiation. They are not, however, as sensitive either as vacuum photomultiplier tubes or as the devices that are described next.

The internal photoelectric effect

If a junction is formed between n-silicon containing donor impurities giving an excess of electrons and p-silicon containing acceptor impurities and an excess of holes, a contact potential is generated with the p-material negative. This is shown in Figure 17. The system is in dynamic equilibrium. The potential barrier determined by the contact potential inhibits the flow of electrons (the majority carriers in the n-material) from the n- to the p-material. Any electrons generated as minority carriers in the p-material are, however, free to cross the junction. In equilibrium the majority and minority electron currents just balance. Similarly, the majority carrier-hole current from p to n is just balanced by a minority carrier-hole current from n to p. If reverse bias is applied to the junction, making the p-material still more negative, the majority carrier currents are completely cut off, leaving only the minority carrier currents. These, in a typical diode, may amount to only 10^{-9} ampere or so. When light falls on the semiconductor, electron–hole pairs are generated in both the p- and n-material, and any holes generated in the n-material or electrons generated in the p-material are swept across the junction and yield an additional current. Each photon absorbed transfers one electronic charge across the junction. The device therefore acts as a photo-

detector, yielding one electronic charge in the external circuit for each photon absorbed. As a device for measuring weak photon fluxes the reverse-biassed photodiode is rather impractical largely because, although it has nearly unity quantum efficiency, it has no internal current gain such as occurs in a photomultiplier tube. As a result, fluctuations in the succeeding electronic amplifier (and also fluctuations in the dark current) mask weak input signals. On the other hand, when it is used to measure small changes in a large photon flux, it can be shown to achieve almost the ultimate theoretical sensitivity.

If no bias is applied to the diode, the holes generated in the *n*-material and the electrons generated in the *p*-material flow across the junction, driven by the contact potential difference. The resulting charge transfer reduces the contact potential, and the process goes on until the increased majority carrier flow, allowed by the reduced contact potential, just balances the additional photoelectric minority carrier current. Just as in thermoelectricity, a localized change in contact potential is available as an electromotive force in an external circuit connected to the diode. The diode now behaves as a photovoltaic detector of radiation. At low light intensities the output voltage is proportional to light intensity, but at high intensities the voltage saturates at a value not far off the initial value of the contact potential (but of the opposite sign). The light intensity then determines the current available from the diode. Although the photovoltaic diode can be used to detect and measure incident radiation, it is not as sensitive as the reverse-biassed diode. Its most important application is in the solar cell used (especially in artificial satellites) to generate electric power from solar radiation. In favourable circumstances a solar cell can give a 50 percent conversion efficiency, though a more usual figure is somewhat less than 10 percent. For solar radiation a typical power output is from five to 10 milliwatts per square centimetre of junction area. It is perhaps worth noting that this corresponds to several hundred kilowatts per acre.

The photovoltaic diode

Although the main use of all types of photoelectric effect is in devices that either detect light or convert radiant energy to useful electrical energy, the photoelectric effect is also useful as a research tool. The study of the energy distribution of photoelectrons released from either solids or single molecules in a gas is also a powerful technique for investigating the energy levels of the system (see SEMICONDUCTOR DEVICES).

V. Alternating electric currents

Attention has been paid so far only to steady electric currents, steady voltages, and fields and static distributions of charge. Most of the important practical applications of electricity are, however, concerned with currents, voltages, and fields that vary rapidly in time. For example, the domestic electricity supply in the United States reverses the sign of the voltage 120 times per second (called 60 cycle ac); but in electronic apparatus, voltages and currents are dealt with that change appreciably in times sometimes as short as 10^{-9} second; and in optics, the electromagnetic fields vary periodically in time with frequencies of around 10^{14} hertz (cycles per second). This section includes consideration of the behaviour of time-dependent currents in circuits, and especially one particular class of time-dependent current, the periodic current having a wave form that can be expressed as either the cosine or the sine of a phase angle that increases linearly with time. In other words, these are currents the time dependence of which can be expressed as either $I(t) = I_0 \cos(\omega t + \theta)$ or $I_0 \sin(\omega t + \chi)$, in which t is time, I_0 is the maximum current attained during a cycle, and ω, θ and χ are constants. Currents that can be expressed in this form are referred to as sinusoidal. Since $\cos(\omega t + \theta + 2\pi) = \cos(\omega t + \theta)$ and $\sin(\omega t + \chi + 2\pi) = \sin(\omega t + \chi)$, sinusoidal currents repeat at intervals given by $t = 2\pi/\omega$. The time length of one cycle is $2\pi/\omega$, and therefore the frequency (f) of repetition is $f = \omega/2\pi$, or $\omega = 2\pi f$, in which ω is called the angular frequency. Here, f and ω will be indiscriminately referred to as the frequency, the factor 2π being ignored.

If a coil (of area A and N turns) rotates about an axis normal to a steady magnetic field $\boldsymbol{B}$ at an (angular) frequency ω and the plane of the coil is perpendicular to the direction of $\boldsymbol{B}$ at zero time, the flux linking the coil is $ANB \cos \omega t$ and the induced electromotive force in the coil, written $V(t)$ for the emf at time t, is $V(t) = -\omega ANB \sin \omega t$. Thus, a system of this kind acts as a source of an alternating emf. Other sources of alternating emf can be constructed using electronic devices, gas discharges, microphones, or mechanical interruption in a direct current (dc) circuit. Some of the properties of alternating current (ac) sources will be treated in a later section but here it is necessary to know only that they exist. Alternating current circuits containing only resistive components—*i.e.*, those that obey the law that the voltage $V(t)$ at time t is equal to the resistance R times the current $I(t)$ at the same instant, $V(t) = RI(t)$—are no different from dc circuits. If, however, a circuit contains a capacitance (C), the voltage across the capacitor is related to the charge (q) by the constant C, or $q(t) = CV(t)$, and the charging current in the leads to the capacitor is $I(t) = dq(t)/dt = CdV(t)/dt$. Thus, with a time-dependent emf the behaviour of circuits containing capacitors begins to show new features. The peculiar simplicity of sinusoidal (also said of a variation with cosine) currents and voltages arises from the fact that the variation of a sine or cosine function with time is another sine or cosine function; *i.e.*,

$$\frac{d}{dt}(\sin \omega t) = \omega \cos \omega t = \omega \sin(\omega t + \pi/2)$$

$$\frac{d}{dt}(\cos \omega t) = -\omega \sin \omega t = \omega \cos(\omega t + \pi/2).$$

Thus, because of the relation $I = CdV(t)/dt$,

$$I = C\omega V_0 \sin(\omega t + \pi/2),$$

that is, if the voltage $V(t)$ applied to a capacitor is sinusoidal, the current across it is also sinusoidal with the same frequency.

A resistance is an element that dissipates electrical energy as heat (although resistance can also be used to represent the circuit properties of a device such as a motor, which converts electrical energy to mechanical work). A capacitor is an element that stores electrical energy and can then release the energy at a later time. The energy in a capacitor can be regarded as stored in the electric field between the plates. Magnetic fields can also store energy, and the question then arises as to how this will influence the flow of currents, because a current is always accompanied by a magnetic field. This is dealt with in the next section, and, although it is dealt with at more length in the article MAGNETISM, it is interesting to see what can be deduced from energy considerations alone. The magnetic field produced by a current (I) in a conductor is proportional to I and, by analogy with the electric case, the magnetic stored energy could be expected to be proportional to the square of the magnetic field and thus to the square of I. If the energy (U) is written $U = \frac{1}{2}LI^2$, L being a proportionality constant, and I increases slowly at a rate $\dot{I}$ (a superdot means the rate of change of a quantity with time), then $dU/dt = LI\dot{I}$; but the rate at which the source of the emf does work (during the increase of I) is VI (*i.e.*, $dU/dt = VI$), and thus $V = L\dot{I}$; and so the circuit produces a back emf $-V = -L\dot{I}$. The coefficient L is known as the inductance (or self-inductance) of the circuit. From the equation $V = L\dot{I}$, it is seen that if a voltage $V(t)$ is applied to an inductance, the current also will be sinusoidal with the same frequency. The three passive elements, resistance (R), capacitance (C), and self-inductance (L), together with a new concept, mutual inductance (M), which will be introduced in the following section, form the background of any treatment of ac circuits.

Self-inductance

FARADAY'S LAW OF ELECTROMAGNETIC INDUCTION

When a conductor moves in a magnetic field $\boldsymbol{B}$ with a velocity $\boldsymbol{v}$, the magnetic force $q\boldsymbol{v} \times \boldsymbol{B}$ acting on the charge

carriers q leads to a separation of positive and negative charge in the conductor and thus to an electromotive force. Faraday discovered that an emf also existed in a closed circuit when, instead of moving the circuit, he either moved or changed the sources of the magnetic field. The law of electromagnetic induction can be expressed as follows:

If a magnetic flux (ψ)—*i.e.*, the area integral of $\boldsymbol{B}$ threading a closed loop (which may coincide with an actual physical conductor or be a mathematically defined closed line)—changes, the loop remaining fixed, then the electromotive force induced around the loop is $-d\psi/dt$. The sense of the emf is given by Lenz's law: If the electromotive force acts in a real conducting loop, the resulting current produces a field that tends to oppose the change in $\boldsymbol{B}$ and ψ.

Faraday's law can be expressed in mathematical form by considering a plane area S bounded by a closed loop with a line element $\boldsymbol{dl}$. If the positive normal to S—that is, $\boldsymbol{dS}$—is taken to be in the direction that a right-handed screw would advance as the path $\boldsymbol{dl}$ is traced out, then the emf acting around the loop is the integral expression

$$\oint \boldsymbol{E} \cdot \boldsymbol{dl} = -\frac{d}{dt}\int_S \boldsymbol{B} \cdot \boldsymbol{dS}, \tag{47}$$

and, by considering a loop of infinitesimal area, this leads to the equation

$$\nabla \times \boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t}. \tag{48}$$

Equation (48) will not be needed in this section but is required below in the section on *The primary effects and properties of electric fields and currents.* It is one of the most important formulas in the whole of electromagnetism. For this section the original statement of Faraday's law is adequate.

If a changing current I_1 flows in a circuit, the flux linking a nearby circuit will also change. According to Faraday's law there will be an induced emf proportional to an $\dot{I}$ equal to dI/dt in the second circuit. If this is written as $V_2(t) = M_{21}\dot{I}_1(t)$, M_{21} is called the mutual inductance between the two circuits (1) and (2). The units of M are volt ampere^{-1} second and are expressed as a henry (H).

Mutual inductance

The current in the first circuit, as it changes, will also change the flux in the first circuit, and there will be an induced emf in the first circuit. The sign will be such as to oppose the change in I. Treated as a back emf in the sense that the back emf in a resistance is RI and in a capacitance q/C, it gives $V_1(t) = L_1\dot{I}_1(t)$, and L_1 is the self-inductance of circuit (1). If two circuits have self-inductances L_1 and L_2 and mutual inductances M_{21} and M_{12} and if the current in (1) is raised to I, that in (2) remaining at zero, then the work done by sources of emf in (1) is

$$W_1 = \int I_1 V_1 dt = \int I_1 L_1 \dot{I}_1 dt = \frac{1}{2}L_1 I_1^2.$$

If the second current is raised to I_2, the source of emf in circuit (2) has to do work

$$W_2 = \frac{1}{2}L_2 I_2^2;$$

but, because of the back emf in (1) from $\dot{I}_2$, the first source also does work

$$W_{12} = \int I_1 M_{12} \dot{I}_2 dt = M_{12} I_1 I_2.$$

Thus the total work done to reach a final state, with I_1 in one circuit and I_2 in the other, is

$$\frac{1}{2}L_1 I_1^2 + \frac{1}{2}L_2 I_2^2 + M_{12} I_1 I_2.$$

This state could have been reached by increasing I_2 first and then I_1, which gives $\frac{1}{2}L_2 I_2^2 + \frac{1}{2}L_1 I_1^2 + M_{21} I_2 I_1$. These two expressions must be equal, and thus $M_{12} = M_{21}$.

THE MATHEMATICAL AND GRAPHICAL REPRESENTATION OF SINUSOIDAL PHENOMENA

As mentioned above, the basic circuit elements that constitute alternating current circuits are the voltage generator (source of alternating emf, symbolized ~), resistance (R), capacitance (C), self-inductance (L), and mutual inductance (M). Figure 19 shows a circuit incorporating all these elements. The equations that govern the operation of this circuit are

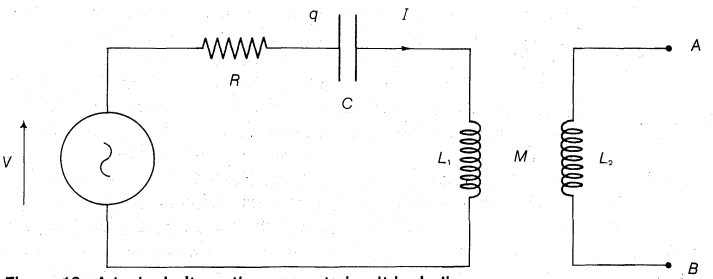

Figure 19: A typical alternating-current circuit including resistance R, capacitance C, inductance L, and mutual inductance M (see text).

$$V(t) = RI(t) + \frac{q(t)}{C} + L_1\dot{I}(t),$$

$$I(t) = \frac{dq(t)}{dt},$$

and

$$V_{AB}(t) = M\dot{I}(t),$$

in which V_{AB} is the voltage between terminals A and B. Finding the current in terms of voltage involves solving a set of linear differential equations with constant coefficients.

As shown above, the current in a circuit with resistance, capacitance, or inductance is sinusoidal if the impressed voltage is sinusoidal and is of the same frequency. The current and voltage, however, are not necessarily in phase, or step—*i.e.*, they do not rise and fall in unison so that they are maximum or minimum simultaneously. If there is only resistance in a circuit in which $V = V_0 \cos \omega t$, then because $I = RV$, or $I = RV_0 \cos \omega t$, it is seen that both V and I oscillate with $\cos \omega t$ and are in phase. If there is only an inductance L in the circuit, the current and voltage associated with L are related by $V = L\dot{I}$, and if $I = I_0 \cos \omega t$, then $V = -\omega L I_0 \sin \omega t = \omega L I_0 \cos(\omega t + \pi/2)$. Thus the amplitude of V is $\omega L I_0$, and it leads I by a phase angle $\pi/2$. If there is only a resistance in the circuit, the amplitude is RI_0 and the phase angle is zero. If there is a capacitance alone in the circuit, $I = C\dot{V}$, the amplitude of I is $\omega C V_0$, and I leads V by $\pi/2$; or, if I is given, the amplitude of V is $I_0/\omega C$, and V lags I by $\pi/2$. Figure 20 shows these relations, expressed in terms of V as the in-phase vector.

A circuit with inductance, resistance, and capacitance in series may now be considered. When a current $I(t) = I_0 \cos \omega t$ flows through the circuit the voltage is a sum of three terms of amplitudes I_0R in phase, $I_0/\omega C$ lagging by $\pi/2$, and $I_0\omega L$ leading by $\pi/2$. If these are represented on a vector diagram, as in Figure 20, the amplitude and phase can be found by simply adding the three vectors. Clearly, the amplitude is

$$V_0 = \left[R^2 + \left(\omega L - \frac{1}{\omega C}\right)^2\right]^{1/2} I_0,$$

and the phase (leading is positive) is

$$\theta = \tan^{-1}\frac{\omega L - 1/\omega C}{R}$$

Although these relations are somewhat simple, they become hopelessly intricate when dealing with complicated circuits.

In order to simplify these relations, use is made of the notation of complex numbers. With real numbers, no meaning is attached to the square root of a negative num-

ber. If, however, an imaginary number j is defined to be the square root of -1 (*i.e.*, $j = \sqrt{-1}$) it is possible to define complex numbers; *e.g.*, $c = a + jb$, in which a and b are real, and therefore, $c^2 = a^2 + 2jab - b^2$. If b is equal to 0, then c is the square root of a positive number; if a is equal to 0, then c is the square root of a negative number.

Real numbers and imaginary numbers of the form jb are entities of different kinds and so if $c = a + jb$ and $\gamma = \alpha + j\beta$, the equation $c = \gamma$ implies the two equations $a = \alpha$ and $b = \beta$. If two complex numbers are equal, their real and imaginary parts are separately equal. This is reminiscent of vectors. If two vectors P and Q in two dimensions are equal, then their x components and y components are separately equal. Furthermore, the law of addition $c + \gamma = a + \alpha + j(b + \beta)$ is like the law of vector addition $(P + Q)_x = P_x + Q_x$, $(P + Q)_y = P_y + Q_y$. Thus, complex numbers can also be represented by a vector diagram, or Argand diagram, so-called because Jean Robert Argand, a Swiss mathematician, first used it (see Figure 21). The complex number c is regarded as a vector of length $(a^2 + b^2)^{1/2}$ at an angle $\theta = \tan^{-1}\frac{b}{a}$. This corresponds to writing c in the form

The Argand diagram

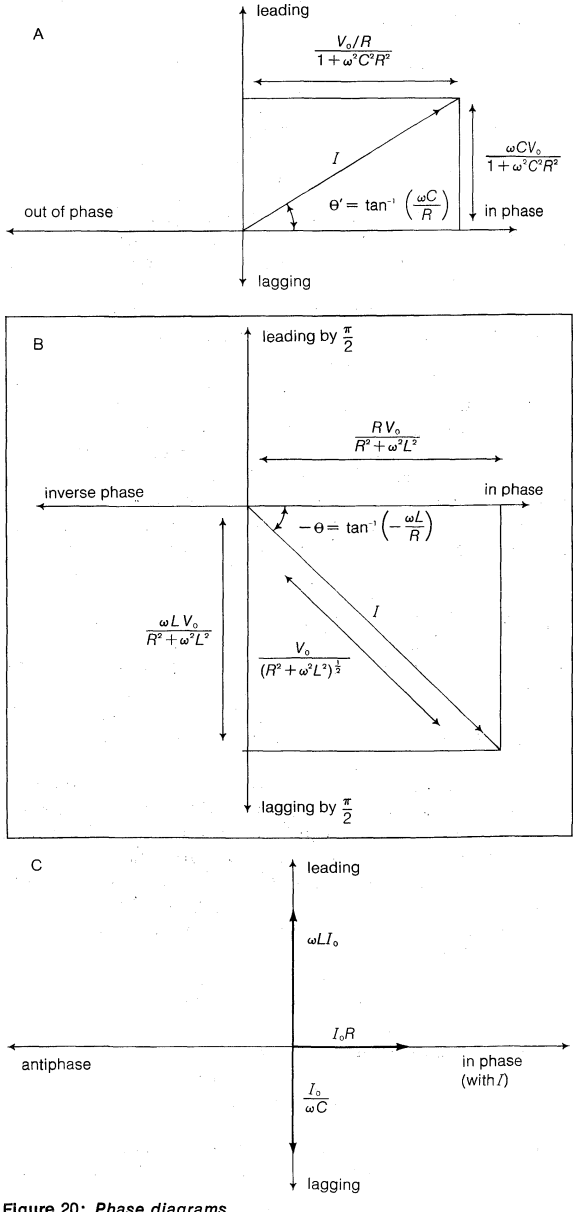

Figure 20: *Phase diagrams.*
(A) Resistance R and capacitance C in series; (B) resistance R and inductance L in series; (C) resistance, inductance, and capacitance in series (see text).

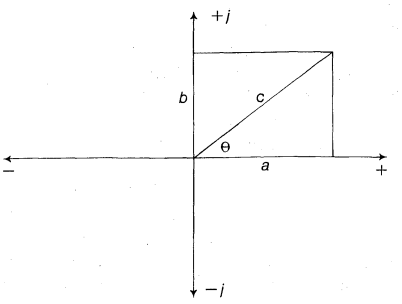

Figure 21: Argand diagram for a complex number $c = a + jb$ (see text).

$$c = (a^2 + b^2)^{1/2}\cos\theta + j(a^2 + b^2)^{1/2}\sin\theta$$
$$= (a^2 + b^2)^{1/2}(\cos\theta + j\sin\theta).$$

As an example in the application of complex numbers, a current $I_0 \cos \omega t$ flows through a circuit in which the voltage $V(t)$ across the circuit has been found to be $V(t) = I_0(R\cos\omega t - X\sin\omega t)$, so that the amplitude of $V(t) = I_0(R^2 + X^2)^{1/2}$ and the phase leads by $\tan^{-1}\frac{X}{R}$. This could be expressed in complex notation simply as $V = I(R + jX)$, and the Argand diagram for V with I defining the positive real axis would be the same as the vector diagram for $V(t)$ with $I(t)$ defining the in-phase axis.

The complex notation is a powerful technique for solving ac problems. With sinusoidal currents and voltages of frequency ω (strictly $\omega/2\pi$) each inductance L is replaced by an "effective resistance" $j\omega L$, and each capacitance C is replaced by an effective resistance $1/j\omega C$. A resistance remains a real number R. The total effective resistance is then calculated as though dealing with dc phenomena. At the end of the calculation the real part of the effective resistance describes the in-phase terms and the imaginary part describes the out-of-phase terms.

These considerations so far have been based on the analogy between the Argand diagram and the vector diagram. There is a much more fundamental and useful way of arriving at the same results, based on De Moivre's theorem (named after the French-born British mathematician Abraham De Moivre). De Moivre's theorem makes it easier to find solutions to the differential equations of ac theory. This theorem states that the logarithmic base (e) raised to an imaginary power is equal to the sum of a real and an imaginary number, $e^{j\theta} = \cos\theta + j\sin\theta$.

It follows from De Moivre's theorem that

$$e^{j\omega t} = \cos\omega t + j\sin\omega t$$

and that

$$\cos\omega t = Re(e^{j\omega t})$$
$$\sin\omega t = Im(e^{j\omega t})$$

in which *Re* means "real part of" and *Im* means "imaginary part of."

The simplification that results from complex notation is ultimately the result of the fact that

$$\frac{d}{dt}(e^{j\omega t}) = j\omega e^{j\omega t}.$$

As a result all time derivatives are simply replaced by $j\omega$. Because of this relation, the differential equations pertinent to the circuit in Figure 19 may be reduced to algebraic equations. This may be contrasted with the first two equations in this section, which involve both a multiplication by ω and a phase shift.

The rules for dealing with sinusoidal phenomena can now be summarized. If $I(t) = A\cos\omega t + B\sin\omega t$, then $I(t)$ is represented as either $Re(I_0e^{j\omega t})$, in which $I_0 = A - jB$, or, if preferred, by $I(t) = Re(I_{00}e^{j\omega t + j\phi})$, in which $I_{00} = (A^2 + B^2)^{1/2}$ and $\tan\phi = -B/A$. In the differential equations describing the circuit $I(t)$ is replaced by $Re(j\omega I_0e^{j\omega t})$. In the complete equations all the *Re* signs are dropped and the common factors $e^{j\omega t}$ are can-

celled. This leaves a set of algebraic equations relating complex numbers. When these equations have been solved and V_0 is given in terms of I_0, for example, the real time-dependent voltage is $V(t) = Re(V_0 e^{j\omega t})$. Further, if $V_0 = (X - jY)$, the amplitude of

$$V(t) = (X^2 + Y^2)^{1/2}$$

and its phase angle is $\tan^{-1} y/x$. In practice this reduces to leaving resistances as real quantities and replacing inductances L and capacitances C by reactances $j\omega L$ and $1/j\omega C$. The circuit equations are then solved using dc techniques.

Reactance and impedance

The term reactance is reserved for an imaginary quantity such as $j\omega L$, $1/j\omega C$, or $j(\omega L - 1/\omega C)$. A mixed term (*e.g.*, $R + j\omega L$) is called an impedance.

If $c = a + jb$, the number $c^* = a - jb$ is called its complex conjugate (cc), and, therefore, the product of a number and its complex conjugate is $cc^* = a^2 + b^2$. Thus $(cc^*)^{1/2}$ is the length of c on the Argand diagram. If γ and c are complex numbers and $\gamma = \alpha + j\beta$, then

$$\frac{\gamma}{c} = \frac{\gamma c^*}{cc^*} = \frac{\alpha a + \beta b + j(a\beta - \alpha b)}{a^2 + b^2}. \qquad (49)$$

The denominator is real and so equation (49) can be used as a general rule for picking out the real and imaginary parts of a complex fraction.

If $V(t) = Re(V_0 e^{j\omega t})$ and $V_0 = U + jW$, this means that $V(t) = U \cos \omega t - W \sin \omega t$. Similarly, if $I(t) = Re(I_0 e^{j\omega t})$ and

$$I_0 = H + jJ, I(t) = H \cos \omega t - J \sin \omega t,$$

then

$$I(t)V(t) = UH \cos^2 \omega t + WJ \sin^2 \omega t - (UJJ + WH) \sin \omega t \cos \omega t.$$

The average power (P_{av}) dissipated in a circuit in a time T is given by

$$P_{av} = \frac{1}{T}\int_0^T I(t)\, V(t) dt,$$

into which the preceding equation of three terms can be substituted. It is presumed that T contains many cycles or that T is exactly an integral number of cycles. In other words, either $\omega T \to \infty$ or $\omega T = 2n\pi$, with n an integer. The three resulting integrals may be integrated as follows:

$$\frac{1}{T}\int_0^T \cos^2 \omega t\, dt = \tfrac{1}{2}, \qquad (50)$$

$$\frac{1}{T}\int_0^T \sin^2 \omega t\, dt = \tfrac{1}{2},$$

$$\frac{1}{T}\int_0^T \sin \omega t \cos \omega t\, dt = 0,$$

resulting in an expression for the average power, $P_{av} = \tfrac{1}{2}(UH + JW)$.

From the relations

$I_0 V_0^* = (H + jJ)(U - jW) = UH + JW + j(JU - HW)$

and

$$I_0^* V_0 = UH + JW - j(JU - HW),$$

it follows that the average power can be written as either

$$P_{av} = \tfrac{1}{2}\, Re(I_0 V_0^*),$$

$$P_{av} = \tfrac{1}{2}(Re I_0^* V_0),$$

or

$$P_{av} = \tfrac{1}{4}(I_0 V_0^* + I_0^* V_0).$$

Assuming that

$$V_0 = ZI_0 = (R + jX)I_0,$$

then the average power becomes

$$P_{av} = \tfrac{1}{2}\, Re([R + jX]I_0 I_0^*) = \tfrac{1}{2} R I_0 I_0^*,$$

so that P_{av} depends only on the real part R of the impedance Z.

The results (50) are of course of more general interest. If a current $I_0 \cos \omega t$ or $I_0 \sin \omega t$ flows in a resistance R, the average power is $\tfrac{1}{2} R I_0^2$. In many cases, especially power engineering, the power (the basis of the monetary charge) is of more interest than anything else. Thus it is quite usual to find in texts a voltage $V_0 \cos \omega t$ or a current $I_0 \cos \omega t$ specified in terms of its rms (root mean square) amplitude $V_0/\sqrt{2}$ or $I_0/\sqrt{2}$. For example, the 120-volt main has a root-mean-square voltage of 120 volts; however, its amplitude or peak voltage is 170 volts. The peak to peak voltage is 340 volts. (The use of amplitudes in this article will not be abandoned for rms quantities unless explicitly stated.)

With a little practice the use of complex numbers to represent ac quantities becomes easy, and, when, for example, it is found that $V_0 = (R + jX)I_0$, it is unnecessary to remark that the amplitude of $V(t)$ is $(R^2 + X^2)^{1/2}$ times that of $I(t)$ and that $V(t)$ leads the phase of $I(t)$ by $\tan^{-1} X/R$; a second thought need not be given to the mathematical infrastructure.

THE BASIC ALTERNATING-CURRENT CIRCUIT LAWS

In dc circuits the basic laws are those defining emf (electromotive force) and Ohm's law together with Kirchhoff's laws. In ac circuits, Ohm's law is extended so that the back emf's caused by capacitors and inductors can be included; in addition, there is a completely different type of effect involving four terminals, the mutual inductance. The back emf's due to resistance R, capacitance C, and inductance L are IR, q/C and LI and in addition, for a capacitance $I = dq/dt$.

Kirchhoff's laws applied to ac circuits maintain the same form. The sum of all the currents leading to any node is zero and the sum of the emf's around any closed loop is zero.

Kirchhoff's laws in ac circuits

Next, the physical significance of the two Kirchhoff laws in ac circuits may be considered. If two resistances bring currents I_1 and I_2 to a node connected to a capacitance with a charge q, conservation of charge implies that $I_1 + I_2 = dq/dt$; but dq/dt is, in ac circuit terms, the current I_3, and so the law $I_1 + I_2 - I_3 = 0$ still depends on the law of charge conservation. In dc circuits the second Kirchhoff law is related to the property of the electrostatic field expressed by $\nabla \times \boldsymbol{E} = 0$—*i.e.*, the line integral of $\boldsymbol{E}$ round any closed loop is zero. In time-dependent situations, Faraday's law gives $\nabla \times \boldsymbol{E} = -\boldsymbol{B} \neq 0$. In the circuit shown in Figure 22, the line integral of

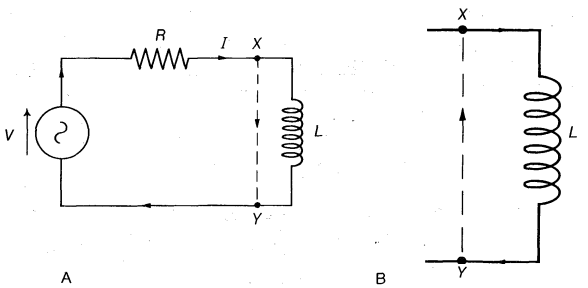

Figure 22: *Paths of integration (shown by arrows).* (A) Excluding changing magnetic flux; (B) including changing magnetic flux (see text).

$\boldsymbol{E}$ is taken round a closed loop that starts at the top of the voltage generator, passes through R, then leaves the conductor passing outside L from X to Y, and rejoining the conductor below L, finally returns through the generator, and is zero because it links no changing magnetic flux. The contribution to this line integral from the path XY outside L is LI, which is equal to $d\psi/dt$, the flux change linked by the windings of L. The electric field in these windings satisfies the equation

$$\oint \boldsymbol{E} \cdot \boldsymbol{dl} = -\frac{d\psi}{dt}, \qquad (51)$$

taking the closed path of integration as shown in Figure 22B. Because the section YX contributes $-d\psi/dt$, $\boldsymbol{E}$ must be zero in the actual conductor. Thus Kirchhoff's law is no longer related to the line integral of $\boldsymbol{E}$ round the actual circuit but to the equation (51). By including back emf's from self-inductance, or induced emf's from mutual inductance, however, the term $d\psi/dt$ has been explicitly included in the circuit equations.

In dc circuits any real source of emf, such as a battery, has a finite internal resistance. Real sources of alternating emf's such as motor alternators or electronic oscillators will not only have internal resistance but may also have a more complicated internal impedance. Whatever load is connected to the terminals, the voltage V_L and current I_L in this load must bear a linear relation to each other. In complex notation this gives

$$V_{LO} = -ZI_{LO} + V_{SO},$$

in which $Z = R + jX$ may be complex. The open circuit voltage is V_{SO}, and the short circuit current is V_{SO}/Z. Thus a source of emf can always be represented by an equivalent circuit incorporating an internal impedance Z. It is notable, however, that Z will almost certainly depend on the frequency of the alternating voltage. Again, as in dc circuitry, impedance can be measured as the ratio of the open circuit voltage to the short circuit current. Here a new problem may arise, for the short circuit current and the open circuit voltage need not be in phase. Thus the measurement gives only Z's magnitude *i.e.*, $|Z| = (ZZ^*)^{1/2}$. To obtain a complete specification requires a more elaborate measurement.

The power delivered to the load, averaged over a cycle, is $\frac{1}{2}R_L I_0 I_0^*$ and this is a maximum when the load reactance X_L is chosen to cancel the reactance X. It is then

$$P_{av} = \tfrac{1}{2}R_L V_0 V_0^*/(R + R_L)^2,$$

and this can be further maximized by choosing R_L to be equal to R. When this is done the maximum average power is $V_0 V_0^*/8R$, or, in terms of the rms open circuit voltage, $V^2_{rms}/4R$. The available power thus depends only on voltage V_0 and resistance R and not at all on reactance X. Whereas in dc circuits the optimum load is equal to the internal resistance of the generator, in ac circuits the optimum load is the complex conjugate of the internal impedance $Z_L = Z^* = R - jX$.

In some applications, particularly those in which there are a number of circuit elements in parallel across a source emf, it is convenient to represent the source as a current generator in parallel with an impedance Z. If the strength of the current generator is $I(t) = Re(I_0 e^{j\omega t})$, the open circuit voltage is $V(t) = Re(I_0 Z e^{j\omega t})$ and the short circuit current is $I(t) = Re(I_0 e^{j\omega t})$.

In dc circuits the conductance (G) of a circuit element is the inverse of its resistance. In ac circuits the quantity $Y = 1/Z$ is called the admittance and is complex. If $Z = R + jX$, the admittance is

$$Y = \frac{1}{R + jX} = \frac{R - jX}{R^2 + X^2};$$

and, when the admittance Y is separated into real and imaginary parts, $Y = G + jB$, the conductance G is

$$G = \frac{R}{R^2 + X^2},$$

and the susceptance B is defined as

$$B = -\frac{X}{R^2 + X^2}.$$

THE DETECTION AND MEASUREMENT OF ALTERNATING CURRENTS AND VOLTAGES

Heating effects of ac in a resistance

The simplest method of detecting the presence of either ac currents or voltages is by observing their heating effects in a resistance. A number of ac meters operate on this principle. In one form of the hot wire ammeter, the current flows in a fine wire attached to a pivoted needle, and thermal expansion of the wire moves the needle. A somewhat more sensitive instrument uses the heat produced to alter the temperature of a small bead of a semiconducting compound, and the heat produced is detected or measured by observing the change in the dc resistance of the bead. This technique is especially useful at high (microwave) frequencies. If the frequency lies in the audio range, quite weak ac signals can be detected using a pair of headphones. The force acting between the two plates of a capacitor is proportional to the square of the potential difference. If this is $V \cos \omega t$ the force $KV^2 \cos^2 \omega t = \frac{1}{2}KV^2(1 + \cos 2\omega t)$, in which K is a constant, contains a static component that can be measured. This is not a sensitive method of detecting weak signals, but it can be used to construct a simple instrument for measuring alternating voltages above about 100 volts. The usual electrostatic voltmeter found in the laboratory is not an accurate instrument, but it is possible to construct accurate meters and these are of practical importance.

The most sensitive method of detecting the presence of a weak ac signal undoubtedly involves the use of an electronic amplifier to bring it up to a level at which it can be used to operate a loudspeaker, a cathode ray oscilloscope, or some form of meter. The two most basic methods of measuring alternating currents and voltages are by the cathode ray oscilloscope and by the use of a rectifier to produce a direct current that can then be measured in the usual way.

In the cathode ray oscilloscope (CRO), or cathode ray tube (CRT), an electron beam in a high vacuum is focussed to a point on a fluorescent screen, where it produces a bright spot of light. The beam passes in vacuum between two pairs of electrostatic deflection plates, and potential differences applied across these plates deflect ("sweep") the beam, and the spot of light, horizontally (by convention, the X direction) or vertically (in the Y direction). The amplitude of an alternating voltage can be measured to about one-percent accuracy by the magnitude of the deflection it produces. The phase angle between two different voltages can be obtained by applying one voltage to the X plates and the other to the Y plates and observing the elliptical trace that is produced. The most usual mode of using a CRO is, however, to apply a linear sweep to the X plates and the unknown voltage to the Y plates. If the sweep duration occupies several cycles of the alternating voltage, the wave form is traced out on the screen. The cathode ray tube itself is a relatively insensitive device and requires a potential difference between the Y plates of 100 volts to produce a full scale deflection; an amplifier is thus usually required to detect and measure small signals. Most commercial oscilloscopes incorporate a calibrated linear amplifier and a time-base circuit for producing the linear X sweep. An oscilloscope in conjunction with a sensitive, high-gain amplifier is perhaps the most useful instrument for detecting the presence of small alternating signals.

Rectifying ac currents

A junction between n-type and p-type silicon passes current easily when the n-type material is made negative and is almost an insulator when the polarity is reversed. Many other systems have this property in varying degrees and can be used to rectify alternating currents. If a perfect rectifier, one which behaved as a short circuit in one direction and an open circuit in the other, existed, it would rectify all small alternating signals. Practical rectifiers are not perfect and usually, although little current flows with reverse voltage, an appreciable voltage, of from 0.1 volt to one volt is required before the forward current begins to rise rapidly. As a result, ac instruments based on the dc measurement of rectified ac cannot be used at extremely low voltages unless they are preceded by an amplifier. Numerous electronic circuits have been devised to overcome this problem, and in practice there is no difficulty in measuring ac voltages down to a few millivolts.

The simple rectifier circuit consisting of a rectifier element and a dc meter in series is not an efficient system and most ac instruments use the bridge rectifier shown in Figure 23. When the point X is positive with respect to Y, the rectifiers A and C are conducting, the + output lead is connected to X, and the — lead is connected to Y. When X is negative, D and B conduct and again the + lead is connected to the positive input, which is now Y, and the — lead is connected to X, which is negative. Both half cycles of the alternating voltage contribute to the output.

In general, with modern equipment, ac measurements at frequencies below about one megahertz (10^6 Hz) are no more difficult than dc measurements, although the accuracy attainable is appreciably less. Above about one

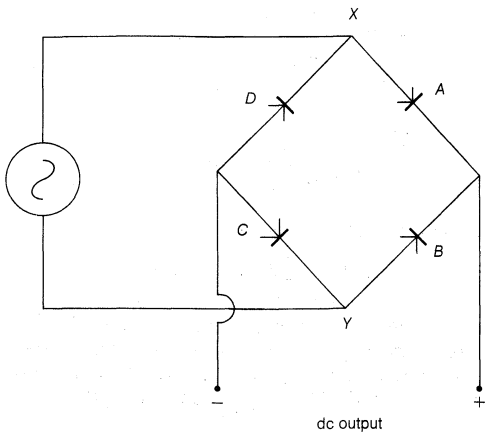

Figure 23: Bridge rectifier (see text).

megahertz, effects caused by stray lead inductance and capacitance become a serious nuisance, and, in addition, the sensitivity and calibration of measuring instruments tends to deteriorate. The only high-frequency electrical measurement of high accuracy that can be made with any ease is that of frequency itself.

In the subsections below it is assumed that no problems arise in the detection and measurement of ac quantities. It should be kept in mind, however, that elaborate calculations of the properties of ac networks at high frequencies are of doubtful utility when precise measuring instruments, as well as precisely specified circuit components, are not available. Computer applications to ac circuit theory are justified only because the calculations are faster and simpler, not because they are more accurate, than manual calculations.

RESONANT CIRCUITS

The parallel resonant circuit shown in Figure 24 is not only important in its own right but its behaviour also has far-reaching analogies throughout the rest of physics. The equations that relate the current (I), the charge (q), and the voltage (V) in terms of the capacitance (C) and inductance (L) are

$$I = \frac{dq}{dt},$$
$$q = CV,$$
and
$$L\dot{I} + V = 0.$$

If the quantities I and q are eliminated from the above three equations there remains

$$LC\frac{d^2V}{dt^2} + V = 0.$$

This is the classical harmonic oscillator equation and its general solution is

$$V(t) = A\cos\omega_0 t + B\sin\omega_0 t,$$

in which

$$\omega_0 = \left(\frac{1}{LC}\right)^{\frac{1}{2}}. \qquad (52)$$

This solution corresponds to an undamped oscillation of natural frequency $\omega_0/2\pi$. The current in the circuit is $I(t) = C(dV/dt) = \omega_0 C(B\cos\omega_0 t - A\sin\omega_0 t)$.

The general solution can also be written as

$$V(t) = V_0\cos(\omega_0 t + \phi)$$

and

$$I(t) = \omega_0 CV_0\cos(\omega_0 t + \phi + \pi/2).$$

The energy (U) stored in the system is

$$U = \tfrac{1}{2}LI^2(t) + \tfrac{1}{2}CV^2(t),$$

and, since $\omega_0^2 LC = 1$ from (52), this can be expressed as

$$U = \tfrac{1}{2}CV_0^2(\cos^2[\omega_0 t + \phi + \pi/2] + \cos^2[\omega_0 t + \phi]) = \tfrac{1}{2}CV_0^2.$$

In terms of the peak current, $I_0 = \omega_0 CV_0$, this is

$$U = \tfrac{1}{2}LI_0^2.$$

At the instant when V reaches its peak value, I is zero and all the energy is stored in C; a quarter of a cycle later, I reaches its peak value and V is zero; the energy is now all stored in L. Thus the energy oscillates back and forth between the capacitor and the inductor.

If the resonant circuit contains resistance in series with L as shown in Figure 24B, the basic equations will be $I = dq/dt$, $V = q/c$, and $L\dot{I} + RI + V = 0$; and these give the differential equation

$$LC\frac{d^2V}{dt^2} + RC\frac{dV}{dt} + V = 0.$$

The behaviour of the solutions of this equation depends critically on whether $(RC)^2 \geq 4LC$, or $(RC)^2 < 4LC$. If $(RC)^2 > 4LC$, the solution is of the form

$$V(t) = Ae^{-\alpha_1 t} + Be^{-\alpha_2 t},$$

in which the coefficients α_1 and α_2 are real. This behaviour corresponds to an exponentially decaying excitation. When $(RC)^2 = 4LC$ the solution is of the form

$$V(t) = (A' + B't)e^{-Rt/2L}$$

and is also exponentially damped. The most interesting case is that in which $(RC)^2 < 4LC$ and, in fact, in most cases $(RC)^2 << 4LC$. In this case the general solution is a damped oscillation

$$V(t) = (A\cos\omega t + B\sin\omega t)e^{-Rt/2L} \qquad (53)$$

in which

$$\omega = \omega_0\left(1 - \left[\frac{R}{2\omega_0 L}\right]^2\right)^{\frac{1}{2}},$$

and $\omega_0 = (LC)^{-\frac{1}{2}}$ is the natural (angular) frequency of the undamped oscillations.

The dimensionless parameter $\omega_0 L/R$ is of such importance that it is given a name, the quality factor Q. In terms of Q,

The quality factor Q

$$\omega = \omega_0\left(1 - \frac{1}{4Q^2}\right)^{\frac{1}{2}}.$$

In practice, the quality factor is usually quite large, values of from 10 to 10^5 occurring in resonant circuits, and so approximately

$$\omega \simeq \omega_0\left(1 - \frac{1}{8Q^2}\right).$$

Even if Q is as small in value as three, ω differs from ω_0 by only 1.3 percent. The difference between ω and ω_0, the damped and undamped frequencies, may almost always be neglected in calculations.

The exponential decay term in (53) can be expressed in terms of Q as $e^{-\omega_0 t/2Q}$. Thus the amplitude of the oscillations decays by a factor e^{-1} in a time $\frac{2Q}{\omega_0}$, and in this time the number of cycles of oscillation is Q/π. The decay (damping) in one cycle of oscillation is $e^{-\pi/Q}$, and the parameter π/Q is sometimes called the logarithmic decrement.

The stored energy in the circuit can be expressed in terms of the peak current (I_0) as $\frac{1}{2}LI_0^2$. This current flows through the resistance (R) and the average power (P) dissipated is $P = \frac{1}{2}RI_0^2$. The dimensionless ratio $\omega_0 U/P$ is equal to the quality factor since

$$\frac{\omega_0 U}{P} = \frac{\omega_0 \frac{1}{2}LI_0^2}{\frac{1}{2}RI_0^2} = \frac{\omega_0 L}{R} = Q.$$

Thus Q can also be regarded as a measure of how long, measured in radians of the oscillation, it takes the stored energy to decay. For many purposes this is the most useful definition of Q. It can be used in circumstances in which Q is not given by any simple expression in terms of circuit parameters, such as L, C, and R.

The parameter Q has two other important properties related to the response of a resonant circuit to an impressed electromotive force or current. Figure 24 includes in the circuit a voltage generator $v \cos \omega t$, in which ω is not necessarily equal to ω_0. The current in the circuit is

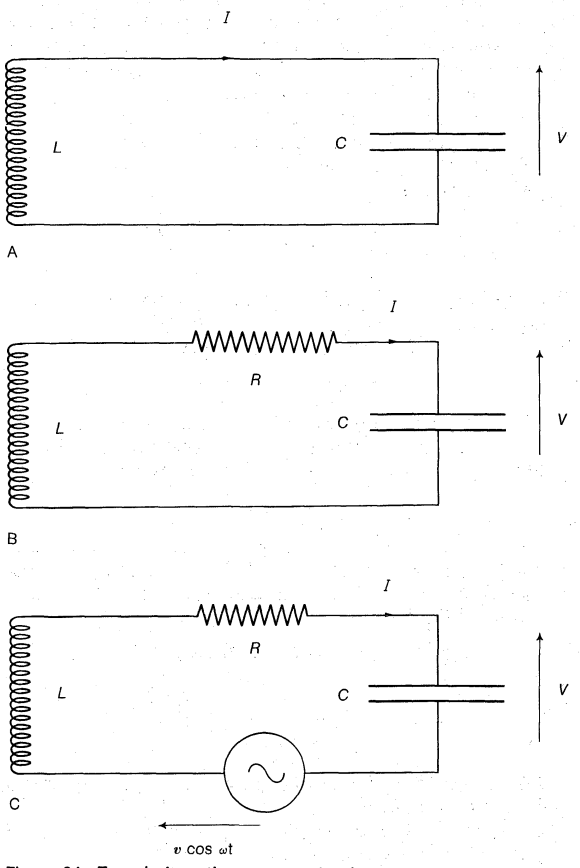

Figure 24: *Tuned alernating current circuits.*
(A) Lossless; (B) series loss; (C) forced (see text).

$$I = \frac{v}{j\omega L + R + \frac{1}{j\omega C}}$$

and the voltage (V) across the capacitor is

$$V = \frac{I}{j\omega C};$$

so that

$$V = \frac{v}{1 - \omega^2 LC + j\omega CR}$$

or

$$V = \frac{[(1 - \omega^2 LC) - j\omega CR]v}{(1 - \omega^2 LC)^2 + \omega^2 C^2 R^2}.$$

It can be seen from this equation that there are in-phase and out-of-phase components of V and that

$$|V|^2 = \frac{v^2}{(1 - \omega^2 LC)^2 + \omega^2 C^2 R^2}.$$

In many applications in electronics, a tuned circuit is used as a frequency selective element, and the interest is in the behaviour of the impedance or admittance of the circuit, especially near the resonant frequency. The impedance Z measured across the capacitance C of the circuit of Figure 24C when the voltage generator $v \cos \omega t$ is removed is

$$Z = \frac{j\omega L + R}{1 - \omega^2 LC + j\omega CR}.$$

If ω is near the resonance frequency, $\omega_0 = (LC)^{-\frac{1}{2}}$, Q is large, and it is permissible to neglect R in the numerator compared with ωL and express Z as

$$Z = \frac{Z_0}{1 + j\frac{\omega_0 L}{R}\left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega}\right)},$$

or

$$Z = \frac{Z_0}{1 + jQ\left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega}\right)},$$

in which the constant Z_0 has the value

$$Z_0 = \frac{L}{CR} = \frac{Q}{\omega_0 C} = Q\omega_0 L$$

and is the impedance at resonance when $\omega = \omega_0$. If Q is large and only the region near resonance is of interest and ω is expressed as $\omega = \omega_0(1 + \Delta)$ in which Δ is small, the resonance term Z/Z_0 can be approximated by the function

$$F = \frac{1}{1 + jQ\left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega}\right)} \simeq \frac{1}{1 + 2jQ\Delta}.$$

This can also be written as

$$F = \frac{1 - 2jQ\Delta}{1 + 4Q^2\Delta^2}.$$

The real part—*i.e.*, the part of Z (or Y) that leads to a component of voltage (current) in phase with the impressed current (voltage)—has a peak when $\Delta = 0$ (*i.e.*, when $\omega = \omega_0$) and is down to half its peak value at $\Delta = \pm \frac{1}{2}Q$. Thus the bandwidth, or frequency interval, between these points is ω_0/Q in terms of angular frequency, or ν_0/Q in terms of frequency $\nu = \omega/2\pi$. The imaginary, or out-of phase, component has a positive peak in which $F = +j/2$ at $\omega = \omega_0(1 - \frac{1}{2}Q)$ and a negative peak in which $F = -j/2$ at $\omega_0(1 + \frac{1}{2}Q)$.

The modulus, or absolute value, of F is

$$|F| = \left(\frac{1}{1 + 4Q^2\Delta^2}\right)^{\frac{1}{2}},$$

and this peaks at $\Delta = 0$. At $\Delta = \pm \frac{1}{2}Q$, $\omega = \omega_0(1 \pm \frac{1}{2}Q)$, $|F|$ is reduced by $1/\sqrt{2}$. The two frequencies $\omega_0(1 \pm \frac{1}{2}Q)$ are often referred to as the half-power points.

Half-power points

Many practical applications (*e.g.*, in radio receivers) require resonant circuits in which the quality factor Q and selectivity are higher than can easily be achieved with simple inductances or coils. In practice it is relatively easy to achieve values of Q of about 200 at frequencies up to about 100 megahertz, and above 100 megahertz, although ordinary tuned circuits of high Q are difficult to construct, it is possible to use resonant lines or hollow cavities.

Indeed, in the optical region it is practicable to design resonant systems with quality factors exceeding 10^6. There is, however, a need for circuits with Q of this order at low radio frequencies, and, for this purpose, quartz-crystal piezoelectric resonators are employed.

If a quartz crystal is mounted between two plates, the piezoelectric stress S induced in the crystal is proportional to the plate voltage, thus $S = \gamma V$, in which γ depends on the plate geometry and the piezoelectric coefficient of the crystal. The induced polarization (β) of the crystal, and thus the charge (q) on the plates, is proportional to the strain s resulting from the stress S—*i.e.*, $q = \beta s$. Thus the current in the lead to the plate is $I = \beta \dot{s}$. The crystal is a mechanical resonant system the natural frequency ω_0 of which is determined by its shape and elastic moduli. The resonance is damped by internal friction and also air damping and the presence of the electrodes. It is then possible to show that, if ρ is the frictional damping term, the frequency response of the admittance (Y) is

$$Y = \frac{Y_0}{1 + j\frac{\omega_0}{\rho}\left(\frac{\omega}{\omega_0} - \frac{\omega_0}{\omega}\right)},$$

which is a typical resonant response with $Q = \omega_0/\rho$. The importance of the quartz-crystal resonator is that Q can easily exceed 10^5 throughout the frequency range 10^5 to 10^8 hertz—*i.e.*, the normal radio frequency range. It is also relatively easy to design the crystal so that Y_0 has a value compatible with conventional electronic circuit components.

When two tuned circuits are coupled together, new phenomena appear. If both circuits have the same natural resonance frequency ω_0 and quality factor Q and if a coupling term γ is defined so that, when V_1 and V_2 are the voltages across the two circuits, the stored energy can be expressed as $U = \frac{1}{2}\Gamma_1 V_1^2 + \frac{1}{2}\Gamma_2 V_2^2 + \gamma(\Gamma_1\Gamma_2)^{\frac{1}{2}} V_1 V_2$, then, when $Q\gamma$ exceeds unity, the single resonance at $\omega = \omega_0$ splits into two resonances (here Γ_1 and Γ_2 are energy coefficients or capacitances associated with the individual tuned circuits). If the coupling is through a capacitance, one resonance occurs at $\omega = \omega_0$ and the other at a lower frequency. If, as in the interstage transformers of a radio receiver, the coupling is through mutual inductance, the two frequencies lie above and below ω_0. The coupled, tuned circuit finds widespread applications in electronics as a band-pass element.

ALTERNATING-CURRENT BRIDGES

In dc circuits the Wheatstone bridge is a simple and accurate instrument for measuring resistance. The ac analogues of the Wheatstone bridge are equally important for determining the impedance of circuit elements. There are, however, a number of significant differences between ac and dc measurements. First of all, an ac impedance involves two numbers. These numbers may be regarded as either its real and imaginary parts, or as its in-phase and out-of-phase parts, or as its magnitude and phase angle, but, however they are regarded, a more elaborate measurement is required. A second difference is that both components of an impedance are likely to be frequency dependent so that measurements may be needed over a range of frequencies. A third difference is that, whereas in dc measurements all possible elements are of the same type—*i.e.*, resistances—in ac measurements there are four basic elements: the resistance, the capacitance, the inductance, and the mutual inductance. Furthermore, with the possible exception of capacitance, these elements are rarely separable, any real coil of wire has not only inductance but also resistance and some stray capacitance, and any real resistor also has inductance and stray capacitance. It is in fact difficult to construct standard elements of R, L, and C with which to compare an unknown element. Finally, the wiring of the bridge itself contributes significant components of R, L, and C, especially at high frequencies. For this reason ac bridge measurements are usually rather less accurate than dc measurements, except at low frequencies. In many cases it is easier to obtain accurate values by other methods. As an example, if an element is known to be an inductance (L) about one microhenry (10^{-6} henry) and a resistance (R) of about 0.1 ohm much the easiest way of measuring L is to place a standard capacitance C in parallel with the element and measure the resonant frequency ω_0; then $L = 1/\omega_0^2 C$. At the same time, if Q is obtained from the frequency response, then $R = \omega_0 L/Q = 1/Q\omega_0 C$. In the practical laboratory concerned with ac measurements, the Q meter, measuring both ω_0 and Q, is much more generally useful than a bridge.

Differences between ac and dc measurements

Obviously any bridge measurement is only as accurate as the reference elements used in the arms of the bridge, and it is also desirable that the elements should be as nearly as possible simple resistances, capacitances, or inductances. It is relatively easy to construct a capacitance with negligible series inductance and resistance in its leads and not too difficult to construct a resistance in such a way that it has only a slight series inductance or parallel capacitance. It is, however, almost impossible to wind an inductance coil of negligible resistance. Thus, as far as possible, in an ac bridge an attempt is made to use only resistances and capacitances in the reference arms.

The basic ac bridge circuit is similar to the Wheatstone bridge, Figure 13, but has the resistances replaced by impedances. The null detector may be an ac meter, although it is usually more convenient to use an amplifier and oscilloscope. The bridge is balanced and the null detector reads zero when

$$\frac{Z_1}{Z_2} = \frac{Z_1'}{Z_2'}.$$

Because the impedances are complex, this implies two conditions involving both the real and imaginary parts. If $Z_1 = R_1 + jX_1$ is the unknown impedance, then at least one of the other impedances must be complex. There is no need for all three to be complex. If X_1 is positive so that Z_1 is inductive, it would be inconvenient to make Z_1' and Z_2' real since then Z_2 would have to be inductive, which is to be avoided. The impedances Z_2 and Z_1' may be made real, however, and Z_2' capacitative —*i.e.*, $Z_2 = R_2$, $Z_1' = R_3$ and $Z_2' = R_4 - jX_4$. The balance condition then becomes $(R_1 + jX_1)(R_4 - jX_4) = R_2R_3$, or, $R_1R_4 + X_1X_4 = R_2R_3$ and $R_1X_4 = R_4X_1$. If $Z_1 = R_1 + j\omega L_1$ and $Z_2' = R_4 + 1/j\omega C_4$, as shown in Figure 25 (top), then the two balance conditions become

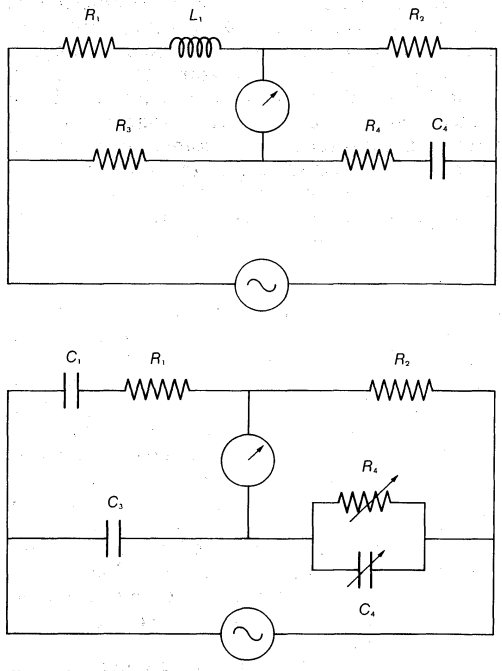

Figure 25: *Alternating-current bridges.*
(Top) Impractical circuit; (bottom) Schering capacitance bridge (see text).

$R_1R_4 + L_1/C_4 = R_2R_3$ and $\omega^2 L_1 C_4 R_4 = R_1$. This result is most unsatisfactory, first of all because the second condition depends on ω, which may not be known, and also because variation of R_4 or C_4 to satisfy this second condition upsets the balance implied by the first condition. For this reason, practical ac bridges do not usually take this form. It is impossible to discuss all possible forms of bridge but one special case: the Schering capacitance bridge, named for the German engineer H. Schering, serves to illustrate the principles involved.

The Schering capacitance bridge

The Schering bridge is shown in Figure 25 (bottom). The unknown capacitance is C_1, R_2 is a fixed known resistance, and C_3 a fixed known capacitance of the same order of magnitude as C_1. Balance is achieved by varying the calibrated components C_4 and R_4. The balance condition is

$$j\omega C_3(R_1 + 1/j\omega C_1) = R_2(1/R_4 + j\omega C_4),$$

and the in-phase and out-of-phase, or real and imaginary, equations are

$$C_3R_4 = C_1R_2 \quad (54)$$
$$C_3R_1 = C_4R_2 \quad (55)$$

Both equations are independent of ω, and (54) can be sat-

isfied by variation of R_4 alone, whereas (55) is satisfied by variation of C_4 alone. Thus, the procedure is first to minimize the detector reading by varying R_4 and then to obtain the final null using C_4.

It has been pointed out above that one of the most useful laboratory ac instruments is the Q meter, and this section on bridges ends with a brief résumé of its operation. The basic circuit is shown in Figure 26. Provided that the

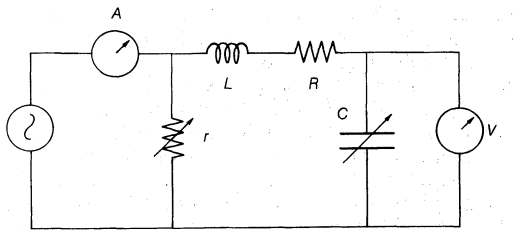

Figure 26: The Q meter (see text).

voltmeter V has a high enough impedance, its reading is a maximum when $\omega^2 LC$ equals one and has the value QIr. In practice neither the ammeter A nor the voltmeter V is accurate enough to make much use of this relation, and, in the usual instrument, the source of the ac voltage is adjusted to bring the ammeter reading to a fiduciary mark, say half full scale; C is then adjusted to maximize the voltmeter reading, and finally the variable resistor r is adjusted to bring this reading to another fiducial mark. The instrument is calibrated so that the value of Q can be read from the setting of r. A typical instrument has a variable frequency-calibrated oscillator covering a range of, say, 100 kilohertz to 100 megahertz.

NONLINEAR ELEMENTS

Metallic resistors, air-cored inductors, and capacitors employing normal dielectric insulators are nearly linear elements; *i.e.*, in the equations $V = IR$, $V = L\dot{I}$, and $V = q/C$, the quantities R, L, and C are nearly independent of V, I, or q. There are, however, many practical components the behaviour of which is appreciably nonlinear. An extreme case is the semiconductor diode in which the current-voltage relation is of the form $I = I_0(e^{V/V_0} - 1)$, in which I_0 and V_0 are constants, but in many other cases there are less drastic departures from linearity. For example, in an iron-cored inductor, the value of L decreases at high currents because of saturation, and, in a capacitor with a ferroelectric ceramic dielectric, the relation between charge and applied voltage is quite often extremely nonlinear.

In most cases the presence of nonlinear components in a system has undesirable effects, but in a few cases the nonlinear response can be put to practical use. The basic effects associated with nonlinear components can easily be seen by considering a nonlinear resistor passing a current $I(t) = I \cos \omega t$. If the voltage current relation can be expressed as the sum of current components (1), (2), (3), etc.,

$$V(t) = R_1 I(t) + R_2 I^2(t) + R_3 I^3(t) + \text{etc.},$$

then, since

$$\cos^2 \omega t = \frac{1}{2}(1 + \cos 2\omega t),$$

$$\cos^3 \omega t = \frac{1}{4}(\cos 3\omega t + 3 \cos \omega t), \text{ etc.},$$

the voltage across the resistor will, in addition to terms at the fundamental frequency, contain terms at the second and third harmonic frequencies 2ω and 3ω. Furthermore, if the current $I(t)$ contains terms at two or more frequencies ω_1, ω_2, the voltage will contain terms at the various beat frequencies $\omega_1 + \omega_2$, $2\omega_1 + \omega_2$, etc. If, for example, the nonlinear element forms part of an audio amplifier used for the reproduction of music, the spurious tones generated in the output will produce a most disagreeable effect on the listener.

The parametric amplifier used in the sensitive microwave receiver required for satellite communication relies on the nonlinear voltage–charge relation $V = Aq^2$ in a special semiconductor diode, utilizing a reverse-biased junction. If the diode is fed with both a signal current at ω_1 and a large "pump" current at $\omega_1 + \omega_2$, it generates an idler voltage at ω_2. This idler voltage drives current at the same frequency ω_2 in a resistive load, and then this idler current recombines with the pump current at $\omega_1 + \omega_2$ to generate a component at ω_1. The new signal frequency current can, if conditions are right, deliver more power to a load than is extracted from the signal source. The device is, therefore, an amplifier. Because it generates much less internal noise than conventional amplifiers, it is particularly useful in dealing with weak signals.

ELECTRIC WAVES IN CABLES

Capacitance and inductance in cables

Any two-wire cable—*e.g.*, a coaxial cable, a parallel wire line, or a twisted pair—has some stray capacitance between the two wires of the cable. Furthermore, when a current flows in the cable, it produces a magnetic field near the conductors, and, when the current changes, the changing magnetic field produces a back electromotive force in the cable. Thus, in general, any cable has a certain capacitance and self-inductance. The capacitance and inductance are proportional to the length of the cable and so may be defined as a capacitance C per unit length and an inductance L per unit length. In some cases, in which the shape and arrangement of the conductors are particularly simple, L and C can be calculated. For example, in a coaxial cable having a circular inner conductor of radius a within a circular sheath of radius b and with the space between the two conductors being filled with an insulator of dielectric constant ϵ, the values for inductance and capacitance are

$$L = \frac{\mu_0}{2\pi} \log \frac{b}{a} \quad \text{and} \quad C = 2\pi\epsilon\epsilon_0 \left(\log \frac{b}{a}\right)^{-1}$$

In this case the product is $LC = \mu_0\epsilon_0\epsilon$, which not only is independent of the dimensions of the line but also can be written $LC = (1/c')^2$, in which c' is the velocity of light in the dielectric. This is in fact a particular example of a general result that follows from Maxwell's field equations. For any cable, the quantity $(LC)^{-1/2}$ is less than the velocity of light in vacuum; if the cable consists of uniform straight conductors $(LC)^{-1/2}$ equals c', in which c' is the velocity of light in the medium surrounding the conductors. It will not be unexpected to find, as explained below, that $(LC)^{-1/2}$ is the velocity with which electric signals propagate in the cable. The fact that $LC \geq (1/c')^2$ means that a cable cannot be designed to have a low stray capacitance C without at the same time increasing its self-inductance L, and vice versa. As an example, the low-capacitance cable used to connect the stylus pickup of a record player to the audio amplifier is not suitable for connecting the amplifier to the speaker, for which a low-inductance cable is required.

If, as this suggests, electric signals propagate with a finite velocity along cables, then, when a sinusoidal voltage $V \cos \omega t$ is applied to one end of a cable of length l with a phase velocity v, the phase of the voltage at the other end of the cable is changed by $\omega l/v$ and the voltage is $V \cos (\omega t - \omega l/v)$. If $\omega = 2\pi \times 60$ second^{-1}, which corresponds to a 60-hertz supply frequency, and, if v is about equal to the velocity of light, 3×10^8 metres per second, then $\phi \simeq 4\pi 10^{-7} l$ and will not be appreciable unless the length, l, is approximately 1,000,000 metres, or 1,000 kilometres, or about 600 miles. On the other hand, if $\omega = 2\pi \times 10^8$ second^{-1} (a typical high radio frequency), then, if $l = 0.75$ metre (about two feet), the phase change is $\pi/2$ (*i.e.* 90°). This phase change is clearly significant. At high radio frequencies the phase shifts and time delays that occur in normal laboratory lengths of wire cannot be disregarded.

Figure 27 illustrates in a schematic way a long two-wire cable with a current I in the upper conductor (and I in the lower conductor) and a voltage V between the conductors. It also shows the series inductance Ldx and capacitance Cdx associated with elements of the line of length dx. Both the voltage and the current vary with

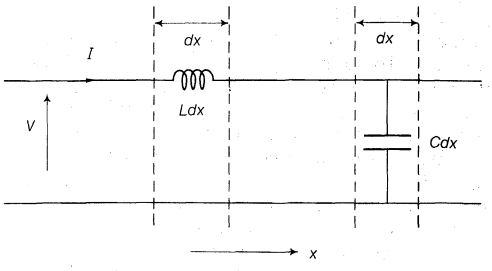

Figure 27: Series inductance and parallel capacitance in a transmission line (see text).

position and time. The instantaneous power flow to the right, past a point x, is $V(x,t)I(x,t)$.

The voltage drop in a length dx is $Ldx\ \partial I/\partial t$, and this yields the differential equation

$$\frac{\partial V}{\partial x} = -L\frac{\partial I}{\partial t}. \tag{56}$$

The charge stored in dx is $CVdx$, and, since a current I flows into dx from the left and $I + dI$ flows out from the right, this charge decreases at a rate dI. This, therefore, gives

$$\frac{\partial}{\partial t}(CV) = -\frac{\partial I}{\partial x},$$

or, because the capacitance C is independent of time,

$$\frac{\partial I}{\partial x} = -C\frac{\partial V}{\partial t}. \tag{57}$$

Equations (56) and (57) govern the behaviour of signals in the line. Before the general solution is written down it is useful to define two new quantities $v = (LC)^{-\frac{1}{2}}$ and $Z_0 = (L/C)^{\frac{1}{2}}$. In terms of these parameters v and Z_0, the current at time t is expressed as

$$I(x,t) = I_f(x - vt) + I_r(x + vt) \tag{58}$$

and the voltage as

$$V(x,t) = V_f(x - vt) + V_r(x + vt) \tag{59}$$

in which

$$V_f = +Z_0 I_f, \tag{60}$$

$$V_r = -Z_0 I_r. \tag{61}$$

The quantities I_f and V_f are functions of x and t in the combination $x - vt$, whereas I_r and V_r involve $x + vt$. If I_f is now defined as $dI_f/d(x - vt)$ and $I_r' = dI_r/d(x + vt)$ this gives $\partial I_f/\partial x = I_f'$, $\partial I_r/\partial x = I_r'$, $\partial I_f/\partial t = -vI_f'$, and $\partial I_r/\partial t = vI_r'$. Equation 56 then yields

$$Z_0(I_f' - I_r') = +Lv(I_f' - I_r'),$$

which is an identity, since $Lv = L(LC)^{-\frac{1}{2}} = (L/C)^{\frac{1}{2}} = Z_0$. The equation (57) is also satisfied identically. Thus the expressions (58) and (59) are the general solution of the cable equations if V and I are related by (60) and (61).

If $I(x,t) = I_f(x - vt)$, the current has the same value at $x = x_0 + vt$ at time t as it had at x_0 at $t = 0$. This solution represents a wave travelling to the right with velocity v. It is a forward wave. Similarly, $I_r(x + vt)$ represents a reverse wave travelling to the left with velocity v.

When only a forward wave is present,

$$V = V_f = Z_0 I_f = Z_0 I,$$

and the power flowing to the right is $VI = Z_0 I^2 = V^2/Z_0$, which is positive. When only a reverse wave is present, $V = -Z_0 I$, and the power flowing to the right is negative —*i.e.*, power flows to the left. In each case the power flows in the direction of travel of the wave.

Characteristic impedance

The quantity Z_0 is called the characteristic impedance of the line. It is the ratio of V to I in a pure forward wave. For a coaxial air-spaced cable,

$$Z_0 = \left(\frac{L}{C}\right)^{1/2} = \frac{1}{2\pi}\left(\frac{\mu_0}{\epsilon_0}\right)^{1/2} \log\frac{b}{a} \simeq 60 \log\frac{b}{a} \text{ ohms}.$$

For reasonable values of b/a, Z_0 lies between 20 and 200 ohms. Other types of cable—*e.g.*, parallel wire lines—have somewhat higher characteristic impedances, but Z_0 rarely exceeds 1,000 ohms. Practically, a two-wire cable will terminate in a resistance R. The voltage (V) at the end of the line has a value IR, but also $I = I_f + I_r$, and $V = V_f + V_r = Z_0(I_f - I_r)$,

so that

$$Z_0\frac{I_f - I_r}{I_f + I_r} = R,$$

and therefore

$$\frac{I_r}{I_f} = \frac{Z_0 - R}{Z_0 + R}.$$

Unless the resistance R and impedance Z_0 are equal, there must be a reflected wave on the line, and some of the power incident on R from a source connected to the left end of the line will be reflected back to the source. When $R = Z_0$, all the power delivered to the line by the source is absorbed in the load R and there is no reflected wave. The load R is then said to be matched to the line. This is a desirable state of affairs to achieve when cables are used to transmit radio-frequency power.

So far no assumptions have been made about the wave form of the electrical signal. There is no need for it to be sinusoidal. The results apply equally well to a train of pulses or a single pulse. If it is specifically assumed that the waves are sinusoidal so that a typical forward wave is

$$\cos\beta(x - vt) = \cos(\beta vt - \beta x),$$

then $\omega = \beta v$ is the (angular) frequency of the wave and $\lambda = 2\pi/\beta$ is the wavelength. Furthermore, $\beta = \omega(LC)^{\frac{1}{2}}$. The typical forward wave can also be expressed as an exponential function so that

$$I_f(x,t) = \mathrm{Re} I_f e^{j(\omega t - \beta x)},$$
$$V_f(x,t) = \mathrm{Re} V_f e^{j(\omega t - \beta x)},$$
$$V_f = Z_0 I_f.$$

The reverse wave is

$$I_r(x,t) = \mathrm{Re} I_r e^{j(\omega t + \beta x)},$$

with

$$V_r(x,t) = \mathrm{Re} V_r e^{j(\omega t + \beta x)},$$

in which

$$V_r = -Z_0 I_r.$$

If in this example the origin of x is taken to be at the load so that x is negative along the line toward the electromotive source, this gives

$$\frac{V_r}{V_f} = -\frac{I_r}{I_f} = \frac{R - Z_0}{R + Z_0},$$

and the voltage at x is

$$V = (V_f e^{-j\beta x} + V_r e^{j\beta x})e^{j\omega t}.$$

The square of the voltage amplitude is found by multiplying the voltage (V) and its complex conjugate (V^*) together,

$$VV^* = V_f^2 + V_r^2 + 2V_f V_r \cos 2\beta x,$$

and this has a maximum value $(V_f + V_r)^2$ when $2\beta x$ equals $n\pi$ ($n = 0, 1, 2, 3$, etc.), and a minimum value $(V_f - V_r)^2$ when $2\beta x$ equals $(n + \frac{1}{2})\pi$. The voltage standing wave ratio (VSWR) is the ratio of the maximum to minimum amplitudes—*i.e.*,

$$\text{VSWR} = \frac{V_f + V_r}{V_f - V_r} = \frac{R}{Z_0}. \tag{62}$$

(Definitions of VSWR differ; many books define the ratio as minimum to maximum rather than maximum to minimum.) A measurement of the VSWR relates R to Z_0. This is an important technique in radio engineering.

The power (P) transferred to the load is $Z_0(I_f^2 - I_r^2) = (1/Z_0)(V_f^2 - V_r^2)$ (using root-mean-square amplitudes). This can be expressed in terms of the maximum rms amplitude: $V_{max} = V_f + V_r$ as $P = \frac{1}{Z_0}\frac{V^2_{max}}{\text{VSWR}}$ or $V^2_{max} = Z_0 P(\text{VSWR})$. Thus, if the load is badly matched to the line and the VSWR is high (it is implicitly assumed in writing [62] that $R > Z_0$, and V_f and V_r have the same sign), then V_{max} is much greater than it need have been to achieve the same power transfer with a matched load. Because at high radio and microwave frequencies the

power-handling capacity of a line is often limited by voltage breakdown, this is a strong reason for attempting to match the load to the line.

Similar calculations can be used to obtain the ratio V/I at points on the line a distance l back from the load. This is, of course, the impedance that would be measured at this point. The calculation, though straightforward, is tedious, and the result is

$$Z = \frac{V}{I} = Z_0 \frac{R \cos \beta l + jZ_0 \sin \beta l}{Z_0 \cos \beta l + jR \sin \beta l}.$$

Here, $\beta l = 2\pi l/\lambda$ so that $\beta l/2\pi$ is the length of the line measured in wavelengths.

Whenever $\beta l = n\pi$ ($n = 0, 1, 2, 3$, etc.)—*i.e.*, the line is an integral number of half wavelengths long—this gives $\sin \beta l = 0$ and $Z = R$ again; but if $\beta l = (n + \frac{1}{2})\pi$—*i.e.*, the line is an odd number of quarter wavelengths long—this gives $\cos \beta l = 0$ and $Z = Z_0^2/R$. The larger R is made, the lower is the value of Z measured at the other end of the line. A quarter wavelength of line acts as an impedance transformer. A cable of characteristic impedance Z_0 and a load R can be matched by inserting a quarter wavelength of line of characteristic impedance Z_0' so that $Z_0 = Z = (Z_0')^2/R$. In other words, Z_0' is the geometric mean of Z_0 and R. This is a useful technique in microwave electronics. It may also be noted that it is essentially the principle underlying the use of thin surface layers (lens coating, or blooming) to reduce reflection of light waves from optical components, such as camera lenses. In the case when R is equal to zero—*i.e.*, the line is shorted at the end—then

Impedance matching

$$Z = jZ_0 \tan \beta l. \tag{63}$$

When βl is small, $\tan \beta l \simeq \beta l$ and this gives

$$Z \simeq jZ_0 \beta l = j(L/C)^{1/2} \omega (LC)^{1/2} l = j\omega Ll.$$

In other words, the line appears to have an inductance Ll, which is hardly unexpected because L is the inductance per unit length. If R is infinite—*i.e.*, the line is open circuited—the result is

$$Z = \frac{Z_0}{j \tan \beta l};$$

and, if βl is small,

$$Z \simeq \frac{Z_0}{j\beta l} = \frac{1}{j\omega Cl}.$$

The line behaves in this case like a capacitance Cl. The effects resulting from the use of cables having lengths that are a small fraction of a wavelength can be treated solely in terms of inductance Ll and capacitance Cl. This is the standard low-frequency approximation.

When $\beta l = \pi/2$, equation (63) shows that $Z \to \infty$. Thus a shorted line one-quarter wave long appears at the other end as an open circuit. As the frequency is changed so that $\beta l = \omega l(LC)^{1/2}$ increases through $\pi/2$, the phase angle of Z changes from $\pi/2$ to $-\pi/2$ and $|Z|$ goes through a sharp maximum. This is much like the behaviour of a tuned circuit; indeed, in microwave electronics, short-circuited lines are used as substitutes for tuned circuits. Although real lines have resistive loss and this broadens the resonance, the effective quality factor Q is still high. At 3,000 megahertz, when the wavelength is 10 centimetres, a line 2.5 centimetres (one inch) long behaves as a resonant circuit. This example demonstrates the way in which the transmission delay in cables makes microwave circuit analysis quite different from low-frequency ac circuit analysis.

Real transmission lines always have a finite resistance R per unit length. If finite resistance is included in the theory, the equation that replaces (56) is

$$\frac{\partial V}{\partial x} = -L\frac{\partial I}{\partial t} - RI,$$

and the wave, instead of propagating unattenuated as $e^{j(\omega t - \beta x)}$, propagates as $e^{(\omega t - \beta x) - \alpha x}$, in which $\alpha \simeq R/2Z$. The value of R is determined by the so-called skin effect (see below) and increases with frequency as $\omega^{1/2}$. At 100 megahertz—*i.e.*, a frequency used for radio and television transmissions—α is of the order of 3×10^{-3} metre^{-1}. The amplitude of the voltage and current on the line decrease exponentially along the line as $e^{-\alpha x}$ and the power as $e^{-2\alpha x}$. In the laboratory, with a few metres of line, the decrease is not serious, but if, for example $x = 10^4$ metres (six miles), the power is reduced by a ratio $e^{-60} \simeq 10^{-26}$. If 10^6 watts are fed into one end of the line, a power of only 10^{-20} watt emerges at the other end, and this would be barely detectable. Attenuation by the skin effect in cables at radio frequencies, although at first sight small, is a serious bar to their use for distributing radio signals over extended paths. Practical cable-distribution systems rely on amplifiers to boost the signal. These amplifiers have to be placed at frequent intervals in the cable.

It will be seen then that, at fairly low frequencies in which cables and connections are only a fraction of a wavelength long, the time delay in the cable can be more or less neglected and at most an allowance made for the total capacitance and inductance of the cable. At high frequencies, however, the time delay introduces quite new effects. The theory of the propagation of waves on cables is a highly developed branch of electrical engineering, but it has a more general significance. In many ways the behaviour of waves on cables is simpler and better understood than any other form of wave motion. Thus, notions drawn from transmission-line theory, especially the concepts of characteristic impedance and matching, are widely used in other branches of physics, particularly in acoustics and optics.

Importance of transmission line theory

FILTERS

A filter is a circuit network built up by the repetition of a single basic unit. This can be taken to be the T-section shown in Figure 28, which also indicates the currents

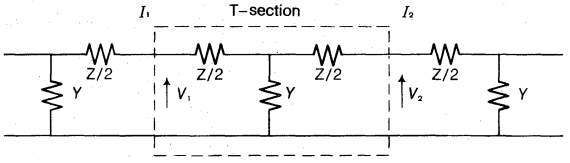

Figure 28: Filter partitioned as T-section (see text).

and voltages I_1, I_2 and V_1, V_2 at the ends of a typical section (Y represents some repeated combination of inductance and capacitance). If Kirchhoff's laws are applied to this T-section, they give the relations

$$V_2 = (1 + \tfrac{1}{2}ZY)V_1 - \tfrac{1}{2}Z(2 + \tfrac{1}{2}ZY)I_1$$

and

$$I_2 = -YV_1 + (1 + \tfrac{1}{2}ZY)I_1.$$

If, as the signal progresses through the chain of filter elements, it is to change regularly by the same amount as it traverses each element, the ratio V/I at the input to each element must be the same. In other words, $V_2 = \lambda V$, and $I_2 = \lambda I_1$ must be the input to the next section, in which λ is a (possibly complex) number. If λ is substituted in the equations for V_2 and I_2, there results, by eliminating V_1 and I_1, a quadratic equation for λ,

$$\lambda^2 - 2(1 + \tfrac{1}{2}ZY)\lambda + 1 = 0.$$

This equation has two roots, λ_1 and λ_2, which satisfy the relations $\lambda_1\lambda_2 = 1$ and

$$\lambda_1 = 1 + \tfrac{1}{2}ZY - \sqrt{\left(1 + \tfrac{1}{2}ZY\right)^2 - 1}\,.$$

One of the roots, say λ_1, corresponds to a signal propagating to the right (Figure 28) through the filter. The other root with λ_2 equals $1/\lambda_1$ gives V_1 equals $\lambda_1 V_2$ and I_1 equals $\lambda_1 I_2$. This corresponds to a signal propagating in the opposite direction.

The nature of the constant λ_1 depends, first, on whether ZY is real and, second, on whether $(1 + \frac{1}{2}ZY)^2$ is greater or less than one. If ZY is real and $(1 + \frac{1}{2}ZY)^2$ is less than one, it is possible to write $1 + \frac{1}{2}ZY = \cos \phi$, and then

$$\lambda_1 = \cos \phi - \sqrt{\cos^2 \phi - 1} = \cos \phi - j \sin \phi = e^{-j\phi}.$$

In this case the signal, as it passes each section, is merely shifted in phase by ϕ and corresponds to a signal in the pass band of the filter. If ZY is real and $(1 + \frac{1}{2}ZY)^2$ is greater than one, λ_1 is real and less than unity; the voltage V_2 and current I_2 will be less than V_1 and I_1 and the signal will be attenuated as it passes through the network. When ZY is complex the root λ_1 is also complex. If it is written as $\lambda_1 = \alpha e^{-j\phi}$, then $\alpha < 1$ and the signal is both attenuated and shifted in phase as it traverses each filter section. Most practical filters have attenuation and so further exact analysis becomes tedious and rather unprofitable. Fortunately, however, most of the properties of filter networks constructed of T-sections, as shown in Figure 29, can be understood by considering four basic

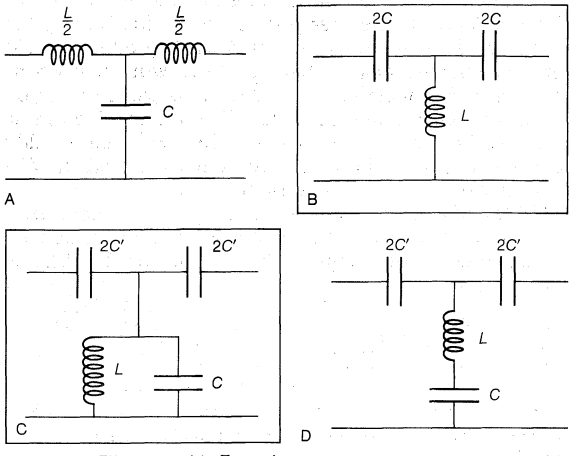

Figure 29: *Filters used in T-sections.*
(A) Low-pass; (B) high-pass; (C) band-pass; (D) band-stop (see text).

idealized types, the low-pass filter 29A, the high-pass filter 29B, the band-pass filter 29C, and the band-stop filter. If the filter is operating in a pass band with a phase shift ϕ per section, it must satisfy $\cos\phi = 1 + \frac{1}{2}ZY$. Because $-1 < \cos\phi < 1$, the condition defining a pass band becomes simply $-4 < ZY < 0$. In the low-pass filter of Figure 29A, in which Z equals $j\omega L$ and Y equals $j\omega C$, the pass band is defined by $-4 < -\omega^2 LC < 0$. Thus the pass band extends from dc up to the angular frequency $(4/LC)^{1/2}$. In the high-pass filter of Figure 29B,

$$Z = \frac{1}{j\omega C}, \quad Y = \frac{1}{j\omega L},$$

and then

$$-4 < -\frac{1}{\omega^2 LC} < 0.$$

This filter therefore passes all frequencies above $1/(4LC)^{1/2}$. For the band-pass filter of Figure 29C, in which

$$Z = \frac{1}{j\omega C'}$$

and $Y = j\omega C + \dfrac{1}{j\omega L}$, the condition becomes

$$\left(\frac{1}{L(C + 4C')}\right)^{1/2} < \omega < \left(\frac{1}{LC}\right)^{1/2}.$$

Thus in this case there is transmission only over a finite range of frequencies. If $C' << C$ and $\omega_0 = (1/LC)^{1/2}$, the pass band extends from $\omega_0(1 - 2C'/C)$ to ω_0, and the width of the pass band is $2\omega_0 C'/C$. The band-pass filter is an exceedingly useful type of network section for picking out wanted signals in a limited range of frequencies from a background of unwanted signals. At microwave frequencies it is quite feasible, using resonant cavities rather than tuned circuits, to design filters that transmit signals in a band width of only five megahertz about a centre of frequency of 10,000 megahertz. At lower radio frequencies resistive loss in the inductance limits the fractional frequency resolution to about 1 percent, but filters using resonant piezoelectric elements can have a much better resolution.

Usefulness of band-pass filter

For the band-stop filter shown in Figure 29D, $Z = \dfrac{1}{j\omega C'}$ and $Y = \dfrac{j\omega C}{1 - \omega^2 LC}$, and this gives transmission only when $\omega > (LC)^{-1/2}\left(\dfrac{C + 4C'}{4C'}\right)^{1/2}$. However, if C' greatly exceeds C, high attenuation only occurs near $\omega = (LC)^{-1/2}$. Ideal band-stop filters require extra circuit elements.

All these filters have one important feature in common, namely, $\cos\phi = \pm 1$ at the edges of the pass band. This means that the phase shift ϕ per section lies in the range $0 < \phi < \pi$. This is a characteristic feature of all periodic structures built up by repetition of identical units and is not confined to electrical filters. It applies equally well to the quantum mechanics of electrons in a crystal lattice, the propagation of sound waves (phonons) in a crystal lattice, and the propagation of electromagnetic waves through the periodic structures used in linear accelerators and microwave tubes.

TRANSIENT PHENOMENA

Usually in discussing ac circuits it is assumed that there are only sinusoidal currents of constant amplitude and frequency. There are, however, many cases in which currents vary in a rather more complicated way. For instance, it may be necessary to know what happens in a circuit, either immediately after the current is switched on or immediately after it is switched off. In radio and electronics there are modulated alternating currents in which amplitude and phase change rapidly, and in some applications the response of circuits to short pulses and sudden changes in an otherwise steady direct current is also required. There is an elegant mathematical technique based on the use of the Laplace transform for dealing with all these transient phenomena, but it will not be employed here; rather there will be a qualitative treatment of what is expected to happen in a number of simple cases. Only at the end of this section is there a brief outline of a more general approach.

Any circuit that contains inductive or capacitative elements is capable of storing electrical energy, and thus, when a circuit is first switched on, a finite time will be taken to acquire this energy. Equally, when the circuit is switched off, it takes time for the stored energy to disappear. If the stored energy is U and the time in which it is dissipated is τ, then the rate of dissipation U/τ can often be much greater than the power handled by the circuit in its steady-state condition. In this case, switching transients may lead to the destruction of the circuit. If the circuit contains both inductance and capacitance, it is also possible for it to resonate, and this resonance can be shock-excited by a switching transient. In high-power circuits this too can lead to destructive effects, and in low-power electronic equipment to spurious responses.

The problem of switching off an electromagnet illustrates most of the features that accompany switching transients. In a typical magnet used in high-field experiments, the windings have an inductance of about 0.02 henry, a resistance of 0.1 ohm, and operate at a current of 3,000 amperes. In addition, the windings have a distributed capacitance of the order of 10^{-7} farad. The magnet is energized by a motor-generator set having a low internal resistance. If the switch is in an open position, the magnet forms a tuned circuit. The behaviour of this circuit is determined by the parameter $(L/CR^2)^{1/2}$, essentially the quality factor Q of the circuit. If Q is greater than $\frac{1}{2}$, the circuit is underdamped and can resonate. In this case $(L/CR^2)^{1/2} \simeq 2{,}200$ and the circuit is highly resonant at a frequency $(LC)^{-1/2}/2\pi \simeq 3{,}000$ hertz. In practice the Q is appreciably less than this because of eddy currents in the metal casing and of skin effect losses, but, nevertheless, Q is of the order of 100.

If the switch is closed and the coil energized with $V_0 = 300$ volts and $I_0 = 3{,}000$ amperes, the energy stored in C is only $\frac{1}{2}CV_0^2 = 10^{-2}$ joule, but the energy $\frac{1}{2}LI_0^2$ stored in the coil is 10^5 joules. If the switch is now opened, it is as though a tuned circuit has been caught at the instant when all the energy is stored in the in-

ductance. Half a cycle later—*i.e.*, in just over one millisecond—all this energy is transferred to the capacitance C. The voltage across C rises to V, giving $\frac{1}{2}CV^2 = \frac{1}{2}LI_0^2 = 10^5$ joules. Because C equals 10^{-7} farad, V rises to about 10^6 volts or, rather, would rise to 10^6 volts if a destructive spark had not already occurred at the open switch or through weak insulation.

Importance of transient effects

The example just given was chosen as an extreme case to illustrate the magnitude of transient effects in high-power systems, but similar if less spectacular effects can also occur whenever current is suddenly interrupted in an inductive circuit. Transients are used in the ignition system of an automobile to generate a spark, but in most cases their effects are harmful rather than useful. In particular, electronic apparatus incorporating transistors (which are easily destroyed by transient over-voltage) has to be carefully designed to avoid high peak voltages being generated by transient effects when switches are closed or opened.

A rather different aspect of transient phenomena is associated with nonsinusoidal wave forms. In electronics, where short pulses, trains of pulses, and triangular or sawtooth wave forms occur, little is gained by attempting to interpret the response of circuits in terms of their response to sinusoidal signals. For example, the basic equations for a circuit in which a voltage V_{in} is applied to a capacitance C through a resistance R are

$$V_{in} = \frac{q}{C} + R\frac{dq}{dt} \text{ and } V_{out} = R\frac{dq}{dt}.$$

If q in this circuit changes relatively little in a time RC, the first equation can be replaced by $V_{in} \simeq q/C$, and so

$$V_{out} = RC\frac{dV_{in}}{dt}.$$

Thus, for slowly varying signals, this circuit gives an output proportional to the time derivative of the input. It can be verified that if the input is a regular train of square pulses in which q changes abruptly (dq/dt is large), the output is a sequence of alternately positive and negative spikes.

In radio, and especially in the electronic reproduction of music, short bursts of more or less sinusoidal signals occur. Thus, for example, a pizzicato double bass note may consist of only 10 complete oscillations of a wave of frequency 30 hertz (duration ⅓ second, a transient signal), whereas a triangle produces a few hundred oscillations at frequencies above five kilohertz. In general, provided that the response of the electronic circuit to sinusoidal signals varies smoothly with frequency in the frequency range of interest, transient signals such as these will be faithfully reproduced. Bad transient response in audio equipment is more likely to be associated with a poor overall response or mechanical resonances in the transducers (*e.g.*, stylus pickup) than with any peculiar features of the ac circuits themselves.

This section ends with a brief résumé of a more general approach (the Laplace transform) to transient phenomena using the theory of complex variables. In a linear system —*e.g.*, an ac bridge, a filter network, or an electronic amplifier driven by an external time-dependent electromotive force, $V(t)$—the application of Kirchhoff's laws to the system leads to a set of simultaneous linear differential equations for the voltages and currents at various points in the network. With a sinusoidal input voltage of the form $Ve^{j\omega t}$, these equations yield the voltage $Ve^{j\omega t}$ at one particular point in the network in the general form

$$v = \frac{f_0 + f_1(j\omega) + f_2(j\omega)^2 + \text{etc.}}{g_0 + g_1(j\omega) + g_2(j\omega)^2 + \ldots g_N(j\omega)^N} V,$$

in which the numerator and the denominator are finite polynomials in $j\omega$ with real coefficients. For a voltage input of a more general form, Ve^{pt}, in which p replaces $j\omega t$, p may be real, complex, or imaginary. When the input equals zero the output v will be zero unless the denominator vanishes. This will occur for N different values of p. Each of these so-called poles of the expression for v corresponds to a natural resonance of the system. If a typical pole is of the form $p = -\alpha + j\omega$, the system has a damped resonance of frequency ω with a decay constant α. The theory of the Laplace transform implies that the transient response of the system is entirely determined once the location of the poles of the response in the complex p plane is determined.

A modest familiarity with Laplace transform usage is necessary in order to follow current progress of work in electronics, feedback network design, and control system engineering.

EDDY CURRENTS AND THE SKIN EFFECT

In a shorted turn around a transformer core, large currents will circulate when the primary is energized by a source of ac. This current is caused by the electromotive force induced by the changing magnetic flux linking the turn, and it is in such a direction as to produce a field opposing the flux change. Similar effects will occur whenever there is a metallic or conducting object in a region of a changing magnetic field. The resulting currents are then known as eddy currents. The existence of eddy currents has many important consequences, and the discussion begins with the most familiar example.

Eddy currents

If a transformer is wound on a solid core, the core itself will act as a shorted turn. For a long, cylindrical core (see Figure 30) of length l and radius a, the flux linking

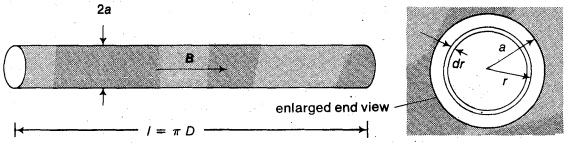

Figure 30: Equivalent cylindrical core; side and end views (see text).

an annular ring of radius r and thickness dr is $\pi r^2 B$, and, if the conductivity of the iron is σ, the current flowing in this ring is

$$dI = \sigma\pi r^2\left(\frac{dB}{dt}\right)\frac{l\,dr}{2\pi r}.$$

The rate at which heat is dissipated in the ring is

$$\frac{2\pi r}{\sigma l\,dr}(dI)^2, \text{ and this is } dQ = \frac{\pi}{2}\sigma l\left(\frac{dB}{dt}\right)^2 r^3 dr.$$

The total rate of dissipation in the core is the integral of dQ, or

$$Q = \frac{\pi}{2}\sigma l\left(\frac{dB}{dt}\right)\int_0^a r^3 dr = \frac{\pi}{8}\sigma l\left(\frac{dB}{dt}\right)^2 a^{24}.$$

The total stored magnetic energy in the core is $\frac{1}{2}\pi a^2 lHB$, in which $H = B/\mu\mu_0$ and μ is the relative permeability. The rate of change of this energy is $\dot{U} = \frac{\pi a^2 l}{\mu\mu_0} B\frac{dB}{dt}$ which is a measure of the rate at which energy flows in and out of the core because of the excitation of the primary winding. The ratio $Q/\dot{U}$ is a measure of the fraction of this energy lost as heat. If ω is the frequency of the ac, then $dB/dt \simeq \omega B$ and $Q/\dot{U} = \frac{1}{8}\omega\mu\mu_0\sigma a^2$.

For iron, $\mu \simeq 500$, $\sigma \simeq 10^7$ mho metre^{-1}, and $\mu_0 = 4\pi \times 10^{-7}$ so that, if $\omega = 2\pi \times 60$ hertz and $a = 10^{-2}$ metre (one centimetre), this gives $Q/\dot{U} \simeq 30$. Since this is greater than unity, all that can be deduced is that virtually all the energy fed into the primary will be dissipated as heat. Not much is left to drive whatever load may be connected to the secondary. This type of yoke or core would be of little use in a transformer. The ratio $Q/\dot{U}$, it should be noted, depends on a^2. Thus, if the core were subdivided into, say, 1,000 insulated iron filaments of much smaller radius, this would also reduce $Q/\dot{U}$ by a factor of 1,000. In fact, it is not only easier but also more effective to build up the core from thin, flat, insulated laminations, as indeed all transformers are. Further improvement is also obtained by using iron alloys of lower electrical conductivity than pure iron.

Next to be considered is a rather similar case using a

nonmagnetic core, a copper tube of radius a and wall thickness z with its axis parallel to a changing magnetic field dB/dt. The current flowing round the tube per unit length of the tube is $-\frac{\sigma z}{2\pi a}\cdot\pi a^2\frac{dB}{dt}$. This produces an additional field $-\frac{1}{2}\mu_0\sigma a z B_0$ within the tube, and this in turn induces a further current and produces yet an additional field. For a field B within the tube and a current I per unit length, $B = B_0 + \mu_0 I$ and $I = \frac{1}{2}\sigma a z\frac{dB}{dt}$.

If the fields vary with time as $e^{j\omega t}$, this leads to

$$B = B_0 - \frac{1}{2}j\omega\mu_0\sigma a z B,$$

so that

$$B = \frac{B_0}{1 + \frac{1}{2}j\omega\mu_0\sigma a z}.$$

The field within the tube lags behind B_0 in phase, and its magnitude is reduced by a factor $(1 + \frac{1}{4}\omega^2\mu_0^2\sigma^2a^2z^2)^{-\frac{1}{2}}$. If, for example, a equals 2.5×10^{-2} metre (one inch) and z equals 2.5×10^{-3} metre, then with $\omega = 2\pi \times 60$ hertz, $\mu_0 = 4\pi \times 10^{-7}$, and $\sigma = 10^8$ metre^{-1}, this gives a reduction factor of 0.8. Thus, even a nonmagnetic copper tube tends to exclude a changing magnetic field.

In this example the field in the tube had to be calculated allowing for the reaction of the field induced by the current. At high frequencies or with thick conductors, this effect eventually alters the field within the conductor itself. This leads immediately to the consideration of the skin effect.

In the section below, *Electromagnetic radiation*, it is shown that in a conductor a wave decreases exponentially in amplitude as it progresses through a conductor. It decreases by a factor $1/e$ (*i.e.*, 0.368) in a distance

$$\delta = \left(\frac{2}{\omega\mu_0\sigma}\right)^{1/2}.$$

This distance is known as the skin depth. All quantities associated with the wave decrease in the same way. Thus the electric and magnetic fields and the current density J all decrease in this way. For copper with $\sigma \simeq 6 \times 10^7$ mho metre^{-1}, at a frequency ν hertz, $\delta \simeq 1/15\nu^{\frac{1}{2}}$ metres. Thus at a radio frequency of one megahertz, the skin depth is approximately 1/15 millimetre, whereas at power frequencies (60 hertz) the skin depth is about 8.5 millimetres.

Skin effect

Alternating currents in conductors are driven by fields applied to their surfaces, and if, therefore, wave fields penetrate only a few skin depths, it is quite obvious that the alternating currents can only flow in a layer a few skin depths thick near the surface. This is generally known as the skin effect. It is a serious problem both in radio-frequency engineering and in power engineering. If an alternating electric field at the surface of a block of metal is E_0 and the current density parallel to E_0 at the surface is $J_0 = \sigma E_0$, then the current density (J) a distance x below the surface is $J = J_0e^{-x/\delta} = \sigma E_0e^{-x/\delta}$, and the total current, per unit length normal to E, is

$$I = \sigma E_0\int_0^\infty e^{-x/\delta}\,dx = \sigma\delta E_0.$$

It is as though there were a current density σE_0 in a layer of thickness δ.

In a thick metal bar of width w and length l, when δ is appreciably less than the thickness z, the resistance will be $R \simeq l/2\omega\delta\sigma$ rather than $l/\omega z\sigma$. Because of the skin effect there is little point in using conductors the thickness of which is much larger than δ. Thus, for example, the bus bars used in a power station are usually built up from strips about six millimetres (¼ inch) thick rather than from more massive copper bars. Equally, there is little point in using round section conductors that have diameters more than about $\frac{1}{2}\delta$. If a lower resistance conductor is required, it is more economical to use a tube of wall thickness $\frac{1}{2}\delta$ or less. At radio frequencies the concern is not so much with economizing on material but with achieving a low resistance at almost any price. In the frequency range up to about 10 megahertz, it is common to use litz wire made up of many fine strands of insulated wire. Above 10 megahertz even this artifice becomes less and less worthwhile, and rather high resistive losses must be tolerated. The resistance per unit length of a round wire of diameter d approaches $1/\pi d\sigma\delta$, compared with the dc resistance $4/\pi d^2\sigma$. The ratio $d/4\delta$ for wire of one millimetre diameter at 100 megahertz is about 40. At still higher frequencies there is a need to keep the wire circumference down to about ¼ wavelength or less. Thus ultimately at microwave frequencies the lowest resistance per unit length that can be achieved is about $4/\lambda\sigma\delta$. This expression can be simplified to $1.7 \times 10^{-2}\lambda^{-3/2}$ ohms per metre for copper. If λ equals 10^{-2} metre it gives 17 ohms per metre. In a coaxial cable of 50 ohms characteristic impedance, this leads to a reduction in the power in a wave by a factor of $1/e$ in only three metres.

In a metal such as iron, in which the relative permeability μ is different from unity, the skin depth δ is $(Z/\omega\mu\mu_0\sigma)^{\frac{1}{2}}$, and as a result the skin depth is further reduced and the resistivity increased. The skin depth in soft iron at 60 hertz is a fraction of a millimetre. This is one of the reasons why electric trains, which use the iron rails as a return conductor, have either to operate on dc power or to use a high-voltage, low-current ac distribution system.

In ac circuits perhaps the most important consequence of the skin effect is the influence it has on the resistance of inductors and thus on the quality factor Q attainable with tuned circuits. It also influences the minimum attenuation that can be achieved in filter networks. There are, however, some benefits that arise from the skin effect; for example, in copper δ is approximately equal to 10^{-2} millimetre at 50 megahertz, and so a thin-walled can of metal is adequate to exclude all unwanted signals of this frequency from the interior of electronic apparatus.

Because the skin depth in iron at power frequencies is only a fraction of a millimetre, at radio frequencies it is so small that it is impracticable to make thin enough laminations for use in transformer cores. In the 1930s, those transformers for use at radio frequencies that were not air-cored used cores made up of iron dust dispersed in an insulating resin or wax. This type of dust core is still in general use, but the postwar developments in ferrites, a new type of insulating ferromagnetic material, have now made available an alternative means of producing cores for radio-frequency transformers. Ferrites are free of both eddy current and skin effects and so can be used even at microwave frequencies.

POWER GENERATION AND DISTRIBUTION

The technology of this subject is covered in the article ELECTRIC POWER, and here only the general principles will be of concern. At its simplest, an electric alternator is a device that rotates a coil of wire in a magnetic field and picks up the induced electromotive force by a system of slip-rings and sliding contacts. It is instructive to consider a generator from this point of view. If a plane loop of wire of area A rotates about the axis, at an angular rate ω in a field B normal to the axis, and if at time (t) equal to zero the loop is normal to B, the flux linking the loop will be $AB\cos\omega t$, and the induced emf is therefore equal to $+\omega AB\sin\omega t$. This emf causes a current I to flow in the load. The current I also flows in the loop, and as a result the loop experiences a couple (Γ), which is easily seen to be equal to $ABI\sin\omega t$. The motor driving the coil must exert an equal and opposite couple to maintain the rotation. It therefore does work on the coil at a rate $\omega\Gamma = \omega ABI\sin\omega t$. But $\omega AB\sin\omega t = V$, and so the rate at which the motor does work is equal to the rate IV at which energy is delivered to the load. The machine is apparently a perfectly efficient device for converting mechanical to electrical power. It may, therefore, reasonably be asked why practical generators are so much more complicated than this and consist of com-

The electric alternator

plex systems of iron armatures with many windings and elaborate iron-cored stator coils. The reasons for this are varied, and only the most important will be mentioned. First of all, no notice has been taken of resistive losses in the rotating loop. As an example, a single turn of copper strip 10 centimetres by one centimetre in cross section is made into a loop one metre square, which then rotates at 60 hertz in a steady field (B) of one tesla (weber per metre^2). The peak induced emf is $2\pi \times 60 \simeq 400$ volts, and if, say, the mean power is 100 megawatts (10^8 watts), the peak current must be about 5×10^5 amperes. The resistance of the loop is, however, about 6×10^{-5} ohm, and so 30 volts are dropped in the loop and something approaching 7.5×10^6 watts dissipated in the loop as heat. Not only has the efficiency dropped to 92 percent but there is a serious cooling problem.

The field B was assumed to have a strength of one tesla. This is a large field, and to produce a field of this order over a region of a cubic metre or so using permanent magnets would be quite impracticable. Thus the field must be produced by an electromagnet. Almost the entire power output of the generator would be required to produce the field, and hence iron must be used to concentrate the field near the windings. This will also help to get more flux through a smaller and lower resistance winding.

The power delivered to the load $IV = V^2/R$ varies with time as $\sin^2 \omega t$. Since the rate of rotation of the generator is constant, the couple exerted by the motor driving the generator must also vary as $\sin^2 \omega t$. Such a reaction would lead to serious mechanical problems, comparable to trying to run a single-cylinder internal-combustion engine at constant speed with almost no flywheel. By mounting several coils at different angles on the generator axle, thus forming an armature for the generator, the load on the motor should be smoothed out. In fact, if there are three coils at 120° to each other ($2\pi/3$), the couple varies as

$$\sin^2\omega t + \sin^2\left(\omega t + \frac{2\pi}{3}\right) + \sin^2\left(\omega t + \frac{4\pi}{3}\right)$$

$$= \frac{1}{2}\left(3 - \cos 2\omega t - \cos\left[2\omega t + \frac{4\pi}{3}\right] - \cos\left[2\omega t + \frac{2\pi}{3}\right]\right),$$

which is seen to be constant and equal to 3/2. Thus, provided the coils are equally loaded, the load on the motor is steady. Placing more coils on the shaft has a further advantage because the field is now used more of the time. There is indeed no reason why there should not be six, nine, or 12 equally spaced coils on the same shaft. Thus practical considerations lead from the original idealized device to something like a conventional power-station generator. The final form of the generator is, of course, further influenced by the electrical, magnetic, and mechanical properties of available materials and mechanical-design considerations.

Power distribution

It will be useful to turn from the problem of generating ac power to the problem of distributing it, setting aside such important and difficult problems as switchgear. With ac, transformers can be used, and it is immaterial whether the power is distributed at high voltage and low current or low voltage and high current. When a power P equal to IV is distributed by a line having resistance R, however, power lost in the line is equal to PIR/V. Thus the higher the voltage and the lower the current, the less power is lost in the line. For this reason power transmission usually employs the highest practicable voltage. This brings other problems to bear—*e.g.*, insulation and breakdown and hazardous operation. In an overhead cable, a compromise has to be struck between the cost of power loss and the cost of higher towers and better insulation. A further factor enters into this calculation. The field at the surface of a circular conductor of radius r at a voltage V is approximately V/r, and, when this ratio exceeds the breakdown strength of air, a discharge is likely to be initiated. There is therefore a minimum radius for the conductors, which increases with V. In practice, conductors are grouped to produce a larger effective radius, but, even so, there comes a point at which further increase in V (although it reduces I) actually increases the cost of the conductors. In the case of long-distance cross-country power lines, carrying large power, the optimum (rms) voltage is in the range 100,000 to 500,000 volts. In metropolitan areas, at lower powers, and in underground installations, the optimum balance may be struck at a much lower figure—*e.g.*, 5,000 volts.

As explained above, if the armature or a generator has three windings arranged at equal angles to each other on the shaft and each supplies a similar load, the load on the motor or prime mover is constant. This type of generator will produce three separate output voltages: $V_0 \cos \omega t$, $V_0 \cos(\omega t + 2\pi/3)$, and $V_0 \cos(\omega t + 4\pi/3)$, and is known as a three-phase generator. The advantages of three-phase generation are by no means confined to the simplification of generator design. A typical three-phase distribution line will have three live conductors carrying currents $I_0 \cos \omega t$, $I_0 \cos(\omega t + 2\pi/3)$, and $I_0 \cos(\omega t + 4\pi/3)$, and a single neutral conductor that will carry a current (in the return direction) I_0 times a factor

$$\left(\cos \omega t + \cos\left[\omega t + \frac{2\pi}{3}\right] + \cos\left[\omega t + \frac{4\pi}{3}\right]\right).$$

As can be seen, this factor is zero. Thus if $R/2$ is the resistance of each conductor, the average power loss is $3(R/2)\ (I_0^2/2) = \frac{3}{4}RI_0^2$ for a generated power $\frac{3}{2}I_0V_0$. The ratio is $\frac{1}{2}RI_0/V_0$. If this is compared with a single-phase system with two conductors of resistance $R/2$, each carrying a current I_0 and dissipating energy $\frac{1}{2}RI_0^2$ for a generated power $\frac{1}{2}I_0V_0$, it will be seen that the fractional loss in a three-phase system is reduced by a factor of $\frac{1}{2}$. Thus the use of three-phase currents not only simplifies generator design but also reduces transmission losses. The ac distribution of electric power almost invariably employs three-phase working. A standard system of domestic power distribution is to provide consumers in one group of houses with a neutral-line and a single-live-phase, whereas houses in other groups are furnished with the neutral line and one or the other of the two remaining live phases. Because the balance of current in the final main neutral line depends on each phase being equally loaded, the groups have to be chosen so that there is a good statistical chance that each group will at any one time be drawing roughly the same current. Large installations are usually supplied with all three phases. It is then desirable that equal loads be presented to each phase. In particular, if one phase has a resistive load; *e.g.*, a heater, it is especially important that another phase should not have a reactive load; *e.g.*, a large transformer running on low load. If the currents in two phases are $I_0 \cos(\omega t + 2\pi/3)$ and $I_0 \cos(\omega t + 4\pi/3)$ and the current in the third phase $I_0 \cos(\omega t + \phi)$ has a large phase angle ϕ, the current in the neutral lead will be of magnitude $2I_0 \sin \frac{1}{2}\phi$. If $\phi = \pi/2$, this is $\sqrt{2}I_0$ and might seriously overload the neutral line.

A schematic drawing of a three-phase generating system is shown in Figure 31A and of a typical load in Figure 31B. This circuit, for obvious reasons, is known as a star-connected or Y-connected system. There is, however, available between the phases a set of voltages

$$V_{12} = V_0\left(\cos \omega t - \cos\left[\omega t + \frac{2\pi}{3}\right]\right)$$

$$= V_0\sqrt{3} \sin\left(\omega t + \frac{\pi}{3}\right);$$

$$V_{23} = V_0\sqrt{3} \sin\left(\omega t - \frac{\pi}{3}\right);$$

$$V_{31} = V_0\sqrt{3} \sin(\omega t + \pi).$$

Delta connections

Another way of connecting a load is shown in Figure 31C. This is known as a delta (Δ) connection. The current in the neutral line is now automatically zero, but, unless $Z_{12} = Z_{23} = Z_{31}$, the currents in the three phases

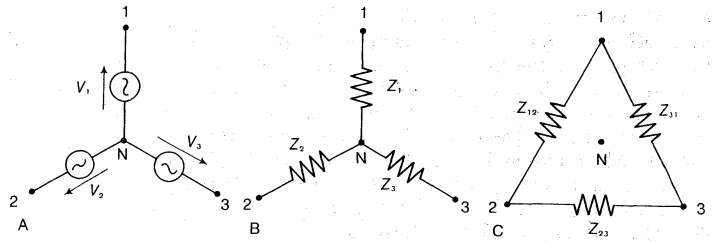

Figure 31: *Three-phase connections.*
(A) Three-phase voltage source; (B) star-connected three-phase load; (C) delta-connected three-phase load (see text).

will be different, although their algebraic sum is still zero. At the generator end one of the phases supplies more power than the others, and this puts an unbalanced load on the generator.

The usual electrical supply uses alternating current, rather than direct current, so that transformers can be used. Thus power transmission over a distance can be made at high voltage, minimizing resistance loss in the cables, and yet the final domestic supply can be reduced to a safe voltage, using step-down transformers. Furthermore, the domestic supply can be further transformed to give voltages appropriate for use in electronic equipment, furnace control gear, and so on. From the consumer's point of view, ac has few disadvantages. Perhaps the most important one is that it is difficult to design large ac motors that will start under load.

The primary disadvantages of ac power transmission are twofold. First of all, the skin effect limits the worthwhile thickness of conductors to about six millimetres (¼ inch), and secondly, the power delivered depends on the root-mean-square voltage, V_{rms}, whereas breakdown and insulation problems depend on the peak voltage $V_p = V_{rms}\sqrt{2} \simeq 1.4V_{rms}$. Thus, for a given power, an ac system must be able to stand some 40 percent higher voltage. Furthermore, in a three-phase system the peak voltage between phases is $\sqrt{3}$ times the peak voltage of each phase measured from neutral; *i.e.*, $\sqrt{6}V_{rms} \simeq 2.5V_{rms}$. There is, therefore, a good reason in considering high voltage dc for long-distance power transmission. High voltage dc transmission is used in Sweden in a main feeder cable that originates at a generating plant in the Arctic and ends in the south of the country. The voltage used is 400,000 volts, which presents no greater insulation problems than 160,000 volts three-phase. The power is generated as ac and then rectified for transmission. The power derived from the line is finally reconverted to ac using solid-state switching devices, so that ac is available for local distribution. The transmission of dc is also used in a number of underwater links—*e.g.*, that between England and France. Here the reason is somewhat different. A submarine cable has, necessarily, to be a closed, insulated structure and, as a result, has a rather high capacitance between conductors, which would produce intolerable switching transients in ac circuits. The transient response is easier to handle in a dc system.

In treating polyphase systems of generation and transmission, attention has been concentrated on three-phase systems because these are not only in common use but also illustrate most of the principles involved. There is, however, no difficulty in winding a generator armature to produce a greater number of phases, and, in some cases, especially if the output is to be rectified, this may be worthwhile.

It is worth considering briefly the reasons that determine the choice of frequency for an ac power supply system. Most systems operate at either 50 or 60 hertz, although there are a few much lower frequency systems —*e.g.*, 15 hertz and, in marine equipment, 600 hertz is common, whereas in some aircraft systems frequencies of 400 hertz and above are used.

VI. The primary effects and properties of electric fields and currents

This section deals with the magnetic effects of currents and electric fields, the way fields store and transport energy and stress, and electromagnetism. The material here mentioned forms the core of classical electromagnetic theory (see also the article on ELECTROMAGNETIC RADIATION).

MAGNETIC EFFECTS OF STEADY ELECTRIC CURRENTS

The magnetic field $\boldsymbol{B}$ caused by a current I flowing in a wire in vacuum (see Figure 32A) can be calculated by summing the contributions from line elements of the wire. The contribution $d\boldsymbol{B}(r_1)$ to the field at position $\boldsymbol{r}_1$ coming from a line element $d\boldsymbol{l}(r_2)$ at $\boldsymbol{r}_2$ is

$$d\boldsymbol{B}(r_1) = \mu_0 \frac{Id\boldsymbol{l}(r_2) \times \boldsymbol{r}_{12}}{4\pi r_{12}^3}. \qquad (64)$$

It obeys an inverse square law and is at right angles to $d\boldsymbol{l}$ and $\boldsymbol{r}_2$. Equation (64) is called the Biot-Savart law,

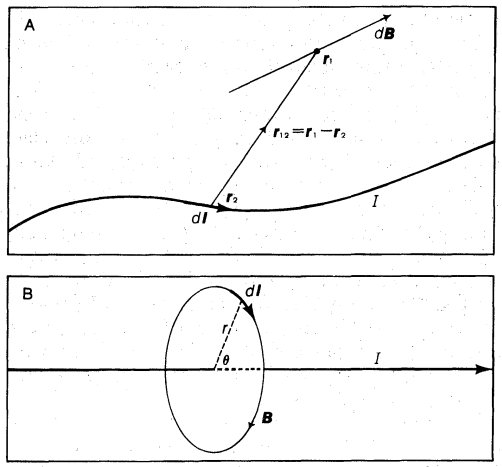

Figure 32: Magnetic fields $d\boldsymbol{B}$ and $\boldsymbol{B}$ arising from current I in a wire. (A) Elemental distance $d\boldsymbol{l}$ along a wire, (B) $d\boldsymbol{l}$ measured along field line around a long, straight wire (see text).

first enunciated by the French physicists Jean-Baptiste Biot and Félix Savart. The force experienced by a line element $d\boldsymbol{l}$ at r of a circuit carrying a current I when the magnetic field $\boldsymbol{B}$ at r is

$$d\boldsymbol{E} = Id\boldsymbol{l} \times \boldsymbol{B} \qquad (65)$$

and is at right angles to the wire element ($d\boldsymbol{l}$) and the magnetic field.

If equation (64) is applied to the calculation of the field that results from a current I flowing in a long straight wire, it shows that the lines of $\boldsymbol{B}$ form closed circular loops about the wire (as shown in Figure 32B) and that the value of the field at a distance r from the wire is $\mu_0 I/2\pi r$. The line integral of $\boldsymbol{B}$ around a closed field-line loop—that is, the integral of the scalar product of $\boldsymbol{B}$ and a loop element $d\boldsymbol{l}$—is

$$\oint \boldsymbol{B} \cdot d\boldsymbol{l} = \int_0^{2\pi} Brd\theta = \int_0^{2\pi} \frac{\mu_0 I}{2\pi r} rd\theta = \mu_0 I.$$

Ampère's law

This result can be generalized to give Ampère's law: the line integral of $(1/\mu_0)\boldsymbol{B}$ around any closed loop in vacuum is equal to the total current threading the loop. If in some region of space there is a current density $\boldsymbol{J}$ and a plane loop defining a plane area is taken the surface element of which is $d\boldsymbol{S}$ (see Figure 32B), this law can be expressed as

$$\oint \boldsymbol{B} \cdot d\boldsymbol{l} = \mu_0 \int \boldsymbol{J} \cdot d\boldsymbol{S}$$

and, by taking an infinitesimal area, converted to a differential equation involving the curl of $\boldsymbol{B}$. This equation is

$$\nabla \times \boldsymbol{B} = \mu_0 \boldsymbol{J}. \qquad (66)$$

All magnetism is due to currents. These may be either currents circulating in wires or currents circulating in atoms. Equation (64) can then be used to show that the

total number of lines of force of the field $\boldsymbol{B}$ emerging from any closed volume is zero. In mathematical terms, if S is a closed surface with dS as a positive outward normal (*i.e.*, a vector perpendicular to the surface and pointing away from the centre), then

$$\oint_S \boldsymbol{B} \cdot d\boldsymbol{S} = \oint_S B_n dS = 0,$$

and this can be expressed in terms of the divergence of $\boldsymbol{B}$ as

$$\nabla \cdot \boldsymbol{B} = 0. \tag{67}$$

Equations (66) and (67) are together equivalent to (64) in the same way that the electrostatic equations

$$\nabla \times \boldsymbol{E} = 0.$$
$$\nabla \cdot \boldsymbol{E} = \rho/\epsilon_0$$

are equivalent to the inverse square law of forces between charges. These electric equations express the following properties of $\boldsymbol{E}$. Lines of electrostatic field do not form closed loops ($\nabla \times \boldsymbol{E} = 0$). Lines of electrostatic field terminate on charges. Equations (66) and (67) express the properties of $\boldsymbol{B}$, which are very different from electric-field properties. Lines of $\boldsymbol{B}$ form closed loops ($\nabla \cdot \boldsymbol{B} = 0$) and do not terminate. The value of $\boldsymbol{B}$ around any closed loop depends on the current linking the loop.

Equations (66) and (67) are still valid for magnetic fields in the presence of matter, provided that the current density ($\boldsymbol{J}$) includes not only currents circulating in circuits or caused by streams of free electrons and ions but also currents circulating within atoms. In practice, just as in electrostatics, it is convenient to distinguish between free, or accessible, charges (ρ_f) and atomic, or bound, charges (ρ_b) by introducing auxiliary vectors—$\boldsymbol{P}$, the polarization, and $\boldsymbol{D}$, displacement—so in magnetism the current density $\boldsymbol{J} = \boldsymbol{J}_f + \boldsymbol{J}_b$ is separated into free, or accessible, currents $\boldsymbol{J}_f$ and bound, or atomic, currents $\boldsymbol{J}_b$. Because the atomic currents are bound in atoms, the net flux of bound current $\boldsymbol{J}_b$ out of any finite volume containing many atoms is zero. Mathematically this is expressed by $\nabla \cdot \boldsymbol{J}_b = 0$, and this makes it possible to express $\boldsymbol{J}_b$ in the form of the curl of another vector ($\boldsymbol{M}$), written $\boldsymbol{J}_b = \nabla \times \boldsymbol{M}$. Ampère's law thus becomes $\nabla \times \boldsymbol{B} = \mu_0(\boldsymbol{J}_f + \nabla \times \boldsymbol{M})$.

Just as the vector $\boldsymbol{P}$ in electrostatics (initially introduced as a way of representing bound charge density by $\rho_b = -\nabla \cdot \boldsymbol{P}$) can be identified with the electric dipole-moment density in a medium, so can the new vector $\boldsymbol{M}$ be identified with the atomic magnetic dipole-moment density. That is, if there are N atoms each with circulating currents resulting in an atomic moment $\boldsymbol{m}$ in unit volume, then $\boldsymbol{M} = N\boldsymbol{m}$.

At this point a new vector ($\boldsymbol{H}$), unfortunately for terminology also known as the magnetic field, is introduced and defined as

$$\boldsymbol{H} = \frac{1}{\mu_0}\boldsymbol{B} - \boldsymbol{M};$$

This vector satisfies the equation

$$\nabla \times \boldsymbol{H} = \boldsymbol{J}_f; \tag{68}$$

i.e., the line integral of $\boldsymbol{H}$ around a closed path is equal to the linked free, or accessible, current. In vacuum the equivalence $\boldsymbol{H} = \frac{1}{\mu_0}\boldsymbol{B}$ exists. The vector $\boldsymbol{H}$ not only satisfies (68) but also $\nabla \cdot (\boldsymbol{H} + \boldsymbol{M}) = \frac{1}{\mu_0}\nabla \cdot \boldsymbol{B} = 0$, or $\nabla \cdot \boldsymbol{H} = -\nabla \cdot \boldsymbol{M}$. Thus, lines of $\boldsymbol{H}$ are not necessarily closed loops and can terminate as discontinuities in the magnetization $\boldsymbol{M}$ of a body. In some media—*e.g.*, permanent-magnet steels—the magnetization $\boldsymbol{M}$ is mainly determined by the chemical composition and heat treatment of the material. In other cases, $\boldsymbol{M}$ depends on $\boldsymbol{B}$ and therefore also on $\boldsymbol{H}$. The relation between $\boldsymbol{M}$ and the magnetic field is rarely linear (*i.e.*, directly proportional), but for many media over an appreciable range of fields there is an approximately linear relationship between $\boldsymbol{M}$ and $\boldsymbol{B}$ or $\boldsymbol{H}$. For reasons that are mainly matters of custom, this relationship is usually expressed as $\boldsymbol{M} = \chi\boldsymbol{H}$, in which χ is dimensionless (a pure number) and is known as the magnetic susceptibility of the medium. In this case $\boldsymbol{B} = \mu_0(1 + \chi)\boldsymbol{H} = \mu_0\mu\boldsymbol{H}$, and μ is known as the relative permeability or simply as the permeability. Most practical magnetic problems are concerned with cases in which either the dipole-moment density ($\boldsymbol{M}$) has a specific value, as in a permanent magnet, or $\boldsymbol{M}$ is proportional to $\boldsymbol{H}$, and $\boldsymbol{H}$ is generated by true currents in coils in a way specified by equation (68).

Magnetic susceptibility

The force between two accurately constructed circuits carrying the same current (I) can be used to measure the current. This is the basis of the current balance and is the primary measurement used in establishing electrical units and standards.

MAGNETIC EFFECTS OF CHANGING CURRENTS

The theory of magnetism due to steady currents is based on the Biot–Savart law (64), which, together with (65), summarizes the experimental laws found in this branch of magnetism. This law leads to Ampère's law $\nabla \times \boldsymbol{B} = \mu_0\boldsymbol{J}$. It would seem that since the divergence of the curl of any vector is identically zero, it follows directly from this equation that $\nabla \cdot \boldsymbol{J} = 0$—*i.e.*, that the flow of current out of any closed surface must be zero. This conclusion is obviously false. If a charged sphere is placed inside the surface and then pulled through the surface, there has to be a net outflow of charge and a net outward current. Thus Ampère's law can be only an approximation. The generalization of Ampère's law to deal with systems in which charge is accumulating and $\nabla \cdot \boldsymbol{J} \neq 0$ is due to Maxwell.

To see how Maxwell arrived at this generalization, a solid cylindrical conductor with a gap (Figure 33) will be considered, which carries an alternating current $I(t)$

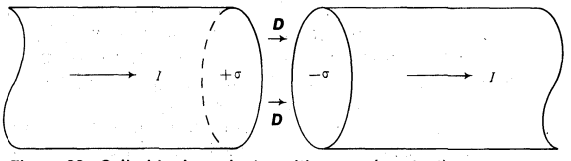

Figure 33: Cylindrical conductor with a gap (see text).

that flows across the gap. There will be a surface charge on the faces of the gap. If I is replaced by the current density J in the conductor and σ is the surface charge per unit area then

$$J = \frac{d\sigma}{dt}.$$

In the gap, lines of what Maxwell called the displacement, $\boldsymbol{D}$, originate on the surface charge on the left face and terminate on the right face and therefore $D = \sigma$. Thus, passing left to right from the conductor through the gap from a region in which $J \neq 0$, $dD/dt = 0$, through a region where $J = 0$, $dD/dt \neq 0$, and then to a region where $J \neq 0$ and $dD/dt = 0$, the sum $J + dD/dt$ remains constant. If the sum $J + dD/dt$ were regarded as the total current density, then $J + dD/dt$ would be a continuous quantity satisfying (in three dimensions) the divergence relation $\nabla \cdot (\boldsymbol{J} + \partial\boldsymbol{D}/\partial t) = 0$; when combined with $\nabla \cdot \boldsymbol{D} = \rho$, however, this equation becomes $\nabla \cdot \boldsymbol{J} + \partial\rho/\partial t = 0$, which can be recognized as the differential statement of the law of charge conservation. The quantity $\partial\boldsymbol{D}/\partial t$ is known as the displacement current (density). To see how Maxwell's hypothesis arises it is useful to consider how the magnetic field lines associated with the divided conductor are obtained by applying Ampère's law. These field lines (the circular lines) are shown in Figure 34; they do not obtrude into the gap. To Maxwell this limitation seemed entirely unreasonable and he therefore hypothesized that displacement current $\partial\boldsymbol{D}/\partial t$ is just as effective as the convection current $\boldsymbol{J}$ in generating a magnetic field. The static form of Ampère's law (66) is therefore to be replaced by

$$\nabla \times \boldsymbol{B} = \mu_0\left(\boldsymbol{J} + \frac{\partial \boldsymbol{D}}{\partial t}\right) \tag{69}$$

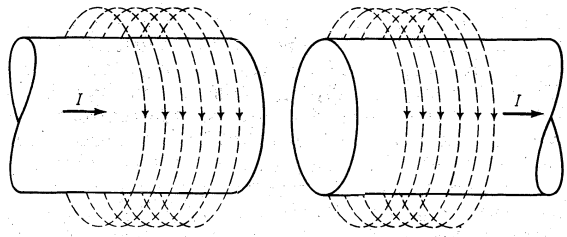

Figure 34: Lines of magnetic force at a gap according to Ampère's law (see text).

as the general law. In vacuum and in the absence of any currents this equation reduces to $\nabla \times \boldsymbol{B} = \mu_0\epsilon_0\partial\boldsymbol{E}/\partial t$, the consequences of which are considered in later sections. It is clear that both currents and changing electric fields generate magnetic effects. It is, however, notable that within a conductor the additional effects due to the displacement current ($\partial\boldsymbol{D}/\partial t$) are almost always negligible. In a medium of conductivity σ, and dielectric constant ϵ, at a frequency ω, the conduction current is $\boldsymbol{J} = \sigma\boldsymbol{E}$, and the order of magnitude of $\partial\boldsymbol{D}/\partial t$ is $\omega\epsilon\epsilon_0\boldsymbol{E}$. The ratio is $(\omega\epsilon\epsilon_0)/\sigma$, and, even in a poor conductor, with $\sigma \simeq 10^6$ mho metre^{-1} and a high value of $\epsilon \simeq 100$, this is only $10^{-15}\omega \simeq 10^{-14}\omega/2\pi$. Thus, at all radio frequencies and lower frequencies, $\partial\boldsymbol{D}/\partial t$ is vanishingly small compared to $\boldsymbol{J}$.

When equation (69) is combined with the other field equations, especially Faraday's law of induction, $\nabla \times \boldsymbol{E} = -\partial\boldsymbol{B}/\partial t$, it shows (see below *Electromagnetic radiation*) that electromagnetic fields propagate with a finite velocity. In vacuum this is $c = (\mu_0\epsilon_0)^{-1/2} \simeq 3 \times 10^8$ metres per second. The two main differences between the fields produced by alternating currents and those produced by steady currents arise from this finite velocity of propagation and from the fact that they can induce potential differences according to Faraday's law.

Velocity of propagation of electromagnetic fields

A disturbance or signal of frequency $\nu = \omega/2\pi$ propagating with a velocity c has a wavelength $\lambda = c/\nu$. In a circuit of linear dimensions (l) comparable with λ there will be an appreciable phase difference between currents in different parts of the circuit because of the finite propagation time. In the opposite case, in which l is much less than λ, the fields near the circuit retain their alternating nature but are not appreciably different from the static fields. The distant fields are quite different and lead to a radiative loss of energy. In the laboratory, circuits are rarely dealt with that have linear dimensions much greater than a few metres, and so the effects associated with the finite velocity of propagation become significant only at high frequencies. For example, even at one megahertz the free space wavelength is 300 metres. At power and audio frequencies, a small fraction of a megahertz, the only new effects associated with alternating, rather than steady, currents are those associated with electromagnetic induction. The most important effects of this type are those that are utilized in transformers and inductors.

In designing a transformer core, efforts are made to minimize energy loss due to eddy currents (circulatory currents induced in metal) in the core, but in other cases use is made of these eddy currents to produce a heating effect. Thus in metallurgy and vacuum-tube manufacture it is often necessary to heat conducting or metallic bodies in vacuum; *e.g.*, in outgassing the anode of a triode. A simple method of doing this is to place a coil carrying radio-frequency alternating current around the assembly and outside the vacuum case (which, through necessity, must not be conducting). The changing magnetic field caused by the current induces eddy currents in the material inside the vacuum case. In general, eddy currents and heating effects occur whenever conducting bodies are placed in the changing magnetic field caused by a changing current.

FORCE, ENERGY, AND POWER ASSOCIATED WITH FIELDS

This section considers one of the most important properties of the electromagnetic field, the way in which it transmits force and energy. The notions of force and energy arise from the study of mechanics, and so it follows that a general treatment of electromagnetic force and energy is based on the equation $\boldsymbol{F} = q\boldsymbol{E} + q\boldsymbol{v} \times \boldsymbol{B}$ for the force ($\boldsymbol{F}$) acting on a particle of charge, q, and velocity, $\boldsymbol{v}$, in an electric field, $\boldsymbol{E}$, and a magnetic field, $\boldsymbol{B}$. The rate at which the two fields do work on the particle is $\boldsymbol{F} \cdot \boldsymbol{v}$ and, therefore, because the magnetic force is at right angles to $\boldsymbol{v}$, only the electric field contributes to the rate of increase of particle energy, which is the product $q\boldsymbol{E} \cdot \boldsymbol{v}$.

For a system of N particles of charge q_k and velocity $\boldsymbol{v}_k$ at positions $\boldsymbol{r}_k$ in a volume V, the total rate at which the fields in V are transferring energy (U) to the particles (p) is $dU_p/dt = \dot{U}_p$; the sum for all N particles is

$$\dot{U}_p = \sum_{k=1}^{N} q_k \boldsymbol{v}_k \cdot \boldsymbol{E}(\boldsymbol{r}_k);$$

and, if the particle distribution is described in terms of a current density $\boldsymbol{J}(\boldsymbol{r})$, this equation can be replaced by the volume integral

$$\dot{U}_p = \int_V \boldsymbol{J} \cdot \boldsymbol{E}\, dV.$$

In a similar way, if $d\boldsymbol{M}_p/dt$ is the momentum of the particles in volume V, it is possible to express $d\boldsymbol{M}_p/dt$ in terms of a charge density ρ and a current density $\boldsymbol{J}$, the volume integral being

$$d\boldsymbol{M}_p/dt = \sum_{k=1}^{N} \boldsymbol{F}_k = \int_V (\rho\boldsymbol{E} + \boldsymbol{J} \times \boldsymbol{B})\, dV.$$

The general results for energy and stress, or force, associated with the fields then follow by combining these equations with the field equations and the laws of conservation of energy and momentum. Though the complete derivation is given in the case of energy, only part of the results are cited in the case of momentum. The reason for this is that the complete momentum formulas involve the use of the stress tensor (a higher order vector), and the result is not sufficiently important here to justify the introduction of a new mathematical technique, tensor analysis.

In vector notation, Faraday's law of electromagnetic induction is $\nabla \times \boldsymbol{E} = -\partial\boldsymbol{B}/\partial t$, and Ampère's law, augmented by the inclusion of Maxwell's displacement current density ($\partial\boldsymbol{D}/\partial t$), is $\nabla \times \boldsymbol{H} = \boldsymbol{J} + \partial\boldsymbol{D}/\partial t$. These two equations can be combined to give the relation

$$\boldsymbol{E} \cdot (\nabla \times \boldsymbol{H}) - \boldsymbol{H} \cdot (\nabla \times \boldsymbol{E}) = \boldsymbol{E} \cdot \boldsymbol{J} + \\ + \boldsymbol{E} \cdot \frac{\partial \boldsymbol{D}}{\partial t} + \boldsymbol{H} \cdot \frac{\partial \boldsymbol{B}}{\partial t},$$

and, if use is made of the formal mathematical identity (symbolized by $\equiv$),

$$\boldsymbol{E} \cdot (\nabla \times \boldsymbol{H}) - \boldsymbol{H} \cdot (\nabla \times \boldsymbol{E}) \equiv -\nabla \cdot (\boldsymbol{E} \times \boldsymbol{H}),$$

then the result will be

$$\nabla \cdot (\boldsymbol{E} \times \boldsymbol{H}) + \boldsymbol{E} \cdot \boldsymbol{J} + \boldsymbol{E} \cdot \frac{\partial \boldsymbol{D}}{\partial t} + \boldsymbol{H} \cdot \frac{\partial \boldsymbol{B}}{\partial t} = 0.$$

When this relation is applied to a volume V within a closed surface S with a positive outward normal $\boldsymbol{n}$ and use is made of the relations,

$$\int_V \nabla \cdot (\boldsymbol{E} \times \boldsymbol{H}) dV = \oint_S (\boldsymbol{E} \times \boldsymbol{H})_n dS$$

and

$$\int_V \boldsymbol{E} \cdot \boldsymbol{J}\, dV = \dot{U}_p \text{ (particle energy)},$$

there results

$$\oint_S (\boldsymbol{E} \times \boldsymbol{H})_n dS + \int_V \boldsymbol{E} \cdot \frac{\partial \boldsymbol{D}}{\partial t}\, dV + \int_V \boldsymbol{H} \cdot \frac{\partial \boldsymbol{B}}{\partial t}\, dV + \dot{U}_p = 0,$$

in which $(\boldsymbol{E} \times \boldsymbol{H})_n$ is the magnitude of the normal component of the vector $\boldsymbol{E} \times \boldsymbol{H}$.

If this result is applied to a volume V, the closed surface S of which coincides with a perfectly conducting metal

wall, then the tangential component of E on the wall vanishes, so that the vector product $E \times H$ has no component normal to S; thus the surface integral vanishes. Further, in the case in which J and D are constant in time, the magnetic field B is constant and therefore $\frac{\partial B}{\partial t} = 0$; hence, only two terms from the above equation remain, namely,

$$\dot{U}_p + \int_V E \cdot \frac{\partial D}{\partial t}\, dV = 0.$$

It then follows, from the conservation of energy, that in this case, the equation $\dot{U}_E = \int_V E \cdot (\partial D/\partial t)\, dV$ must represent the rate of change of the electric-field energy. This result was obtained by a different route in the section *Static electricity*. Next, $\partial D/\partial t$ and J are allowed to vary in time, so that $\partial B/\partial t$ is no longer zero; again, conservation of energy identifies the term

$$\dot{U}_M = \int_V H \cdot \left(\frac{\partial B}{\partial t}\right) dV$$

as the rate of change of magnetic-field energy. Finally, in the most general case in which the surface S is purely a notional mathematical surface, the term $(E \times H)_n$ need not vanish on S. The scalar equation

$$\oint_S (E \times H)_n dS + \dot{U}_p + \dot{U}_E + \dot{U}_M = 0,$$

together with energy conservation, now implies that the surface integral represents the outward flux of energy carried by the field through the surface S. Thus, in a sense, $E \cdot J$, $E \cdot (\partial D/\partial t)$, and $H \cdot (\partial B/\partial t)$ can be interpreted as the rates at which particle, electric-field, and magnetic-field energy densities are increasing and the vector $E \times H$ as the flux of energy, or power flow, per unit area. This vector is usually known as Poynting's vector (after English physicist John Henry Poynting).

Poynting's vector

In a medium with linear constitutive relations—*i.e.*, a medium in which $D = \epsilon\epsilon_0 E$ and $B = \mu\mu_0 H$, with ϵ and μ constant, the two relations $\dot{U}_E = E \cdot (\partial D/\partial t)$ and $\dot{U}_M = H \cdot (\partial B/\partial t)$ can be integrated to give the electric- and magnetic-field energy densities as $\dot{U}_E = \frac{1}{2} E \cdot D$ and $\dot{U}_M = \frac{1}{2} HB$. These results, though often useful, are not as generally valid as the expressions for the time derivatives, which are always correct.

The expressions that arise by considering momentum conservation are altogether more complicated, largely because momentum is a vector, whereas energy is a scalar. There are, however, two results that are relatively simple. In vacuum the pressure p exerted across a surface S with a normal n is, expressed in general form,

$$p = \frac{1}{2}\left(\epsilon_0 E^2 + \frac{1}{\mu_0} B^2\right) - \left(\epsilon_0 E_n^2 + \frac{1}{\mu_0} B_n^2\right),$$

in which E_n and B_n are the normal components of the fields the magnitudes of which are E and B. The momentum g per unit volume carried by the fields in vacuum is

$$g = \frac{1}{\mu_0 c}(E \times B) = \frac{1}{c}(E \times H),$$

in which c is the velocity of light; thus g is equal to Poynting's vector divided by c. If n is taken as the number of photons of energy $h\nu$ (Planck's constant times frequency) that cross unit area per second, the momentum carried across the same area per second is $\frac{nh\nu}{c}$, which can be expressed in terms of the wavelength, λ, as $n\frac{h}{\lambda}$. Thus, a photon of frequency ν and wavelength λ has a momentum h/λ. This is the starting point for the development of quantum mechanics.

Some examples of the use of these results, beginning with Poynting's vector, are the following: A straight wire of circular cross section and radius r, with a resistance R per unit length, has a current I flowing through it. At the surface of the wire there will be an electric field $E = IR$ parallel to the length of the wire and, according to Ampère's law, there will be a magnetic field H parallel to the circumference of the wire, of magnitude $I/2\pi r$. These fields are mutually perpendicular, and Poynting's vector $E \times H$ is directed in towards the centre of the wire. Its magnitude is $I^2R/2\pi r$. But $2\pi r$ is the area of the surface of unit length of the wire, so that the total energy flow per second from the field into unit length of wire is I^2R. The energy flux described by Poynting's vector is, therefore, just equal to the energy dissipation caused by ohmic (resistance) heating in the wire.

This example does no more than confirm that the use of Poynting's vector leads to standard elementary results. In the next derivation, the use of Poynting's vector is essential. If a radio transmitter puts out a total power P evenly distributed over a hemisphere, the energy flux at a distance r is $P/2\pi r^2$ and, if r is reasonably large compared with the wavelength, the radiation is effectively in the form of plane waves. In a plane wave (see below *Electromagnetic radiation*), the fields E and H are perpendicular to each other and to the direction of propagation, so that Poynting's vector is in the direction of propagation and its magnitude is EH. Furthermore, for a plane wave, $H = (\epsilon_0/\mu_0)^{1/2} E$, and so $P/(2\pi r^2) = EH = (\epsilon_0/\mu_0)^{1/2} E^2$. The field strength ($E$) at a distance r is therefore

$$E = \left(\left[\frac{\mu_0}{\epsilon_0}\right]^{1/2} \frac{P}{2\pi r^2}\right)^{1/2}.$$

If, for example, $p = 10^4$ watts and $r = 10^4$ metres, then, since $\left(\frac{\mu_0}{\epsilon_0}\right)^{\frac{1}{2}}$ has a value of approximately 120π ohms, this gives $E \simeq 8 \times 10^{-2}$ volts metre^{-1}. Calculations such as this are essential in determining the signal strength picked up by distant receivers.

Next to be considered is the pressure associated with an electrostatic field in the absence of a magnetic field, or $B = 0$. Thus, from the general equation above, the pressure (p) is

$$p = \frac{1}{2}\epsilon_0(E^2 - 2E_n^2).$$

At a metal surface, the field $E = E_n$ and the field E is zero within the metal. There is, therefore, an unbalanced pressure $p = -\frac{1}{2}\epsilon_0 E_n^2$ acting outwards from the metal surface. Because $\epsilon_0 \simeq 10^{-11}$ farad per metre, this pressure is small, unless E_n is large. Even when E_n is 10^6 volts per metre, the pressure amounts to only five newtons per metre^2, or 5×10^{-5} atmosphere. If a plane electromagnetic wave falls at normal incidence on a metal surface and is reflected, the normal components are $B_n = E_n = 0$, and the pressure exerted on the surface is $\frac{1}{2}\epsilon_0 E^2 + \frac{1}{2\mu_0} B^2$, which is equal to the energy density U just outside the surface. Thus, for normal incidence on the surface the radiation pressure is $p = U$. For incidence at an angle θ to the normal, $p = U \cos^2\theta$, and for thermal radiation, evenly incident from all angles, the average over θ gives $p = \frac{1}{3} U$. This result is the basis for the thermodynamic treatment of radiation. For further details see the article MAGNETISM.

ELECTROMAGNETIC RADIATION

A changing current in a circuit produces a changing magnetic field, and this, in turn, induces a changing electric field. The displacement current represented by the changing electric field leads to a further magnetic field, and the repeated operation of these effects causes an electromagnetic disturbance, or wave, to propagate away from the circuit. The propagation of this wave is analyzed in more detail below; here it is enough to note that it travels with the velocity of light $c = (\mu_0\epsilon_0)^{-1/2}$. Static fields, because of static charges or steady currents, obey an inverse-square law, and so the Poynting vector, or energy-flux vector, $E \times H$, decreases with distance R

Consequence of the displacement current

from the circuit, as $1/R^4$. The integral of $E \times H$ over a closed surface at a distance decreases as $1/R^2$ because the surface of integration is only proportional to R^2 (in fact the integral is zero) and there is no net loss of energy from the circuit to the field. The fall-off is quite different for changing currents and charge distributions, for which the fields have components that decrease only as $1/R$, and, as a result, $E \times H$ is proportional to $1/R^2$, and its integral over a distant closed surface is independent of the distance of the surface. The wave propagating away from the circuit carries with it energy, and the circuit loses energy by radiation.

If a circuit has an alternating current $I \cos \omega t$ (also denoted by the exponential form $Ie^{j\omega t}$, in which $j = \sqrt{-1}$) flowing through it, the radiated power (p) averaged over a cycle will be proportional to I^2, which can be written $P = \frac{1}{2}R_r I^2$. The resistance R_r is known as the radiation resistance of the circuit.

The value of the radiation resistance R_r depends on the frequency ω and the nature, size, and shape of the circuit. If l is the largest linear dimension of the circuit and $\lambda = 2\pi c/\omega$ is the wavelength, the general form of R_r is

$$R_r = \left(\frac{\mu_0}{\epsilon_0}\right)^{\frac{1}{2}} Gf\left(\frac{l}{\lambda}\right),$$

in which $(\mu_0/\epsilon_0)^{1/2} \simeq 120\pi$ ohms, G is a dimensionless shape factor, and f is a function of $l/\lambda = \omega l/2\pi c$. For example, a circular ring of wire having radius a much less than wavelength λ has a radiation resistance

$$R_r = \frac{\pi}{6}\left(\frac{\mu_0}{\epsilon_0}\right)^{\frac{1}{2}}\left(\frac{2\pi a}{\lambda}\right)^4.$$

In general, R_r is small when the linear dimensions of the circuit are small compared with λ and reaches peak values at about 100 ohms when a linear dimension associated with the current is an integral multiple of $\lambda/2$.

If the circuit has an ohmic resistance R, the fraction of the power supplied to the circuit that is radiated is R_r/R. In the laboratory, most circuits have dimensions that are small compared with a wavelength, and so this ratio is generally negligible, although even a small radiated power may cause instability in electronic equipment or lead to interference with nearby equipment. In antennas the dimensions of the circuit are made comparable with wavelength to ensure a large value of radiation resistance at the same time the ohmic resistance is minimized, so that most of the power supplied to the antenna is radiated, rather than lost as heat.

The radiation from a circuit is not isotropic—that is to say, it is not evenly distributed in all directions, and there is always some direction in which the energy flux is zero. For circuits small compared with a wavelength, the energy-flux distribution almost always follows a $\sin^2 \theta$ law in which θ is the angle measured from the null direction. Antennas for which the linear dimensions are large compared with wavelength have a much more complicated angular distribution of radiation, or polar diagram. One of the main problems in antenna design is to achieve a well-defined beam of radiation in the desired direction. If the antenna dimensions are large compared with a wavelength the problem is essentially the same as the problem of attaining good angular resolution in optics and is subject to the same laws. The minimum angle in which the radiation can be confined is approximately λ/l, in which l is the linear dimension of the antenna structure perpendicular to the beam direction.

There is a direct connection between the properties of a circuit or antenna as a radiator and its properties as a receiving element; for example, the polar diagrams in the two cases are identical and a structure that is an efficient transmitter is also an efficient receiver.

A transmission line of length l, short-circuited at both ends, behaves as a resonant (oscillating) circuit at frequencies in which $l = n\lambda/2$ and n is integral. In general, any more or less linear circuit of length l will also be resonant when $l \simeq n\lambda/2$. At the same time, it will act as an efficient antenna. Thus, if a circuit is shock-excited either by interrupting current or suddenly shorting the circuit, it is likely to excite resonances at just those frequencies that radiate most efficiently. A well-known example of this behaviour is the radio and television interference generated by automobile ignition systems. Because the lengths of wire involved are a few metres, the radiation occurs in just that part of the radio spectrum used for FM radio and television.

These general and qualitative considerations will now be expressed more formally. The first group of results are concerned with the propagation of plane electromagnetic waves. A plane wave is a wave propagating in a definite direction, say the z-axis, the wave fronts, or surfaces of constant phase, being planes normal to the direction of propagation. In a medium of relative permeability μ and dielectric constant ϵ these waves are found to propagate with a velocity

The propagation of plane waves

$$c' = (\mu\mu_0\epsilon\epsilon_0)^{-\frac{1}{2}}. \tag{70}$$

In vacuum this velocity becomes

$$c = (\mu_0\epsilon_0)^{-\frac{1}{2}} \simeq 3 \times 10^8 \text{ metres per second.} \tag{71}$$

Most of the media considered in optics have μ almost exactly equal to unity, and so the refractive index

$$n = \frac{c}{c'} = \epsilon^{\frac{1}{2}}. \tag{72}$$

This relation between the refractive index and the dielectric constant at optical frequencies shows how the dielectric response of the atoms of a material medium influences the propagation of waves.

In a metal of conductivity σ, the wave propagates as

$$A \cos(\omega t - z/\delta)e^{-z/\delta},$$

in which the skin depth is δ—*i.e.*, the distance within which the amplitude decreases by $1/e$ is given by

$$\delta = \left(\frac{2}{\omega\mu_0\sigma}\right)^{\frac{1}{2}}. \tag{73}$$

Equations (70), (71), (72), and (73) refer only to the propagation of waves and not to the behaviour of the fields E and B associated with these waves. The first and most important result is that these fields are at right angles to the direction of propagation and to each other; thus, if the waves propagate along the z axis, E and B lie in the xy plane. Furthermore, if a wave has electric-field components E_x and E_y, it has magnetic-field components $B_x = -1/c\, E_y$ and $B_y = 1/c\, E_x$. Thus Poynting's vector, the energy-flux vector, has a single component:

$$(E \times H)_z = \frac{1}{\mu_0}(E \times B)_z = \left(\frac{\epsilon_0}{\mu_0}\right)^{\frac{1}{2}}(E_x^2 + E_y^2) = \left(\frac{\epsilon_0}{\mu_0}\right)^{\frac{1}{2}} E^2.$$

These results not only give the electromagnetic interpretation of phenomena associated with polarized light (light vibrating in one plane) but also relate the energy-flux vector to the fields.

The second group of results is concerned with calculating the radiation from a circuit or a localized distribution of current. The radiated power is obtained by integrating $E \times H$, or $\frac{1}{\mu_0}E \times B$, over a large sphere or closed surface surrounding the system, and E and B themselves are derived from a quantity called the vector potential A, using the formula

$$B = \nabla \times A$$

and

$$\epsilon_0\mu_0\frac{\partial E}{\partial t} = j\omega\epsilon_0\mu_0 E = \nabla \times B = \nabla \times (\nabla \times A).$$

The vector potential A at a point r_1 and time t_1 is related to the current density J at r_2 at an earlier time $t_2 = t_1 - r_{12}/c$, in which $r_{12} = r_1 - r_2$, by the integral taken over the volume v,

$$A(r_1, t_1) = \int_V \frac{\mu_0 J(r_2, t_2)dV_2}{4\pi r_{12}}. \tag{74}$$

The retarded potential

The volume integral extends over the whole region containing currents. The vector potential A given by equation (74) is known as the retarded potential. The relation between t_1 and t_2 expresses the fact that the effects of a current element $J\,dV$ at r_2 take a time r_{12}/c to propagate to r_1, the value of A determining the fields E and B. In some respects (74) is the most important result of this section. It expresses in an unambiguous fashion the fact that changes in currents at r_2 are not experienced as changing forces on charges and current at r_1 until a time r_{12}/c has elapsed. It is also the basic formula in calculating the fields or radiation caused by a prescribed set of currents in an antenna or circuit. Except for simple systems, it leads to exceedingly complicated expressions. A further general result is that, if J corresponds to an alternating current varying as $e^{j\omega t}$ in a system of finite dimensions (located near the origin of the coordinate system), the part of A at a large distance R that contributes to radiation can be expressed as

$$A(R, t) = \frac{\mu_0 e^{j\left(\omega t - \frac{\omega R}{c}\right)}}{4\pi R} F\left(\omega, \frac{R}{R}\right).$$

Here, R is the magnitude of R, and $F(\omega, R/R)$ is a vector function of the frequency and the direction (but not magnitude) of R relative to some fixed direction related to the current distribution in the source. The form of the function F depends on the dimensions and shape of the source, as well as the strength of the currents. If, for example, the source is an oscillating electric dipole of moment $pe^{j\omega t}$, then F is simply equal to $j\omega p$; but, for more general distributions, F is likely to be a formidably complicated function. An oscillating electric dipole is equivalent to a current $Ie^{j\omega p}$ flowing in a short straight length of wire specified by the vector l, in which $Il = dp/dt = j\omega p$.

This formula can be used to calculate the power radiated when a short length l of wire is exited at its centre with a current $Ie^{j\omega t}$, which charges the stray capacitance, between the ends of the wire. The result for the power radiated into a solid angle ($d\Omega$) in a direction making an angle θ with the axis of the wire is

$$dP = \frac{\omega^2 \mu_0 l^2}{32\pi^2} \sin^2\theta \, d\Omega,$$

and the total power radiated into all angles is

$$P = \frac{1}{2} I^2 \left\{ \frac{1}{6\pi} \left(\frac{\mu_0}{\epsilon_0}\right)^{\frac{1}{2}} \left(\frac{\omega l}{c}\right)^2 \right\}.$$

The radiation resistance is therefore

$$R_r = \frac{1}{6\pi} \left(\frac{\mu_0}{\epsilon_0}\right)^{\frac{1}{2}} \left(\frac{\omega l}{c}\right)^2 \simeq 20 \left(\frac{2\pi l}{\lambda}\right)^2 \text{ ohms},$$

in which λ is the wavelength. This calculation is only valid if $2\pi l << \lambda$, and a more elaborate calculation shows that for a uniform straight wire, R_r has a maximum value of 73.2 ohms when $l = \lambda/2$. For larger values of l, the resistance decreases and then rises to a second maximum of 201 ohms when $l = \lambda$. There are further, and larger, maxima when $l = \frac{3\lambda}{2}$, 2λ, etc.

Calculations of the radiation from circuits are appreciably more complicated than for the simple dipole. In practical antenna design, recourse usually has to be made to approximate methods. The basic formula (74) also applies to optical radiation from atoms and gamma radiation from nuclei. In these cases, although the quantum nature of the radiating system introduces some complications, the problem is essentially much simpler because the dimensions of the radiating system are much smaller than the wavelength involved. If the origin is taken somewhere near or within the source region, r_1, can be substituted for r_{12} in the denominator of Equation (74). In this case the integral can be expanded in a power series in r_2; *i.e.*, in terms of the linear dimensions of the system. If these dimensions are denoted by a, the radiation specified by the nth term in the expansion is proportional to $(a/\lambda)^{-n}$ and, since this decreases rapidly with n, only the first nonvanishing term is usually significant. In the optical (light) spectra of atoms, only the electric dipole term with $n = 1$ is usually of any significance. If this term vanishes because of symmetry, the corresponding spectral line will be extremely weak or absent.

Maxwell's field equations provide a complete description of the wave aspects of radiation at, as far as known, all frequencies from dc up to 10^{20} Hz or more but, as the frequency is increased, the quantum of energy $h\nu$ associated with a wave becomes more and more significant. Although, with care, quantum effects can be observed at radio frequencies, at optical and higher frequencies the quantal aspects become more easily observable. At the frequencies associated with high energy reactions, the most obvious phenomena are quantal. It is, however, possible to observe wave effects. For example, even with one MeV gamma rays of frequency 2.5×10^{20} Hz, the polarization of the rays can be measured using a technique not essentially different from that applied to radio waves at 10^9 Hz. A more expansive treatment of this subject may be found in the article ELECTROMAGNETIC RADIATION.

VII. The effects of electricity on matter

PIEZOELECTRICITY

In the direct piezoelectric effect, stress (force) S applied to a crystal produces a polarization P proportional to S; and in the converse effect, an applied field E produces a strain (distortion) σ proportional to E. The change in external conditions of a crystal, that is, the work done by external agencies, is the sum of the stress energy and the strain energy, or $-PdE + Sd\sigma$; and so, neglecting thermal effects, this is also the change in the internal energy U. The change in a function (H), when defined as $H = U - S\sigma$, is therefore

$$dH = dU - Sd\sigma - \sigma dS = -PdE - \sigma dS.$$

Because H is a definite function of the state of the crystal, this gives

$$\frac{\partial P}{\partial S} = -\frac{\partial^2 H}{\partial S \partial E} = -\frac{\partial^2 H}{\partial E \partial S} = \frac{\partial \sigma}{\partial E}.$$

Setting the two partial differentials for P and σ equal to the same coefficient (d)—*i.e.*, $\partial P/\partial S = \partial\sigma/\partial E = d$—they can be integrated to give the basic piezoelectric equations

$$P = dS$$
$$\sigma = dE.$$

Materials that display a strong direct effect also display a strong converse effect and vice versa.

It is sometimes convenient to relate P to the strain and the stress S to the electric field E. In this case

$$P = dK\sigma \qquad (75)$$
$$S = -dKE, \qquad (76)$$

in which K is the elastic modulus, a constant equal to the ratio of stress to strain. In (76) S represents the external stress needed to keep the strain (σ) constant when E is applied; thus if the external stress is actually zero, the relation is $-S/K = dE = \sigma$ by equation (75).

Piezoelectricity arises, in molecular terms, from the displacement of ions in a crystal lattice, which clearly couples the displacement of charge associated with P to the mechanical change in the lattice shape or dimensions associated with the strain. The electric fields that bind ions in position in a crystal lattice are of the order of 10^{10} volts per metre (one volt per angstrom) and a field E might be expected to produce a fractional change in their position; *i.e.*, a strain, of the order of $10^{-10}E$. In other words, the coefficient d in equation (75) will be about 10^{-10} metre per volt. This is, in fact, the value for one important material ADP (ammonium dihydrogen phosphate), but most crystals—*e.g.*, quartz with $d = 3 \times 10^{-12}$ metre per volt—have smaller coefficients because geometrical factors associated with the lattice tend to cancel the piezoelectric effect.

The strain σ in a deformed elastic body is a measure of its fractional change in dimensions and shape. The stress S is a measure of the internal forces transmitted across a plane in the body and mathematically both σ and S are second-rank tensors (a kind of higher order vector; see below). This makes the treatment of piezoelectricity quite complicated. The tensor nature of σ and S and also the vector nature of E and P have so far been ignored in order to keep the equations as simple as possible.

One consequence of the nature of the variables is of considerable importance. If, in an undeformed body, two points A and B have a vector separation r with Cartesian components x, y, and z, and in the deformed body their separation is $r + s$, in which s has components u, v, and w, the strain tensor σ involves nine ratios u/x, u/y, u/z; v/x, v/y, v/z; and w/x, w/y, w/z. The components u/x, v/y, w/z describe simple extensions, whereas the mixed components—*e.g.*, u/y—describe shear strains. Similarly, if the force per unit area acting across a plane with a positive normal n (with components $[k, l, m]$) is p (with components $[q, r, s]$), the stress tensor involves nine ratios q/k, q/l, q/m; r/k, r/l, r/m; and s/k, s/l, s/m. The components q/k, r/l, and s/m correspond to the extensive stress, and the mixed components—*e.g.*, q/l—correspond to shear. Because σ and S are defined in terms of the ratios of the components of two vectors, an inversion of the coordinate system, which takes x to $-x$, y to $-y$, and z to $-z$, does not affect the components of σ or S, but, in a relation such as $\sigma = d\,E$, the components of E change sign. Thus, under inversion, the coefficient d must also change sign. In a gas, a liquid, an amorphous solid, or a crystal, each with a centre of inversion symmetry, both coordinate systems before and after inversion are completely equivalent and d must be the same in both systems. Since now the transformed coefficient $d' = d$ and also $d' = -d$, this means that $d' = d = 0$. Piezoelectricity is therefore confined to acentric crystals; *i.e.*, crystals with no centre of inversion symmetry. Furthermore, if the crystal has almost perfect inversion symmetry, the coefficient d will be small, and in general crystal symmetry will exert a profound influence on the allowed or nonvanishing components of the piezoelectric coefficient d, which, mathematically, is a third-rank tensor with $27 = 3^3$ components.

Limits of piezoelectricity

Although the piezoelectric coefficient d is small, generally less than 10^{-10} metre per volt, the elastic modulus K is large, generally greater than 10^{10} newton per square metre and so, in the relation $P = d\,K\sigma$, the product $d\,K$ is about one coulomb per square metre. An infinitesimal strain will therefore produce an appreciable polarization, and if the crystal is equipped with electrodes, as shown in Figure 35, will lead to a large induced potential of the order of $P/\epsilon\epsilon_0$, in which ϵ and ϵ_0 have the same meaning as before. If a charge q is placed on, say, the upper electrode, it will be related to the displacement vector D in the crystal and D' on the upper face of the electrode; but usually D' will be small and can be neglected, and therefore, it follows that $q = AD$, in which A is the area of the electrode. In the crystal, D contains a component $-P$ resulting from the piezoelectric effect produced by strain and a component $\epsilon_0\epsilon\phi/x$ resulting from normal dielectric polarization; hence,

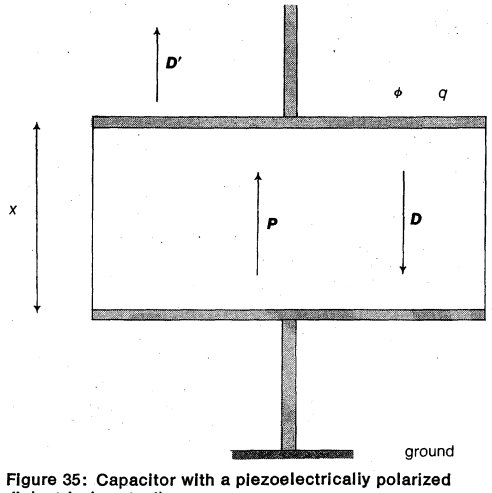

Figure 35: Capacitor with a piezoelectrically polarized dielectric (see text).

$$q = \frac{\epsilon\epsilon_0\phi A}{x} - PA.$$

If the upper electrode is isolated and uncharged so that the charge q is zero, the induced potential is

$$\phi = \frac{x}{\epsilon\epsilon_0}P = \frac{x}{\epsilon\epsilon_0}Kd\,\sigma.$$

But $x\sigma$ is of the order of magnitude of the displacement δ corresponding to the strain σ and so $\phi = \frac{K\,d}{\epsilon\epsilon_0}\delta$.

If, for example, values appropriate to the compound *ADP* are inserted into the last equation—*i.e.*, $K \simeq 10^{10}$, $d \simeq 10^{-10}$, $\epsilon \simeq 50$—then, since $\epsilon_0 \simeq 10^{-11}$, this gives $\phi \simeq 2.10^9\delta$, and a displacement of only five angstroms (5×10^{-10} metre) is required to generate a volt. A displacement of 10^{-4} metre (0.1 millimetre) produces 200 kilovolts. The direct piezoelectric effect is thus very substantial and, for example, even the small displacements of a phonograph stylus attached to a piezoelectric crystal can be easily converted to appreciable voltages.

The converse piezoelectric effect is, by contrast, small. Thus, in a crystal one centimetre thick with 10 kilovolts applied across the crystal, giving a field of 10^6 volts per metre, the strain is only 10^{-4} and the displacement 10^{-4} centimetre. There are a few applications of the static converse piezoelectric effect (*e.g.*, in lasers to alter the mirror spacing), but, in general, most practical applications involve alternating fields at a frequency coinciding with a natural mechanical resonance of the crystal. In this case, the strain for a given field is increased by the quality factor Q of the mechanical resonance. In quartz, because Q usually exceeds 10^4 and can be as high as 10^6, the effective piezoelectric coefficient is increased from 3×10^{-12} metre per volt to about 10^{-6} metre per volt. The resonant quartz crystal can be used as an efficient transducer for converting electrical energy at high frequencies to ultrasonic waves. Because the coupling between the crystal and sound waves in the surrounding medium increases as the square of the frequency, however, the technique is of practical importance only at frequencies above the audible range. The radiated ultrasonic power for a given strain also depends on the acoustic impedance of the medium, and since the maximum strain is limited by the strength of the crystal, not only the efficiency but also the maximum power are only appreciable at high frequencies and in relatively dense media such as liquids.

Pyroelectricity, the appearance of a polarization P proportional to a change in temperature T, can be partially attributed to piezoelectric effects accompanying thermal expansions, but there is also an intrinsic effect; for a change in T also alters the interionic forces and can lead directly to a change in P. Because T is a scalar, the coefficient α in the basic equation

Pyroelectricity

$$P = \alpha T \qquad (77)$$

must be a vector and will necessarily vanish if the medium has a centre of symmetry. Indeed, since equation (77) associates a vector with the crystal, the crystal must not only be acentric but must also belong to one of the polar symmetry classes with a unique axial direction. The effect is generally small, but in a few cases—*e.g.*, triglycine sulfate—the pyroelectric induced voltage can be used to detect thermal radiation. Special camera devices, which detect hot bodies by the bodies' own radiation, have recently been constructed using a pyroelectric screen.

The piezoelectric strain in an applied field leads to a change in refractive index and an indirect electro-optic effect (see next section) but the effect is of little interest.

Finally, it may also be noted that many common materials of scientific interest—*e.g.*, urea, sodium chlorate, and cadmium sulfide—are piezoelectric, and spurious weak resonances that occur in sophisticated electric instruments, such as nuclear quadrupole resonance spectrometers, can often be attributed to piezoelectric effects.

ELECTRO-OPTIC PHENOMENA

The electric field that binds electrons in atoms is more than 10^{10} volts per metre and so the displacement that accompanies the application of an electric field of even 10^6 volts per metre is small and nearly proportional to the applied field. This, as noted above, leads to a linear relation $P = \epsilon_0 \chi E$ between the polarization P in a dielectric and the field E. The relation is not, however, exactly linear and in treating either the effect of strong fields or fine details of the dielectric response it is necessary to include extra terms in the relation between P and E; *e.g.*,

$$P = \epsilon_0(\chi E + \beta E^2 + \gamma E^3 + \text{etc.}). \qquad (78)$$

In solids, the linear coefficient χ is not far from unity and it is reasonable to expect that the nonlinear coefficients β and γ are of the order of $1/E_a \simeq 10^{-10}$ metre per volt and $1/E_a^2 \simeq 10^{-20}$ metre^2 volt^{-2}, in which E_a is the field acting on the electrons in an atom. If a field $E \cos \omega t$ is applied at an optical frequency and a dc field E_0, then the polarization P will contain the following terms,

$$P = \epsilon_0(\chi + 2\beta E_0 + 3\gamma E_0^2) E \cos \omega t;$$

thus the medium will behave as though its optical susceptibility has been changed from χ to

$$\chi' = \chi + 2\beta E_0 + 3\gamma E_0^2.$$

Because refractive index n is related to χ by the relation $n^2 = 1 + \chi$, there will be a change in the refractive index n dependent on dc field. The approximate change δn in n from using the term $2\beta E_0$ is $\delta n = \frac{\beta E_0}{n}$; and if $\beta = 0$ the change made by using the term $3\gamma E_0^2$ is $\delta n = 3\gamma E_0^2/n$. When a coordinate system is inverted, the components of P and E both change signs, and so the coefficient β from equation (78) must also change sign. It follows, as it did for the piezoelectric coefficient d, that β must be zero except in acentric crystals. Thus, in liquids and glasses the only electro-optic effect is that represented by the cubic term γ. The change in n is then quadratic in E_0 and is a so-called quadratic electro-optic effect. Except in certain liquids that exhibit an anomalously large effect, the Kerr effect, to be introduced below, the quadratic effect is small and unimportant. In acentric crystals in which β is not zero, the change in n is linear in E_0 and there is a linear electro-optic effect, named after F. Pockels, a German physicist.

The Pockels effect

If $\beta \simeq 10^{-10}$ metre per volt and $n \simeq 1.5$, then in a field of 1.5×10^6 volts per metre the change δn in n is $\delta n \simeq 10^{-4}$; thus in a crystal one centimetre long traversed by light of wavelength 5,000 angstroms, the change in optical length of the crystal is two wavelengths. Because a change in optical length of half a wavelength is sufficient to produce substantial changes in the optical properties of the system it can be seen that, even though β is small, the linear electro-optic effect is of practical importance. It can be used to modulate beams of light in optical experiments, in optical communication systems, and in optical data-processing systems.

The magnitude of the nonlinear coefficient β that leads to the linear electro-optic effect depends not only on the acentricity of the crystal lattice and the molecular constituents of the crystal but also on the ease with which the atomic electrons are displaced by an applied field. An important empirical rule, which also has a theoretical basis, states that the electro-optic coefficient is proportional to the static dielectric susceptibility and to the square of the optical susceptibility. Thus, in terms of n and the static dielectric constant ϵ, this gives

$$\beta \simeq (n^2 - 1)^2 (\epsilon - 1) \Delta,$$

in which the quantity Δ is a constant. The value of Δ varies by a factor of about 10 from one material to another but, because n can vary from 1.4 to 2.8, and ϵ from three to 3,000, the value of $(n^2 - 1)^2 (\epsilon - 1)$ varies from two to 1.5×10^4, and, as a result, only materials with high values of n or ϵ have appreciable linear electro-optic coefficients. A useful measure of the strength of the electro-optic effect is the half-wave voltage $V_{\frac{1}{2}}$. This is the voltage that when applied across a cube-shaped crystal produces an optical path change of half a wavelength. Its value is $V_{\frac{1}{2}} = n\lambda/2\beta$, and at $\lambda = 5{,}000$ angstroms it varies from a few hundred volts in some titanates and niobates to several hundred thousand volts in, for example, the potassium–magnesium compound $K_2Mg_2(SO_4)_3$. In KDP (potassium dihydrogen phosphate) it is 7,500 V. KDP is an important electro-optic material because it is readily available in large crystals of optical quality and has low dielectric loss even at microwave frequencies. It can be used to construct optical shutters that operate at frequencies up to at least 10^{10} hertz.

The quadratic electro-optic effect, which alone can occur in centrosymmetric crystals, glasses, and liquids is ordinarily too small to be of practical importance. If the coefficient $\gamma \simeq 10^{-20}$ metre^2 volt^{-2}, the field required to produce a change of one part per million in the refractive index is 10^7 volts per metre, which is verging on the limit of practicability. There is one exception to the coefficient being so small. Some liquids (nitrobenzene is an important example) have molecules that are not only highly acentric but also have a large permanent electric dipole moment p. The linear electro-optic effect of the molecules is neutralized by their random orientation, but in a field E at a temperature T the molecules are partially oriented, to an extent pE/kT, and there is then a partial linear electro-optic effect. The net effect is still quadratic in E because the orientation is proportional to E as well. The effective quadratic coefficient that results is approximately $\gamma \simeq \beta p/kT$, in which β would represent the effect for a completely oriented system. This Kerr effect leads to values of γ some thousand times larger than normal. The effect is still small compared with the linear electro-optic or Pockels effect in a good crystal but, because it occurs in a liquid, there is virtually no practical limit to the length of optical path that can be employed. Optical shutters based on the Kerr effect are used in the laboratory and were also employed in early experimental television systems.

In quantum mechanical terms, both the linear optical susceptibility and the nonlinear Pockels and quadratic electro-optic effect are associated with a change in the energy of the atomic ground state in an electric field. A quadratic energy change with field, for example, leads to the linear term χ. These changes in the energies of atomic states also lead to an electric field-induced shift in atomic spectral lines known as the Stark effect (discovered in 1913 by Johannes Stark, a German physicist). The line shift is usually quadratic in the field and is mainly of significance to the spectroscopist because it leads to a broadening of spectral lines from a gas discharge, the broadening being a consequence of strong random electric fields that occur in the discharge. The Stark effect on the first excited state of the hydrogen atom is, however, linear. The transition from the ground state ($S_{\frac{1}{2}}$) to the first excited state ($2P_{\frac{1}{2}}$) is the strongest line in the hydrogen absorption spectrum. The $2P_{\frac{1}{2}}$ level, however, coincides almost exactly in energy with the $2S_{\frac{1}{2}}$ state and the interaction between these two states leads to an anomalously large Stark effect that, except at low fields, is linear with the strength of the electric field. Linear Stark effects can also be observed in molecular spectra, but generally the Stark effect is of much less significance than its counterpart, the Zeeman effect, in which spectral lines are affected by magnetic fields.

The Stark effect

THERMAL EFFECTS

The most widespread and important thermal effect of electricity is ohmic or resistance heating. Electrons moving in a conductor pick up energy from an applied field and by collisions excite random atomic vibrations in the

lattice of the conductor and thus increase its temperature. If the applied field and current are increased, the vibrations may become so violent that they disrupt the lattice and the conductor melts or evaporates. This principle is used in the fuses that protect electrical circuits; a low-melting-point wire is used so that the circuit will be interrupted before the temperature in the wire has become high enough to constitute a fire hazard.

The conversion of electrical to thermal energy in a resistance is complete and so, when electrical heating is employed, all the energy supplied can be utilized. It is this total conversion that makes it possible to measure potential (volts) and current (amperes) by resistance heating. The ampere is defined in absolute terms and the volt is related to the value of the permittivity in vacuum, ϵ_0, obtained from the velocity of light and the comparison of a resistance with a standard capacitance using this value of ϵ_0 and an absolute unit of time. Secondary standards of resistance and voltage of high accuracy are readily available and so the joule ohmic heating in a resistance R, voltage squared divided by resistance (V^2/R), is normally used as the primary thermal standard in physics, chemistry, and engineering.

Reversible thermoelectric effects in conductors are dealt with above, and so only the thermal effects of fields in insulators will be considered here. Irreversible thermal effects occur whenever an alternating electric field is applied to a dielectric the polarization of which lags behind the applied field by a time comparable with the period of the field, or when the period of the field is comparable with the period of the natural electronic or ionic resonance in the medium. The effect is negligible at radio frequencies in quartz and polyethylene, but in some media—*e.g.*, porcelain or polyvinyl chloride plastics—it is appreciable. Dielectric heating can be usefully employed to cure and weld many plastics.

Dielectric media, mainly those comprised of molecules having permanent dipole moments, which exhibit a temperature-dependent susceptibility, show reversible thermal effects in static or slowly varying fields. At higher frequencies, these effects lead to irreversible heating and dissipation. The effect is particularly strong in water at microwave frequencies and is a main contributor to the heating in a microwave oven. Dead organic matter (*i.e.*, food) nearly always contains appreciable amounts of water.

The highest power densities that can be achieved by ohmic or dielectric heating are limited by the properties of solid and liquid materials. Much higher densities can, however, be achieved in plasmas and electron beams. For example, an electron beam of 50 kilovolt electrons carrying one ampere can be focussed onto an area of one square millimetre giving 5×10^{10} watts per square metre. Because thermal radiation at 10,000° K can produce only 6×10^8 watts per square metre; *i.e.*, about 1 percent of this energy density, electron beams (and plasma jets) are preferable for welding, machining, and cutting refractory materials.

Finally, it may be remarked that the heating of a solid body by incident thermal radiation is ultimately caused by the effect of the electric field of the radiation on the electrons or ions in the body.

THE ELECTRICAL PRODUCTION OF LIGHT

For the two most important practical light sources, the incandescent filament lamp and the gas discharge tube, see text article on LIGHTING AND LIGHTING DEVICES. This section is concerned with rather less familiar effects.

Accelerated or decelerated electrons radiate, and if an energetic electron travelling in vacuum is suddenly brought to rest on impact with a solid electrode, it will produce continuous electromagnetic radiation called bremsstrahlung radiation. Bremsstrahlung radiation is not a practical source of light because the effect occurs only with relatively high energy electrons and the resultant radiation lies in the X-ray region. It is, however, one of the two main processes, the other being the excitation of resonance X-radiation from target atoms in the operation of X-ray tubes (see X-RAYS).

Electrons moving in circular orbits in a high-energy machine such as a cyclotron, betatron, or synchrotron are subject to an inward acceleration and therefore radiate. Although the radiation is of some interest as a source to the spectroscopist, its chief importance is that it limits the energy to which electrons can be accelerated in a cyclic machine. Eventually, a point is reached at which the radiation loss just balances the energy input.

Electrons moving with a uniform velocity v (*i.e.*, in a straight line without acceleration) in vacuum do not radiate because v is always less than the velocity of light. If, however, energetic electrons pass through a medium of refractive index n in which the velocity of light c/n would be less than v, they produce Cherenkov radiation (named after Pavel Alekseyevich Cherenkov, a Soviet physicist) at an angle θ to the electron trajectory, given by $\cos\theta = c/nv$. The fraction of the electron energy radiated is small and is confined to wavelengths in which the refractive index n exceeds c/v. Cherenkov radiation is used in high-energy particle physics to record the passage of fast-charged particles.

Cherenkov radiation

Electrons of more than about one kilovolt energy impinging from vacuum on almost any dielectric will excite target atoms and cause some radiation. Usually, the radiation is reabsorbed in the target medium and little escapes, but if a dielectric with the correct energy level structure is used, reabsorption can be eliminated and appreciable efficiency of energy conversion to light, of the order of several percent, can be achieved. Furthermore, the energy level structure of the medium determines the spectral distribution or colour of the light. This is the principle used in the screen phosphors of the cathode-ray tube and the television picture tube. It is also used in nuclear physics to detect charged particles, especially electrons. Electrons impinging on some dielectrics, notably potassium chloride (KCl), can also produce light-absorbing centres and render a screen opaque.

Conduction electrons moving in a solid under the influence of an electric field usually lose kinetic energy in low-energy collisions as fast as they acquire it from the field. Under certain circumstances in semiconductors, however, they can acquire enough energy between collisions to excite atoms in the next collision and cause radiation. A necessary condition for this to occur is that there must be regions, in the semiconductor, of intense electric field. If this field is not to cause destructively large currents to flow, the region must be one in which there are very few mobile electrons (or holes). Such a region occurs in zinc sulfide, a large energy-gap material, and a voltage applied across a thin layer of zinc sulfide powder causes an electroluminescent effect, the detailed mechanism of which is not understood and the efficiency of which is low. At present, electroluminescent panels are of more interest as signal indicators and display devices than as a source of general illumination. A somewhat similar effect occurs at the junction in a reverse-biassed semiconductor, *p-n*-junction diode, *i.e.*, a *p–n*-junction diode in which the applied potential is of a sense opposed to that which produces a substantial current. Electrons in the intense field at the depleted junction easily acquire enough energy to excite atoms. Little of this energy finally emerges as light, although the effect is easily visible under the microscope.

When a junction between heavily doped *n*-type material and less doped *p*-type material is forward biassed, the current consists mainly of electrons injected from the *n* material into the conduction band of the *p*-type material. These electrons ultimately drop into holes in the valence band and release energy equal to the energy gap of the material. In most cases this energy (E) is dissipated as heat, but in gallium phosphide, and especially in gallium arsenide, an appreciable fraction appears as radiation the frequency ν of which satisfies the relation $h\nu = E$. In gallium arsenide, although up to 30 percent of the input electrical energy is available as radiation, the wavelength, 9,000 angstroms, is in the infrared. Gallium phosphide gives visible light but with low efficiency, and alloys have intermediate properties. At present, injection diodes are mainly used as indicator lamps, but, at least in principle,

there is no reason why materials with worthwhile efficiencies in the visible should not be discovered. Gallium nitride, for example, has recently been shown to emit blue-green light, though with low efficiency. The electroluminescent injection diode is also used as a laser, and many proposed optical communication systems are based on this device. Compared with a gas laser or an optically pumped laser, it has the advantage that it can be directly modulated at high frequencies.

Diode laser

CHEMICAL EFFECTS

The direct effects of electric fields on chemical reactions are, on the whole, negligible, and the most important electrochemical effect, electrolysis, involves the motion of charged ions, constituting an electric current. Electrolysis is considered in detail in the article ELECTROCHEMICAL REACTIONS, and in this article only the basic principles are presented. Many substances—*e.g.*, sodium chloride (NaCl), hydrogen sulfate (H_2SO_4), and potassium hydroxide (KOH)—when dissolved in water or other polar solvents, dissociate into positive and negative ions. Water itself is in any case slightly dissociated, to the extent of one part in 10^9, into H^+ and OH^- ions. Under the influence of an electric field, these ions drift in opposite directions, and, for example, in an aqueous solution of H_2SO_4, the positive H^+ ions will accumulate at the negative electrode and the SO_4^{2-} ions at the positive electrode. What happens at the electrodes then depends to a great extent on the material of the electrodes. If the positive electrode is made of a reactive metal, metal ions will go into solution, whereas if it is an unreactive metal such as platinum, the excessive concentration of SO_4^{2-} ions will suppress the hydrogen-ion concentration and cause more water to dissociate to H^+ and OH^-. The OH^- ions are then neutralized at the electrode and the reaction $4OH^- \rightarrow 2H_2O + O_2$ releases oxygen gas. The details of the reactions at the electrodes are not important, but it is noteworthy that the chemical species released is not necessarily related to the ions transported toward the electrode.

Electrolytic conduction differs from electronic in two important ways. First, the charge carriers are massive ions rather than light electrons and the mobilities are low, less than 10^{-4} of the mobility of conduction electrons in a metal. Second, the concentration of charge carriers in aqueous solutions is usually low. As a result, electrolytes are rather poor conductors and electrolytic conduction is primarily of interest for its chemical consequences. It can be applied either to deposit films of metal as in electroplating or in the separation of an element; *e.g.*, nickel from its salts.

However complex the reactions are that occur at the electrodes, electrolytic processes are subject to the laws of thermodynamics, and a number of important conclusions, especially about chemical reaction constants, can be derived from electrochemical measurements. From the point of view of electrical theory, however, the most important results that emerge are Faraday's laws. These laws state that the quantity of a substance released at an electrode is proportional to the total charge passed and that it is also proportional to the chemical equivalent (combining rates, relative to hydrogen) of the substance. The interpretation of these laws in terms of a fundamental unit of atomic, ionic, or electronic charge has influenced the whole subsequent development of physics.

Electrolytic conduction is not confined to aqueous solutions. Many molten salts and solutions of salts in other molten salts are good electrolytes and this is the basis of industrial processes; *e.g.*, the separation of aluminum. Some solids are also electrolytic conductors, especially at elevated temperatures. Both the mobility of the ions and their concentration are usually low and, regarded as a conduction process, the effect is not very substantial. It can, however, also be regarded as a failure in an otherwise good insulation and, in some cases, the products of the electrolytic process can be a serious nuisance.

Although in electrolysis the centre of interest is in the chemical substances released at the electrodes, in some cases, the transport of the ions themselves is important and also subsidiary effects associated with ionic transport—*e.g.*, electro-osmosis and electrophoresis. Before these subjects can be considered, it is necessary to investigate ionic motion in somewhat greater detail.

Ionic motion

The first thing that is noticeable in a table of ionic mobilities in aqueous solution is that ions differing considerably in mass and size have much the same mobility. Thus, for example, the ions Cl^-, Br^-, and I^- have almost identical mobilities although it might be expected that the heavy and bulky I^- ion would have a much lower mobility than the lighter and smaller Cl^- ion. Even more surprisingly, the small and light lithium (Li^+) ion has only about half the mobility of the heavy cesium (Cs^+) ion. This is generally attributed to the fact that ions collect a group of water molecules around themselves, which move as a unit with the ion. This is to be expected because a water molecule with its permanent electric dipole moment is strongly attracted toward the region near an ion, where the electric field is strongest. Further evidence for this view comes from the study of the colours and optical spectra of transition group ions in solution. For example, it is well established that the purple colour of potassium chromium alum crystals is caused by the influence on the chromium (Cr^{3+}) ions of a coordinate octahedron of molecules of water of crystallization. Since this colour persists in aqueous solution, the coordinated octahedron must be retained in solution. Further, if the solution is heated (and the octahedron destroyed), the ions take up a new configuration that gives a green solution. Crystals of chrome alum cannot be obtained from this green solution.

If ions can attach to themselves a considerable number of water molecules, it is obvious that ions can also be attached to solid surfaces; *e.g.*, the walls of the container or material particles suspended in solution. For example, manganese dioxide (MnO_2) particles, as a fine suspension, form a suitable substrate for sulfate (SO_4^{2-}) ions in sulfuric acid solution. A single particle of manganese dioxide (MnO_2) cannot, however, hold many SO_4^{2-} ions, simply because by so doing it would acquire a large negative charge and repel the approach of fresh ions. What actually happens is that the particle acquires almost exactly equal numbers of SO_4^{2-} ions and pairs of H^+ ions. The SO_4^{2-} ions are attached to the particle and the H^+ ions form a neutralizing sheath outside the layer of SO_4^{2-} ions. Thus, the particle is enclosed in an electrical double layer, with its positive surface outward, and complete H_2SO_4 molecules are abstracted from the solution. Many of the otherwise puzzling phenomena that accompany the flow of currents in electrolytes and particle suspensions involve the capacity of ions to attach themselves to solid surfaces or to attach molecules of the solvent to themselves.

If a porous pot is immersed in a beaker of water with two electrodes, one inside the pot and the other outside it in the beaker, a potential difference between the electrodes causes water to flow into the pot, raising the water level and causing a pressure difference. This phenomenon is known as electro-osmosis or electro-endosmosis. It is to be noted that a porous pot is used and not, as in normal osmotic pressure experiments, a semipermeable membrane. The flow is caused by surface effects on the walls of the pores of the pot. The basic process can be understood as follows. Figure 36 shows

Electro-osmosis

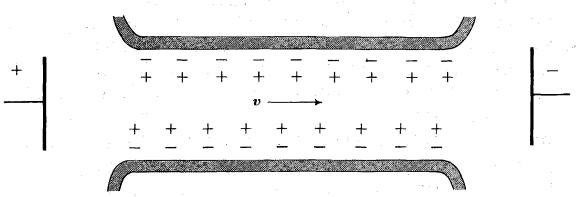

Figure 36: Electro-osmosis in a single pore (see text).

a capillary pore with an electrical double layer of charge adsorbed on its surface. If the liquid is water, the negative ions that are bound to the surface are hydroxyl OH^- ions and the outer positive layer consists of H^+ ions. The

field gradient, due to the electrodes, causes these H^+ ions to glide over the OH^- ions toward the negative electrode and this sweeps the fluid in the centre of the tube along in the same direction with a velocity v for, as the ions move, they make collisions with the non-ionized water molecules of the liquid and therefore transfer momenta to them.

A porous pot is generally made of refractory metal oxides and silicates—*e.g.*, aluminum oxide (Al_2O_3)—which in contact with water tends to form the base $Al(OH)_3$; thus, in this case, it can be seen why a double layer is formed with the OH^- ions relatively firmly attached to the wall. If, on the other hand, the pot is replaced by a porous plug of an electronegative element such as sulfur, this will tend to bind the H^+ ions, leaving the OH^- ions as the outer mobile layer. The flow is then reversed with respect to the potential gradient.

Electrolytes added to the water generally slow down the electro-osmosis. A potassium salt added to the water replaces some of the H^+ ions in the outer layer by K^+ ions and, if these are more tightly bound to the underlying OH^- layer, the flow for a given field is reduced. When the surface layer on the wall is negative, as in Figure 36, the reduction of the flow is determined mainly by the positive ions of the solute and increases rapidly with their valency or positive charge. Thus the barium (Ba^{2+}) ion is more effective than K^+, and a thorium salt containing the thorium (Th^{4+}) ion exerts a very strong effect. The effect is further increased if the positive ion has, in any case, a tendency to adsorb on the wall. This is especially the case with organic ions, which therefore exert an exceptionally strong effect.

The converse effect to electro-osmosis is the production of a streaming potential when liquid is forced through a tube. If in Figure 36 the water is imagined to flow through the tube to the left, caused by pressure gradient applied across the ends of the tube, the positive ions are swept to the left and the electrode marked + in the figure acquires a positive charge and potential. This potential builds up, as ions accumulate near the electrode, until the normal electrolytic conduction current through the tube, in the reverse direction, just balances the rate of arrival of ionic charge. The potential difference (ϕ) between the two electrodes then maintains a steady value, which can be related to the pressure difference (p) between the ends of the capillary.

The result is $\phi = \epsilon\epsilon_0\zeta p/\eta K$, in which η is the viscosity of the liquid, K its electrical conductivity, and ζ the potential difference across the double layer on the surface. Experimentally, streaming potentials of the order of one volt are found to occur for one atmosphere pressure difference, and the values of ζ deduced from the measurements are of the order of 50 millivolts.

Electrophoresis is in many ways similar to electro-osmosis. If small particles of matter are suspended in water in which two electrodes are immersed, the particles are observed to move toward one of the electrodes. The effect is due to the electrical double layer of ions at the surface of the particles. For example, if ferric hydroxide, $Fe(OH)_3$, is suspended in water, there will be some ferric Fe^{3+} ions in solution and these are attracted toward the particles and form the innermost layer of ions. The outer layer consists of OH^- ions. In an electric field there is a net force on the particle with its sheath of iron (Fe^{3+}) ions and this attracts the particle toward the negative electrode. The loosely held OH^- ions slide over the surface of the particle as the particle moves toward the negative electrode.

If σ is surface charge on a particle of superficial area A and u is its velocity, the magnitude of the force is $AE\sigma$ in a field E. The viscous retarding force is of the order of $u\eta A/\lambda$, in which λ is the layer thickness. Thus $u = \lambda\sigma E/\eta$, and again this can be expressed in terms of the potential difference ζ across the double layer as

$$u = \frac{\epsilon\epsilon_0\zeta}{\eta} E.$$

Just as in electro-osmosis, the addition of electrolytes has a strong effect on the motion. In a suspension of gold particles in pure water, for example, the layer of ions next to the gold surface consists of negative OH^- ions. The addition of metal salts containing, for example, aluminum (Al^{3+}) ions leads to a definite reduction or even to a complete reversal of the sign of the charge in this layer.

Different particles in suspension move with different velocities in the same field and this can be used—*e.g.*, in protein chemistry—to effect a separation of the contents of the suspension. The procedure can, for example, be used to separate the constituents of a suspension applied to a strip of filter paper by placing electrodes in contact with the paper. This technique is known as paper electrophoresis.

Paper electrophoresis

BIOELECTRIC EFFECTS

The configuration of enzymes and their biochemical activity depends on the hydrogen ion concentration, and, on a molecular level, this is an electric effect. At the other extreme, large currents destroy tissue by heating and electrolysis. This section deals with an intermediate range of effects associated with nerve, brain, and muscle action, in which small, but macroscopic, potential differences occur and can be influenced by applied potentials. Electric shock is closely related to these processes. For more detail about the biological aspects of electric currents, the reader should consult the article on BIOELECTRICITY.

A beginning can be made by considering how macroscopic potential differences arise in living matter. Biological function depends on chemical reactions in aqueous solution and most of these reactions involve ions. In many cases, they occur at membranes that separate solutions of different ionic composition. If the membrane is permeable to one or more of the ions present in different concentrations on its two sides, the diffusion of these ions down the concentration gradient will lead to charge separation and establish a potential difference across the membrane. In equilibrium, the ionic flows caused by the potential and by the concentration gradients just balance.

If, for one type of ion of charge q, the two concentrations are n_1 and n_2, the potentials on the two sides of the membrane satisfy

$$\frac{n_1}{n_2} = \exp\left(-\frac{q[\phi_1 - \phi_2]}{kT}\right), \qquad (79)$$

in which k is Boltzmann's constant and T is the temperature. This can be expressed as

$$\phi_1 - \phi_2 = -\frac{kT}{q}\log_e\frac{n_1}{n_2};$$

or, changing from $\log_e$ to $\log_{10}$, inserting numerical values for k and T, and setting $q = e$ (the electronic charge), (79) can be expressed as

$$\phi_1 - \phi_2 = -57 \times 10^{-3}\log_{10}\frac{n_1}{n_2}\text{ volts.}$$

The concentration ratios that occur in biological material are usually in the range one to 100 and so the general order of magnitude of these potential differences is less than 100 millivolts.

Usually, the concentrations will finally equalize themselves unless either external influences (*e.g.*, pressure differentials) act on the system or external sources of ions maintain the two concentrations at different values. It is possible, however, even in passive inorganic systems, for potentials of this kind to develop, as will now be seen.

In this example (see Figure 37), a membrane, permeable to sodium (Na^+) ions, chlorine (Cl^-) ions, and water molecules, separates a solution of sodium chloride (NaCl) from a mixed solution of NaCl and NaX, in which X is some large organic ion to which the membrane is impermeable. If $[Na^+]_1$ represents the ionic concentration in region (1) then, the application of equation (79) to the oppositely charged Na^+ and Cl^- ions gives $[Na^+]_1[Cl^-]_1 = [Na^+]_2[Cl^-]_2$. But, because both of the solutions are neutral, $[Na^+]_1 =$

$[Cl^-]_1 + [X^-]_1$, and $[Na^+]_2 = [Cl^-]_2$; from these equations, the ratio of concentrations follows:

$$\frac{[Na^+]_1}{[Na^+]_2} = \left(\frac{[X^-]_1 + [Cl^-]_1}{[Cl^-]_1}\right)^{1/2}.$$

Thus, in equilibrium, there will be a potential difference

$$\phi_1 - \phi_2 = -\frac{57}{2}\,10^{-3}\log_{10}\left(\frac{[X^-]_1 + [Cl^-]_1}{[Cl^-]_1}\right) \text{volts}.$$

The existence of this type of equilibrium, and the Donnan potential (named after Frederick George Donnan, a British chemist) to which it gives rise, follows directly

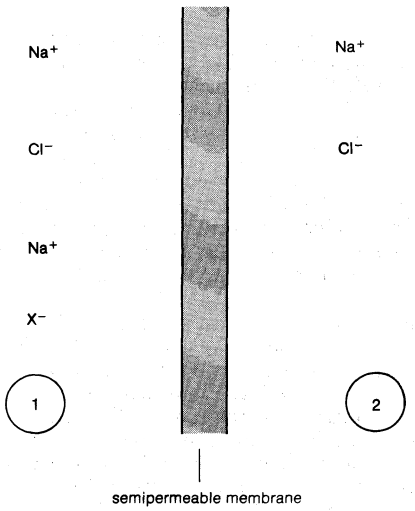

Figure 37: Donnan equilibrium (see text).

from thermodynamic laws, and the potential difference is maintained with no expenditure of energy. In biological systems, however, there is no true thermodynamic equilibrium, and concentration differences leading to potential differences can also be maintained by active processes. Thus, for example, it is possible for a membrane to be permeable to one ion, say the Na^+ ion, only in one direction, provided that energy is continuously supplied to the membrane by biochemical reactions deriving the energy from metabolic processes. Something of this kind occurs in nerves.

Permeability in membranes

A nerve fibre is a tube with an insulating semipermeable wall. The fibre contains in its interior a solution containing predominantly K^+ and negative organic ions together with much smaller quantities of Na^+, Cl^-, and other inorganic ions. The interior fluid is therefore an electrolytic conductor. The fibre is bathed in an exterior fluid containing predominantly Na^+ and Cl^- ions with a much lower concentration of K^+ ions. In some respects, the system resembles a coaxial cable, and, because it is found experimentally that nerve impulses are electrical impulses that advance along a nerve, it is tempting to regard the system as analogous to a coaxial cable in radio. There is, however, one major difference. In a radio cable, the conductors have a low resistance and the propagation of the signals is almost entirely determined by the capacitance (C) and the inductance per unit length. In a nerve, the resistance (R) per unit length is high and the effects of inductance are negligible. This leads to a diffusion equation. A pulse introduced into a nerve fibre is distorted and attenuated to zero within a few millimetres.

If V is the voltage difference between the inner and outer fluids and I the axial current in the inner fluid, the voltage drop per unit length (dV/dx) is RI, whereas the current leakage is $C\frac{dV}{dt}$. This gives the two equations

$$\frac{dV}{dx} = -RI$$

and

$$\frac{dI}{dx} = -C\frac{dV}{dt},$$

which lead to

$$\frac{d^2V}{dx^2} = RC\frac{dV}{dt}.$$

If at $x = 0$ a sinusoidal signal $V_0 \cos \omega t$ is introduced, the signal at position x is

$$V(x,t) = V_0 \cos\left(\omega t - \left[\frac{\omega CR}{2}\right]^{1/2} x\right) e^{-(\frac{1}{2}\omega CR)^{\frac{1}{2}}x}$$

and the phase velocity is $(2\omega/CR)^{1/2}$ which depends on ω. Thus, if a short pulse is introduced into the nerve, the high frequency components of the pulse propagate fastest and are attenuated most quickly. This destroys the shape of the pulse, and, finally, in a distance of the order of $(\tau/CR)^{1/2}$ in which τ is the pulse length, the entire pulse disappears. Because nerve pulses apparently propagate unchanged for considerable distances, this analogy to a coaxial cable is not valid. For a pulse to be maintained, there must be a continuously acting energy source replenishing the pulse energy lost by ohmic dissipation in R.

To return to the electrochemical conditions in a nerve fibre, in the resting condition there is a membrane separating an interior solution, rich in potassium (K^+) ions, from an exterior solution, rich in sodium (Na^+) ions. This condition cannot be a static equilibrium if the membrane is systematically permeable to both ions, for the potential difference associated with the K^+ ions is of the opposite sign to that required to balance the Na^+ concentration gradient. Experimentally, it is found that the inner fluid is about 60 millivolts negative with respect to the outer fluid. This potential difference is almost enough to balance the K^+ concentration gradient, and, further, it varies with the external K^+ ion concentration but not with the Na^+ concentration. It therefore appears that, in the resting condition, the membrane is permeable to K^+ but not to Na^+. This is not, however, sufficient to explain why the potential difference exists, for eventually the K^+ concentration would equalize on the two sides of the membrane. The potential difference is in fact maintained by a continuous, energy-consuming process involving primarily the Na^+ ions. The membrane is not simply passively impermeable to Na^+ but actively pumps Na^+ ions outward. This pumping action not only has to compete with the concentration gradient but also with the potential gradient, and it establishes a slight deficit of positive ions in the interior fluid. This gives it its negative charge and potential. Because the electronic charge is so large, the deficit in positive ions needed is, in chemical terms, small. It is about one part in 10^6 of the total ionic content of the interior fluid.

The resting state

In the resting state, the interior of the nerve has a negative potential of about -60 millivolts; K^+ ions are diffusing relatively freely, though against the potential gradient, through the membrane, and the sodium pump is running. When a nerve impulse (which is a positive potential excursion of the inner fluid) arrives, the impulse, for reasons that are not completely understood, alters the permeability of the membrane and allows the ingress of Na^+ ions down their concentration gradient. This carries the internal potential to a still higher positive potential. The number of ions required is so small that it hardly alters the ionic concentrations. At this stage, the membrane suddenly becomes impermeable to Na^+ ions again, and a net efflux of K^+ ions begins (which returns the inner potential to a negative value) and the sodium pump then brings the nerve back to its resting state. The actual details of these events, which take place during a few milliseconds, are perhaps rather more complicated than this description suggests, but from an electrical point of view, the important consequence is that the energy stored electrically and in concentration gradients by the sodium pump is released and thus augments the energy of the nerve impulse. The mechanism is almost exactly analogous to the operation of a repeater station in a radio pulse-code modulation system. The energy

stored in the repeater is consequently released to form a new pulse in a process that is triggered by the arrival of an input pulse.

In live animals, the initial nerve impulse is generally triggered by chemical action and then propagates along the nerve to a terminal where it triggers further chemical action, thus resulting in a physiological response. Nerve impulses, impulses associated with brain function and impulses associated with muscular contraction can, however, be observed and recorded electrically and also induced by externally applied potentials. Using refined experimental techniques, it is possible to excite single nerves and to produce specific physiological responses, but the simple application of a potential difference across a region of live tissue is more likely to produce a confused response caused by the random stimulation of several nerves at once. Thus, an electric shock in which an appreciable current flows through the body may produce local potential gradients that stimulate either sensory nerves, producing a variety of subjective sensations, or motor nerves, producing uncontrolled muscular contractions. Even if the experimental techniques are crude, however, the experimental electrical stimulation of either muscular tissue, or nerves attached to muscular tissue, is most likely to evoke the typical muscular response; *i.e.*, contraction. This, presumably, was the case in the pioneer observations of twitching frog legs made by the Italian physiologist, Luigi Galvani, which not only laid the foundations of bioelectricity but also influenced the whole subsequent development of practical and theoretical electricity and magnetism.

Attention has been concentrated on nerve transmission because this is the best understood, and most obviously electrical, phenomenon involving electrical effects on living matter. Similar effects occur in muscular tissue, but, on the whole, other biological processes, though controlled by ionic movement and absorption, do not lead to readily observable potential differences and are not affected in any direct way by experimentally applied fields.

BIBLIOGRAPHY

The development of concepts and theories: MICHAEL FARADAY, *Experimental Researches in Electricity*, 3 vol. (1839–55; reprinted in 2 vol., 1965), provides a lucid, immediately comprehensible description of the greatest discoveries and the most important concepts. Also highly readable is EDMUND T. WHITTAKER, *A History of the Theories of Aether and Electricity*, 2 vol. (1910 and later editions), a work of great erudition. HENDRIK A. LORENTZ, *The Theory of Electrons and Its Applications to the Phenomena of Light and Radiant Heat* (1909; 2nd ed., 1953), is the classic exposition of the atomic approach to electricity. Although partially outdated by subsequent developments a remarkably large part of the book is still relevant. A more recent work is LEON ROSENFELD, *Theory of Electrons* (1951). ABDUS SALAM, "Elementary Particles," *Contemp. Phys.*, 1:337–354 (1960), is a readable introduction to the latest ideas. Two advanced texts on charged particles are F. ROHRLICH, *Classical Charged Particles* (1965); and RICHARD P. FEYNMAN, *Quantum Electrodynamics* (1961). WALLACE R. HARPER, *Contact and Frictional Electrification* (1967), gives a modern account of the phenomenon with which the whole science of electricity began.

Basic mathematics: On vectors, BERNARD HAGUE, *An Introduction to Vector Analysis for Physicists and Engineers*, 6th ed. rev. by DANIEL MARTIN (1970), is a good short treatment; DAVID E. RUTHERFORD, *Vector Methods, Applied to Differential Geometry, Mechanics, and Potential Theory*, 9th ed. (1957), is somewhat formal. Several general mathematical texts have suitable sections on vectors. A good example is HENRY MARGENAU and GEORGE M. MURPHY, *The Mathematics of Physics and Chemistry*, 2nd ed. (1956; vol. 2, 1964).

Basic aspects of electricity and magnetism: ARTHUR F. KIP, *Fundamentals of Electricity and Magnetism*, 2nd ed. (1969), is a straightforward text at about the same level as this article. MAX ABRAHAM, *Theorie der Elektrizität*, 8th ed. (1930; Eng. trans. rev. by RICHARD BECKER, *The Classical Theory of Electricity and Magnetism*, 1932 and subsequent reprints), is a rather formal text but not difficult. The treatment of vector methods is notably thorough and the mathematical approach is somewhat more rigorous than usual. ROBERT V. LANGMUIR, *Electromagnetic Fields and Waves* (1961), is a slightly more advanced text, concise but clear. JOHN D. JACKSON, *Classical Electrodynamics* (1962), is a thorough advanced text. It is particularly good on topics with applications in atomic and nuclear physics. An alternate text of similar scope is WOLFGANG K.H. PANOFSKY and MELBA PHILLIPS, *Classical Electricity and Magnetism*, 2nd ed. (1962). ROBERT S. ELLIOTT, *Electromagnetics* (1966), another advanced text, begins each chapter with a colourful, historical survey. SIMON RAMO, JOHN R. WHINNERY, and THEODORE VAN DUZER, *Fields and Waves in Communication Electronics* (1965), is particularly suitable for those whose interests incline more to radio. L.D. LANDAU and E.M. LIFSHITZ, *Electrodynamics of Continuous Media* (1960; orig. pub. in Russian, 1957), is an advanced text and unique in its coverage. It deals authoritatively with innumerable topics associated with conducting and dielectric media. A.S. KOMPANEETS, *Theoretical Physics*, 2nd ed. corr. (1962; Eng. trans. from 2nd Russian ed., 1957; reissued with new introduction as *Physics in the Soviet Union*, 1963), contains a section on electrodynamics that makes a good introduction to more advanced topics. The following books are more specialized: HERBERT FROHLICH, *Theory of Dielectrics*, 2nd ed. (1958), a useful introduction and not too advanced; JOHN H. VAN VLECK, *The Theory of Electric and Magnetic Susceptibilities* (1932, reprinted 1965), still the most important advanced text; HELEN D. MEGAW, *Ferroelectricity in Crystals* (1957), a compact introduction; FRANCO JONA and G. SHIRANE, *Ferroelectric Crystals* (1962), relatively more advanced; N. BLOEMBERGEN, *Nonlinear Optics* (1965), a difficult text on a subject of current interest; and J.D. CRAGGS and J.M. MEEK, *High Voltage Laboratory Technique* (1954), a useful, straightforward introduction to the subject. The remaining books are not recommended as texts so much as sources of information. They all contain solved problems in electromagnetic theory of considerable use in practical and theoretical work. JAMES CLERK MAXWELL, *A Treatise on Electricity and Magnetism*, 2 vol. (1873); JAMES H. JEANS, *The Mathematical Theory of Electricity and Magnetism*, 5th ed. (1925, reprinted 1960); WILLIAM R. SMYTHE, *Static and Dynamic Electricity*, 3rd ed. (1968); JULIUS A. STRATTON, *Electromagnetic Theory* (1941).

Direct electrical currents: Few books devote more than a brief section to direct current circuits. General network theorems are usually given in the context of ac circuits although they also apply to dc circuits. A clear and useful introduction to circuit analysis is ERIC A. FAULKNER, *Principles of Linear Circuits* (1966). For a more detailed treatment one has to refer to older texts such as ANDREW GRAY, *Absolute Measurements in Electricity and Magnetism*, 2nd ed. (1921, reprinted 1967); and DONALD G. FINK and JOHN M. CARROLL (eds.), *The Standard Handbook for Electrical Engineers*, 10th ed. (1968), a useful source of information.

The conduction of electricity: There is a general discussion of conduction in BETTY I. BLEANEY and BREBIS BLEANEY, *Electricity and Magnetism*, 2nd ed. (1965). More detailed discussions of conduction in solids will be found in the many texts on solid state physics. The three listed here are in increasing order of difficulty: ROBERT L. SPROULL, *Modern Physics*, 2nd ed. (1963); CHARLES KITTEL, *Introduction to Solid State Physics*, 4th ed. (1971); and JOHN M. ZIMAN, *Principles of the Theory of Solids* (1964). The following books deal with more specialized topics: FRANS M. PENNING, *Electrische Gasontladingen* (1955; Eng. trans., *Electrical Discharges in Gases*, 1957), an excellent simple introduction to this subject; ALFRED VON ENGEL, *Ionized Gases*, 2nd ed. (1965); WILLIAM SHOCKLEY, *Electrons and Holes in Semiconductors, with Applications to Transistor Electronics* (1950), the classic work on the subject; ROBERT A. SMITH, *Semiconductors* (1963); ALISTAIR C. ROSE-INNES and E.H. RHODERICK, *Introduction to Superconductivity* (1969), a readable introduction; A.B. PIPPARD, *The Dynamics of Conduction Electrons* (1965), an advanced and specialized text; D.K.C. MACDONALD, *Thermoelectricity* (1962); S.M. SZE, *Physics of Semiconductor Devices* (1969), deals with a number of topics—*e.g.*, conduction processes in semiconductors and photoeffects; JOHN R. PIERCE, *Theory and Design of Electron Beams* (1949), a clear account of the principles that govern the operation of electron tubes employing electron beams —deals with the effects of both space charge and thermal velocities and the basic principles of electron optics.

Alternating electric currents: RAMO, WHINNERY, and VAN DUZER (*op. cit.*), has a good introduction to the use of complex numbers in ac theory and also deals with waves on transmission lines. BLEANEY and BLEANEY (*op. cit.*), has sections on ac theory, measurements, and filters. FAULKNER (*op. cit.*), is a useful introduction to more advanced mathematical methods and the theory of transients. BERNARD HAGUE, *Alternating Current Bridge Methods*, 6th ed. rev. by THOMAS R. FOORD (1971), is comprehensive. F.N.H. ROBINSON, *Noise in Electrical Circuits* (1962), gives an introduction to concepts and principles; ALDERT VAN DER ZIEL, *Noise* (1954), gives a fuller treatment.

DAVID P. HOWSON and R.B. SMITH, *Parametric Amplifiers* (1970), gives a treatment of one particular type of nonlinear circuit and its applications.

The primary effects and properties of electric fields and currents: LANDAU and LIFSHITZ (*op. cit.*), provides the best coverage of field energy and stress; in particular, their treatment of the relation between thermodynamics and electromagnetism is superior to anything to be found elsewhere. Books on relativity abound. A good example, which does not ignore the relation between relativity and electromagnetism, even though it is at an elementary level, is CLAUDE KACSER, *Introduction to the Special Theory of Relativity* (1967). ROLF HAGEDORN, *Relativistic Kinematics* (1963), is an advanced text mainly concerned with applications in particle physics. It does, however, contain an exceptionally clear exposition of the basic theory. JOHN F. NYE, *Physical Properties of Crystals* (1957), treats piezoelectricity, pyroelectricity, and the electro-optic effect. This is not a difficult book but it does introduce and use tensor notation. WARREN P. MASON, *Piezoelectric Crystals and Their Application to Ultrasonics* (1950), is a useful work on piezoelectricity. AMNON YARIV, *Quantum Electronics* (1967), deals with the electro-optic effect, also light emission from semiconductors. SZE (*op. cit.*), may also be consulted for light emission from semiconductors. HENRY F. IVEY, "Electroluminescence and Related Effects," *Adv. Electronics Electron Phys.*, Suppl. 1 (1963), deals at length, but without using advanced theoretical concepts, with this topic. Black body radiation is dealt with in most texts on modern physics. MAX BORN, *Moderne Physik* (1933; Eng. trans., *Atomic Physics*, 8th ed., 1969); and SPROULL (*op. cit.*), are good texts.

The effects of electricity on organic matter: FRANCIS O. RICE and EDWARD TELLER, *The Structure of Matter* (1949), is a useful introduction to general ideas about atomic physics. HUGO R. KRUYT and J.T.G. OVERBEEK, *Inleiding tot de physische chemie*, 15th ed. (1958; Eng. trans., *An Introduction to Physical Chemistry for Biologists and Medical Students*, 1960), is also a useful introduction to electrochemistry for physicists. DUNCAN A. MACINNES, *The Principles of Electrochemistry* (1939, reprinted 1961), is an adequate introduction despite the date of its original publication. R.V. COXON and ROBERT H. KAY, *A Primer of General Physiology* (1967), gives the biological background for bioelectric effects. ALAN L. HODGKIN, *The Conduction of the Nervous Impulse* (1964); and BERNARD KATZ, *Nerve, Muscle, and Synapse* (1966), deal more specifically with nerves.

(F.N.H.R.)

Electric Motor

An electric motor is a device for converting electrical energy to mechanical energy. It is the complement of the electric generator, a device that converts mechanical energy into electrical energy, the two devices together providing the link between electrical and mechanical systems. In general, generators may act as motors and, conversely, motors may act as generators; they differ only in some construction details and in their auxiliary equipment.

HISTORY

The history of the electric motor begins with Hans Christian Ørsted (1777–1851), who discovered that electricity in motion produces a magnetic field. In searching for a demonstration of the converse of Ørsted's discovery, Michael Faraday in 1821 built an apparatus that demonstrated the principle of the electric motor. In 1823 Peter Barlow and William Sturgeon in England wrapped a current-carrying conductor around an iron bar to produce a strong electromagnetic force, and Joseph Henry in the U.S. learned that insulated wire wrapped several layers thick around a piece of iron made a more powerful electromagnet. In 1833 a young American blacksmith named Thomas Davenport first saw an electromagnet. He began experimenting with electromagnets and batteries, and, after considerable effort, invented an electric motor. In 1835 Davenport showed his invention to Henry, who gave him a certificate attesting to the importance and originality of the device. Though Davenport obtained a patent, his motor was never a very great commercial success.

The first electric motor of commercial significance was demonstrated in Vienna in 1873 by Zénobe Théophile Gramme, a Belgian-born electrical engineer. Developer of the ring armature, which enormously improved the efficiency of early electric generators, he had discovered that if a large dynamo were electrically connected with a smaller one, the smaller dynamo would revolve and act as an electric motor. Hence, Gramme's motor was a combination of two direct-current dynamos, acting as generator and motor, respectively. In 1888 Nikola Tesla invented the first alternating-current electric motor, the prototype for most of the electric motors in use today.

BASIC PRINCIPLES

Electrical and mechanical coupling methods

The coupling method between electrical and mechanical systems can be (1) electromagnetic, in which forces are established as a result of an interaction between magnetic fields created by stationary and moving parts; (2) electrostatic, in which forces are produced by the interaction of electric fields created by the stationary and moving parts (see ELECTRICITY); (3) magnetostrictive, represented by the microscopic change in size experienced by ferromagnetic materials when subjected to an external magnetic field (see MAGNETISM); (4) piezoelectric, represented by the deformation of certain crystals when subjected to an electric field (see PIEZOELECTRIC DEVICES); and (5) magnetohydrodynamic, or the production of a force due to the interaction between magnetic fields and electrically conductive fluids and gases (see MAGNETOHYDRODYNAMIC DEVICES). By far the most commonly exploited phenomenon is the electromagnetic, because it makes possible the conversion of the most energy per unit weight, volume, and cost. Electric motors, which utilize this phenomenon, may range in output from a fraction of a watt (0.0001 horsepower) for use in instrument control systems and servomechanisms, to several thousand horsepower, for pumps and wind-tunnel drives.

Two general principles involved in motor and generator operation are those of Ampère and Faraday. Ampère's law says that a conductor will experience a force if a component of current in that conductor flows at right angles to a magnetic field. Faraday's law states that a potential difference will exist between the ends of a conductor if that conductor is given a component of motion perpendicular to the magnetic field.

The rotor and stator

To exploit these principles and convert electrical energy into mechanical energy, motors must consist of two parts—a rotor and a stator. The rotor is usually round and is the moving portion. It contains conductors to establish and shape magnetic fields that will interact with other magnetic fields produced by the stator. The rotor also may have a contacting device (slip rings or commutator) to connect it electrically with the external circuit, together with a supporting shaft and bearings, an integral blower for cooling, etc. The stator consists of similar magnetic materials and electrical conductors to establish and shape the magnetic fields, as well as the frame to support the whole machine. The manner in which the conductors are arranged (and in which the magnetic fields are controlled) determines the type of motor and its characteristics.

INDUCTION MOTORS

In an induction motor, one winding—a conductive path, usually wire—induces a current into another winding. Usually the stator winding is connected to an external power source; the other, on the rotor, consists of continuous wire loops. The magnetic field established when currents flow in these conductors is concentrated in a narrow air gap between the stator and the rotor. The purpose of the windings connected to the external energy source is to produce a rotating field that interacts with the induced currents in the rotor conductors, thereby establishing forces on those conductors.

To set up a rotating field, there must be at least two windings carrying currents whose phase—the time when the amplitudes are a maximum—is not the same. Figure 1A illustrates two alternating currents whose amplitudes —the magnitudes of the wave, or peak value measured from zero—are the same but whose phase relationship is

90°. Figure 1B shows schematically a stator on which four coils have been wound; coils 1 and 3 are so connected that if the current i_1 is in the direction shown, the polarities of the magnetic field at the stator surface will be north at the upper and south at the lower coils. When the current i_1 reverses, so do the polarities of the fields. Coils 2 and 4 are also connected so that a current i_2 produces a similar field. As shown in Figure 1A, at a given instant of time t_1, i_1 is a maximum and i_2 is zero. Under these conditions the field situation is as shown in Figure 1C. A quarter-period later, at t_2, the current i_1 is zero, and i_2 has risen to a positive maximum. The resulting field conditions are now as shown in Figure 1D. At a third instant, t_3, i_1 has advanced to a maximum, but in the negative sense, while i_2 has fallen back to zero from a positive maximum. The field situation is now that of Figure 1E. Finally, at t_4, i_1 has again become zero and i_2 has reached a negative maximum, and Figure 1F shows the resulting fields. The north pole is found to travel around the periphery of the stator, making one complete revolution while the current goes through one cycle. Hence a revolving field is produced, and its speed depends solely upon the geometry of the coils and the time required for one cycle. For a 60-hertz power supply, 60 revolutions will be made in one second, or 3,600 revolutions in one minute. The speed of the revolving field is known as the synchronous speed.

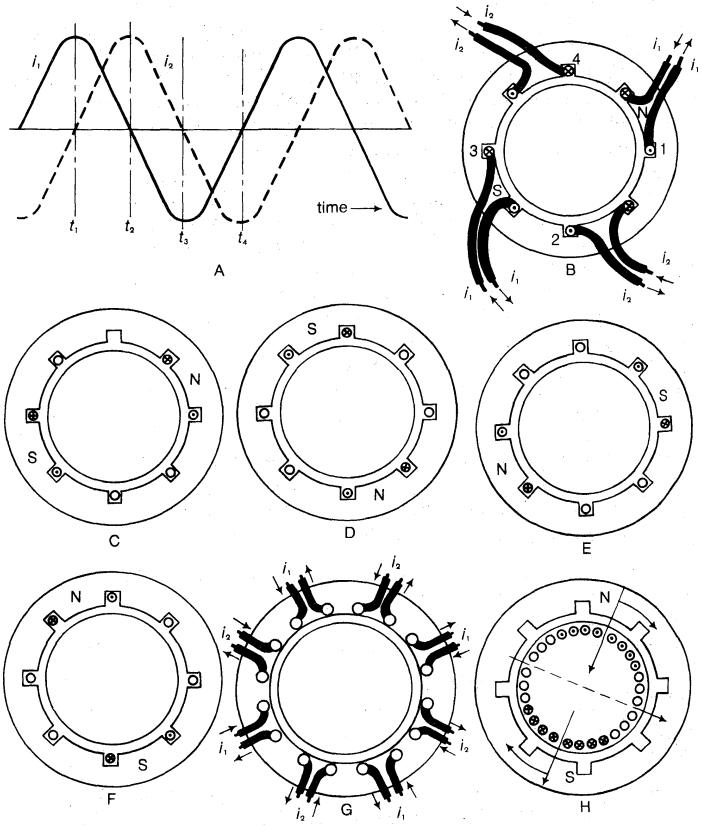

Figure 1: Induction motor fields and their interaction with rotor and stator conductors. ⊙ indicates that the flow of current is directed toward viewer, perpendicular to page; ⊗ current is directed away from viewer (see text).

If each coil is reduced in size so that it spans just one-half the stator surface (Figure 1G), the revolving field will travel only half as far for each cycle of the supply current, and the speed of the revolving field will become 1,800 revolutions per minute for a 60-hertz supply. The coil arrangement of Figure 1B is said to produce a two-pole motor, since at any instant there is but one north and but one south pole. The arrangement of Figure 1G, on the other hand, will produce two north poles and two south poles at any instant and therefore is a four-pole stator. It is not uncommon to have as few as two or as many as 100 poles in a motor. The speed of the revolving magnetic field in revolutions per minute in any motor is $120\,f/p$, in which f is the frequency in hertz and p is the number of poles.

The four-pole stator

In a practical motor the stator will have more coils than indicated here, and these will be distributed around its periphery in equally spaced slots. This arrangement makes better use of the available space than does the concentrated-coil arrangement described above, but the result is still the same—a revolving field is established.

If a set of conductors is uniformly spaced around the periphery of a rotor, as shown in Figure 1H, and if the rotor is stationary and a two-pole revolving field is located in the position shown, a voltage will be induced (according to Faraday's law) in a direction out of the page in the upper conductors and into the page in the lower conductors. If these conductors are now short-circuited through a slip ring—a device for making electrical connections between stationary and rotating contacts—currents will flow in the same directions as the induced voltages. These currents in turn will produce their own magnetic field, and its direction will be shown by the dashed line in Figure 1H. The north pole of the rotor and south pole of the stator will attract each other, and a torque will be exerted on the rotor tending to turn it in the direction of the rotating field.

If the rotor is travelling at the same speed as the revolving field, there will be no induced voltage in the conductors, no current flow, and no torque. Hence, at synchronous speed the torque drops to zero. If the rotor travels faster than synchronous speed, the direction of the induced voltage and the current will be reversed, thus reversing the torque; the motor is now serving as an induction generator.

Construction features. The rotor and stator are built up of laminations of 0.25 percent to 3.50 percent silicon steel, from 0.014 to 0.025 inch (0.36 to 0.63 millimetre) thick. The laminations are sometimes coated with an insulating varnish to reduce the magnitude of currents induced in the laminations (eddy-current losses). Uniformly distributed slots are punched in the steel to receive windings.

The coils (usually the stator coils) which are connected to the external energy source may be preformed and insulated and then inserted into the slots, or the conductors may be placed directly into the slots and the insulation applied afterward. The former technique is presently used for motors rated at more than 600 volts or about 100 horsepower.

Types of secondary windings

The conductors that form the secondary winding may be of three types: wound, squirrel-cage, or solid. To make the wound type, a two-phase winding (having a phase difference of 90 electrical degrees, or one-quarter cycle) or three-phase winding (differing in phase by one-third of a cycle, or 120 electrical degrees) is placed in the rotor slots; and some of the terminals are brought out to slip rings, the insulated brass or bronze rings on which carbon brushes ride, to provide an electrical connection to the rotor coils.

The squirrel-cage winding may be either cast from aluminum or copper or built up from copper or brass bars welded to a common end ring. To cast such a winding, a stack of rotor laminations is inserted in a centrifugal casting machine and molten aluminum or copper is introduced. The result, after the metal solidifies, is an integrally cast set of longitudinal conductors and two end rings. The cast winding generally is used for standard production line motors in sizes under 100 horsepower. For larger motors the welded bar type is more common.

An example of the solid or continuous winding is the drag-cup motor, in which a nonmagnetic metal is rotated in a magnetic field to generate a torque or voltage proportioned to its speed. A solid copper sheath shrunk on the rotor steel will also provide a continuous conductor. Continuous-winding rotors are used principally for servomotors.

Polyphase induction motors. The three-phase stator connection is by far the most common, because most in-

dustrial power distribution systems are three-phase. In this type of motor the revolving field is produced by three different currents whose phase relationships are 120° instead of the 90° shown in Figure 1A.

Both squirrel-cage and wound-rotor motors may be used in polyphase service; however, the latter are usually reserved for speed-control applications because of the added cost of manufacture. Squirrel-cage motors may also be classed in terms of their starting current and their speed-torque curves.

Single-phase induction motors. In describing how a revolving field was produced it was pointed out that a necessary condition was the existence of at least two currents out of phase in time and flowing in coils displaced in physical position from one another. While it is possible to satisfy the spatial requirement when a single-phase supply is used, it is more difficult to satisfy the time relationship for the currents flowing in the two sets of coils. The most common ways of solving this problem are described below.

Capacitor-start, capacitor-run motor. For this type of motor the stator is built as for a two-phase motor—*i.e.*, with windings spaced 90° apart in a two-pole case (Figure 2A). The main winding is connected directly across the

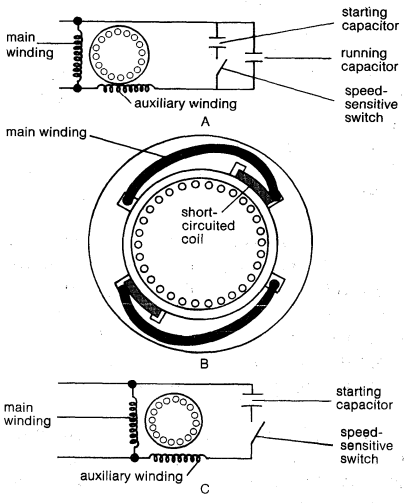

Figure 2: *Single-phase motor circuits.* (A) Capacitor-start, capacitor-run; (B) shaded pole; (C) capacitor-start (see text).

power line, and an auxiliary winding is connected to the line through a suitable capacitor, a device that stores an electric charge, to provide a means of starting. The electric field in the capacitor tends to overcome the effect on the circuit of the magnetic field in the motor so that the current flowing in the auxiliary winding (containing the capacitor) is out of phase with that in the main winding and the necessary theoretical conditions are satisfied. One difficulty with this arrangement is that the 90° phase relationship is obtained only during operation at the rated speed. In order to obtain satisfactory characteristics during the starting period, another capacitor is placed in the circuit to retain the 90° phase relationship; the second capacitor is then taken out of the circuit at about 80 percent of rated speed through the use of a centrifugal switch.

Shaded-pole motor. If a permanently short-circuited coil is placed over a portion of the main field coil, thus "shading" it as shown in Figure 2B, the result will be a field similar to that produced by two out-of-phase currents. Because the winding cannot be displaced 90° and the currents cannot be 90° out of phase in time, such a motor has a low speed–torque curve and is used for the most part to run fans, phonographs, and household appliances.

Other types. Another group of motors employs a revolving field only during the starting period and then runs on a pulsating field, which may be regarded as two counter-rotating fields of equal magnitude. If the rotor response was the same to both fields, the net torque would be zero and the motor would not run at all. The rotor impedance can be made higher to the field rotating in the reverse sense than to the field rotating forward, however; thus, less reverse current flows in the rotor bars and a net forward torque results. At a standstill, on the other hand, the forward and backward torques are equal, and the motor will not start unless some special provision is made. For example, an auxiliary field may be put into the circuit for starting and then switched out when the motor attains about 80 percent of its rated speed; or internal connections may be provided that in effect make the motor a different type for starting (*e.g.*, the repulsion-start motor, a single-phase motor in which the stator winding is subsequently connected to the source of power and the rotor winding to the commutator), after which the connections are changed automatically so that the motor will run on the pulsating field.

Of the auxiliary field types, the capacitor-start motor is very common; its circuit is shown in Figure 2C. In the resistance split-phase motor the capacitor is omitted, and consequently there is lower starting torque, since the currents cannot be shifted 90° out of phase. Repulsion-motor principles are also used. During the starting period the motor operates as a repulsion motor until a centrifugal switch short-circuits the repulsion winding. Thereafter the machine operates primarily as an induction motor.

Applications of capacitor-start motors

Capacitor-start motors are used for refrigerators, compressors, and other equipment in which there is a high starting torque requirement. Resistance split-phase motors are used for light tools and other equipment starting unloaded. Repulsion-start motors have been largely replaced by capacitor-start, capacitor-run motors.

Servomotors. The motors used in control systems may be operated from two-phase or single-phase supplies. Figure 3 shows the usual method of energizing a servomotor through an amplifier (a device that draws power from a source other than the input signal and that produces as an output an enlarged reproduction of its input). The reference-phase voltage is constant, but the control phase has a variable voltage impressed upon it from the amplifier, which in turn receives its signal from the rest of the control system. If the rotor resistance is relatively high, the motor will exhibit variable speed characteristics.

These motors sometimes have drag-cup rotors, but they are more commonly of the squirrel-cage type. They are limited to small outputs because much of the power input must be dissipated as heat in the rotor.

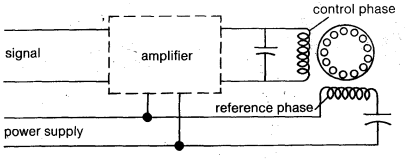

Figure 3: Elements of a typical servomotor circuit.

Linear motors. High-speed ground transportation needs have stimulated the development of the linear induction motor. Linear induction motors may take several forms. Most often encountered is the double stator with a continuous rotor as shown in Figure 4. When used on a rail vehicle the continuous sheet "rotor" is suitably fastened to the roadbed, and the "stator" is suspended between the wheels in the centre of the vehicle. The polyphase power supply is generated either by a source of power on the vehicle or picked up by trolley from a suitable line paralleling the track. Besides applications in ground transport, linear motors have been used for belt conveyers, shuttles in textile looms, curtain rods, aircraft launchers, and electromagnetic pumps in which the solid "rotor" is replaced by a conducting fluid (such as the sodium–potassium alloy, NaK, or mercury).

From a theoretical point of view, a linear motor may

be regarded as a cut-and-unrolled cylindrical motor, with suitable adjustments in the theory to account for the transients occurring at the two ends of such an unrolled cylindrical motor. In practical linear machines, these end effects account for about 10 percent reduction in the force produced.

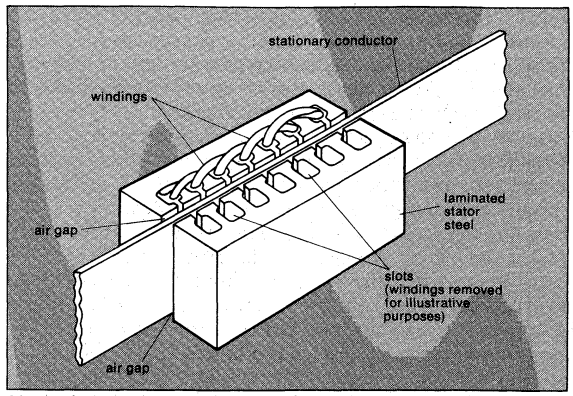

Figure 4: Semi-cutaway view of a linear motor of the type used experimentally for propelling rail passenger vehicles.

The tubular motor

Another type of linear motor is the tubular motor, which resembles the linear accelerator (see ACCELERATOR, PARTICLE). These motors use concentric coils and, when excited by a polyphase current supply, a travelling wave is developed. This wave interacts with any conductor, producing a force that tends to make the conductor travel at the same velocity as the travelling magnetic wave. Such machines are useful as electromagnetic cannons or missile launchers.

Speed control. Induction motors basically are constant-speed devices and are used most frequently as such. If, however, speed control is desired, several methods are available: frequency control, pole changing, addition of rotor or secondary resistance, stator voltage control, and counter-rotor voltage control.

In the discussion on the revolving field it was pointed out that the speed of the field is a function solely of the power-supply frequency and the design of the winding. Thus, if the frequency is varied, the synchronous speed of the field will change and, depending to some extent on the load, the shaft speed will also change. This method requires some external device to alter the ordinarily unvarying frequency of the power supply. With the advent of a high-current silicon controlled rectifier (SCR), primary frequency control has become extensively employed for speed control purposes.

The pole-changing method involves connecting the individual stator coils (as in Figure 1G) externally. Thus, adjacent coils may be of either the same or opposite polarity, depending on how they are connected. If adjacent coils are of the same polarity, the result will be half as many magnetic poles as when the coils are of opposite polarity, and the synchronous speed will be doubled. However, this method makes it possible to change the motor speed only in discrete steps (usually 2:1); it does not provide for continuous variation.

Control of motor speed by varying the power-supply voltage is not effective in alternating-current induction motors (except in servomotors), though some speed variation is possible within narrow limits.

Secondary or rotor resistance control can be applied only to a wound-rotor motor. One difficulty is that the losses in the external resistor may become so substantial that it is desirable to offset them by employing counter-voltage methods. These involve the use of auxiliary machines and are justifiable only when the rotor loss is sufficiently important economically to warrant the investment in additional equipment.

Starting and protection. Induction motors are extremely rugged and in the smaller sizes (under 25 horsepower) usually will withstand sudden application of full voltage at standstill without damage. For larger motors, however, the electrical supply system must be protected against sudden surges arising from the large starting currents produced. All induction motors (except servomotors and those used in speed-control service) during the starting period draw from four to six times the normal running current. When the electrical system will not withstand such currents there are four techniques that may be used: reduced-voltage, resistor or reactor, Y-delta, or part-winding starting.

Starting techniques

For reduced-voltage starting an autotransformer—a single-coil transformer in which primary and secondary are part of the same coil—is used to lower the applied voltage to 65–80 percent of normal. Because the current is proportional to the square of the voltage, an 80 percent reduction in voltage will mean that only 64 percent of the full-voltage current will be drawn. Autotransformers, however, are designed to be used only for only very short periods of time.

The second method involves simply the provision of resistors and reactors that can be switched into the supply lines to limit the current during starting.

For motors operating on three-phase power, the windings may be connected either with both ends across the line (delta) or with one end on the line and the other connected to the remaining two windings (Y). If a motor designed with delta-connected windings is reconnected Y, the voltage across the windings is reduced to 57 percent of normal and the current will be only one-third that drawn at full voltage.

Part-winding starting is possible if connections are provided so that only part of the motor winding is in the circuit during starting, the remainder being switched in as the motor picks up speed.

Protecting induction motors is primarily a problem of preventing damage to the windings from excessive heat. On motors under five horsepower, internal temperature-sensitive switches are sometimes provided to open the main line if the temperature rises above a certain value. Temperature detectors embedded in the windings are used on large motors.

SYNCHRONOUS MOTORS

Synchronous motors, like induction motors, operate on the principle of the revolving magnetic field, produced usually by the stator; the rotor of the synchronous motor is designed so that it can produce a constant field. If, for example, a two-pole rotor of this type is excited with direct current through slip rings, a north and a south magnetic pole will be produced on the rotor. If the rotor is travelling at the speed of a revolving stator field such as that shown in Figure 1 (C, D, E, F), the two fields will lock together and the rotor will be pulled around at the same speed as the revolving field.

Construction. In most synchronous motors the winding that produces the revolving magnetic field (known as the armature winding) is on the stator, and the design of such a stator is essentially the same as for an induction motor. (For a synchronous motor that has its armature winding on the rotor, the design is much the same as for a wound-rotor induction motor.) A unidirectional field, to interact with the revolving field produced by the stator armature winding, is consequently produced on the rotor by exciting a direct-current winding from a direct-current source.

Motors using direct-current fields must have some means of starting. In most motors this is accomplished by installing a squirrel-cage winding in the pole faces of the rotor. Such a motor operates on induction motor principles up to about 95–97 percent of synchronous speed, at which point the direct-current field is applied. The motor then locks into synchronism—that is, an exact relationship is established and maintained between motor speed and power supply frequency. Motors with this type of field winding usually are more costly to build than general-purpose induction motors in sizes up to 300–500 horsepower.

In small motors it is possible to eliminate the need for a direct-current power source by building the field struc-

ture from the same metals used for permanent magnets. The field structure then is given a permanent residual magnetic field that locks in with the revolving field at synchronous speed. So-called hysteresis motors have a lower power-to-weight ratio than the direct-current excited types described above, but they are useful in some low-load applications in which constant speed is important—as gyro-spin motors in navigational equipment, in phonographs and tape recorders, and in clocks.

Hysteresis and reluctance motors

Another type of field construction is found in the reluctance motor, in which no rotor winding is used at all, the toothed design of the rotor producing the synchronous motor characteristics. If the rotor lags behind the revolving field, the average magnetic energy stored in the air gap around the rotor decreases. This produces a greater positive ratio between the stored magnetic energy and the displacement angle, and a greater torque is established, pulling the motor back into synchronism. The power-to-weight ratio here is even more unfavourable than in the hysteresis motor, but the reluctance motor is economical to construct and is therefore often used to power certain instruments and electric clocks.

Polyphase synchronous motors. Like most induction motors, synchronous motors are designed to operate on three-phase power in sizes above one horsepower. Furthermore, in such sizes they are always direct-current excited. The source of direct current may be rectifiers, direct-current generators (exciters) driven from the motor shaft, or separate motor-generator sets.

One important feature of synchronous motors is that control of the field current affords a means of power factor control. When the direct-current field of a synchronous motor is overexcited, the motor must draw a demagnetizing component of current from the power lines to compensate for the overmagnetization that takes place. The demagnetizing current drawn by the synchronous motor will balance some of the magnetizing current drawn by other induction machines on the same power line. This component of alternating current transmits no energy but does cause additional loss in all associated equipment, such as transmission lines and transformers. In most cases, power company rates are adjusted to reflect the cost of supplying magnetizing current, and it is often economically feasible to correct for this condition in a manufacturing plant rather than to pay the power company to do so. Thus, a synchronous motor may serve the dual purpose of driving a load at constant speed and at the same time reducing the net magnetizing current drawn from the power lines. In fact, in some cases it is economically justifiable to operate a motor solely for the purpose of power factor correction. A motor designed for this service has no output shaft and is referred to as a synchronous capacitor.

Single-phase synchronous motors. As was the case for induction motors, a revolving field is needed, and to produce it a capacitor may be inserted in the second phase of a two-phase motor, or a shaded-pole structure may be used. Thus a revolving field is established, although it is inferior to that provided by a polyphase supply.

There is relatively little demand for direct-current, field-excited motors in sizes under one horsepower, so virtually all small motors are hysteresis or reluctance types. Such motors rarely develop more than 20 percent to 50 percent of the power that could be expected from a magnetic circuit of the same size in an induction motor.

Electric clock motors

Of special interest is the single-phase synchronous motor used in electric clocks. A two-pole rotating field is set up by means of shaded-pole construction, in which one or more auxiliary short-circuited stator windings are provided and displaced magnetically from the main winding. The resulting rotating field reacts with one or more thin disks of hardened steel especially chosen for their desirable magnetic properties and housed in a sealed metal container. The rotating field starts the motor by eddy-current action in the container and brings the motor up to speed, usually 3,600 revolutions per minute (rpm). As the motor approaches synchronous speed, the rotating field magnetizes the disks and they then are locked in with the revolving field. A sealed gear train reduces the speed to one revolution per minute at the motor shaft. While these motors have efficiencies of less than 1 percent, they are very inexpensive to build and operate.

Speed control. Synchronous motors are less amenable to speed control than are induction machines. Only two methods are suitable: frequency control and pole changing. The principles are the same as for induction motors.

Starting and protection. Small synchronous motors of the hysteresis and reluctance type are started on full voltage and are protected (if at all) by a thermal cutout in the same fashion as induction machines.

Larger machines using direct-current fields have more troublesome starting problems than any other class of electric motors. Not only must the current inrush to the motor from the power source be controlled, as was the case for the induction motor, but the field must be protected from high voltages arising from transformer action. Then, when the rotor has been accelerated up to synchronous speed, direct current must be applied to the field at the proper instant. On the other hand, synchronous motors may be designed to have almost any type of starting torque characteristic without sacrificing good running features. Starting torques of from 400 percent to 600 percent of full load may be obtained, with corresponding starting currents 250–600 percent of normal. The method of limiting current inrush to the armature winding is the same as for induction motors.

During the starting period, the field winding is generally short-circuited. When the machine has accelerated to 95–97 percent of synchronous speed, direct current is introduced to the field and the motor locks into synchronism. Application of the direct-current field current at the proper moment can be done automatically by taking advantage of two motor characteristics: as the motor nears synchronous speed, the frequency of the current induced in the rotor circuit approaches zero; and as the rotor "slips" with respect to the revolving field, there are corresponding pulsations in the line current. These conditions can be detected either by a frequency-sensitive relay in the field circuit or by a special relay in the line, and the relays can then initiate the switching on of the direct-current field current.

The protection of synchronous motors, while more complicated than in the case of induction motors, centres on the same basic problem: prevention of damage to the windings from heat caused by excessive currents. Specifically, the problems encountered and their solutions are (1) excessive stator current, usually detected by external sensors or embedded temperature detectors; (2) excessive field current, detected by external sensors; (3) excessive field voltage, which can be controlled by short-circuiting the field winding through a resistance during starting or by the use of discharge gaps between the slip rings; (4) squirrel-cage over-heating, controlled by external timers; and (5) phase failure (causing abnormally high current in the squirrel-cage winding), detected by external sensors.

COMMUTATOR (DIRECT-CURRENT) MOTORS

Commutator motors excited with direct current (called direct-current motors) were the forerunners of induction and synchronous machines, because many cities had well-established direct-current distribution systems for both lighting and power while alternating-current systems were still speculative. Hence the direct-current member of the commutator motor family was well established when Nikola Tesla invented the induction motor. Modern commutator motors find their main use in speed-control applications.

Basic principles. Unlike induction and synchronous machines, commutator motors (with a few exceptions) make use of stationary rather than revolving fields—in fact, the sole purpose of the commutator is to control the position of the rotor field irrespective of the speed of rotation or the frequency of the current in the windings. For the purpose of explaining how such motors work, it is most effective to develop the principles for direct-cur-

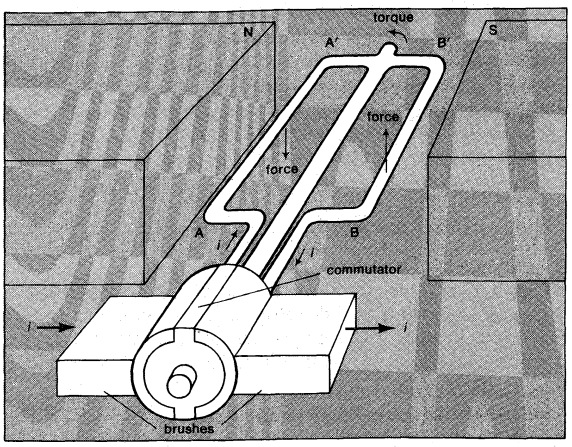

Figure 5: Operating principles of a direct-current motor (see text).

rent motors and then extend those concepts to alternating-current motors.

In Figure 5 a coil is mounted on a shaft so that it is free to rotate in the magnetic field. If current i is caused to flow in the directions shown, a downward force will be evident on the left side of the coil and an upward force on the right side, and the coil will tend to rotate in a counterclockwise direction. To maintain this rotation, however, the current i must be reversed by the time the conductor AA′ comes under the south pole. This is accomplished by the commutator, which consists of an insulating member, carrying two copper segments, that rotates with the coil. Riding on the commutator but fixed to the motor frame are two brushes, usually made of graphite. These provide the connection to the external circuit. When the current i is forced into the left brush, it flows through the copper commutator bar and thence into the coil side AA′. It returns through B′B to the other commutator bar segment and out the right-hand brush. When coil side AA′ has moved around to BB′ the current in the coil will have been reversed.

In an actual motor, greater field strength in the vicinity of the conductor will be achieved if the magnetic circuit cross section is like that of Figure 6. Also, in an actual motor the number of coils is multiplied so that there may be from three (in very small, low-voltage motors such as those used in models) to 300 or more (in very large steel mill motors). The number of commutator segments also will increase, for there must be one for every coil.

When the current in a rotor (armature) coil is suddenly reversed by the commutator, the coil is momentarily short-circuited, and the voltage induced in it by the changed current may cause sparking at the brushes and consequent eroding of the commutator. In motors under one horsepower this is not a serious problem, but in larger motors it is customary to reduce sparking by inducing a voltage equal and opposite to that caused by the change in current. Shifting the brushes will do this, but a different angle of shift is needed for each load condition. The use of an interpole, or commutating pole, whose winding carries the same current as the armature, is a more satisfactory way of inducing an opposite voltage. The location and relative size of the interpoles is shown in Figure 6.

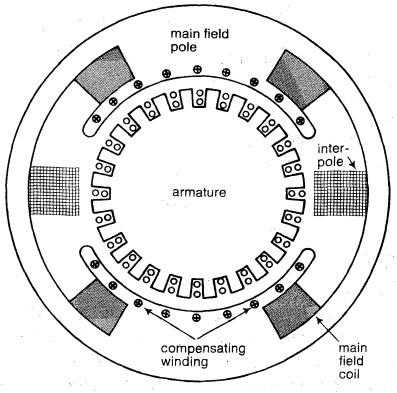

Figure 6: Simplified cross section of direct-current motor (see text).

In large motors that must operate under rapidly changing load conditions, an additional winding may be used to reduce the problems created by rapidly changing armature current. Such a winding is called a compensating winding and is placed in the pole faces as shown in cross section in Figure 6. This winding is in series with the armature conductors, but it is arranged so as to oppose the field established by the rotor conductors.

The compensating winding

The actual construction of a commutator motor is similar to that of induction and synchronous machines. Thin steel laminations are stacked together to form the armature and the field poles. Coils are usually preformed, although for some small motors the coils are wound on automatic winding machines that insert the wire turn by turn into the slots. The commutator is built up of segments of copper and then either cast in an insulating compound or fastened together with compression clamps.

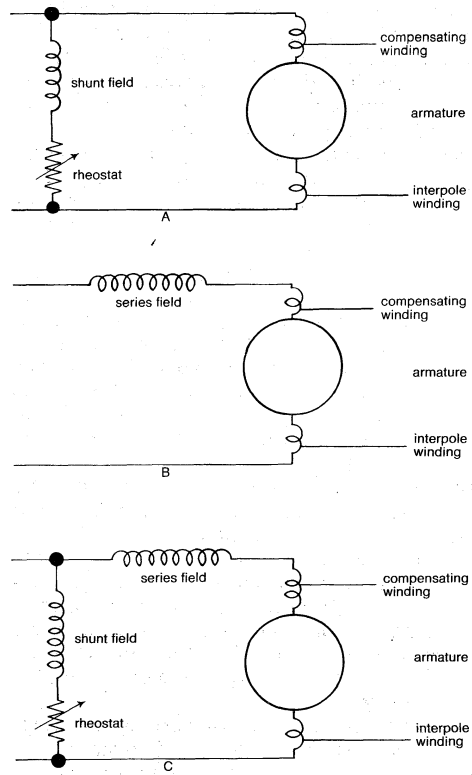

Figure 7: *Connections for direct-current motor.* (A) Shunt; (B) series; (C) compound (see text).

Direct-current motor characteristics. The operating characteristics of direct-current motors are determined solely by the manner in which the main field is excited.

In the shunt motor, the main field coil is placed across the direct-current line (Figure 7A). This type of excitation tends to give a constant magnetic field, and the speed–torque characteristic would fall off only because of the resistance drop in the armature circuit. However, the armature field arising from the currents in the rotor conductors (armature reaction) tends to demagnetize the main field to some extent. The result is that the shunt motor usually has a slightly concave upward speed–torque characteristic.

A series motor (Figure 7B) has its field winding in the same circuit with the armature. This produces a speed-torque curve with a high no-load speed. Because of their very high starting torque, these motors are useful for traction service.

Compound motors (Figure 7C) have both shunt and series windings, giving them composite characteristics. Usually the series field has small effect under a normal load condition. For example, a motor whose series field aids the shunt field tends to run as a shunt motor under normal load, but it also will develop higher starting torques than a shunt motor because of the contribution of the series winding at standstill.

ALTERNATING-CURRENT COMMUTATOR MOTORS

An alternating-current commutator motor presents two problems that do not arise in direct-current motors: the phase relationships between currents in different parts of the motor may not permit interaction and there are now voltages present due to transformer action.

In the series alternating-current motor, the phase problem is not present because the currents in both the armature and field are the same. Hence the armature current reverses at the same instant the field current reverses and a unidirectional torque is produced. These motors are very common in such household appliances as vacuum cleaners, mixers, and hand-held drills. These small motors for domestic use are sometimes called universal motors, since they may be used on direct-current or on any alternating-current frequency to 60 hertz. In larger sizes, series motors are used for alternating-current railway service, especially on 25- and 16⅔-hertz power.

Speed control. Mention has been made of the use of commutator motors for alternating-current speed control; however, the direct-current machine is more commonly used for variable-speed applications.

The simplest way to control the speed of a shunt motor is to vary the field current or the armature voltage. This can be accomplished with a variable field resistor (marked rheostat in Figure 7A) and a variable armature resistor. If both of these are set for zero resistance, the motor will operate at its base speed. Decreasing the field current (*i.e.*, increasing the field resistance) but keeping the armature voltage unchanged will cause the motor to increase in speed. Because of the centrifugal forces involved, the maximum speed that can be achieved in this way is about double the base speed. If the field resistor is set at zero and if the armature voltage is decreased by inserting more resistance in series with the armature, the speed will be decreased.

Direct-current motors may be controlled very effectively from alternating-current supplies using rectifiers and SCR's in various circuit arrangements.

Starting and protection. Except for very small sizes (⅛ horsepower), all direct-current motors must have reduced-voltage starters. Often this is a simple rheostat in the armature circuit; as the motor comes up to speed, the external resistance is gradually reduced to zero. In many cases this is done automatically by timers or current- or voltage-sensitive relays.

Overcurrent protection, a means of keeping the windings from being overheated, is common. Thermal relays, which remove the motor from the line when the motor is too warm, are often used. To protect the commutator from flashover—a disruptive discharge through air—there is sometimes provided current trip set to open the circuit at 200–300 percent of rated current.

Overspeed is a problem not often encountered in synchronous and induction motors, but it can be serious in many commutator motors. Centrifugal switches are commonly used to detect an overspeed condition and shut off or reduce the power.

Field failure on shunt motors produces very heavy armature currents and a tendency for the motor to accelerate dangerously. A field-protection relay therefore is provided to shut off power if the field current drops to zero.

Electric Power

Electric power, which is basic to modern life, is largely responsible for the high standard of living and advanced level of industrialization of much of the world. The consumption of electric power, which has expanded steadily in the 20th century, is expected to continue doubling roughly every ten years.

The modern electric-power industry was founded on a series of inventions and developments for converting the mechanical energy of falling water and the heat energy of fossil fuels (coal, petroleum, natural gas) into electrical energy.

Three distinct functions are involved in supplying electricity to the consumer: generation, transmission, and distribution. These functions correspond to the manufacture, transportation to market, and retail distribution of many other products, the chief differences being that electricity moves from the point of generation to the point of ultimate use in a continuous flow at a speed approaching that of light and that it cannot be stored in its original form.

Energy produced at central stations

Generation, the production of electrical energy from mechanical energy, takes place at central stations that may be either thermal power plants, in which the energy source is steam-driven turbines; or hydroelectric plants, in which the energy source is water-driven turbines. Transmission is the moving of this electrical energy from generating plants to bulk delivery points called substations, whence distribution delivers it to the consumer.

Generation and transmission facilities are usually economically interdependent in that the choice of location, design, and scale of generating capacity must take into account the associated cost of transmission and vice versa. Responsibilities for generation and transmission customarily go together. Distribution can be, and frequently is, conducted efficiently as a separate operation.

For many technical and economic reasons, the most appropriate arrangement for electric service to all customers in a given area is provided by a strongly integrated complex of generation and transmission facilities with sole responsibility for meeting all of the power requirements.

In distribution, the area economically covered by a single complex can be relatively small. Real distribution economies depend on the load density, while the most economical generation and transmission depend upon integration over a large interconnected area.

I. Historical background

BEFORE WORLD WAR II

The history of electric power goes back to 1878, when a plan to transmit electric energy to customers for the purpose of lighting was first proposed by an English inventor, St. George Lane-Fox, and by the U.S. inventor Thomas A. Edison. The first public power station was

placed in operation in London on January 12, 1882, and the second on September 4 of that year in New York City. The systems produced direct electric current (dc) of low voltage; service areas of these early central stations were limited by the short distance over which this low-voltage dc power could be economically distributed. Transmission losses made service to another city prohibitive, and not uncommonly a single city was served by a dozen or more separate systems. Consequently, although such systems played an important early role, more suitable methods were soon sought.

Development of alternating-current systems. In 1881 a Frenchman, Lucien Gaulard, and an Englishman, John D. Gibbs, had obtained English patents for a "series alternating current system of distribution," in which the current alternated from positive to negative and back a number of times every second. These patents were purchased in 1885 by an American inventor and manufacturer, George Westinghouse. William Stanley, a young U.S. inventor working with Westinghouse, perfected a transformer based on these patents and developed an alternating-current (ac) constant-potential generator. In 1886 Westinghouse and Stanley demonstrated the practicability of alternating current in Great Barrington, Massachusetts, by transmitting electric power 4,000 feet (1,200 metres), using one transformer (a device for changing ac voltage from one value to another) to increase the voltage at the source to 3,000 volts and another at the receiving end to reduce this to 500 volts. The primary advantages of the alternating-current distribution system were thus first demonstrated.

Practicability of alternating current demonstrated

No truly successful ac motor then existed. In 1888 Nikola Tesla, a Croatian-born inventor, proposed a new system known as the polyphase ac system. Its heart, or essence, was an induction motor, characterized by a rotating magnetic field. Westinghouse realized the fundamental importance of Tesla's ac system and acquired patents. The first public impact of this new system was at the World's Columbian Exposition in Chicago in 1893, where a two-phase generator, providing two voltages 90° out of phase with each other, supplied electric power for motors and lamps.

In Europe, the world's first three-phase 100-kilowatt generators (see below) were built at Lauffen power station in Germany, and the first three-phase ac transmission, between Lauffen and Frankfurt, began in 1891.

The International Niagara Commission, charged with finding the best means of transmitting hydroelectric power from Niagara Falls to the city of Buffalo, a distance of 22 miles (35 kilometres), selected alternating-current transmission in 1893. Generators were installed at Niagara Falls in 1894, and ac transmission to Buffalo began in 1896.

In the 1880s the merits of dc and ac systems were hotly debated. Though the dc system had already been somewhat developed and the ac system was new, the inherent superiority of ac was soon recognized and it rapidly became dominant. By 1898 alternating-current transmission had been sufficiently developed that a 30,000-volt, three-phase, 75-mile (120-kilometre) line from Santa Ana, California, to Los Angeles was placed in service; and in 1899 a 40,000-volt, 70-mile (110-kilometre) line from Colgate Hydro, California, to Sacramento was opened. Development of higher voltage transmission was restricted by the limitations of the pin-type insulator then available, but in 1907 the U.S. electrical engineers Edward M. Hewlett and Harold W. Buck developed the first suspension insulators, making practical higher voltages. By 1920 voltages up to 132,000 were common, and some lines were being operated at 150,000 volts.

In the 1890s steam-reciprocating-engine-driven ac generators predominated, but they had many deficiencies; they were too large and heavy, and the rotation was pulsating. In 1903 a 5,000-kilowatt steam-turbine-driven ac generator was put into service in the United States, and its output gradually increased. The steam-turbine generators of that time also had certain limitations, however, primarily limited output capacity and high fuel consumption. As a result, hydroelectric generation came to be favoured for large-scale electric-power generation. Developments were rapid. From the 1920s many large-scale hydroelectric plants were constructed, and transmission lines capable of operating at 220 kilovolts (a kilovolt is 1,000 volts) or more were constructed in many parts of the world. In 1922 Pit River transmission line and Big Creek transmission line, both designed to operate at 220,000 volts, were placed in operation in California. In 1934 power generated at Boulder (later Hoover) Dam on the Colorado River was transmitted to Los Angeles, a distance of 270 miles (430 kilometres), at 287,000 volts.

High-voltage operation. Corona (electrical discharge from the surface of lines operating at high voltages) with its related phenomena is an important problem at 220,000 volts, and conductor diameter was increased to as much as an inch (2.5 centimetres) and more, irrespective of current, to minimize the loss of power resulting from this effect. During World War II, Germany made fundamental experiments both on ac extra-high-voltage (EHV) transmission (380 kilovolts ac) and EHV dc transmission (440 kilovolts dc). In EHV ac, to solve the problem of corona at 380 kilovolts, the Germans devised the multiconductor system, using four conductors. In EHV dc they manufactured the world's highest voltage mercury-arc rectifiers (for converting ac to dc) and constructed an underground dc cable transmission line some 60 miles (100 kilometres) long, between the Elbe hydroelectric station and Berlin. Tests were discontinued at the end of the war, but their experiences greatly affected technological development in EHV transmission.

AFTER WORLD WAR II

Large-scale projects. Post-World War II developments were characterized by the emergence of large capacity machines, especially steam turbines. The maximum sizes of steam-turbine generator units in the United States (the world's largest) were 260 megawatts (260,000,000 watts) in 1956, 450 megawatts in 1960, 650 megawatts in 1963, and 1,000 megawatts in 1965. These large units reduced construction cost per kilowatt for steam power stations; thermal power generation increased because of the low price of oil and coal and the exhaustion of favourable sites for hydroelectric generation in most developed countries (except the Soviet Union and Canada). This situation changed the role of hydroelectric generation in many countries. Formerly hydro had been the principal power source and steam power an auxiliary; then thermal power took the base load and hydropower the extra, or peak, load. Pumped hydro for peak use was common in the 1970s in many countries.

Soviet and Canadian hydro projects

Despite this trend, many large-scale hydroelectric power projects have been instituted in the Soviet Union and Canada. In the Soviet Union the world's largest hydroelectric station, Krasnoyarsk, with its total generating output of 6,000 megawatts (12 hydroturbines of 500 megawatts each) began operation in 1971, and the 6,500-megawatt Sayan–Shushenskoye station with its ten 650-megawatt hydroturbines was under construction in the early 1970s. In Canada, the Churchill Falls project, with an ultimate capacity of 5,200 megawatts, and the James Bay hydroelectric project (14,000 megawatts) were under consideration.

In the developing countries, the early 1970s saw many large-scale hydroelectric projects already completed or under construction: Kariba Dam (final 1,500 megawatts) in Rhodesia, Aswān High Dam (2,100 megawatts) in Egypt, Furnas (final 1,200 megawatts) in Brazil, and Guri (final 6,000 megawatts) in Venezuela.

After World War II, widespread fear that such conventional fuels as coal and oil would be exhausted led to the promotion of nuclear power as a new energy source. Thus, gas-cooled reactors were developed in the U.K., and light water-cooled reactors in the U.S. It was difficult, however, for nuclear power to compete in cost with power generation by conventional fuels, because from the end of the 1950s oil and coal continued to be abundant and cheap. By the mid-1960s, however, nuclear power had become competitive with conventional thermal power.

Nuclear power generation is described below (for further information see NUCLEAR FISSION).

Extra-high-voltage transmission. After World War II it became evident in many countries that, with the tremendously increasing demand for electric energy, high-voltage transmission would be needed to transmit ever larger amounts of power, and studies and experiments on demonstration lines with voltages of 500,000 and beyond were undertaken. In Great Britain a 275,000-volt transmission system (supergrid) was constructed to transmit large amounts of power from one part of the system to another, and the original extensive 132,000-volt British grid, construction of which had begun in 1926, was almost relegated to the role of subtransmission, or delivery to a distribution network. The first higher voltage line became operative in Sweden in 1954, a 380,000-volt line from the hydroelectric station at Harsprånget, 22 miles (35 kilometres) north of the Arctic Circle, to southern Sweden, 600 miles (970 kilometres) away. This line marked an advance in extra-high-voltage (EHV) transmission technology, with the first practical use of bundle conductors (actually double conductors in this case), previously studied by the Germans. The line's success revealed the possibility of raising transmission voltage even higher, to say 1,000,000 volts, without incurring corona loss. This line also first used large-capacity series capacitors on EHV lines, making long-distance transmission economical.

Later, in the United States, Canada, and Australia, 330,000-volt to 345,000-volt lines came into use, while Germany, France, Sweden, the Soviet Union, and other countries began 380,000-volt transmission. Next, 500-kilovolt lines were developed in the Soviet Union and the United States. In 1965 lines in Canada, from Manic dams to Montreal via Quebec, began operation at 765,000 volts, the world's highest voltage transmission line up to the early 1970s. Studies and experiments in many countries, however, aimed at 1,000 kilovolts and higher.

New interest in direct current. Direct-current transmission systems, after more than half a century, also began receiving renewed attention because of the development of high-voltage mercury-arc rectifiers. In 1954 an experimental dc submarine cable, operated at 100,000 volts and carrying 20,000 kilowatts of power, was put into service between the mainland of Sweden and the island of Gotland, 60 miles (100 kilometres) away. This installation was another triumph for Sweden in the EHV transmission field, and a Swedish manufacturer provided the high-voltage mercury-arc rectifiers for nearly all subsequent dc transmission projects in the world.

Submarine cables

Submarine cables under the English Channel from Dungeness in Kent, England, to Le Portel, a suburb of Boulogne, France, a distance of 30 miles (48 kilometres), began operation in 1961, carrying 200,000 volts dc with a total capacity of 160,000 kilowatts. In 1965 other systems began operation, with voltages ranging from 200 to 500 kilovolts and transmitted powers from 200 to 600 megawatts. Most of these projects used undersea cable, but the Volgograd–Donbass line in the Soviet Union (800 kilovolts, 750 megawatts, 290 miles [470 kilometres]) and Pacific Intertie in the United States (800 kilovolts, 1,440 megawatts, 825 miles [1,330 kilometres]) use overhead lines only.

New developments in generation and transmission. In the power-generation field, fast breeder reactors, which produce more fuel than consumed; magnetohydrodynamic power generation, in which the thermal efficiency may be more than 50 percent; and, finally, nuclear fusion reactors (see below) will emerge.

In the electric-power transmission field, cryogenic (supercooled and superconducting) and microwave systems (transmitting power by radio waves) appear to be feasible in the future, while 1,000,000-volt transmission seems feasible using present-day technology.

Pollution considerations. New problems, primarily environmental, emerged, however, which the utility industry must solve. From the middle of the 1960s, gaseous effluents, such as sulfur dioxide and dust, from fossil-fuelled power stations caused much public concern. Water from thermal stations that has been heated in cooling the condensers (*i.e.*, thermal pollution) has also caused alarm. Also, gaseous and liquid effluents from nuclear stations contain slight amounts of potentially dangerous radioactive substances, and the possibility of a major accident, releasing large amounts of radiation, drew critical attention. Pollution problems are described more fully below and in the article POLLUTION CONTROL.

Operating frequencies. In the history of the power industry, frequencies of ac generators (the number of oscillations per second of the ac output) were very diverse, ranging mainly from 16⅔ hertz (cycles per second) to 133 hertz. Generators with different frequencies, however, cannot be operated in parallel. After many years of efforts at standardization, two frequencies, 50 hertz and 60 hertz, remain. In the United States and Canada, 60 hertz is commonly used for general utility purposes; while on the European continent and in Great Britain, 50 hertz is the rule. Japan is an exception, both 50 hertz and 60 hertz being used nearly half and half. To link regions of different frequencies, a frequency changer using high-voltage mercury-arc rectifiers is needed. Lower frequencies such as 25 hertz and 16⅔ hertz are used for electric railways in many countries.

North American and European systems

II. Power generation

There are only two basic sources for driving electrical generators: hydro and thermal. Hydroelectric power is derived from generators turned by falling water. Most other electric power is produced by generators turned by steam pressure; the steam may be produced either by burning fossil fuel or by a nuclear reactor.

Hydroelectric power has many advantages. It is continuously renewable because of the recurring cycle of rainfall, runoff, evaporation, and transpiration. Hydroelectric power plants require neither fuel nor cooling water and create no thermal pollution problem. Their maintenance is relatively easy, and their plants, often located at remote sites, can be designed for automatic or remote-control operation. Their water-turbine generating units are more reliable than steam-electric units because they operate at relatively low speeds and are not subject to temperature stresses.

On the other hand, the steam power plant is not dependent on rainfall or water availability and can supply power during all seasons of the year. Site selection is much more flexible, and consequently the transmission line from the plant is usually shorter. Steam-electric units can be designed to burn several kinds of fossil fuels and to change from one fuel to another on short notice to take advantage of price changes.

In the United States, coal is burned to produce more than 60 percent of the electricity from fuel, while natural gas supplies more than 20 percent and oil about 10 percent. In the United Kingdom and West Germany, the share of coal is higher (more than 80 percent), whereas in Italy and Japan most of the electrical energy from fuel (more than 70 percent) comes from imported heavy oil.

Thermal-power countries

The proportions of the two forms of power also vary from country to country, depending on the respective availability of fuel and waterpower. In the United Kingdom almost all electricity comes from fuel (98 percent); in the United States, the Soviet Union, and West Germany, thermal power contributes more than 80 percent, and in Japan nearly 70 percent. These are called thermal-power countries. Canada, Norway, Switzerland, and Sweden are termed hydropower countries. In Norway 98.5 percent of electric power is hydro-generated, in Switzerland more than 90 percent, in Sweden 85 percent, and in Canada 80 percent. France and Italy stand between, with approximately equal quantities of hydro and thermal power generated.

In the early days of the power industry, hydropower was cheaper than thermal power and played the main role in supplying electricity, with thermal power an auxiliary. Since the 1930s, however, and especially since World War II, technology in thermal-power generation has progressed tremendously; since the late 1950s, fuel has been abundant and relatively inexpensive. Thus the

cost of thermal-power generation has decreased. Furthermore, in many developed countries, favourable hydro sites are becoming exhausted. Thus the proportion of thermal power to the total power generated rises year by year in many developed countries.

Though nuclear power has considerable potential, its actual contribution to total electric-power generation in the early 1970s was very slight (less than 2 percent) in many countries, except the United Kingdom, where its contribution was more than 10 percent (12 percent in 1969). At the same time, construction of nuclear power stations in such countries as the United States, West Germany, and Japan was being carried out vigorously, and by 1980 the share of nuclear-power generation was expected to amount to more than 20 percent.

DC POWER GENERATION

For industrial use, dc power has special advantages in some motor applications and in electrochemical and electrolytic processes. This power is generated locally in industrial plants, sometimes by engine-driven or turbine-driven dc generators but more frequently by motor-generator sets that combine an ac motor and a dc generator.

Since the late 1930s, dc power has been generated by such electronic devices as mercury-arc rectifiers that convert ac power into dc power (see ELECTRON TUBE). These generally have important advantages over motor-generator sets, such as lower construction cost, less weight, and less area required for installation. Maintenance and repair costs are usually simpler, and start-up is easier. Consequently, motor-generator sets have gradually become obsolescent.

In the 1950s the silicon-controlled rectifier (see also SEMICONDUCTOR DEVICES) emerged, and in the 1960s it supplanted the mercury-arc rectifier in industrial applications, except for high-voltage dc transmission, in which high-voltage, high-power, mercury-arc rectifiers are used. In the early 1970s, large-capacity silicon-controlled rectifiers were being employed experimentally in high-voltage dc power-transmission projects.

THERMAL POWER GENERATION

In the generation of electric power from fuel, the heat energy of the fuel is first converted into mechanical energy by a prime mover and then into electrical energy by a generator. Until about 1900 the only prime movers available to the industry were slow-speed steam engines, the ratings of which were limited to less than 2,500 horsepower. The introduction of the steam turbine broke the prime-mover bottleneck by permitting much larger concentrations of output in a single unit.

Continuous technical progress with boilers, steam turbines, and turbo-generators steadily improved the efficiency and reliability of the steam-electric process, enabling the industry to increase steaming capacity of the boiler and to increase the temperature and pressure of steam available at the turbine, which in turn led to larger turbine-generator sets and overall improvements in plant design. In the turbines the advances included fabrication of longer blades and higher efficiencies through improved steam condition; in the generators, they included increases in capacity in relation to generator size through hydrogen cooling and, later, water- and oil-cooling.

The thermal efficiency of steam electric generation, which was as low as 5 percent in 1900, increased to more than 40 percent in the 1960s. In terms of fuel consumption, this increase meant that an eightfold reduction had been achieved since the beginning of the century. These achievements are dramatically reflected in the rapid increase in the size of individual units. Figure 1 shows the history of increase of unit capacity of turbine-generator sets in the United States; they were the world's largest ones then available.

Steam temperature and pressure at the turbine throttle continued to increase steadily until the beginning of the 1960s. The steam condition of the Eddystone, Pennsylvania, station, in the United States, is the world's highest,

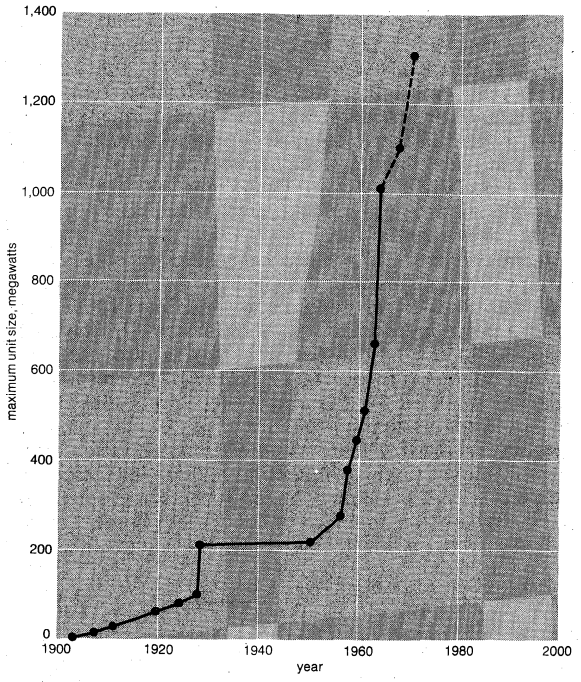

Figure 1: Growth in the unit size of electrical generating plants driven by steam power (U.S.).

with a temperature of 1,200° F (650° C) and a pressure of 5,000 pounds per square inch (350 kilograms per square centimetre). Since then the steam temperature has shown a downward trend, because adoption of temperatures as high as 1,200° F raised difficulties in finding satisfactory metals. In the early 1970s, the general practice was to use steam at temperatures of about 1,000° F (540° C) and at pressures of 3,500 pounds per square inch (245 kilograms per square centimetre).

This retreat halted the trend toward higher efficiency by improving the steam condition and caused designers to strive for higher efficiency by enlarging the individual unit. The largest units in operation in the early 1970s were in the U.S.; the No. 3 unit of the Ravenswood plant in New York, 1,000 megawatts (1965), and the No. 3 unit of the Paradise, Kentucky, plant, 1,130 megawatts (1970). The largest unit under construction was also in the U.S., the No. 1 unit of the Cumberland, Maryland, station, which is rated at 1,380 megawatts (see Figure 1). It appears highly probable that 1,500-megawatt or 2,000-megawatt units will be manufactured in the 1970s. Future developments in high-temperature metallurgy may make relatively cheap metals available for use at high temperatures, again permitting improvements of the steam condition for high efficiency.

Use of the binary cycle

Two other methods can be utilized to improve the efficiency of the thermal power station. One is to employ a binary cycle, the other is through the combined operation of a gas-turbine steam-turbine cycle. The binary cycle is a combination of a mercury-vapour cycle and a steam cycle. High-temperature mercury vapour can be attained at relatively low pressure, in contrast to steam; the increased initial temperature increases the overall efficiency. By the early 1930s, several power stations used binary cycles. Facilities were complicated, however, and many new technical problems arose in the design of mercury turbines and boilers, and so in the end construction of the binary-cycle plant using mercury was abandoned. For a description of the combined operation of gas-turbine steam-turbine cycle, see below and also the article STEAM POWER.

Some types of thermal power stations produce both electricity and heat. Heat in the form of process steam is used in the industrial plant, and heat in the form of steam and hot water is used for heating residences.

Where the industrial factory needs both electricity and process steam for treatment, drying, and heating of raw materials, it is frequently preferable to have a high-

pressure boiler producing high-pressure steam for electricity generation and to obtain process steam from bleeding steam or from the exhaust from the turbine, rather than to install separate boilers for electricity generation and for process steam. This type of dual-purpose plant is used in many countries for the paper and food industries, oil refineries, and chemical plants. Many countries, especially the Soviet Union and West Germany, have plants that produce both electricity and by-product steam for residential use.

Steam turbines. The electrical generator of a steam-turbine system is usually designed for a turbine speed of 3,600 revolutions per minute and sometimes 1,800 revolutions per minute in the 60-hertz system. In the early days, 1,200 revolutions per minute was also used, but this speed was rare by the early 1970s. Corresponding turbine speeds in the 50-hertz system are 3,000, 1,500, and 1,000 revolutions per minute.

Steam turbines for thermal power stations fall into two classifications: single cylinder and multicylinder (see also TURBINE). In the single-cylinder turbine the steam expands from boiler pressure to condenser pressure in one cylinder. Such a turbine is shown in Figure 2A. This

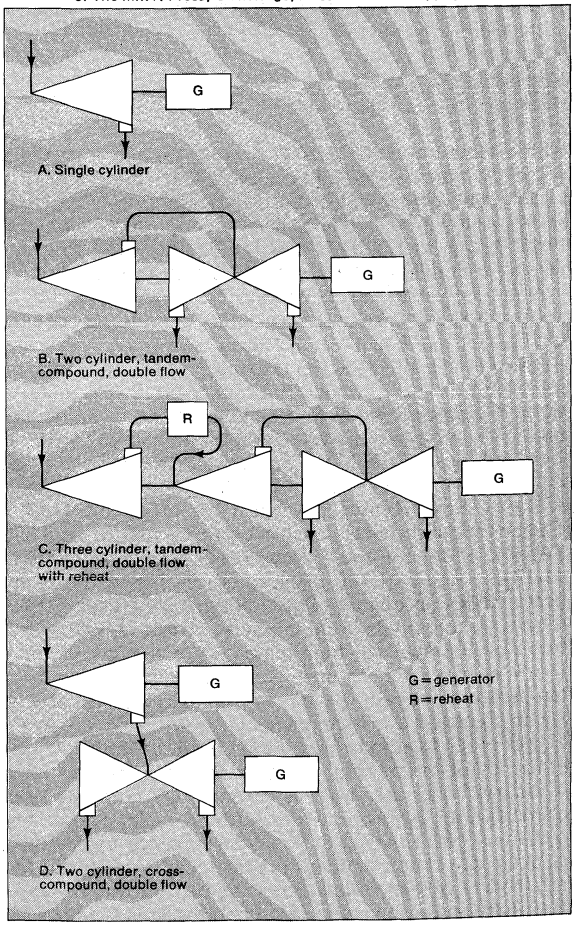

Figure 2: Typical turbine arrangements in steam plants (see text).

kind is always connected to a single generator. In the multicylinder turbine the steam expands from boiler pressure to condenser pressure in two or more cylinders, which may be tandem-compound (single shaft) or cross-compound (multi-shaft). Figure 2B shows a two-cylinder tandem-compound turbine. Steam from the high-pressure cylinder is conducted into the low-pressure cylinder, which has a double exhaust. With a given maximum peripheral speed, it is the blade length in the last row of blades that determines the turbine output. Practically, the length of the last blade is limited by the mechanical strength of the metal of which it is fabricated.

Multi-cylinder turbines

Figure 2C shows a tandem-compound, three-cylinder, double-flow turbine. The steam on leaving the first cylinder is returned to the boiler and reheated (R) to its initial temperature before being fed into the second medium-pressure cylinder.

Cross-compound turbines also consist of a high-pressure cylinder and one or more low-pressure cylinders, but each is connected to its own generators as shown in Figure 2D. Sometimes a high-pressure turbine generator runs at 3,600 revolutions per minute and the low-pressure unit at 1,800.

As mentioned above, the length of the last-stage blade in the low-pressure turbine is the limiting factor for output increase. The 1,100-megawatt turbine at the Paradise plant can be expressed as CC4F-52″; that is, a cross-compound four-flow turbine with the last blade being 52 inches (1.3 metres) long. A large-capacity turbine is often of the cross-compound type (multishaft); the largest under construction in the early 1970s was 1,380 megawatts. The largest capacity of the tandem-compound turbine (single shaft) was around 800 megawatts.

Electric generators. Generators in thermal power stations are two-pole and four-pole machines (3,600 or 1,800 revolutions per minute at 60 hertz), direct-connected to the steam turbines. In cross-compound units, two or more generators constitute one unit and are treated electrically as a single machine.

Rating electric generators

Generators are rated in kilowatts and kilovolt-amperes at a certain power factor and short-circuit ratio. The rating and dimensions of generators are affected by all these factors and by the pressure of the hydrogen used for cooling. Standard generators are rated at 0.85 power factor, 0.8 short-circuit ratio, and 0.5 pound per square inch (0.035 kilogram per square centimetre) hydrogen pressure. The power factor is the ratio of the real power to the apparent power, that is, kilowatts to kilovolt-amperes. The short-circuit ratio is the ratio of the field current required to generate rated voltage at no load to the field current required to circulate rated armature current through the short-circuited armature, both at rated frequency.

The effect of the short-circuit ratio on generator rating is not as simple as that of power factor, but in general the higher the short-circuit ratio, the larger the machine; so that for a given physical size, the lower the short-circuit ratio, the higher the generator's rating. In practice, the short-circuit ratio is seldom less than 0.8. When a generator is short-circuited, the initial current is very high but drops rapidly and after one or two seconds stabilizes at a final value determined by its synchronous reactance. Synchronous reactance is the value of reactance that exists in the machine after all transient effects have died out.

The purpose of a high short-circuit ratio is to keep the machine in synchronism with the system during a disturbance, because the higher the short-circuit ratio, the lower the synchronous reactance. With improved voltage-regulating systems, however, there is a tendency to adopt a short-circuit ratio lower than 0.8, and a value as low as 0.6 has been adopted in some large-capacity generators.

The steam-turbine-driven generator has a far higher speed of rotation than a hydroturbine-driven generator; its rotor is cylindrical, and usually the shaft is horizontal. As the output of a turbo-generator becomes higher, the cost per kilowatt decreases. Thus there is a general trend to adopt higher output machines. Under ordinary conditions, however, it is preferable to adopt standard-output machines, because the cost is low, delivery time is relatively short, and they are rather flexible in application. The limiting factor in increasing unit size is the rotor. Because of the high rotational speed, centrifugal force limits the diameter of the rotor, necessitating an increase in length for higher ratings. To attain high strength, the rotor is usually forged in one piece, out of carbon steel for small machines, nickel steel for medium sizes, and high-tension steel for high-capacity units.

Developments of materials and fabrication techniques have contributed much toward the larger capacity ma-

chines, but most important have been improvements in generator cooling techniques. Either natural cooling or forced cooling by fans was once employed, but from the early 1950s hydrogen-cooling was widely used, phenomenally increasing capacity. Later, the introduction of direct cooling methods with water or oil made it possible to design and fabricate even higher capacity machines.

Nearly all turbo-generators above 20-megavolt-ampere capacity are hydrogen-cooled, thus necessitating building them with gas-tight housings and facilities to prevent formation of explosive mixtures with air; the advantages are such that the extra complication is justified. The effect of hydrogen-cooling on the rating is to reduce the losses for a given temperature rise. Because of the lower density of hydrogen, windage losses (frictional losses caused by gas around the armature) in the generator are reduced to one-tenth of what they would be with air at atmospheric pressure. Hydrogen has a thermal conductivity seven times that of air, and the rate of heat transfer in hydrogen is 35 percent greater. The effect of corona is negligible in hydrogen, insulation retains its flexibility longer, and, because hydrogen will not support combustion, the fire hazard is reduced.

In the past, machines were designed for operation at a gas pressure of 0.5 pound per square inch (0.035 kilogram per square centimetre), a design permitting a rating about 25 percent higher than for the same machine with air-cooling. Later, hydrogen pressure was raised to 15 pounds per square inch (one kilogram per square centimetre), giving about a 15 percent output increase, and then up to 30 pounds per square inch (2.1 kilograms per square centimetre) with a further 10 percent increase in output. Gains fall off at higher pressures, so that 30 to 50 pounds per square inch seems to be an optimum.

Direct cooling

A new design, the so-called direct-cooling, or inner-cooling, method, has emerged. The rotor conductors are hollow, and high-pressure hydrogen (45 to 90 pounds per square inch, or 3.15 to 6.3 kilograms per square centimetre) circulates through them. In the stator (stationary part of the turbine), conventional copper strands are used, but between them a thin-walled copper tube runs the length of the slot, and hydrogen is forced through it. Thus, in both the rotor and stator the hydrogen removes the heat directly from the copper conductor instead of through the insulation. The output of a machine is about doubled by this method of cooling. As a medium for this direct-cooling method, water is also used. The Table shows the general trends in cooling methods used for different machine sizes.

Cooling Methods at Different Machine Sizes

rating (megavolt-amperes)	stator	rotor
Up to 200	hydrogen cooling	hydrogen cooling
Up to 350	hydrogen cooling	direct cooling (hydrogen)
Over 400	direct cooling (water)	direct cooling (hydrogen)

Site selection. A most challenging problem repeatedly facing each electric utility is the location of large thermal power stations to provide the desired increase of electric-power supply at the lowest cost. Important factors in locating the plant include fuel supply, load distribution, load growth, availability of land, foundation conditions, and availability of cooling water. Utilities have also had to consider thermal- and air-pollution problems. Generally, availability and cost of fuel are basic to the location of a large generating station.

The number of favourable sites available for large generating stations is decreasing with the increase in population, expansion of the economy, and the more active interest of the general public as well as local public agencies in community matters, and thermal and air pollution. Consequently, electric utilities try to use each site selected for the largest generating plant that can be economically justified.

Most thermal plants are located on rivers, lakes, or the seashore because of the need for an adequate supply of cooling water to condense the steam leaving the turbines. The amount of cooling water required depends upon the size of the plant, its thermal efficiency, and the permissible temperature rise of the cooling water passing through the condenser. For a 1,000-megawatt generating station, a flow of 1,500 cubic feet (42 cubic metres) per second is required, and the minimum river flow would have to be about 4,000 cubic feet (110 cubic metres) per second to limit the temperature rise of the river water to 7° F (4° C).

A shortage of cooling water can be met in two principal ways: by recirculating the water in reservoirs or ponds and by the use of cooling towers, both evaporative and nonevaporative. Each method requires a supply of make-up water to replace water evaporated and otherwise lost. For a 1,000-megawatt generating station, the water requirement for a cooling pond would be 10 to 20 cubic feet (0.3 to 0.6 cubic metre) per second; for an evaporative cooling-tower system, 20 cubic feet (0.6 cubic metre) per second; and for a nonevaporative cooling tower system, about two cubic feet (0.06 cubic metre) per second.

When an ample supply of cooling water is available, the once-through circulation method for condenser cooling is usually the most economical; the recirculation system involving reservoirs and ponds ranks next in economy. The cooling-tower system is relatively expensive, especially the nonevaporative, or dry, cooling-tower system.

Air pollution concerns in site location

Air-pollution problems also pose severe limitations in locating large plants. Special studies must be made of atmospheric conditions in the area, the sulfur content of the fuel burned, and the degree to which the area is developed. Even with modern boiler design, dust collectors, and proper plant layout and stack height, the station size may sometimes be limited by the tolerable pollution level.

Air pollutants of major concern at fossil-fuelled power plants include fly ash and polycyclic hydrocarbons in the particulate group, and the oxides of sulfur and nitrogen in the gases. Modern power plants are normally equipped with mechanical and electrostatic precipitators to provide a substantial degree of control over fly ash. The sulfur-derivative gases are generally the most troublesome pollutants from fossil-fuelled plants, sulfur being present in almost all fossil fuels. Most of the sulfur appears in the stack gases as sulfur dioxide in a concentration that is a function of the sulfur content of the fuel and the amount of excess air in the stack emission.

Removal of sulfur dioxide from combustion gases by techniques known in the early 1970s was difficult and expensive, and experimental work was underway for better methods. As a control, utilities have constructed very high stacks at thermal power stations, in some instances as high as 825 feet (250 metres) or more, to allow the wind to dilute the stack gases. This method has disadvantages, however, because higher stacks can cause nuisance problems covering wider areas.

The search for fuel of low sulfur content was active in the 1970s in many developed countries, but the supply is limited. Instead of extracting sulfur dioxide from stack gas, a technique of extracting sulfur directly from oil was being developed with promising results, but the cost was uncertain. Similar experiments were being conducted on coal.

Gas-turbine stations. The gas turbine, which is widely used as an aircraft engine, was first applied in electric-power production when a 4,000-kilowatt machine was built in Switzerland in 1939. In the 1960s the growing use of turbojet engines for aircraft brought both capacity and performance improvements, and gas turbines found growing application in the electric utility field.

The principal advantages of gas turbines are low construction cost, short construction period, flexibility in the choice of site location, quick start-up, and ease of automation. There are two types of gas turbines, the open-cycle, in which the output is exhausted directly to the atmosphere, and the closed-cycle, in which the exhaust is recirculated back to the input. Although the

open-cycle has lower thermal efficiency, it is preferred because the closed-cycle is more costly and more complicated in layout and in operation. A capacity of 1,000 megawatts is difficult to attain in a single gas-turbine unit, but the unit capacity of gas turbines is higher than that of diesel engines, the output of which is limited to the order of several megawatts.

Single units of the open-cycle type were available in the 1970s in ratings up to about 30 megawatts, and gas-turbine units of larger ratings had been developed by using several aircraft jet engines as gas generators. One design employs several jet engines in tandem and produces an output of 120 megawatts. Another design consists of ten cylindrically mounted aircraft gas turbines operating as gas generators exhausting simultaneously into a single-stage power turbine driving a 100-megawatt generator.

Because the construction period of gas-turbine stations (12 to 18 months) is far shorter than that of fossil-fuel steam-turbine stations (three to five years) and of nuclear power stations (four to seven years), and because the cooling water requirements are far less, gas-turbine stations are popular for building up a standby reserve of generating capacity to use in meeting peak load demands. Gas turbine units can be started, synchronized, and fully loaded in two to five minutes.

Disadvantages of gas turbines

Gas turbines have some disadvantages. Open-cycle units have low thermal efficiencies, around 22 to 24 percent, and are limited to high-grade liquid fuels or gas, which are costly in many areas. As a result, energy costs are high. In most cases, therefore, use of gas turbines was limited to annual plant factors not exceeding 5 to 10 percent; that is, total operating hours of a gas turbine per year did not exceed 500 to 1,000 hours. Construction delays with thermal and nuclear power stations in the U.S. in the early 1970s contributed to the introduction of many gas turbines in the power system. In some installations the plant factor was as high as 20 to 25 percent in 1969 to cover what might otherwise have been a severe supply shortage. The rate of increase was expected to taper off as thermal and nuclear stations under construction and being planned were brought into operation.

Another method of application for gas turbines, however, involves combining them with steam turbines to increase overall plant efficiency as much as 4 percent. Exhaust gas of the open-cycle gas turbine is as hot as 750° F (400° C), and also retains 80 percent of the oxygen in the air. This exhaust gas is used as the preheated air to be injected into the furnace of a steam boiler. The first application of this combined cycle to a utility system was at the Horseshoe Lake station, Oklahoma City, Oklahoma, in 1963. Capacity of the combined unit was 245 megawatts and proved the applicability of the technique. Later, this combined cycle was used in plants in several countries.

Diesel-engine generators. The diesel engine as a power source for generating electricity has a number of advantages: relatively small size, light weight, high reliability, quick start-up (60 to 90 seconds), and high thermal efficiency (30–38 percent). Unit capacity, however, is small, ranging from several hundred to several thousand kilowatts and so cannot be used as the primary generating source for central power stations. Because it is a reciprocating engine, its rotational speed fluctuates during one revolution. To reduce this effect, heavy flywheels are needed.

Nuclear power generation. Like fossil-fuel-fired plants, nuclear power stations generate heat to produce steam to drive turbine generators. The difference is that, whereas conventional thermal plants use heat produced by combustion of fossil fuel, nuclear plants produce heat by fission of nuclear fuel in a reactor. Basically, therefore, a nuclear reactor is substituted for a fossil-fuel boiler (see also NUCLEAR FISSION).

In 1964 the order for the nuclear station at Oyster Creek, New Jersey, was the first to be placed on a competitive basis with fossil-fuelled plants and introduced competitive nuclear power. Later, orders from utilities for nuclear plants in the United States grew phenomenally, and nearly 100 reactors with an aggregate capacity of roughly 85,000 megawatts were ordered by 1971. This success exerted worldwide influence; United States-type reactors were introduced into the power systems of other countries, especially in West Germany and Japan.

Reactor types. Fuels, moderators, and coolants are the major components of reactors, and from their combination can be theoretically considered the many varieties of nuclear reactor types. The number of reactor types actually developed, however, is rather limited, namely light-water reactors in the United States, gas-cooled reactors in the United Kingdom and France, and heavy-water reactors in Canada. Of these three types, the most developed is the light-water reactor. Gas-cooled reactors developed in the United Kingdom (often called Magnox type) have long had excellent operation. In total generated kilowatt-hours by reactors in the early 1970s, the United Kingdom surpassed all other countries. The modified version of the Magnox type, the advanced gas-cooled reactor, was under construction in the United Kingdom in the early 1970s. In 1971 France, which also had developed gas-cooled reactors, adopted instead the United States light-water technology. Canada, uniquely, has consistently developed the heavy-water type, but the total number and capacity of such reactors already developed and under construction was still modest in the early 1970s.

High-temperature gas-cooled reactors, advanced versions of the gas-cooled reactor, were being enthusiastically developed by the United States, United Kingdom, and West Germany. Fast breeder reactors are deemed the ideal reactors for the future, and much developmental effort was being devoted to them by the developed countries. In the early 1970s, leaders in nuclear reactor development were the United Kingdom, the Soviet Union, and France, followed by the United States, West Germany, Japan, and Italy.

Special features. In nuclear power generation, fuel consumption is tens of thousands of times less than in conventional steam power generation, with obvious savings in transportation and storage costs. In general terms, the nuclear power plant has a higher construction cost and a lower fuel cost than a thermal power plant of comparable size; fixed cost is one-third and fuel cost two-thirds, whereas with a nuclear plant the fixed cost is two-thirds and fuel cost is one-third. To obtain cheap electricity from the nuclear plant, construction cost must be kept down, and to this end, larger sizes were being planned and built. The average capacity of nuclear reactors ordered in the early 1970s ranged from 700 to 800 megawatts, and reactors with a capacity as high as 1,100 to 1,200 megawatts were not uncommon.

Fossil fuel versus nuclear power

The spent fuel, or burned-up fuel of nuclear power stations, contains newly born nuclear fuel, plutonium, and partly burned uranium and also highly radioactive fission products. To extract plutonium and partly burned uranium for re-use and to separate fission products for disposal, the burned-up nuclear fuel must be sent to a spent-fuel reprocessing plant. The normal operation of a nuclear power plant also produces minute quantities of gaseous, liquid, and solid radioactive wastes, some of which are released to the environment. National legislation in all nuclear-power countries is designed to control the resultant radiation problems. Operational experience in the 1970s showed the radiation dosage in all localities well below the maximum tolerable values as specified by the International Commission on Radiological Protection (ICRP). The safety review of nuclear power stations, which should be verified by authorized bodies, covers the whole phase of design, construction, and operation. The reason for this strict measure lies in the tremendous amount of fission-product inventory in the reactor. There is a possibility, however remote, that a widespread radiation hazard could occur if a significant part of the fission-product inventory should be released by accident.

Governments and industries have acted in three principal ways to avoid serious consequences: (1) enacting safeguards to prevent or reduce to minor levels accidental release of hazardous radiation and radioactive products

within the reactor structure; (2) building containment structures and other safeguards to confine accidental release of radiation inside the plant; and (3) enacting zoning measures to prevent radiation and radioactive products that may escape inadvertently, despite multiple safeguards, from causing damage to persons and to property.

Nuclear plant insurance

Liability insurance is a special problem for nuclear power plants. Accidents have been few and damage small, so that there is little statistical basis for establishing risks. Meanwhile, conceivable liability risks have been considered to exceed the financial capabilities of the private insurance business. In 1957 and again in 1967 the United States Congress authorized the federal government to provide liability protection up to $500,000,000 for any single nuclear accident. Utilities are required to secure the prescribed amount of private liability insurance up to a limit of $60,000,000, depending on the size of the plant. In other countries, liability insurance for nuclear power plants is treated similarly, but the amount of insurance varies.

The number of economically exploitable uranium mines is limited, and the main uranium-producing countries are the United States, Canada, Australia, and South Africa. World assured reserves of uranium that can be exploitable at less than about $10 a pound of U_3O_8 is estimated at about 800,000 tons. Many countries were actively prospecting for additional uranium reserves in the 1970s.

Natural uranium reactors—that is, reactors that do not use enriched fuel—were being actively developed in only a few countries, principally Canada. The United Kingdom and France had shifted from natural to enriched uranium, which was provided solely by the United States and which was used in almost all reactors.

Thermonuclear power. Nuclear power generation uses the physical process called nuclear fission. In the thermonuclear reaction, or fusion, very light nuclei, such as deuterium or tritium (both isotopes of hydrogen), join together with the release of tremendous quantities of energy (see NUCLEAR FUSION). This process, which takes place in the thermonuclear, or hydrogen, bomb, had not yet been controlled in the early 1970s so that it could be used to generate electric power, but the potential exists. The future of fusion reactors, however, was far from clear; optimistically it was felt that electric power generation by fusion might be possible in 1990 or 1995. Most authorities felt that the fusion reactor would be the technology of the 21st century.

Advantages of the fusion reactor

The advantages of the fusion reactor would be very great. First, fuel resources would be no problem, because deuterium exists in almost unlimited quantities in ordinary water, and tritium can be obtained from lithium, a relatively abundant element. Second, radioactive waste is far less from the fusion reactor than from the fission reactor. Third, a serious accident in the fusion reactor holds no danger of discharging large amounts of radioactive material into the environment, as do fission reactors. The successful fusion reactor would therefore be an ideal energy source, and research and development were actively being pursued in the 1970s in many countries, primarily the United States, Soviet Union, United Kingdom, West Germany, France, and Japan.

HYDROELECTRIC GENERATION

Falling or flowing water formed the earliest of the natural sources of energy to be used for power, but, as has been noted, most of the waterpower in use in the second half of the 20th century was developed from the first decade of the century. Conditions favouring such development included the availability of sites, the higher efficiency in power generation promised by hydroelectric sources as compared with steam plants, and the advent of the technology for high-voltage, long-distance transmission. The hydraulic turbine made it possible to use any head (height of water above the turbine) from 30 to 5,000 feet (nine to 1,500 metres) with high efficiency and at speeds that permitted use of a relatively inexpensive electric generator. Developments in electrochemical and electrometallurgical processes requiring large amounts of cheap electricity created a demand that could under favourable circumstances be satisfied more readily from waterpower plants than from other sources.

Eventually, however, most favourable hydroelectric sites were exhausted. Meantime, construction cost of steam plants was reduced, their efficiency improved, and their fuel costs ameliorated by new transportation techniques, such as pipelines. The trend was consequently reversed, and steam power plants began to overtake and surpass hydroelectric stations in numbers and capacity. In the second half of the 20th century, almost all hydroelectric construction was government-sponsored, with the projects including such other considerations as navigation, flood control, irrigation, city water services, and conservation of resources.

To increase the load factor of thermal power stations, it is necessary to provide peak power by other means. For this purpose pumped-storage facilities are useful.

Hydroelectric site selection. The possibilities of hydroelectric development depend on weather conditions and geographical features. Mountainous regions subject to heavy rainfall close to industrial regions are most favourable for hydroelectric development.

Water may be collected and stored at a high elevation and led through tunnels or pipelines to a station at a much lower elevation, or dams may be erected across a river to raise the level of the water. The power developable by a volume of water is directly proportional to the working head, so that a high-head installation requires a smaller volume of water than a low-head installation to produce an equal amount of power.

Head types

The distinction between high head, medium head, and low head is not clearcut, but generally heads from 20 to 100 feet (six to 30 metres) are referred to as low head; from 100 to 660 feet (30 to 200 metres) as medium head; and those over 660 feet as high head.

Low-head plants are usually associated with dams and high-head plants with penstocks, conduits for carrying water downstream from a considerable height. Between are medium-head plants that may use either scheme. Pipelines and turbines for high-head plants are smaller and the installation in general is cheaper. The volume of water that must be stored during wet weather to allow continuous operation throughout the year is also smaller.

High-head sites offer many advantages, but they are not essential for the successful development of hydroelectric energy. Most of the world's waterpower sites that are reasonably close to industrial communities are in regions in which the stream gradients are medium. The total power developed from medium- and low-head plants is far greater than that from high-head plants.

Water flow in the river is always changing; the ratio between the flow at floodtime and the dry weather flow usually lies between 10 and 100. A hydroelectric plant the capacity of which is only equal to the dry weather flow can provide a continuous output year round, but its capacity is very small, and most of the river flow is wasted. It is usually more sound economically to install a hydro plant of a capacity two or three times greater than that corresponding to the dry weather flow and add a steam plant capable of maintaining the output when the water supply is inadequate.

Hydroturbines. There are five types of turbines for hydroelectric station use: Pelton wheel for high-head use; Francis turbine for medium-head use; Deriaz turbine for medium- and low-head use; and Kaplan and propeller turbines for low-head use (see also TURBINE). Selection of the appropriate type depends largely on the available head. In general, Kaplan turbines are used for heads up to 100 feet (30 metres), Francis turbines for heads from 70 to 1,000 feet (21–300 metres), and Pelton wheels for heads between 300 and 3,000 feet (90–900 metres). In the overlapping ranges, the choice depends upon the size of the installation and other considerations.

Hydroturbines are divided into two classes: impulse (in which the turbine blades reverse the direction of the fluid flow) and reaction (in which the blades travel at about the same velocity as the fluid flow). Pelton wheels are impulse turbines, and the other four types are reaction turbines. Francis and Deriaz turbines are of the mixed flow

type with inward radial flow and axial discharge; the former have runners (rotating parts of the turbine) with fixed blades, the latter with adjustable blades. Propeller and Kaplan turbines are of the axial flow type; the former have runners with fixed blades, the latter with adjustable blades.

The design of a waterwheel for any conditions of head and output is based on an empirical value known as the specific speed. Under conditions of the same output and same head, Kaplan and propeller turbines have the highest speed, Francis and Deriaz turbines are next, and Pelton wheels have the lowest speed.

Turbine efficiencies

The efficiencies of hydroturbines at full load are high and run between 90 and 94 percent for all types; but under part load, efficiencies vary considerably. At one-quarter load, for example, efficiencies of Francis and propeller turbines, with fixed blades, fall within 60 to 70 percent, whereas those of Kaplan and Deriaz turbines, with movable blades, and of Pelton wheels range from 80 to 85 percent.

In case of a fault in the electric power system (*i.e.*, transmission line), the load on a hydroelectric generator may drop suddenly from full load to no load. Because the gate controlling the water flow to the turbine is wide open, a large quantity of water is admitted, and when the load is removed the turbine speed rises until the gate is closed. The runaway speed, the maximum speed that the unit would attain under these conditions, is about two times normal for Francis turbines and three times normal for Kaplan turbines. It is controllable to some extent, however, and the rotors of the generator are usually designed to withstand 180 to 200 percent of normal speed regardless of the types of hydroturbines employed.

The Pelton wheel is a slower-running machine than the reaction turbine and is better suited for very high heads. In addition, because the water is discharged through its one, or at most two, nozzles, these may be of reasonable size when handling the small water volumes normally available in high-head plants.

Pelton wheels, most of which have a horizontal shaft and one or two nozzles, are built in sizes up to 40,000 kilowatts. Speed usually is controlled by a deflector that rapidly cuts off the water jet from the wheel, acting with a central needle in the nozzle that slowly reduces the flow through the nozzle while the deflector returns to its normal position.

The reaction turbine with its full peripheral admission of water is well adapted to using the large water volume necessary in low-head plants. Its higher speed of rotation enables the cost of the electrical generators to be reduced.

Francis turbines are the most extensively used, because of the very wide range for which they are suited, from the lowest economically usable head to high head. They can have either horizontal or vertical shafts, the latter for machines of larger capacity. Very large Francis turbines have been installed with outputs exceeding 200,000 horsepower from a single runner, and outputs of 500,000 horsepower were under construction in the 1970s.

Deriaz turbines, with movable blades, provide improved part-load efficiency for medium-head machines. This design has proved very useful for pumped storage applications, in which significant variations in head and flow for turbine and pump operations exist.

A fixed-blade propeller turbine has higher specific speed and so saves in plant cost compared with the Francis turbine. The low efficiency of the propeller turbine at part-load operation can be compensated for in a multi-unit station by changing the number of operating units as the load fluctuates.

The Kaplan turbine, with adjustable blades, has overcome the deficiencies of the propeller turbine and is very useful for wide flow changes and large head variation.

Turbine generators. Electric generators used with water turbines are of two types: the two-bearing design, in which the thrust bearing and one guide bearing are located above the rotor, with the second guide bearing below the rotor; and the umbrella design, in which a single combination thrust and guide bearing is located below the rotor. The umbrella design has many advantages over the two-bearing design, including reduced cost because the second bearing is eliminated, and less head room is required under the crane for dismantling.

Umbrella generator design

All modern large- and medium-capacity waterwheel generators are installed with a totally enclosed recirculating ventilation system that gives longer insulation life because of absence of dirt, reduced noise level, and lower powerhouse temperature. In small sizes, simple open-type machines are often used.

Of the two common types of ac generators, the synchronous (fixed field, constant speed) and the induction (rotating magnetic field) types (see ELECTRIC MOTOR), the former is used exclusively in many systems and predominates in all systems. The induction type is more rugged, however, and requires fewer controls and no direct current for excitation. Thus the induction generator is sometimes used in remote-controlled and automatic stations.

Automatic stations. The automatic generating station is especially suited to systems in which many small power stations are used. In such circumstances the operating staff expense at each station would be prohibitive, but making each station automatic and linking all into a common distributing system makes the operation economic.

The waterwheel of such an installation has no governor, the gates being preset at some opening corresponding to the desired output of the generator. Suitable control circuits shut down the station in case of overload, overspeed, or any other kind of trouble. Normally the starting and stopping of each generator set is accomplished automatically by the response of float switches actuated by the change in the level of water above the dam. In remote-controlled stations, provisions are made for controlling these operations, as well as the gate openings of the individual turbines, from the central station.

In small stations, induction generators are sometimes used because of their simplicity. They require no exciter, no voltage regulator, and no synchronizing equipment. The disadvantage is that they take their excitation from the system in the form of reactive current, thus lowering the system power factor. They are usually small in number, however, and their advantages often outweigh this disadvantage.

Pumped storage plants. In ordinary hydroelectric power stations, hydraulic turbines and electric generators are the main mechanisms, whereas in pumped storage plants there are also hydraulic pumps and electric motors that drive the pumps.

In such plants, at times of maximum river flow or during off-peak periods, water is pumped into a storage reservoir on a neighbouring height, or simply back from a lower pool (tailrace) into the headwater pool; and at times of low river flow or during peak power periods, this water is used to generate electricity. The storage may be for lengthy periods to offset seasonal shortages or for short periods to compensate for daily peaks.

The world's first pumped storage plant, the Lettern plant near Zürich, Switzerland, began operation in 1892. The station at Vivarone, Italy, in 1912 was the first pumped storage plant to adopt the combined motor-generator system (using the same electrical machine both as a generator and as a motor). These plants are for seasonal regulation.

Later, in order to use effectively the reserve of thermal power generation during the late evening and early morning hours, and to cope with the changing electric load, pumped storage plants for daily or weekly regulation were constructed.

Pump-turbine units

In 1931 the pump turbines emerged, combining the functions of pump and turbine; in such pumped hydro plants as Lago Baltone (Francis turbine), Italy, and Baldeney (Kaplan turbine), West Germany, they were adopted for the first time. Later, in the United States, large-capacity Francis-type pump turbines with high efficiency both as pumps and as turbines were developed and have been widely used.

In a pumped storage plant, the generation of two kilo-

watt-hours of electric energy requires about three kilowatt-hours of off-peak energy because of losses from pumping, power generation, and transmission to and from the load centre. Despite the inefficiency in pure energy terms, however, such facilities are of great practical efficiency because they allow the use of otherwise wasted off-peak power.

III. Transmission

TYPES OF TRANSMISSION SYSTEMS

Direct current systems. The first electric systems operated on two-wire dc. In 1883 a three-wire dc system was introduced and thereafter commonly adopted. The three-wire system has an economical advantage over the two-wire system, as three conductors in the former system can carry the load equivalent of two circuits of the latter—that is, of four conductors. Its inherent disadvantages, however, led very early to replacement by the more flexible ac system. The only exception was the Thury system in France, which provided high-voltage direct current by connecting a number of direct-current machines in series at the sending and receiving ends. Several generators were placed in series to provide 57,000 volts dc for a 112-mile (180-kilometre) line from Montiers to Lyon, which was constructed in 1905. This line remained in service until 1937.

Because of its inherent simplicity and economy, dc transmission made a comeback, as has been seen, when mercury-arc rectifiers became available to convert the direct current into alternating current (necessary because of the number of individual consumer devices requiring the ac form of power to operate). In 1937 the General Electric Company in the United States operated an experimental dc line in western Massachusetts at 27,000 volts, using mercury-vapour converter tubes. In 1939 Brown Boveri Company operated an experimental dc line at the exposition in Zürich, Switzerland, using mercury-arc rectifiers; this experiment served as the prototype of later dc transmission systems.

During World War II, the Germans constructed an experimental dc transmission line from the Elbe power station to Berlin, using a voltage of ± 200 kilovolts (400 kilovolts between terminals), and transmitting 60 megawatts of power. Operation was discontinued at the end of the war.

After the war, dc transmission was actively studied in Sweden for transmitting large blocks of power from north to south. In 1954 the world's first dc transmission line, between the Swedish mainland and Gotland, began operation, using a submarine cable about 60 miles (100 kilometres) long. The power transmitted was 20,000 kilowatts at 100 kilovolts. The excellent performance record of this scheme demonstrated the feasibility of the new mercury-vapour tubes for high-voltage rectification (ac to dc) and inversion (dc to ac).

In 1961 a second underwater dc transmission project was placed in service between England and France, transmitting 160 megawatts at ±100 kilovolts. Other dc projects using underwater cables soon followed, including the Konti-Skån (between Sweden and Denmark); the Sardinia–Italy; the New Zealand (between the South and North islands); and the Vancouver Island project of Canada, all of which were in operation in the early 1970s. Projects using underground cables and dc transmission, all in operation in the early 1970s, included the Kashira–Moscow line, in the Soviet Union, and the Kingsworth–London line, in the United Kingdom. Overhead dc transmission lines are used on the Volgograd–Donbass line, in the Soviet Union, and the Pacific Intertie, in the United States.

Relative costs of ac and dc

Insulation requirements for a nominal voltage are less with dc than with ac, and only two conductors are needed per dc circuit as compared with three for ac. The consequent saving in materials accounts for the cost of a dc line being about two-thirds that of an ac line with comparable capacity. The terminal facilities, however, for converting between ac and dc are a major cost. While high-voltage ac transmission requires transformers at each terminal, dc requires similar transformation plus a reactive power supply, converters, and related controls. The savings in dc line cost and lower transmission losses must offset the additional cost of the terminals to make dc transmission as economical as ac. As a result, overhead dc lines must be several hundred miles long to obtain an economic advantage.

An insulated cable has the characteristic of storing electrical energy, because of the high electrical capacity or capacitance between the conductor and ground or between the conductor and the conduit in which it is placed. The current magnitude required to charge this capacitance is very nearly proportional to the length of the cable. With ac, the full current-carrying capacity of the cable may be required merely to charge the insulation, especially if the cable is fairly long. This requirement imposes a limitation on the length of underground and underwater circuits when ac is employed. In contrast, a dc circuit maintains an essentially constant voltage and thus needs no charging current in the normal operation so that no similar distance limitation applies. In addition, the insulation can be subjected to much higher voltage when used for dc. For these reasons, a given cable can carry two to ten times as much dc power as ac. Therefore, for underground or submarine cable lengths of 25 miles (40 kilometres) or more, dc transmission is more economical than ac.

Alternating-current systems. An ac circuit has three characteristic properties: resistance, inductance, and capacitance. Strictly speaking, conductance (leakage over the insulators, corona discharge) must also be taken into consideration, but this property can often be ignored in well-designed lines. In a transmission system the three main circuit properties are distributed along the line. A detailed discussion of how these properties are taken into consideration in studying the characteristics of an ac circuit is included in the article ELECTRICITY.

For long transmission lines, or in systems in which high accuracy is desired in short lines, special equations have been developed to determine the voltage and current at any point on the line and thus determine system characteristics. For shorter lines, system characteristics can be calculated by approximation. At frequencies of 50 to 60 hertz, up to a maximum distance of 100 miles (160 kilometres) for overhead lines and 15 miles (24 kilometres) for underground, a line with distributed line constants can be treated as a line with concentrated or lumped constants.

The capacitance per unit length in underground cables is about 30 to 100 times greater than that in overhead lines. As pointed out above, this characteristic means that the charging current in underground cables 20 miles (32 kilometres) long may be as high as that in 1,000 miles (1,600 kilometres) of overhead transmission lines. As a result, the current-carrying capacity of cable lines may be reduced by this current, and losses in the transmission of energy may be substantial. When dc is used, however, the high line capacitance has no effect on the power transmission, so long as the steady conditions are maintained.

In interconnected systems involving many transmission lines and generating stations, it is very difficult and time consuming to calculate electrical characteristics (line current, power flow) on the basis of the special equations mentioned above. To speed up these calculations, network analyzers were developed in the 1930s and are extensively used. Power system models are set up on these analyzers, and by applying voltages at points corresponding to generating stations, the current, voltage, and power at any desired point in the system can be readily determined.

Use of digital computers

Since World War II, digital computers have largely replaced network analyzers, permitting solution of system problems with higher precision and with more flexible system arrangements.

Three-phase systems. A single-phase transmission line consists simply of two conductors. Three conductors make possible a three-phase transmission line, in which the voltages and currents in the three wires are out of step by one-third cycle, or 120° in electrical degrees. Such a

system can transmit as much power as three separate single-phase systems with six conductors.

Generators and motors are also built as three-phase units. The constant flow of power, an attribute of three-phase systems, makes them operate much more smoothly and efficiently than they would if the flow of energy were pulsating, as in a single-phase circuit. Also, magnetic interaction between the phases, or windings, of a three-phase motor makes it inherently self-starting (see ELECTRIC MOTOR).

There are two representative connection schemes in the three-phase system. One is the Y, or star, connection, and the other the delta (Δ) connection. In the Y-connected arrangement (see Figure 3, top), the common connection is the neutral. In the balanced three-phase system, the current in the common conductor (or neutral conductor) is always zero, and that conductor can be eliminated entirely. In actual practice, the balance is not always perfect, and some provision must be made for current in the neutral conductor. If the current likely to be encountered is small, the neutral may be connected to earth (grounded), and this small current may be permitted to flow into the earth. In many three-phase distribution systems, especially in the United States, Y connection with a separate neutral conductor is often used. In the delta-connected three-phase system (see Figure 3, bottom), the fault current to ground in case of a single-phase fault is limited to a smaller value determined by the capacitance of the system. This property in turn makes the voltages of the unfaulted phases higher than in the Y-connected system. The delta-connected system is used mostly in distribution lines and in low-voltage transmission lines. A similar arrangement to the three-phase circuit can be established with four phases or even more, the phase differences between successive voltages being equal to one-fourth of a cycle if there are four circuits, and so on. The three-phase system, however, is the most efficient and is almost universally used to the exclusion of all others.

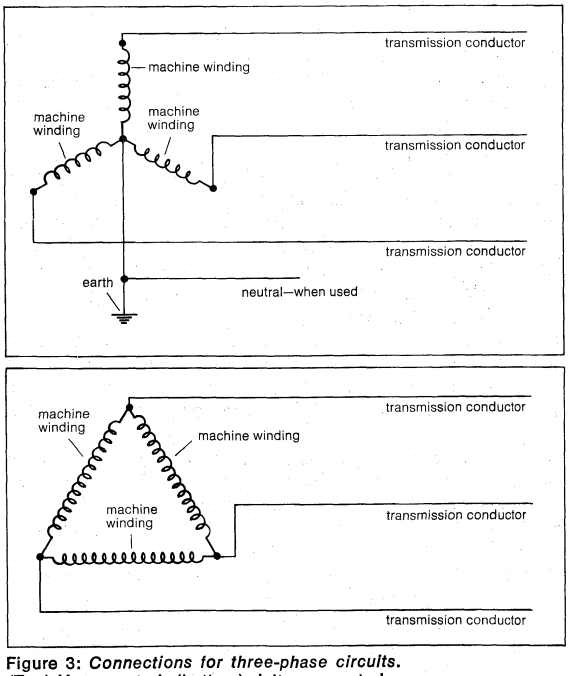

Figure 3: *Connections for three-phase circuits.* (Top) Y-connected; (bottom) delta-connected.

TRANSMISSION LINE DESIGN AND CONSTRUCTION

After a power-plant site has been selected, surveys are made to determine the best routes for the transmission lines. Before construction, studies determine the voltage, conductor spacing, number and type of insulators, conductor size and material, pole or tower design, and the protective features to guard the line against damage from lightning or other hazards. On large systems it is necessary to check normal and abnormal operating conditions, and extensive studies on network analyzers are often necessary.

Digital computers have been used to optimize transmission line design because of the complex relationships between the electrical and mechanical characteristics of transmission lines and their effect on economical design. Because nearly 200 separate items of design, material, and labour cost are used, digital computers can effect large savings in the construction of long-distance extra-high-voltage transmission lines. Several different types of conductor arrangement and supporting tower structures are sketched in Figure 4.

From *McGraw-Hill Encyclopedia of Science and Technology*, 3rd ed. (1971); used with permission of McGraw-Hill Book Co.

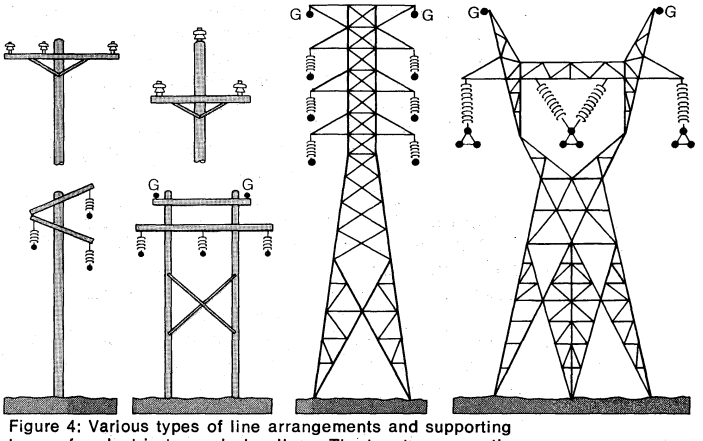

Figure 4: Various types of line arrangements and supporting towers for electric transmission lines. The two towers on the right are steel structures; the others are made of wood poles. G indicates a ground or neutral conductor (see text).

Choice of transmission voltage. The choice of transmission voltage depends on the amount of power to be transmitted, and on the transmission distance.

Effects of higher voltage

For a given amount of transmitted power, adoption of higher voltage reduces the line current, leading to smaller cross-section line conductors and reduced cost. Other items, such as insulator cost, rise because of the adoption of higher voltages, but, generally speaking, transmission line cost decreases with an increase in transmission voltage. In the substations, however, transformers, circuit breakers, and other components rise in cost with an increase in transmission voltage. The substation is the point at which the high voltage from the transmission line is reduced in voltage and redistributed over intermediate transmission lines. The transmission voltage is thus determined by the balance of the gain in transmission lines and the loss in the substations. In long-distance transmission lines, therefore, adoption of higher voltage is justified.

In the early 1970s, 100, 140, 220, 275, 380, 500, and 735 kilovolts were standard transmission voltages, and transmission at 1,000 kilovolts and more was under study.

Conductors. Materials generally used for transmission line conductors are hard-drawn copper and aluminum. A composite conductor called ACSR (aluminum conductor, steel reinforced) consists of aluminum wound around a steel core that provides strength.

Among many requirements for conductor materials, the following are important: (1) high electrical conductivity, (2) high mechanical strength, (3) low specific gravity (weight per unit volume compared with water), (4) low corrosion in air, and (5) ease of jointing.

If the electrical conductivity of soft-drawn copper is taken as 100 percent, that of hard-drawn copper is 97 percent and that of aluminum is nearly 60 percent. In ACSR are combined the high mechanical strength of steel and the relatively high electrical conductivity of aluminum.

The required cross-sectional area of a conductor is determined by the current flowing through it. Losses from the resistance of the transmission line (ohmic losses) can be calculated as the product of the resistance of the line

and the square of the line current. The resistance of the line is inversely proportional to its cross-sectional area.

The transmission line conductor is heated by the ohmic losses, and this heat is dissipated into the air, bringing the conductor to its equilibrium temperature. At high temperatures the mechanical strength of the conductor is reduced, and so its equilibrium temperature must not exceed a certain critical level, generally around 212° F (100° C); to allow a margin of safety the design is usually for about 194° F (90° C). The current required to produce this temperature is the upper limit of line current, called the current-carrying capacity of the conductor. Aluminum alloys with high mechanical strength at relatively high temperature have been developed, making possible a conductor with a higher current-carrying capacity than ordinary aluminum.

Corona and radio interference. As has been seen, if the voltage between conductors in a transmission line exceeds a critical value, a hissing sound comes from and a glow appears around the conductor, a phenomenon known as corona. The critical voltage depends upon the diameter of the conductor, the roughness of its surface, its distance from other conductors, and atmospheric conditions. Corona is caused by intermittent ionization of the air surrounding the conductor, producing high-frequency waves and causing energy loss as well as interference in nearby radio and television receivers. The only practical way to minimize corona is to increase conductor diameter. At sea level, for example, a minimum conductor diameter of about one inch (25 millimetres) is necessary for a 230-kilovolt line, about 1.5 inches (38 millimetres) for 330 kilovolts, and about 2.5 inches (63 millimetres) for 500 kilovolts. Sizes must be increased at higher altitudes, insulation strength of the atmosphere decreasing there.

Aluminum has become preferred for extra-high-voltage transmission line conductors, despite its conductivity being lower than that of copper. The poorer conductivity of the aluminum actually works to its advantage, because a larger diameter (especially with its internal steel core) is required for high voltage.

At 500-kilovolt transmission, the conductors must be 2.5 inches or more in diameter to avoid corona. Such conductors weigh nearly 4 pounds per foot (6 kilograms per metre) and are thus difficult to manufacture, ship, and install. A scheme to alleviate these difficulties and provide other benefits, known as bundling, consists of installing two or more cables (called subconductors) of much smaller diameter spaced one foot (30 centimetres) or more apart, in place of a single large conductor. The electrical stress on the air is reduced to the equivalent of the single large-diameter conductor. This arrangement, known as a bundle conductor, decreases line impedance and increases electrical load capability by 25 percent or more. In Figure 4, the right-hand tower uses bundle conductors, each bundle consisting of three conductors.

Advantages of bundling

A quadruple conductor scheme for 400-kilovolt transmission was studied by the Germans during World War II, but installation of a double conductor occurred first on the 380-kilovolt Harsprånget transmission line in Sweden, in 1952. Since then nearly all transmission lines with voltages ranging from 300 to 735 kilovolts have used the bundle conductor, and future 1,000-kilovolt transmission systems will undoubtedly adopt it also.

Insulators. For overhead transmission lines the conductors are always bare metal. High-voltage conductors are suspended from the poles or towers by strings of insulators, each consisting of several disks of porcelain or glass. As voltages increase, it is merely necessary to add more units to the string. At lower voltages, an insulator of porcelain or glass (a pin-type insulator) suffices.

Insulators must be strong enough to support the weight of conductors and to resist the forces of wind and ice. A type of design in widespread use in the EHV transmission lines is the V string support, using two insulators at an angle of nearly 90° (Figure 4 right). While this design requires additional insulators, the conductor is restrained from swinging in a crosswind, so that reduction in the required size of the tower structure and the width of right-of-way result, which may result in larger savings than the additional insulator cost.

Insulators must withstand not only the normal operating voltages but wherever possible abnormal voltages of short duration caused by lightning or by the operation of circuit breakers. Insulating properties are degraded by dirt and moisture, but the minimum insulation value must prevent electrical breakdowns for normal voltages, even during unfavourable weather. Severe deterioration occurs when salt is deposited on the insulators, and thus the number of disks in each insulator must be increased when the transmission line is installed near a sea coast.

Fortunately insulator failure nearly always occurs as an electric arc discharge through the air around the insulator or over its surface rather than by puncture of the insulator itself. If the line is disconnected from service rapidly by circuit breakers when an electrical fault occurs, the insulator may suffer little permanent damage and the line frequently may be restored to service immediately.

The insulation between conductors on overhead lines consists solely of the air between them; spacing must be adequate to prevent the conductors from coming in contact or from coming so close that a flashover occurs between them.

Towers and poles. Supporting structures for transmission lines are steel towers or poles of steel, concrete, or wood. Steel towers are generally used with voltages of 100 kilovolts or more, but wooden poles may be used up to 220 kilovolts if climate and other local conditions are favourable. Several tower designs are shown in Figure 4.

Effect of climate on tower design

Climatic differences require design variations in transmission towers. In some regions, lines must resist hurricanes or typhoons, while in others they must withstand snow and ice storms. The severity of lightning differs widely from area to area. The topography that a line traverses may vary from open plains to forested mountains. Construction requirements and maintenance, particularly where access is difficult or corrosion is a problem, are important factors in the selection of tower material and design. Conductor configurations at the tower are horizontal, vertical, and sometimes triangular.

A single-circuit transmission tower carries three conductors, a double-circuit tower six (see Figure 4). In large city suburbs, where acquisition of right-of-way for transmission lines is difficult, there may be three-circuit and four-circuit towers.

Spacing between towers is determined mainly by a compromise between two factors. If the span is made larger, the total number of towers needed is smaller, apparently leading to lower construction costs. With increased spacing, however, the sag of the conductors between towers becomes larger. The conductor height above ground is always limited by national regulations, and so to minimize the effects of sag the height of the towers must be increased, leading to a weight and cost increase. Span length is compromised between these two factors. Standard spans widely adopted are: for steel tower lines, between 150 and 300 metres (500 and 1,000 feet); for steel pole lines, between 100 and 150 metres; for wooden pole lines, between 50 and 100 metres. Where highways, rivers, or telephone lines are crossed, special long spans are often necessary.

The major requirement in designing transmission towers is mechanical strength. Besides the weight of the conductors, allowance must be made for wind pressure and, in snowy regions, the weight of snow and ice on the lines. When ice and snow fall off, the line jumps and may contact other conductors, creating a short circuit. To avoid this, consideration is given to the conductor configurations at the towers. Sometimes a large current is circulated through the conductor for ice-melting.

Growing popular awareness of the aesthetics of man-made structures has led to a widespread adoption of high-strength steel alloys to make towers less bulky and of painted towers that blend into the terrain. Existing facilities are being used more intensively to avoid problems in the acquisition of new rights-of-way, such as rebuilding lines to operate at higher voltages and substituting multi-circuit structures for single circuits. Fundamental-

ly, however, low-cost underground transmission lines appear to be the real answer; research and development work in the early 1970s was in progress in several countries.

Lightning protection. Transmission lines are susceptible to lightning, and a direct stroke may produce a serious short circuit unless special protection is provided. Statistical data on lightning in many areas of the world are available, and the number of lightning faults that will probably occur during a year can be forecast. A moderately high level of insulation is provided to prevent insulation failure against all except the more severe lightning strokes, and in especially dangerous locations added protective measures are used. Insulating transmission conductors at each pole or tower against an electrical breakdown that might result from a severe stroke of lightning, however, is usually uneconomical.

Circuit breakers. When insulation failure or other accident occurs on a transmission line, the line must be disconnected quickly from the unaffected portion of the system. Switches for this purpose, called circuit breakers, operate to close and open circuits under load when conditions are normal and to interrupt circuits during abnormal conditions.

The speed factor in circuit breakers

As systems became extended and the problem of system stability became better understood, it was recognized that speed in opening a faulty circuit was a major factor in increasing system stability. Design efforts therefore have been made to shorten the interruption time. In 1926 the interruption time was reduced from 45 cycles to 25 cycles, in 1932 to eight cycles, in 1954 to three cycles. In the 1960s two-cycle circuit breakers were available, and one-cycle breakers were under development in the early 1970s in Japan. Circuit breakers in turn are controlled by precise protective relays that locate failures and cause only the needed circuit breakers to operate. The relays can function in as short a time as one cycle, and thus a section of a transmission line having a failure can be isolated in less than four cycles, or $\frac{1}{15}$ of a second.

Three types of high-voltage circuit breakers are in common use: oil-filled, air-blast, and gas (sulfur hexafluoride)-blast circuit breakers. Because the current cannot be interrupted instantaneously, an electric arc is drawn between the two contact points of the circuit breaker as they separate. In the oil-filled breaker a small amount of the surrounding oil is vaporized, producing a high pressure that drives quantities of unvaporized oil into the path of the arc. Moving electrons, the main elements of the electric current in the arc, become attached to the vaporized oil particles, and their mobility is so restricted that the arc is extinguished. In the air- or gas-blast breaker, the arc is quenched by the force of an air or gas jet.

For a given set of system conditions, the current resulting from a fault can be determined fairly accurately, but the difficulty lies in forecasting future circuit and generating-station changes that, during the expected life of the breaker, materially change the duty (rupturing capacity) it is expected to perform. One method frequently used to keep down breaker investment is to move breakers, as the system grows, from the heavier duty locations to the fringes, where the interrupting requirements are lighter.

Protective relays. Protective relays are usually a complicated assortment of devices used to protect power systems against outages. The original purpose of relays was to protect apparatus, a purpose now secondary to maintaining continuity of service. Relays must be set for short-circuit protection and not for overload; overload protection is the responsibility of the station operators (see below).

Relays receive operating energy from current and from potential transformers connected to the circuit to be protected. The potential transformer reduces the system voltage to 120 volts, and the current transformer reduces the normal maximum line current to five amperes, two values for which relays can be readily built.

Overcurrent relays. The simplest and oldest relay is the ordinary overcurrent relay, still the principal functional unit of protection schemes. The overcurrent relay operates when excessive current passes through the system and normally has a tripping time inversely proportional to the magnitude of the fault current.

Differential relays. For removing faulty generators or transformers from the circuit, differential relays are universally used. The protective schemes are based on the principle of balancing the secondary currents in the current transformers at the equipment terminals so that under normal conditions, or during external faults (that is, faults that are outside the protected zone), a balanced current circulates in the transformer secondaries. A protective relay connected in parallel with this balanced circuit receives current only when a fault occurs in the equipment or inside the protected zone of the transmission line.

Directional relays. For situations in which the current can flow to a fault from two directions, the overcurrent relay must be given a sense of direction if the loss of circuits is to be restricted to the faulty section, a characteristic provided by equipping the relay with an element responsive to the direction of the power flow.

Distance relays. Most power systems incorporate extensive transmission networks with several sources of power. The relaying of such systems with simple overcurrent and directional relays, even where possible, would involve keeping a fault on a line for long periods. Faulted sections of transmission lines must be switched out in the shortest possible time. Relatively complicated and costly relay schemes have therefore been developed. Distance relays measure either the impedance or the reactance of the circuit between the relay and the point of fault as a measure of distance. The greater the distance to a fault, the longer it takes the relay to disconnect (trip) the circuit, the tripping time being proportional to the distance to the fault.

Application of relays. Relays act to open appropriate circuit breakers on either side of the faulty machine or line section by energizing the coils that trip (open) the circuit breakers. Relays have three broad classes: those that protect against individual machine and transformer faults; those that protect against faults in buses (uninsulated bars or rods for interconnecting equipment in generating stations or substations); and those that protect against transmission circuit faults. Differential relays can be used to protect against bus faults by balancing all the incoming currents against all the outgoing currents. If there is a fault in the protected zone, the incoming and outgoing currents will not be equal, and the differential relay will operate.

Protection against transmission line faults is obtained mostly by using distance relays, which have, however, the disadvantage that they cannot be designed to cover the whole section to be protected, because the relay is not accurate enough to allow precise location of a fault just inside or just outside the protected section. Some 10 to 20 percent of the length of the section at either end, therefore, does not have the benefit of high-speed protection. This problem has been solved by superposing a carrier current signalling system on the distance relay. The carrier signal is used to block the tripping of distance relays in the unfaulted sections. Microwave relaying has also been used.

Electronic relays. All the relays mentioned above are called electromagnetic relays, because the operating principle of these relays is based on electromagnetic induction. Electronic relays, which came into use in the late 1960s, have the advantages compared with the electromagnetic relay of faster operation (there are no moving parts and contacts), smaller volume, and less power needed for operation.

Underground cables. Underground cables were used for street lighting when Thomas A. Edison began the operation of dc distribution systems in New York City in the 1880s. The structure of the cable was simple: a copper conductor was wrapped with jute and placed in an iron tube, called the Edison tube. Later, in 1884, use of overhead lines was prohibited in New York City, thus leading to further development of underground cables.

Early dc cables

Still later, ac transmission was introduced, voltages became higher and higher, and new methods for insulating the cables were introduced.

In 1917 Luigi Emanueli, an Italian engineer, established the fundamental principle of oil-filled cables, and in 1922 M. Höchstädter developed modern-type cables. Cables operating at 220 kilovolts were laid in Milan in 1932 and in Paris in 1936. In 1965, 345 kilovolt cables were laid in New York City, and these are the highest voltage underground cables in the world. Cables operating at 380 kilovolts are used at hydroelectric stations, such as Harsprånget, Sweden, but the cable length is quite limited. Cables of 500 kilovolts were under development and extensive testing was under way in the early 1970s, mostly in the United States.

The cable most commonly used because of low dielectric losses and cost is the paper-insulated, oil-impregnated type. Single conductor cables are built up by winding layers of paper tape on a stranded conductor and impregnating them with oil. A tight-fitting extruded lead sheath is applied over all. Three-conductor cables may consist of three round conductors, each insulated with paper, with a jute filler to round out the cable. Around all this is more paper insulation, and a lead sheath over the whole. These cables may be either belted or shielded. In the belted cable, the conductors are insulated with paper, cabled together with a filler piece, and wrapped with more layers of impregnated paper (the so-called belt) before the lead sheath is applied. In the shielded cable, a thin metallic shielding tape is wrapped around the individual conductor insulation to control electrostatic stress, eliminate corona formation, and improve thermal conductivity. In general, single-conductor, paper-insulated cable is used up to 69 kilovolts and three-conductor cable (shielded) up to 46 kilovolts. When the voltage exceeds 69 kilovolts, special designs become necessary.

Besides paper, cable insulation may consist of rubber, varnished cambric, or synthetic compounds. Experience has shown that increasing the thickness of the paper insulation is no guarantee of improved performance. One of the earliest ways of producing better cables, and one still popular, is the use of the Pirelli oil-filled, paper-insulated cable, in which the conductor strands are wound around an open helical spring to form a hollow conductor. Oil under pressure is kept on the cable by means of reservoirs so that no voids can form in the insulation. The oil is relatively thin and remains fluid at all temperatures. This type of cable has been in service in Paris since 1936 at 220 kilovolts.

Another widely used cable for high-voltage service is the Bennet pipe-type cable, consisting of three single-conductor paper-insulated cables laid in a steel pipe six to nine inches (15 to 23 centimetres) in diameter. The pipe is kept filled with oil at a pressure of 200 pounds per square inch (14 kilograms per square centimetre). Nitrogen gas is sometimes used instead of oil.

A third type is the compression cable, like the Bennet except that the three cables retain their sheaths (lead or polyethylene), and pressure is exerted on the sheaths. This external pressure on the noncircular sheath acts on the paper insulation to prevent the formation of voids. An advantage of this type of cable is that threading it into the pipe does not require such meticulous care as with other types.

Economic and aesthetic factors

Because the cost of underground cables is much higher than that of overhead transmission lines, it is not generally economical to place cables underground except in very high load density areas. Elsewhere, however, utilities are often required to place transmission circuits underground for aesthetic reasons. The ratio of construction cost between underground cable lines and overhead lines becomes steadily higher with the increase in the transmission voltages: four to six times at 69 kilovolts and eight to 15 times at 220 kilovolts and upward.

Obtaining rights-of-way for overhead lines in heavily populated areas is becoming increasingly difficult, making it urgent that the utilities develop techniques for economical underground transmission. Several new techniques were under study in the 1970s, including the increase in rating of underground cables simply by forced cooling. Another was the use of sulfur hexafluoride gas instead of oil-impregnated paper; these are gas-insulated pipe-type cables, having very small capacitance.

Cryogenic (low-temperature) cables were also being actively investigated in the 1970s. When certain metals are cooled sufficiently, they become superconducting; that is, the resistance of the conductor becomes virtually zero. Possibly as much as 10,000 megawatts of power can be transmitted over a single circuit of superconducting cable (see also CRYOGENICS, APPLICATIONS OF). As mentioned above, dc transmission is being actively investigated as a technique for transmitting large blocks of power.

IV. Distribution

VOLTAGE CONSIDERATIONS

In early systems, only one step of voltage transformation occurred at each end of a transmission line; but as systems grew, it became necessary to use two or more steps of voltage reduction at the receiving end. The high voltage needed for long-distance transmission was too high for lines on city streets, and yet the secondary voltage was too low for supplying electric energy to consumers over a wide area. Intermediate voltages were therefore introduced into the system via distribution circuits. In many systems one intermediate level is insufficient, and two or more levels are used.

Intermediate voltage

As systems were interconnected, the transmission circuits of the original system often became the distribution circuits of the combined system, so that the distinction between distribution and transmission became vague. Transmission, however, in general implies larger blocks of power delivered at higher voltage to a few main substations, while distribution implies smaller blocks of power delivered at lower voltages to many smaller substations or directly to consumers.

Levels. Three voltage levels are normally involved in the distribution system: (1) subtransmission voltage, used in connecting the supply point on the transmission network to the distribution substations; (2) primary distribution voltage, used on feeder lines from the distribution substations to the line transformers; and (3) utilization voltage, or secondary distribution voltage, for lines from the neighbourhood transformer to the customer. Subtransmission circuit voltage varies roughly from 20 to 70 kilovolts, that of primary distribution circuits from three to 20 kilovolts, and that of secondary distribution circuits from 100 to 500 volts.

The voltage for residential services in the United States is uniformly 120 volts, and in Europe it is mostly 200 or 220 volts, a difference that leads to considerable variation in distribution methods.

In the United States the voltage is reduced in a distribution substation to 2,400 to 13,800 volts, and a second reduction is made to utilization voltage (120 volts) by means of a large number of small transformers mounted on poles, or situated in vaults, known as distribution transformers. In Europe the subtransmission or primary distribution voltage is brought into a kiosk, or vault, and reduced to 220 volts, and a relatively large area is covered at 220 volts. Distribution transformer output in the United States ranges generally from five to 100 kilovolt-amperes, whereas in Europe it is generally from 50 to 600 kilovolt-amperes.

The steady increase in load per customer requires constantly higher capacity circuits. To increase capacity, the voltage is usually increased from the initial level to a higher one as the system grows. In the United States primary distribution circuits of 2,300 or 4,600 volts were considered adequate in the early 1950s, but 12,000, 33,000, and even 69,000 volts were standard in many areas by the early 1970s. Commercial and industrial loads are often supplied at the higher voltages, and high-rise buildings usually are supplied through high-voltage circuits of 480 to 12,000 volts; but the single-family residential service has not changed from 120/240 voltages, which are supplied usually from one phase of the three-phase system, 120 volts by a two-wire system and 240 volts by a three-wire system with midpoint grounded.

Use of three-wire service in homes

Most older residences have only a two-wire, 120-volt supply, but the increased use of household appliances has led to the practice of putting three-wire, 240-volt service into practically all new residences. In these installations fractional horsepower motors are supplied from the 120-volt lighting circuits, while cooking stoves, water heaters, and large single-phase motors up to five horsepower are supplied from the outside wires of the three-wire system at 240 volts.

In Europe, 220 volts are supplied from a single-phase two-wire system. In the United States single-phase three-wire system, the voltage above ground in the normal operating condition is limited to 120 volts, whereas in the European system the full 220 volts always appears on the ungrounded wire.

For power use, 240- and 480-volt, delta, three-phase voltage is provided, and for combined light and power use, 120/208-volt, three-phase, four-wire, star (Y) voltage is used in the United States. The latter is the common practice in metropolitan secondary network systems. In Europe, a 220/380-volt three-phase four-wire Y system is commonly used.

Regulation and regulators. Quality service requires maintenance of proper voltage without interruption. Distribution lines are designed to maintain the voltage at the customer's premises within acceptable limits. A single value of voltage cannot be maintained on any given circuit for all locations and hours of the day, because voltage varies depending on both the distance of the service switch from the supply transformer and the load taken, which varies from morning to night.

Voltage is one of the most important factors in the design of equipment, appliances, and devices, and satisfactory performance cannot be attained with wide variations in the supply voltage. Most appliances and devices operate satisfactorily over some range of voltage, so that a reasonable tolerance is permissible. The total range between maximum and minimum voltages on a system during the whole course of its operation is called the voltage spread. The voltage at the customer's premises is generally highest at off-peak periods, usually around midnight, and lowest during peak loads.

The permissible voltage variation, often specified by government regulations, is plus or minus 5 to 6 percent of the standard value in the urban and suburban areas, with $\pm$ 10 percent variation permitted in rural areas.

As system loads grow, it becomes increasingly difficult to keep voltage variations within a tolerable range. Increasing the voltage level of the system, at either the primary or the secondary distribution level, or both, is an effective method of control, as doubling the voltage permits the permissible load to be quadrupled. Doubling the voltage also increases the shock hazard to consumers, but effective countermeasures, particularly in Europe, minimize such risks. A feasible solution might be to supply homes with a higher voltage for large, built-in appliances and provide a separate transformer for 120 volts for conventional lighting and convenience outlets.

Automatic voltage regulation

It would be uneconomical to design a distribution system in which the voltage drop from no load to full load and from first customer to last customer falls within acceptable limits of voltage regulation. Automatic voltage regulation, therefore, is always provided. The three methods used are: bus regulation in the substation; individual feeder regulations in the substation; and regulation along the line by regulators mounted on poles. Bus regulation can be used only when all the feeders leaving a station are of about the same length and have the same character of load, as is generally the case in any given residential area. Such regulators merely raise or lower the voltage in response to the total load on the substation. Where considerable differences exist between individual feeders, either in length or loading, individual feeder regulators are used.

The problem of regulation on rural lines differs from that in urban areas. The lines being long, the voltage is usually higher and the load per mile is small. The regulators are often mounted on poles along the primary feeder line.

Continuity of service. The other problem is that of continuity of service; that is, how to reduce the number and duration of interruptions of supply (outages) and also to reduce the number of customers affected by the interruptions.

Distribution lines, especially overhead lines, are subject to the effects of lightning storms and high winds and also to such accidents as trucks colliding with distribution poles. Areas affected by such accidents are minimized by the design of the system layout, by use of effective protective measures, and by use of mechanized repair groups to restore service as quickly as possible.

The problem of distribution protection is complicated because in case of a fault it is desirable to remove as little as possible of the faulted circuit in order to minimize service interruptions; yet the protection cost must bear some economic relation to the revenue obtainable from the circuit being protected. This condition means that protective schemes involving circuit breakers and protective relays cannot for the most part be justified.

Primary feeders supply power to distribution transformers. The faults that can occur, therefore, are failure of transformers or the feeders themselves. The transformers are connected to the feeder through a fuse known as the primary cutout. If a feeder supplying many transformers is of considerable length, it is undesirable to drop the whole feeder for a fault some distance away. Between the circuit breaker at the substation and the last distribution transformer, therefore, the feeder is sectionalized by reclosing devices at several locations. The operation of all the fuses and reclosers must be so coordinated that only the fuse or recloser nearest the fault on the supply side locks out if the fault is sustained. When the fault is of a transient nature, after one or more reclosing cycles, the total circuit of the primary feeder resumes operation.

The devices available for this type of protection are single-phase reclosing fuses, single-phase sectionalizers, single-phase automatic reclosers, and three-phase automatic reclosers. Their use is economical because the great majority of faults can be cleared through opening the circuit for only a fraction of a second.

Reclosers are essentially circuit breakers with relatively small rupturing ability, equipped with a mechanism to open and then reclose the circuit automatically. They are usually made to operate four times before locking out. Sectionalizers are similar to reclosers except that they have no rupturing capacity, being designed to open the circuit at zero voltage, that is, after the circuit has been opened by a recloser or circuit breaker.

Advantages of the loop system

The layout of distribution circuits also has a close relation to the reliability of service. In general, with a loop system the affected part in case of a sustained fault is far smaller than with a radial system. Duplicate service is seldom available to residences, but it is often provided to such customers as hospitals, municipal services, and major industrial plants, particularly if material being processed may suffer severe loss during even a short power interruption. Two or more circuits and duplicate apparatus are needed in these cases. Because severe short circuits occasionally involve both circuits of a pair designed to reinforce each other, resulting in a total shutdown, duplication of all facilities will not provide complete assurance of continuous supply.

NETWORKS

Network systems. In metropolitan areas, forms of distribution systems known as network systems have been developed. Begun in New York City in 1922, the secondary network system provides that the outputs of the final transformers, instead of feeding only a few customers, will all be connected directly together over a wide area by large conductors to form a network, and all users will be fed from these secondary lines running along each street. The transformers, instead of being small units, are large, up to 500 kilowatts or more, and are frequently fed directly from the generating stations at generator voltage, often 13,800 volts, by underground cables. The transformers are located in underground vaults, usually

under the streets. The electric system of the secondary circuits is 120/208-volt, three-phase, four-wire Y connection.

Network protectors. Special circuit breakers connecting the transformers to the secondary mains open whenever power feeds from the network to the transformer, even in small amounts. This circumstance may occur when the primary circuits are opened at the generating stations and the transformer idling losses are supplied from the network, or when a transformer defect occurs. Otherwise, whenever power can feed from the transformer to the network, the protector closes. Short circuits in the low-voltage network, which rarely occur because it consists of large conductors, well insulated and placed underground, are cleared by melting of the conductors in the region of the short circuit or by melting of reduced sections known as limiters. Because every main is fed by at least two banks of transformers, one at each end, the first melting of the cable does not cause any interruption in service to customers. Special modifications are used in industrial plants and large office buildings, a system that is economical in regions of high load density.

A modification known as the primary network system extends a similar plan to supply the distribution circuits feeding the final distribution transformers in residential areas. These circuits are usually overhead, and fuses or relays and circuit breakers are relied upon to isolate defective circuits. Each distribution circuit is fed from two sources, however, so that a high degree of reliability is achieved with relative economy. This plan is not as widely followed as the secondary network system.

V. Electric power systems

THE ELECTRIC UTILITY

The electric utility is unique in that it sells a product that must be generated at the instant it is to be used. With existing technology, it is impossible to build up an appreciable stockpile of electric power, so that the utility must be ready to generate enough electricity to satisfy the demand at any time. If the utility has excess generating capacity, it can usually cover any anticipated demand; but an overabundance of excess capacity would mean that too much of the plant would be idle too much of the time, thereby increasing cost. At the same time, few products have a greater need for quality and reliability. Reliability is measured both by the number of interruptions to service and by the number of customers affected. The ideal, to reduce the number of interruptions to zero, would mean exorbitantly high levels of investment; as a matter of practical economics, electric power systems are designed to keep interruptions within tolerable limits. Even to meet this goal requires making appropriate investments in plants and using the latest technology.

Quality of service is measured by the degree of attainment of standard voltage and frequency in the supply of electric power. System design and operation determine how close to the standard the voltage and frequency can be maintained.

Private electric utilities can operate only by the grant of a special privilege or franchise from the national or local government that permits use of streets, subsurfaces, and other public property. The franchise is usually granted only to a single concern in any given area, creating a monopoly. In the past, duplication of service to one area was sometimes permitted to increase competition. In such cases, the streets were cluttered with facilities and equipments were duplicated, leading to an overinvestment. A franchise, therefore, gives the utility certain rights and imposes corresponding duties.

Legal rights of utilities

A utility has legal rights that allow it: (1) to invoke under certain circumstances the law of eminent domain to obtain property—that is, invoke condemnation proceedings to acquire it; (2) to charge and obtain a reasonable rate for the service; and (3) to establish and enforce reasonable rules and regulations under which it provides service. The principal duties are that the utility must: (1) serve all who apply for the service; (2) provide power up to maximum capacity and be prepared to meet future increases in demand; (3) provide service that is adequate and safe; (4) not discriminate unfairly among customers (though it may serve different categories of customers at different rates); (5) not obtain more than a reasonable price for its service.

The physical property of an electric utility usually comprises the following:

1. One or more power stations, which may be thermal stations using coal, oil, gas, or nuclear fuel, a combination of some or all of these, hydroelectric stations, or a combination of both types. Each power station has a switchyard containing transformers, circuit breakers, and control equipment.
2. A transmission line, usually erected on private rights of way.
3. Transmission substations with transformers to reduce the voltage to several subtransmission circuits, and attendant circuit breakers and control equipment.
4. Distribution substations in which the subtransmission voltage is again reduced to supply transformers mounted on poles for general distribution in suburban and rural areas or to supply transformers in vaults for underground distribution. For industrial customers, electricity is delivered at transmission voltage, at subtransmission voltage, or at distribution voltage, depending on the size and location of the factory and the most economical supply in the circumstances.

Divisions of a utility's technical department

To construct and operate these facilities, a utility has three divisions in its technical department: (1) the system planning division (planning, load forecasting, technical research); (2) the system construction division (design and construction of power lines and power stations, engineering standards and specifications); and (3) the system operation division (power generation, power transmission and distribution, load dispatching).

The system planning engineer is responsible for long-term planning. He must anticipate the growth of system load in both time and location because the construction time required for a hydroelectric station is from five to 10 years, for a thermal station three to five years, and for a nuclear power station four to seven years. This planning requires a careful study of civic, residential, commercial, and industrial developments, population growth trends for the district, and plans for roads and bridges. The future availability of fuel resources and cost trends for different fuels—in some cases on an international scale—must also be considered.

The construction engineer is responsible for constructing power stations and lines, but on major construction he usually works in conjunction with an outside engineering firm. He generally lays down the broad outlines of all construction work and also does all the work required for substation and transmission line construction.

The operating engineer is responsible for the day-to-day operation of the system. He supervises personnel in charge of the operation and maintenance of generating stations, transmission lines, and substations, and also a supervisor of operating systems, usually called the load dispatcher, who knows when and where the loads normally come on and go off and must have available the requisite generating capacity. He must also watch the weather because it is closely related to system load and to system disturbances. Sudden darkness causes the lighting load to increase abruptly, and thunderstorms or heavy snows may result in the loss of lines. Even social patterns and events may require monitoring; a popular program on television causes a sudden rise in load.

Economy of operation is important, and because the efficiency of power generation differs for each station at different loadings, the engineer must allocate the generating power to each power station so as to make most efficient use of the system facilities. He must also estimate the power loss in the transmission lines. The most economical load dispatching is a very difficult goal to achieve, and on-line digital computers are often employed to determine the best allocation of load for each power station.

The operating engineer must handle emergencies and be prepared to bring the reserve generating capacity of the

system into operation immediately while arranging for whatever repair work is necessary.

SYSTEM CHARACTERISTICS

In addition to the components of the electric power system named above there is one more, the customer's load, which varies greatly. In residential load, electric lighting is used in the evening, electric cookers are used about mealtime, electric cleaners and irons at any time, and electric refrigerators are switched on and off throughout the day and night by automatic control devices. Radio and television use depends upon the programs. Electric air conditioners and electric room heaters comprise a large residential load, their use depending on the weather.

Effects of weather on residential loads

The commercial load, as for offices and department stores, is high during business hours but low at other times. Lighting and air conditioning account for the greater part of the total load. The industrial load is highest during working hours, which depend on the nature of the factory and the number of shifts. Motor and heating loads usually consume the most electricity.

The load on the electric power system is the varying sum of all the residential, commercial, and industrial loads. An example of a system load curve is given in Figure 5. The demand shown is the hourly integrated average value; instantaneous peak load is 100 percent. Around midnight (M) the load is low, and the facilities are not used very effectively. In order to encourage power consumption during off-peak hours, reduced rates for room heating and water heating are frequently offered. Air conditioning accounts for an increasing percentage of the residential and commercial load and heightens seasonal variations. In some countries, such as the United States and Japan, the summer load exceeds the winter load—as evidenced by brownouts, if not by blackouts, in American urban areas.

A smoothed load curve and the load duration curve are shown in Figure 6. The load duration curve can be derived from the load curve and used for planning purposes. A typical yearly load duration curve for a specific system is shown at the left in Figure 7. This curve may be divided into three parts: base, middle, and peak load. The base load, the lowest load of the system, is present continuously, day and night, throughout the year. Peak load is defined rather arbitrarily as the heavy load portion of heaviest load, accounting for 5 to 15 percent of the hours in the year.

For most economical operation, the base load portion should be supplied by the power stations the operating costs of which are lowest; for example, by run-of-river-

flow-type hydroelectric stations, by the most efficient thermal power stations in the system, and, increasingly, by nuclear power stations. The peak load portion should be supplied by power stations the construction costs of which are low. Peak load is relatively high in kilowatts

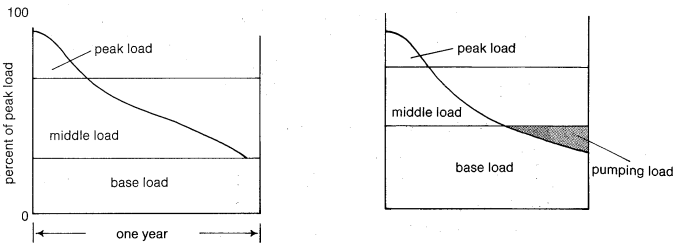

Figure 7: Typical load duration curves for a one-year period, showing how base load can be substantially increased (right) by using power during periods of low demand to operate a pumped storage system (see text).

but relatively short in duration, so that total kilowatt-hours are not great. Peak load may be supplied by pumped-hydro stations, old thermal power stations, and gas turbine stations.

Pumped hydro requires no fuel but requires power for pumping the water to the storage reservoir. Off-peak power can be used for pumping, raising the level of base load (Figure 7, right). The middle load is then supplied by older-type thermal stations. To accommodate starting and stopping of turbines once or twice a day, thermal stations are designed especially for such middle-part use. Effective system planning requires estimates of future changes in the percentages for the three types of load.

INTERCONNECTION

Factors in planning the capacity of a system

To determine how much generating capacity should be built into a power system, a number of factors must be considered. Foremost, of course, is the maximum peak load on the system. Emergency conditions, such as a fault in a generating station or in transmission lines or substations, must be considered, as well as scheduled outages for regular repair and maintenance. To provide the necessary reserve margin above normal peak power requirements, a certain reserve capacity is required, sometimes expressed as 15 percent over peak load and sometimes by the total of the two largest units in the system. Each system must be considered individually. The capacity of the largest generating unit is normally about 7 to 10 percent of the total system capacity.

The investment cost of generating capacity per kilowatt is usually lower as unit size increases, making the use of larger units economically beneficial. In a small system, however, such benefits cannot be realized. Larger systems can be assembled by interconnecting two or more smaller systems, however, thus enabling the use of a larger generator unit. Interconnections must be designed to

give an adequate power flow through interconnecting lines in an emergency. If help from neighbouring systems can be counted on in case of emergency, as can be realized by interconnection, reserve margins can be reduced, resulting in considerable economic benefits.

Interconnection also has economic advantages in day-to-day utility systems operations. Where system load conditions would normally require the operation of a generating station with a relatively low efficiency if the system were operating independently, interconnection can cut fuel costs by making use of more efficient generators from a neighbouring system. Another advantage of interconnection is the flexibility it allows in choosing sites for new generating stations; planning takes into consideration the interconnected systems as a whole, rather than a single independent system. Because of these advantages, electric power systems have grown steadily larger as a result of interconnection between different utilities in a country and even interconnections between countries.

Interconnection introduces many technical problems that must be solved in system operation and planning. Tie-line power flow, for example, in which a tie line transmits to neighbouring electric power systems, must be carefully controlled in the day-to-day operation of the interconnected system. Such power flow is normally predetermined on a contractual basis between the utilities concerned. The complexity of systems with interconnections at many points and at various voltages, however, creates difficult problems, for the solution of which the analog computer has been used since the 1930s. Such computers, known as ac calculating boards, network calculators, or network analyzers, have proved to be effective tools for studying power flow problems in interconnected system operation and planning. In the late 1960s they were being replaced by digital computers, which have greater speed and flexibility. In some instances, on-line computer control is used for the operation of large interconnected systems.

Importance of reliable communications

In addition to the normal voice communication by telephone and radio, a utility requires a large and complex network for telemetering (transmitting measurement information over long distances), circuit protection, and control functions. Extensive use is made of conventional wire circuits, carrier telephony, and microwave networks. In carrier telephony the transmission line acts as a guide for high-frequency waves.

As a power system grows, the fault current during disturbances increases proportionately, requiring that the rupturing capacity of all circuit breakers in the system be increased. A circuit breaker with inadequate rupturing capacity may explode when a system fault occurs. One way to alleviate the problem is to introduce series reactance (a circuit component that impedes the flow of alternating current) into the system to reduce the fault current. Such reactance causes a voltage drop in the system during normal operation, however, and so has drawbacks. Connecting two systems with a dc linking device is also a possibility. No ac fault current flows through the dc linking device; thus fault current is restricted to one system.

Another problem with interconnected systems is the possibility of a large-scale blackout if there is a system fault. Power systems are designed so that a fault can be located almost instantly and the faulted section switched out in a very short time, thus allowing stable operation of the rest of the system, whatever the nature and location of the fault.

Power system design is usually on a single contingency basis, but in system operation two or more contingencies may occur simultaneously, perhaps leading to a widespread interruption of power. Weather disturbances may break down transmission lines, while an error on the part of a load dispatcher, or failure of a protective apparatus (relays or circuit breakers), cannot be excluded. Thus, widespread blackouts, such as that of November 1965 in the northeastern United States and southeastern Canada, can occur. From such large-scale power failures much, at least, can be learned. First, reserve capacity, to be effective in an emergency, should be a spinning reserve; that is, the equipment must be in such a state that the output capacity can be used very soon after the disturbances. The time needed to produce electricity from a thermal station from a "cold" state is several hours. Second, load shedding techniques (*i.e.*, deliberate reductions in load) should be carried out as a necessary evil in case of an emergency. After a serious fault, there may be an imbalance between generation and load. When the load exceeds generating capacity the system frequency drops. Conversely, when generation exceeds load, system frequency goes up. When the system frequency drops by as much as 1.5–2 hertz, steam-turbine generators should be disconnected because of the possibility of mechanical breakdown. This shutdown further increases the difference between generating capacity and load, and system frequency drops even further, eventually resulting in total system breakdown. Consequently, before frequency drops to a critical level, some load must be disconnected. The load dispatcher selects the proper load to be cut off, but if the fault is serious, he may be too late. Thus, it has become the practice to install underfrequency relays at predetermined locations in the system for the purpose of load shedding. Third, in the case of a serious fault, circuit breakers in the system will isolate some of the thermal power stations. It is difficult to start up such stations without outside help. This was one of the main reasons why New York City suffered a prolonged (13-hour) outage in the 1965 blackout. Since then, major thermal power stations have installed gas turbines as auxiliary power sources for start-up. Also the gas turbine, with its quick starting, acts as a spinning reserve in an emergency. Finally, auxiliary power sources should be installed in public buildings, such as hospitals.

The measures mentioned above are countermeasures for alleviating the effect and minimizing the duration of a blackout; it is better to undertake the difficult task of planning, constructing, and operating the power system so that a serious breakdown will not occur. To achieve this objective, preparations must be made for simultaneous faults in the system, or countermeasures must be planned on a multicontingency basis, taking into account possible malfunctions of the system apparatus and human errors. System design work is increasingly so directed.

VI. International aspects

As transmission lines grew to cross national borders and electrical energy became a commodity in international trade, new problems arose and new solutions were developed.

MULTINATIONAL INTERCONNECTIONS

Early international efforts

The first multinational interconnection was introduced in Europe. The Electricity Committee of the Organization for European Economic Co-operation studied the question of international interconnection of supply systems, and in 1951 the Union for the Co-ordination of the Production and Transmission of Electricity (UCPTE) was set up, encouraging international exchange of energy between its members—France, Belgium, The Netherlands, Luxembourg, West Germany, Austria, Switzerland, and Italy. The total energy exchange within this group was about 3,000,000,000 kilowatt-hours in 1950 and about twice that in 1955. By the mid-1950s, the electricity production deficiency in western Europe had been largely made up, and interconnected transmission networks operating at 220 kilovolts (and sections at 380 kilovolts, which was standardized for future transmission) were functioning satisfactorily.

This scheme allowed advantage to be taken of the difference in the annual regimes of thermal and hydroelectric systems and so reduced on an international basis the total installed capacity needed to meet power demands.

The sum of non-simultaneous load transfers was 5,720 megawatts in 1964. Considering the overall transmission capability of the tie lines between the UCPTE countries (9,400 megawatts), the above non-simultaneous loading was 61 percent of the interconnection line capacity. Com-

pared with the load of the group, which amounted to about 72,000 megawatts, total exchange came to 7.94 percent.

The eastern European (Comecon) countries formed an interconnection, first at 220 kilovolts and later at 380 kilovolts, linking the Soviet Union, Poland, Hungary, Czechoslovakia, and Romania. Usually the Soviet Union and Romania are exporting countries and the rest importers.

In the 1960s further international links, between France and the United Kingdom, between Sweden and Denmark, and others began operations.

To encourage discussion of common problems and exchange of technical information, several international organizations were set up. The Conférence Internationale des Grandes Réseaux Électrique à Haute Tension, the World Energy Conference (formerly the World Power Conference), and the Union Internationale des Producteurs et Distributeurs d'Énergie Électrique dealt with transmission, generation, and consumption problems, respectively, while the International Electrotechnical Commission (IEC) was concerned mainly with standardization.

War damage had created a total European deficiency in generating capacity of some 10,000 megawatts by 1945. Reorganization started under the European Recovery Program, assisted by plans made by the Electricity Committee of the Organization for European Economic Cooperation.

The Economic Commission for Asia and the Far East planned an expansion of electric power facilities to increase the installed capacity in Asian countries to more than double the 1950 capacity of some 4,000,000 kilowatts. Postwar reconstruction of electric power systems and development schemes for new generating stations, both thermal and hydroelectric, were assisted financially by the International Bank for Reconstruction and Development.

The high rate of increase in electrical energy demand during the first half of the 20th century led to a corresponding rise in the installed capacity of generating plants. At first, an apparent abundance of coal and much undeveloped waterpower in the industrialized countries allowed production to advance without concern over the exhaustion of resources. The discovery of large reserves of petroleum, also used for electricity generation in some thermal power stations, had the same effect. As the rate of use of these resources in relation to the total proved reserves rose rapidly, however, the position became disquieting. In the decade following World War II the electricity-supply industry was, therefore, greatly concerned with the introduction of new sources of energy. While many sources were studied intensively, it soon became clear that nuclear energy offered the greatest promise as a major future source. The discovery of huge resources of petroleum, however, especially in the Middle East in the late 1950s, changed the energy situation.

Use of oil for power

In the 1960s, petroleum proved to be an abundant and cheap fuel, while domestic coal in many developed countries increased in cost and hydroelectric resources neared exhaustion. Thus many developed countries imported large amounts of Middle East oil for power production. Development of nuclear power was delayed by this cheap oil. Europe in general came to rely on imported oil for some 40 percent of its total energy, and in Italy the rate of dependence reached 70 percent or more in 1969 and nearly the same in Japan. After a decade of cheap oil, the price of oil rose sharply, beginning in the 1970s, because of political changes in many Middle Eastern and African oil-producing countries.

WORLD ELECTRIC POWER

Total electric power production in the world was 4,568,000,000,000 kilowatt-hours and per capita production 1,290 kilowatt-hours in 1969. The situation in various regions is given below.

North America. *United States.* In the early days of the utility industry, private power companies and municipally owned utilities were responsible for the production and distribution of electricity. From the 1930s, federal agencies, public power districts, and rural cooperatives became part of this industry.

In 1960 the number of private utilities was about 480, that of municipal- and state-owned about 2,100, and rural cooperatives about 900. Earlier the number of private utilities had been more than 4,000 and that of municipal- and state-owned more than 3,000.

Although most of the generating capacity was owned by private utilities, their share decreased year by year until about 1961, after which it remained practically constant. Of the total installed capacity in 1936, 91 percent was owned by private companies; this was reduced to 80 percent in 1946, and slightly further since. Federally owned utilities increased from 2 percent in 1936 to 13 percent in 1961.

In 1969 total production of electricity in the United States was 1,551,900,000,000 kilowatt-hours, of which 110,000,000,000 kilowatt-hours was generated by industrial plants and the remainder by utilities. Of the latter, private companies accounted for 76.4 percent, federal facilities 12.8 percent, municipal and state plants 4.8 percent, electric power districts 4.7 percent, and rural cooperatives 1.2 percent. Production per capita was 7,500 kilowatt-hours. Installed generating capacity was 331,900 megawatts, divided much the same as the above percentages. Hydroelectric stations accounted for 16 percent of this capacity and thermal stations, including nuclear and geothermal (tapping steam from underground), for 84 percent.

In the early 1970s there were about 400 privately owned electric utilities in the United States, ranging widely in size, regulated by state commissions or city governments for intrastate or intracity operations. All states had established regulatory bodies by the early 1960s. The state laws require that power companies be permitted to earn a reasonable profit on the part of their investment that is devoted to public use. State agencies determine a reasonable profit level by considering such factors as the cost of borrowing money, the ability to attract money for expansion, the company's financial condition, the effects of inflation, the physical condition of the property, the degree of investor risk, and overall company operations.

Regulation of utilities by state agencies

Regulatory commissions function to protect utility customers from poor service or unfair charges resulting from a misuse of the monopoly status of the utilities and to assure fair treatment for utility investors. Not only are investors a part of the public but good service depends upon the willingness of investors to supply money to the private utilities.

In addition to state and municipal agencies, the Federal Power Commission (FPC) has authority to regulate the rates and conditions of service in which electricity is sold at wholesale in interstate commerce.

Rural electric cooperatives, owned and operated by the people they serve, provided service in the 1960s in nearly every state. More than 96 percent of all farms were electrified, compared with 10 percent when the Rural Electrification Administration (REA) was established in 1935, and cooperatives served 51 percent of these farms.

The FPC issues permits for planning and licenses for construction and operation of nonfederal hydroelectric projects on waters or lands subject to United States jurisdiction. The FPC also issues permits for facilities on the international borders that are to be used to export or import electrical energy to or from Canada or Mexico and reviews and approves proposed rates for the sale of power from certain federal and international projects.

The Federal Water Power Act of 1920 limited the licenses for hydroelectric power sites to 50 years and provided for recapture by the federal government at the end of that period. The act also contains a preference clause stipulating that states, municipalities, or other political subdivisions be granted preference over private applicants in the licensing of proposed hydroelectric projects. The preference clause is used only when the proposals of both public and private applicants are of equal merit.

In the original Reclamation Act of 1902, the Department of the Interior was authorized to begin construction

of water-use facilities to provide for irrigation and municipal water supplies in the arid regions of the West; there was no mention of the production or sale of electric power. In 1906 Congress amended the act so that surplus power generated at the dams of irrigation projects could be leased, giving preference to municipal purposes, for periods not exceeding 10 years.

The Department of the Interior has four subdivisions dealing with the generation and sale of electric energy: the Bureau of Reclamation, the Bonneville Power Administration, the Southwestern Power Administration, and the Southeastern Power Administration. The total amount of energy marketed by the Bureau of Reclamation was approximately 43,000,000,000 kilowatt-hours and that by the Bonneville Power Administration approximately 47,000,000,000 kilowatt-hours in 1969.

The Bureau of Reclamation is concerned primarily with the irrigation of arid and semi-arid lands, and the power it markets is generated at its irrigation projects, at flood-control projects of the Army Corps of Engineers, and at certain reservoir projects of other federal or international agencies. In the late 1960s, the bureau operated about 40 power plants with a total capacity of 7,333 megawatts.

The three remaining Department of the Interior subdivisions deal primarily with power production and marketing. The Bonneville Power Administration was created in 1937 to market power at the Bonneville Dam on the Columbia River in Oregon; later it was given responsibility for distributing power produced at more than a dozen other dams in the Northwest. The Southwestern Power Administration was created in 1943 to market power generated at Corps of Engineers' projects in Arkansas, Missouri, Oklahoma, and Texas, while the Southeastern Power Administration was established in 1950 to sell power generated at 10 Corps of Engineers' projects in the southern and southeastern states.

The objective of all four marketing agencies is to dispose of power from federal projects so as to encourage the most widespread use of electricity at the lowest possible rates to consumers consistent with sound business principles, giving preference to public bodies and rural cooperatives.

The TVA

The Tennessee Valley Authority (TVA), created by an act of Congress on May 18, 1933, developed into the largest single electric power system in the world, with an installed capacity of more than 18,000 megawatts. It is charged with the development of the Tennessee River and its tributaries in the interests of navigation, flood control, and the generation and distribution of electric power. In the late 1960s it was producing annually more than 86,000,000,000 kilowatt-hours, of which more than three-quarters was generated by steam-electric plants and the remainder by hydroelectric plants.

Canada. Development of electricity supply, based on abundant waterpower, is undertaken through provincial power commissions and private undertakings. Some of the commissions are responsible for generation as well as transmission and distribution, while others buy and distribute energy in bulk.

In 1970 the installed capacity of Canadian electric power industries was divided as follows: provincial commissions, over 70 percent; private utilities, 10 percent; and industrial plants, 15 percent. Annual electricity production was more than 203,700,000,000 kilowatt-hours, about three-quarters (77 percent) of which was produced by hydroelectric plants. Total generating capacity was 41,300 megawatts, with hydropower representing 66 percent and thermal power (including nuclear power and gas turbines) 34 percent.

Canada is known for hydroelectric power and extra-high-voltage transmission. The Churchill Falls station in Labrador, one of the largest hydroelectric power stations in the Western world, has a capacity of 5,225 megawatts (11 units of 475 megawatts each). Under consideration in the 1970s was the James Bay project in Quebec, tentatively planned for 17,000 megawatts by 1985. A 500-kilovolt transmission line that carries the hydroelectric power of the Peace River project in British Columbia leads to Vancouver and connects with the Pacific Intertie in the United States. Large amounts of hydroelectric power from the dams in the Manicouagan and Outardes rivers have been transmitted by three-circuit, 735-kilovolt transmission lines, the world's highest voltage transmission lines, to Montreal via Quebec since 1965.

The cost of electricity in Canada is about half that in Europe, but the difference was gradually being reduced in the 1970s. Per capita consumption of electricity in Canada in 1970 was roughly 8,500 kilowatt-hours, second only to Norway.

Europe. Total electric power production in Europe in 1969 was 1,214,100,000,000 kilowatt-hours, about 2,690 kilowatt-hours per capita.

United Kingdom. Municipal and private organizations were governed by various electricity acts from 1900 onward. By 1925, 572 organizations provided electricity and 491 generating stations had a total capacity of 4,422 megawatts.

World War I demonstrated the need for national planning, and the Electricity Act of 1926 established the Central Electricity Board to be responsible for transmission facilities and interconnection of selected generating stations giving bulk supplies to distribution authorities. The construction of a 132-kilovolt national grid, standardized at 50 hertz, was completed by 1938.

After World War II the shortage of generating plants and the need for reorganization became obvious. For several years, load shedding, including blackout (load cut) and brownout (voltage reduction), and the discouragement of energy consumption were resorted to. Not until 1955 did such steps become unnecessary.

Nationalization of the electric industry

In April 1948 the electric industry was nationalized, and about 95 percent of the generation came under government control. In 1957 the industry was reorganized, and the Electricity Council as a planning board; the Central Electricity Generating Board, dealing with electricity generation and transmission; and 12 area boards for electricity distribution were established. Also the North of Scotland Hydro Electricity Board and the South of Scotland Electricity Board were established.

The number of generating stations was reduced and new ones were built, under a succession of annual construction programs that increased the total installed capacity to 24,235 megawatts at the end of 1957. In 1955 a national 10-year program for the construction of 12 nuclear power stations, with a total capacity of 6,000 megawatts, was formulated. Construction started in 1954 on a 275-kilovolt supergrid the total circuit length of which reached 3,932 miles in 1964. In 1963 construction of a new 400-kilovolt supergrid started, with a change from 275-kilovolt lines to 400-kilovolt lines. In 1969 there were 2,340 miles of 275-kilovolt lines and 6,115 miles of 400-kilovolt lines. Total generating capacity had increased to 61,370 megawatts, mostly thermal power (hydropower less than 3 percent). The share generated by industrial plants was about 20 percent in 1955 and decreased to about 10 percent in 1968.

Nuclear power generation in the United Kingdom was the largest of any country in the world in the early 1970s. After a 10-year program, total capacity in eight nuclear power stations was 4,680 megawatts and electricity production 28,500,000,000 kilowatt-hours in 1969. This nuclear power production was about 12 percent of the total power production in the United Kingdom and about one-third of the total nuclear power generation in the world. In the second nuclear power program (from mid-1960s), five nuclear power stations with advanced gas-cooled reactors (total capacity: 6,600 megawatts) were under construction.

Another special feature of the United Kingdom utility industry is the very low load factor of the system. The yearly load factor lies between 60 percent and 70 percent in many countries, but in the United Kingdom it was formerly around 45 percent for long periods and only in the late 1960s rose to 55 percent. To increase off-peak demand, use of electric room heating and electric water heaters is being encouraged by introducing special tariffs (rates).

In Northern Ireland responsibility for electricity supply

is vested in a separate supply board, together with Belfast Corporation, and there are small independent undertakings in the Isle of Man and in the Channel Islands.

France. Since 1935 the national government has made active efforts to lower electric rates. In April 1948 electricity and gas industries were nationalized, and Électricité de France (EDF) was organized, integrating generation and distribution. Generating facilities both from private utilities and industrial plants having a larger capacity than a specified level were transferred to the EDF, except for the Rhône Valley Authority, the National Railways, and the French Coal Corporation.

Increases in French generating capacity

Generating capacity increased steadily: 9,020 megawatts in 1936, 9,540 in 1947, 16,770 in 1956, 21,430 in 1961, and 36,330 in 1969. Total electric energy generated in 1969 was 131,300,000,000 kilowatt-hours, of which 52,700,000,000 was from hydro and 78,600,000,000 from thermal power stations. Per capita generation in 1969 was 2,600 kilowatt-hours.

Export and import of electrical energy are carried out with UCPTE countries and Spain and via Channel cable with Britain. The Rance station on the Rance River Estuary in Britanny is the world's largest tidal power station, with 240 megawatts capacity and a yearly output of nearly 500,000,000 kilowatt-hours.

West Germany. There were, in the early 1970s, approximately 4,000 utilities and nearly 4,100 industrial installations generating some or all of their own electricity in West Germany. Though most of the electric utilities were private enterprises, nearly all were partly financed by public organizations, and purely private industry represented only 4 percent of the total kilowatt-hours. Generating capacity showed a steady increase: 8,320 megawatts in 1936, 9,250 in 1941, 19,180 in 1956, and 50,830 in 1970. In 1970 thermal power contributed 91 percent of generating capacity, the remainder being hydro. Electricity production in 1970 was 93 percent thermal and 7 percent hydro.

Industrial plants contribute a very large share (more than 30 percent) of total power production. Part of this industrial power is fed into the utility network, accounting for as much as 15 percent of total output.

West Germany imports about 7,000,000,000 kilowatt-hours per year, relying heavily on the interconnection by UCPTE. Suitable sites for pumped storage stations are scarce, and some serving West Germany are located in other countries, such as the large Vianden station in Luxembourg. Total capacity of the pumped storage plants used by German utilities is 3,800 megawatts, of which about 2,000 megawatts is outside the country.

Pumped storage is one method of using power in off-peak periods. Room heating and water heating loads using off-peak power are also promoted at special rates; a secondary advantage is air-pollution abatement.

Italy. Before nationalization of the electric power industry in 1963, nearly 75 percent of the total electricity was produced by private utilities. With nationalization, a single government organization was established to generate and sell almost all the electricity in the country. Although hydroelectric capacity has remained essentially constant, its share of total capacity has fallen—82 percent in 1960, 50 percent in 1965, and only 36 percent in 1970—because of the tremendous advances in thermal power generation, from 10,000,000,000 kilowatt-hours in 1960 to 70,000,000,000 kilowatt-hours in 1970, a sevenfold increase. Oil provided the main fuel for this increase, and consumption of oil (mostly imported) in the 1960s increased nearly 10 times.

Italy produces sizable amounts of geothermal power. The first such production there and in the world began in 1905. Capacity in the early 1970s was nearly 400 megawatts and yearly production nearly 3 percent of the total electricity produced. Total installed generating capacity in 1970 was about 33,200 megawatts, and total production was 177,400,000,000 kilowatt-hours, representing nearly 2,200 kilowatt-hours per capita.

Norway. With abundant hydroelectric potential, almost all of Norway's electricity comes from hydroelectric plants. In 1969 about 57,000,000,000 kilowatt-hours of electricity was generated, the world's highest per capita generation, 14,680 kilowatt-hours.

Eastern European countries. Only total power production and per capita generation figures of eastern Europe in 1969 are given here, for brevity's sake. These were: German Democratic Republic, 65,400,000,000 kilowatt-hours and 4,070 kilowatt-hours per capita; Poland, 60,000,000,000 and 1,840; Romania, 31,500,000,000 and 1,580; Czechoslovakia, 43,000,000,000 and 2,990; Hungary, 14,000,000,000 and 1,380.

Soviet Union. After the 1917 Revolution much effort was devoted to increasing the production of electric energy. In 1920 the State Commission for the Electrification of Russia (Goelro) was founded, and in 1927 the First Five-Year Plan was inaugurated. In 1971 the Ninth Five-Year Plan was started.

Before the Revolution, the capacity for electric power generation was very small (1,100 megawatts in 1913). By 1936 it had reached 7,500 megawatts. During World War II, generating capacity increased tremendously, and by 1951 it had reached 22,100 megawatts, second only to the United States. By 1961, capacity reached 74,000 megawatts, nearly ten times more than in 1936.

Total electricity production in 1970 was 740,000,000,000 kilowatt-hours, of which hydro was 17 percent and thermal 83 percent. Total installed capacity in 1970 was 166,000 megawatts, 19 percent hydro and 81 percent thermal.

Hydroelectric power in the Soviet Union

Although the share of hydroelectric generation in the total production is fairly small, Soviet technology is characterized by the construction of giant hydroelectric stations. In the 1940s and 1950s large hydroelectric stations such as the station at Kuibyshev (2,300 megawatts) and the Volgograd station (2,530 megawatts), were constructed; later the Bratsk station (5,000 megawatts, 1967) and the Krasnoyarsk station (6,000 megawatts, 1971) were placed in operation, the latter the world's largest in the early 1970s. The Sayan-Shushenskoye station (6,400 megawatts) was under construction.

The Soviet Union also has large thermal power stations supplying both electricity and heat (hot water and steam) for residential and industrial use. Total capacity of thermal power stations of this type was about 35,000 megawatts and total heat energy supplied was about 5.1×10^{17} calories in 1970.

Because of the Soviet Union's immense land area, extra-high-voltage transmission is a necessity. Moreover, the electric loads are mostly concentrated in European Russia, whereas fuel resources and hydro sites are located mainly in Siberia, and the distance between these two regions is over 1,250 miles (2,000 kilometres).

The Soviet Union had in the early 1970s more than 6,000 miles (10,000 kilometres) of 500-kilovolt lines, a short length of 750-kilovolt lines and 370 miles (600 kilometres) of dc 800-kilovolt lines. For extra-long-distance transmission, 1,150-kilovolt ac transmission and ± 750-kilovolt (1,500-kilovolt) dc transmission (for 1,600 miles) were under extensive study.

Asia. This area, containing almost half of the world's population, was in the 1970s largely underdeveloped in electricity supply except for a few countries, notably Japan, Israel, and North Korea.

The total electric power production in Asia for 1969 is given as 463,000,000,000 kilowatt-hours in the *United Nations Year Book*, but exact figures for China, North Korea, and North Vietnam are not available. Per capita generation, excluding the above three countries, was low, 420 kilowatt-hours in 1969. Because nearly two-thirds of the Asian electric power is produced in Japan, per capita generation in Asia, excluding Japan, was only 170 kilowatt-hours in the same year.

Japan. Several hundred private electric utilities existed in Japan before World War II. During the war, they were incorporated into one Electric Power Generation and Transmission Company and nine regional electric power distribution companies, all privately owned but government-controlled. The company owned about 80 percent of the total capacity of hydro and thermal stations and all of the main transmission facilities. After

the war, however, these government-controlled companies were disbanded, and in 1951 nine regional electric power companies were established, which dealt with the whole field of electric power generation, transmission, and distribution as purely private utilities.

Total installed capacity in 1952 was 10,800 megawatts, of which 6,800 was hydro and 4,000 thermal. In that year, hydro power production was about 2.5 times higher than thermal power production. By 1962–63 the hydropower and thermal power became equal, both in installed capacity and in electricity production. Later, thermal power increased rapidly, and in 1970 the installed capacity was 40,200 megawatts while that of hydropower had increased only to 19,300 megawatts. Per capita generation was 2,450 kilowatt-hours.

Increases in Japanese power production

A special feature of the Japanese electric power industry is the rapid increase in capacity and production. Its increase in the 1950s and 1960s was sevenfold, far surpassing the increase of most other developed countries, placing the Japanese industry in third place in world production since 1966. This rapid increase was made possible by developments in the capacity of thermal power stations fuelled by imported oil.

India. Although electricity was generated in 1903 under the Indian Electricity Act, progress was slow until nationalization of the industry in the 1940s. Both the central and state governments undertook developments, and the annual production of electric energy for public consumption rose from about 2,400,000,000 kilowatt-hours in 1939 to 56,200,000,000 in 1969, though this figure was still only 105 kilowatt-hours per capita. Installed capacity was about 15,500 megawatts, of which 6,130 megawatts was hydro.

Central and South America. Except in large cities electricity consumption remained generally low in the 1970s. The annual electric energy production was 90,300,000,000 kilowatt-hours, and per capita production 350 kilowatt-hours in 1969.

In the past, supplies were developed mainly by private enterprise or municipal authorities, but starting in the 1950s national authorities absorbed an increasing share. Coal resources are very small, but petroleum is produced significantly, especially in Venezuela. Hydroelectric potential (estimated at some 60,000 megawatts, based on ordinary minimum flow) is high, and in the late 1960s development of large hydroelectric plants was undertaken in several countries, such as the Furnas project (final 1,200 megawatts) in Brazil and the Guri project (final 6,000 megawatts) in Venezuela.

Africa. The electric supply situation in this area is quite varied. Relative to the rest of the world, hydroelectric resources are much larger at 187,000 megawatts (at ordinary minimum flow), though only a small fraction of these resources had been developed in the early 1970s. Discoveries of oil and natural gas in the mid-1950s improved the prospects for thermal plants, particularly in Algeria.

The annual electricity production in 1969 for the entire continent was 74,000,000,000 kilowatt-hours and per capita generation 230 kilowatt-hours. Excluding South Africa, this figure was less than 100 kilowatt-hours.

In the Republic of South Africa the Electricity Supply Commission, set up in 1922, is mainly responsible for electrical development. The commission has built large thermal power stations, and electricity, generated from local coal, is cheap. In 1969 the annual production was 44,200,000,000 kilowatt-hours and per capita generation 2,080 kilowatt-hours.

Oceania. *Australia.* The public electricity supply was developed mainly under state electricity commissions with their own networks. Coal, brown coal, and lignite were used for generation, but waterpower, particularly in the eastern section of the Australian Alps and Tasmania, was being developed in the 1970s. The Snowy Mountains hydroelectric scheme, with installed capacity of nearly 2,000 megawatts, produced 2,300,000,000 kilowatt-hours of electric energy in 1969. Total installed electrical generating capacity in Australia in 1969 was 12,260 megawatts, of which hydro's share was 3,600 megawatts. Total electric energy production was 48,700,000,000 kilowatt-hours, and per capita generation was 3,970 kilowatt-hours in 1969.

New Zealand. Regional power boards have long been responsible for source development, and in 1945 a Rural Electrification Reticulation Council was established to coordinate rural supplies. With abundant waterpower, progress in electricity production has been rapid, and in 1969 nearly 80 percent of the total electric energy for public supply was generated by hydro stations. Installed capacity was 3,568 megawatts, of which 777 megawatts was thermal. Per capita generation was 4,660 kilowatt-hours in 1969.

In the North Island little hydroelectric power remains to be developed, and geothermal power is used. The installed capacity of geothermal plants was 192 megawatts and annual production nearly 1,200,000,000 kilowatt-hours in 1969.

Hydroelectric power produced in the South Island was introduced into the North Island through a dc cable across the Cook Strait.

Electrochemical Reactions

In the most general terms, electrochemical reactions are those chemical changes that are associated with the passage of electrons across interfaces between metal and solution. Under ordinary conditions, the occurrence of a chemical reaction is accompanied by the liberation or absorption of heat and not of any other form of energy; but there are many chemical reactions that when allowed to proceed in contact with two electronic conductors, separated by conducting wires liberate what is called electrical energy and an electric current is generated. Conversely, the energy of an electric current can be used to bring about many chemical reactions that do not occur spontaneously. A process involving the direct conversion of chemical energy when suitably organized constitutes an electrical cell. A process whereby electrical energy is converted directly into chemical energy is one of electrolysis; *i.e.*, an electrolytic process. By virtue of their combined chemical energy, the products of an electrolytic process have a tendency to react spontaneously with one another, reproducing the substances that were reactants and were therefore consumed during the electrolysis. If this reverse reaction is allowed to occur under proper conditions, a large proportion of the electrical energy used in the electrolysis may be regenerated. This possibility is made use of in accumulators or storage cells, sets of which are known as storage batteries. The charging of an accumulator is a process of electrolysis; a chemical change is produced by the electric current passing through it. In the discharge of the cell, the reverse chemical change occurs, the accumulator acting as a cell that produces an electric current.

Finally, the passage of electricity through gases generally causes chemical changes, and this kind of reaction forms a separate branch of electrochemistry, which will not be treated here (see GASEOUS STATE).

General principles. Substances that are reasonably good conductors of electricity may be divided into two groups; the metallic, or electronic, conductors and the electrolytic conductors. The metals and many nonmetallic substances such as graphite, manganese dioxide, and lead sulfide exhibit metallic conductivity; the passage of an electric current through them produces heating and magnetic effects but no chemical changes. Electrolytic conductors of electrolytes comprise most acids, bases, and salts, either in the molten condition or in solution in water or other solvents. Plates or rods composed of a suitable metallic conductor dipping into the fluid electrolyte are employed to conduct the current into and out of the liquid; *i.e.*, to act as electrodes. When a current is passed between electrodes through an electrolyte, not only are heating and magnetic effects produced but also definite chemical changes occur at or in the neighbourhood of the negative electrode, called a cathode. The chemical change may be either the deposition of a metal or the liberation of hydrogen and formation of a basic substance, or some other chemical reduction process; whereas at the positive electrode, or anode, it may be either the dissolution of the anode itself, the liberation of a nonmetal, the production of oxygen and an acidic substance, or some other chemical oxidation process.

Electronic and electrolytic conductors

An electrolyte, prepared either by the melting of a suitable substance or by the dissolving of it in water or other liquid, owes its characteristic properties to the presence in it of electrically charged atoms or groups of atoms produced by the spontaneous splitting up or dissociation of the molecules of the substance. In solutions of the so-called strong electrolytes, most of the original substance, or in some solutions perhaps all of it, has undergone this process of electrolytic dissociation into charged particles, or ions. When an electrical potential difference (*i.e.*, a difference in degree of electrification) is established between electrodes dipping into an electrolyte, positively charged ions move toward the cathode and ions bearing negative charges move toward the anode. The electric current is carried through the electrolyte by this migration of the ions. When an ion reaches the electrode of opposite polarity, its electrical charge is donated to the metal, or, an electric charge is received from the metal. The ion is thereby converted into an ordinary neutral atom or group of atoms. It is this discharge of ions that gives rise to one of the types of chemical changes occurring at electrodes.

History. The study of electrochemistry began in the 18th century, bloomed until the early 20th century, and then ebbed, owing to an excessive use of thermodynamic principles in analyzing the processes that take place at points in the system where the various parts form interfaces. Since about 1950 electrochemistry has undergone a change. The study of processes in solutions has been less stressed, but the study of the transfer of electrons between metals and solution has increased explosively. With this new emphasis electrochemistry is becoming a core science and basis to much of the technology. It promises to be an important part of the foundation of the ecology-oriented society of the future, since electricity as a fuel lacks those products that fall generally under the term pollution.

The first electrochemical reactions studied, in 1796, were those in the cell of silver and zinc plates with blotting paper wetted by aqueous salt solution between them; these cells were constructed by the Italian scientist Alessandro Volta, for whom the term volt was named. This cell was the first primary battery used for the production of electricity.

Michael Faraday formulated the laws of electrochemical stoichiometry, the science that deals with the application of laws of definite proportions and of the conservation of matter and energy to chemical activity. These state that a coulomb of electricity, a unit of charge, reacts with fixed quantities of a substance (*e.g.*, with 1.11800 milligram of silver ions) or else, that 1 gram equivalent of any substance reacts with 96,048 ± 2 coulombs. This latter number represents a fundamental quantity known as one faraday of electricity. The relationship between the chemical affinity of the reactants in the cell and the voltage of the cell when it is operating was precisely defined by the U.S. chemist Josiah Willard Gibbs in 1875 while the relation of this affinity to the potential of the electrochemical cell was initially formulated by the German physical chemist Walter Hermann Nernst in 1889.

Faraday's laws

The period 1910 to 1950 was that of decline in electrochemistry until it became limited mainly to the study of solutions. There was almost no progress in the understanding of electrochemical reactions outside of equilibrium conditions and reversibility, and knowledge of these was applied invalidly to reactions occurring at a net rate; *i.e.*, reactions not in equilibrium and not totally reversible. From about 1950 the study of electrified interfaces, with special reference to the study of the transfer of electrons (called electrodics), gained in importance and became the main aspect of electrochemistry. From about 1960, electrodics began to develop as an interdisciplinary area in the search for solutions to problems such as the source of energy in space flights from fuel cells, the stability of metals in moist environments, the electrochemical aspects of biological functions, extractions from mixtures, and the replacement of fossil fuels such as coal and petroleum and their by-products, by electricity produced or stored electrochemically in transportation.

The rise of electrodics

THE ELECTROCHEMICAL PROCESS

Interactions of matter associated with the passage of an electric current depend upon the characteristics of the negatively charged electron. As the basic particle of electricity, the electron has an affinity for positively charged particles of matter, protons, whether in atoms, groups of atoms, or molecules. This affinity is analogous to the chemical affinity that particles exhibit among themselves. In fact, all chemical reactions result from a shift in the electron structure of atoms, and free electrons can combine with particles of matter (reduction) or be released by them (oxidation). The quantitative relationship between the free electrons of an electric current and the particles of a substance in which they cause a reaction is

defined by the laws of Faraday (see above *History*). The substances that take part in electrochemical reactions called electrolytes, or ionic conductors, have been described above.

Electrons are available in large quantities in a relatively free (mobile) state only in substances called electronic conductors, among which metals are the most important. Thus, an electron conductor must be present as a basic component of any system in which electrochemical reactions are to occur. Furthermore, the availability of electrons in a conductor is limited by energy distribution to such an extent that electrochemical reactions take place only in the immediate vicinity of the electronic conductor's surface; *i.e.*, a few angstroms from the conductor into the solution. These reactions are, therefore, normally considered as occurring at the interface, or common boundary, between an electronic conductor, such as an electrode, and an ionic conductor of electricity, such as an electrolytic solution. Electrochemical reaction will take place, however, only to the extent that electricity can flow through such a system as a whole. To achieve this, it is necessary for the system to form a closed loop, electronically speaking. For schematic representation of these details, see Figure 1.

The closed loop of conductors

Location of electrochemical reactions. Electrochemical reactions are located where the electron conductor meets the ionic conductor; *i.e.*, at the electrode–electrolyte interface. Characteristic of this region, considered to be a surface phase, is the existence of a specific structure of particles and the presence of an electric field of considerable intensity (up to 10,000,000 volts per centimetre) across it; the field is caused by the separation of charges that are present between the two bulk phases in contact. For most purposes the surface phase can be considered as a parallel plate condenser, with one plate on the centre of the ions that have been brought to the electrode, at the distance of their closest approach to it, and with the second plate at the metal surface; between the two plates and acting as a dielectric (*i.e.*, a nonconducting material) are oriented water molecules. This structure is termed the electric double layer and is illustrated in Figure 2.

Thermal motion of the positive ions in the solution makes the condenser plate on the electrolyte side of the interface diffuse; *i.e.*, the ions are distributed in a cloud-like way. This condition justifies the division of the potential change between the bulk of metal and the bulk of electrolyte into two parts: first, that between the metal

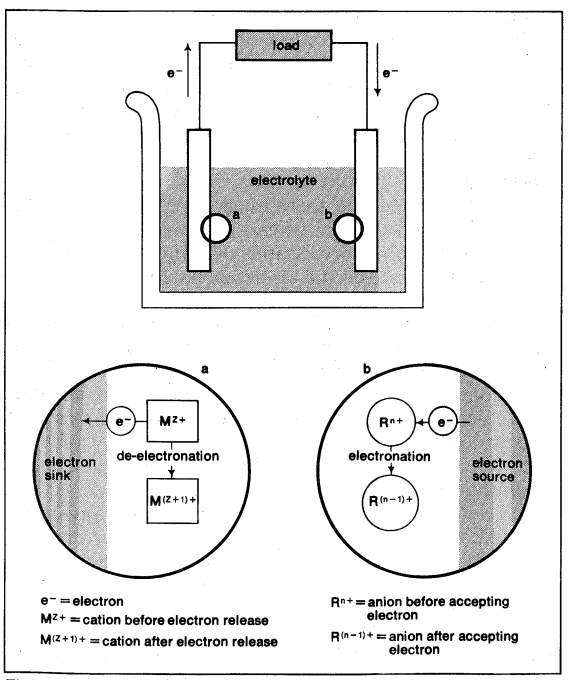

Figure 1: The mechanism of electron movement in an electrochemical cell.

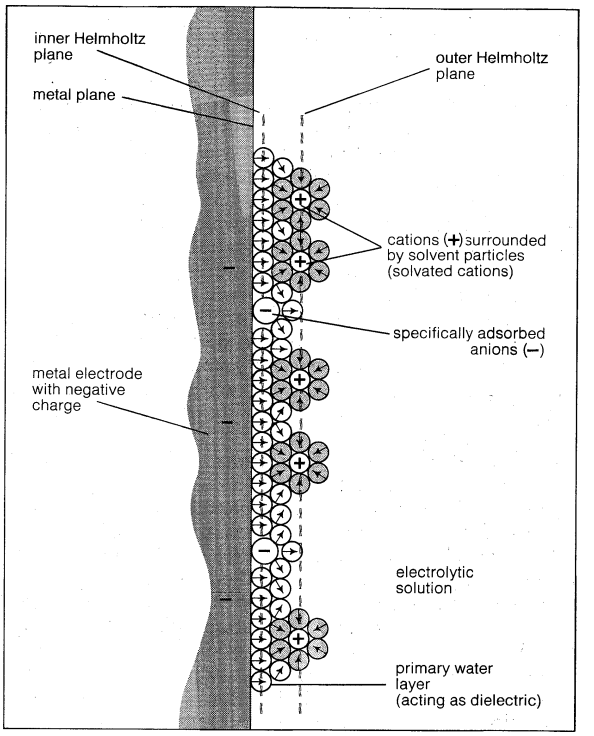

Figure 2: Double-layer structure and change of potential with distance from the electrode surface (see text).

surface and the first ionic layer at the distance of closest approach (called the outer Helmholtz plane, in which the ions are usually surrounded by solvent particles; *i.e.*, are solvated); and second, that between the first ionic layer and the bulk of the solution, the diffuse part of the double layer. The picture is further complicated by the presence of ions in the electrode surface layer in addition to those that are present for electrostatic reasons; *i.e.* by the force of attraction or repulsion between electric charges. Such electrode surface layer ions are said to be specifically adsorbed on the electrode surface. Since this species of ions is attracted by the surface to a distance closer than the "distance of the closest approach" of ions, further subdivision of the inner part of the electric double layer is justified. Hence, the inner Helmholtz plane is introduced as the plane formed by the centres of specifically adsorbed ions. Adsorption of neutral molecules on the surface can also change the properties of the electric double layer. This change occurs as a consequence of replacing the water molecules, and thus changes that part of the potential (electrical) difference across the double layer that is caused by the adsorbed dipoles (water molecules that have a polarity—*i.e.*, they behave like minute magnets—because of their hydrogen-oxygen structure, making one end of the molecule positive and the other end negative).

The absolute value of electrical potential difference, symbolized in calculation by the Greek letters delta and psi, $\Delta\psi$, between the bulk of a metal electrode and the bulk of an electrolyte cannot be measured. Instead, the voltage of a special cell, composed of the specific electrode being studied and of an arbitrarily selected reference electrode, is normally measured; the voltage is referred to as the relative electrode potential, E. Of special interest is that state of the electrode at which there is no net charge (in this case, no unbalanced, or extra positive, charge) at the metal side of the double layer. The relative potential at which this state is achieved is characteristic of each metal. This point is termed the potential of zero charge. At that potential, the field across the double layer is due to orientation of water molecules and other dipoles at the surface only.

Relative electrode potential

Most of the knowledge of the detailed structure of the interface between a metal and an electrolyte arises from experimentation with mercury, the only metal that is

liquid at ordinary temperatures; the double layer structure turns out to have surface tensions that must be measured, and this measurement is difficult with solid metals. By 1970, however, it had been shown that it is possible to measure surface tension changes at the metal-solution interface. Thus, the way to the determination of the double layer structure involving solids was opened.

Substances that are semiconductors can also be employed as electron carriers in electrochemical reactions. Semiconductors are substances which range between serving as insulators at low temperatures and as metallic-type conductors at high temperatures. In the case of semiconductors, however, the electric double layer has a more complex structure in as much as the condenser plate at the electrode side of the double layer also becomes diffuse. Thus, the overall potential difference between bulks of the phases in contact comprises also the potential difference between the bulk of the semiconductor and its surface.

Types of electrochemical reactions. There are several types of electrochemical reactions.

Simple redox reactions. A simple redox reaction is one that involves a change in the electrical charge of a charge carrier, usually a simple or complex ion in the solution, by its taking away, a process called reduction, an electron from the electrode, or its giving an electron to the electrode, a process called oxidation. The same carrier may be present in solution in two states of charge. The higher, more positive charge is called the oxidized state, and the lower, less positive charge is called the reduced state. For example, when ferric and ferrous ions are both present in solution in significant quantity, and when electron exchange with the electrode is sufficiently fast, redox equilibrium is established at the electrode, giving it a well-defined potential, or reversible redox potential.

To summarize, if at one metal-solution interface electrons are coming out of the metal, reducing a component of the solution, there must exist a second metal-solution interface where electrons are going into the metal in the process of oxidation.

The basic electrochemical cell

The two electrodes and the ionic conductor in between (*e.g.*, an aqueous solution of some ionized salt) represent an electrochemical cell. The process occurring in the cell as a whole is a redox process with the reduction of one species spatially separated from the oxidation of another one. As a consequence of Faraday's law, the rates of electrochemical reactions at electrodes (expressed in terms of gram moles per second per square centimetre of electrode surface) are directly proportional to the current density (expressed in amperes per square centimetre); *i.e.*, current flowing through the cell divided by the electrode surface area.

Reactions that produce gases. When hydrogen ions in solution react with electrons ejected from a metal, hydrogen atoms are formed at the surface, where they combine among themselves or with other hydrogen ions and electrons to give gaseous hydrogen molecules. If all the reactions are fast enough, an equilibrium is attained between hydrogen ions and gaseous hydrogen. A metal in contact with solution at which such a situation exists is called the reversible hydrogen electrode, and its electrical potential is arbitrarily taken to be zero; every other electrode can thus be compared with it as it represents the basis for constituting the hydrogen scale of relative electrode potentials. Similarly, negative hydroxyl ions in solution (OH^-) can be made to give up electrons to a metal and, in a series of reactions, the final one is the formation of gaseous oxygen. Chlorine is another gaseous product; it evolves upon electrochemical oxidation of chloride ions in concentrated solutions of neutral and acid salts.

Reactions that deposit and dissolve metals. When a metal ion is reduced and discharged as a neutral atom, or species, it tends to build into the metal lattice of the electrode. Thus, metals can be deposited at electrodes. Conversely, if electrons are taken away from the metal electrode by applying positive potentials to it, the metal ions thus formed can cross the double layer of electric charge at the interface, undergo hydration (combination with water), and enter the solution. The metal electrode thus dissolves. Many metals establish well-defined electric potentials when they are in contact with their own ions in solution.

Oxidation and reduction of organic compounds. A reaction of the oxidation and reduction of organic compounds can also be done at electrodes. Such reactions, however, are mostly irreversible in the literal sense that they lead to products that cannot easily be converted back into the original substance. Exceptions are some oxygen- and nitrogen-containing compounds (quinones, amines, and nitrous-compounds), that can give fairly well-defined reversible potentials.

Mechanism of charge transfer. The causes of the thermodynamically irreversible behaviour of electrode reactions are found in the nature of the elementary act of charge transfer. Like any chemical reaction, this act is inhibited by the existence of an energy barrier between the oxidized and the reduced state. This barrier implies that the reaction could take place only in the special circumstances when, during the course of numerous interactions with other species (atoms, ions, molecules, etc.) surrounding it, a molecule attains an excited state in which it has an abnormal energy content. In most chemical reactions, this energy content must be sufficient for the species to come into what is called the transition state; the transition state characterizes the top of the energy barrier just before a reaction begins. If such a model is applied to electron transfer at an interface, calculation shows that electron exchange reactions at electrodes would be prohibitively slow, a conclusion at variance with the observed phenomena; quantum mechanical laws, however, govern the motion of electrons, and their inclusion changes the calculations to fit reality. Quantum mechanics require that for fast electron exchange to take place, electrons in a particle outside the double layer (*e.g.*, a hydrated ion at the outer Helmholtz plane) must attain certain well-defined quantized energy levels equal to those in which free electrons exist in the metal. Since such states can be attained by the particle at a lower energy-content than that needed for its transfer over the top of the energy barrier, according to the classical view, this fast process of electron exchange between the electrode and a particle in solution is termed electron tunnelling through the energy barrier.

Electron tunnelling

Whereas the rate of chemical processes or, loosely, speed of reaction, can be influenced only by changing the concentrations of reactants or by changing the temperature or both, the rate of electrochemical processes also can be manipulated by changing the electrode potential. Making the electrode more negative increases the number of electrons in the metal ready to *tunnel* to ions and hence the rate of the reduction process increases. Conversely, making the potential more positive decreases this rate and increases the number of particles ready to give away electrons, thus increasing the rate of the oxidation process.

It can be deduced that there must exist a direct proportionality between the rate of reaction and the concentration of the reacting species and also an exponential dependence of the rate on the electrode potential.

At any electrode potential, both reduction of one species and oxidation of the product of reduction are taking place but at different rates; the rate of each reaction is determined by the respective concentration and by the corresponding effects of potential. The rate of an electrochemical reaction can best be described as the electric current density; *i.e.*, a measure of the quantity of electrons moving in a certain volume of space during a specified unit of time.

The relationships can be represented quantitatively by an equation in which the net, or resulting, current (the difference of the rate of electron ejection across the interface to particles in solution, diminished by the rate at which particles in solution inject electrons into the metal) is equated to the difference of the rates of reduction and oxidation and the variables and constants that relate to these reactions. See equation (1), and other equations below in *Calculations* at the end of this article.

Equation (2), known as the Nernst equation, which can be derived from equation (1), gives the value of the electrode potential when the rate of oxidation exactly equals the rate of reduction. Using this value for the electrode potential, equation (3), called the Butler-Volmer equation, can be derived; it represents the most fundamental relationship in electrodic chemistry.

COMPLEX ELECTROCHEMICAL REACTIONS

Electrochemical processes considered so far involve simple reactions of a particle with a single electron to produce a reduced ion (*e.g.*, the ferrous ion of iron with two positive charges, Fe^{++}), or vice versa. Such are the simple ionic redox processes, where the only difference in structure between a reactant and a reaction product may be due to some rearrangement of the neighbouring solvent molecules. When one or more transfers of electrons between the electrode and a species in solution are accompanied by major structural changes (*e.g.*, when hydroxyl ions, OH^-, transform into a molecule of oxygen, O_2, and a water molecule, H_2O, in the process of oxygen evolution at the anode, or positive electrode), the reaction usually consists of a sequence of events, called elementary acts, or unit steps, constituting the reaction mechanism. Intermediate states between the steps usually involve some unstable intermediate species with higher energy content than those of the reactants or of the reaction products.

Complex reaction mechanism

Complex reaction mechanisms can consist of a number of electron transfer steps, with some chemical steps preceding or succeeding the electron transfer steps or taking place in between them. Most organic electrochemical reactions are complex, involving large numbers of electrons in the overall reaction. Usually one step in the reaction encounters the largest energy barrier. The rate of occurrence of this step limits the rate of the overall reaction (*i.e.*, all other steps must occur at the same net rate, although they could provide for a much faster overall change). This step is called the rate-determining step and, for most practical purposes, all intermediate steps before and after it can be considered to be in equilibrium. (It is interesting to note that whenever this is the case, the Butler-Volmer equation [equation 3 below] is applicable, but with specific values of the transfer coefficients α_a and α_c characteristic of the mechanism of the reaction.)

Experimental studies. Measuring the rates of electrochemical reactions (*i.e.*, current densities) as functions of electrode potential under steady-state conditions represents the normal tool of electrodics. Meaningful results could not be obtained, however, until the sensitivity of electrochemical reactions to impurities was realized and high purity techniques were introduced. Even so, the steady-state method often has shortcomings except for relatively slow electrode reactions. In many cases concentration changes at the electrodes prevent using a sufficiently wide current density range for obtaining meaningful Tafel relationships (see Butler-Volmer equation below under *Calculations*). Hence, so-called transient methods have been developed in which one electrochemical factor in the situation is rationally perturbed and the time dependence of others observed. One such method consists of placing a constant current pulse upon an electrode and measuring the variation of the resulting current through the solution. This is called the galvanostatic method for measuring the rate of an electrochemical reaction. Applying a potential pulse while observing the variation of the rate as a function of time constitutes the potentiostatic method. A third method, called the potentiodynamic, or potential sweep, method involves observations of the current as a function of the potential, while the latter is varied at a constant, known rate.

Galvanostatic, potentiostatic, and potentiodynamic methods

The advantages of transient methods over steady-state ones, in which behaviour before the attainment of the steady-state is not part of the observation, are manifold. If observations are made at sufficiently short times, events can be recorded before the onset of concentration changes, and pure activation values can be found. Hence, Tafel relationships can be obtained over a larger current density range (see below *Calculations*) than if one makes measurements over longer times, as is required in the steady-state methods. The structure of the transient states can reveal important information, such as double layer capacitance and surface coverage of the electrode by intermediate species.

Several so-called kinetic parameters, for example, partial derivatives of current density and potential with respect to concentration of chosen reactants, can be extracted from experimental measurements.

Electrochemical measurements have a limited capacity to reveal the state of an electrode surface. Nonelectrochemical methods of studying electrode surfaces, therefore, have been stressed. Optical methods have considerably gained in importance. Ellipsometry (*i.e.*, measuring changes in basic properties of polarized light as it is reflected from an electrode surface) was the first method that made possible a study of monomolecular layers of oxides and adsorbed oxygen as adsorbed organic molecules. Adaptation of such a method to transient use allows change in the surface to be related to the passivity of metals. Another kind of spectroscopy enables infrared spectra of species adsorbed at electrode surface to be taken. Mössbauer spectra may lead to an identification of thin layers on an electrode surface. A good future is seen for further development of refined techniques for the study of electrochemical processes by various combinations of spectroscopic and electrochemical means.

TYPES OF COMPLEX REACTIONS

Electrocatalysis. The problems related to the increase of rates of electrochemical reactions, or, to put it another way, the decrease of overpotential, needed to perform reactions at a given rate are the subject of electrocatalysis. Both increase and decrease are of considerable practical importance since they affect the economics of electrochemical processes. Electrocatalysis is concerned with the electrode as a substrate, or base, for electrochemical reaction and with the effect of its bulk and surface properties on the rate of reaction. Contrary to expectation, the rate of the basic step in electrochemical reaction—electron transfer—is independent of the ease with which electrons are released from the metal. Hence, those simple electrode processes in which no other changes but electron transfer take place have heats of activation virtually independent of the metal substrate.

In a reaction involving the formation of a chemical bond between the electrode substrate and one of the radicals (charged particles) formed on the surface, rates of reaction at a given potential may vary for different substrates by many orders of magnitude. The variation is a function of the strength (or energy) of bonds established between the intermediate species and the surface, and when the substrates are transition metals, regular relations between reaction rate and certain characteristics of the metal's electronic structure are observed. If such bonds are too weak, the catalytic effect of the substrate is small. If they are too strong, the intermediate species is too stable to react further, and the surface of the metal becomes virtually blocked for further reaction. Thus, there is an optimum bond strength that can be seen if the rate of a reaction is plotted against a property of the metal substrate, which is proportional to the ability of the surface to form bonds; *e.g.*, its heat of sublimation.

Electrochemical reactions can also be catalyzed or inhibited by foreign species present in the electrolytic solution. In the most general case, ions can change the rates of reactions by changing the properties of the double layer by specific adsorption effects. Organic molecules inhibit electrochemical reaction by blocking the surface. For some organic ions or dipoles, the blocking effect can begin at a certain well-defined potential. Before attaining it, the electrode reaction gives the usual current density-potential relationship, which is then suddenly interrupted by an abnormal fall of the current, corresponding to adsorption.

Electrocrystallization. Deposition of metals and other substances at electrodes as a consequence of an electrode process exhibits a number of specific features. The electrode process is followed by crystal building, and this re-

sults in a continuous change of the electrode surface. This change, in turn, affects the electrochemical properties of the system—the double-layer capacity and the rate constants of the charge transfer processes. Hence, if electrochemical properties are to be studied, transient methods should be employed that allow measurements to be made before major changes in surface morphology (structure) take place.

Adatoms and adions. Since the two steps, the discharge of ions at the electrode and the incorporation of the discharged ions into the crystal lattice, are separated in time and space, an intermediate species exists at the surface, that of relatively loosely bound and freely moving atoms, called adatoms. Since the electrons tend to join the rest in the bulk of the metal, adatoms appear to have a partial charge, less than that of the elementary positive charge. The adatoms therefore attract solvent molecules, and the species is partially solvated. This reaction justifies adatoms being considered as a kind of adsorbed ion, called an adion, which, however, has already undergone partial discharge.

Because such an intermediate state is possible, ions need not be reduced to the neutral atomic state at the point of incorporation into the crystal lattice. Indeed, energetic considerations reveal this reduction to be improbable. Instead, discharge of ions is favoured on crystal planes. Their motion from the location of discharge to a site on the crystal occurs by surface diffusion. When such surface diffusion is inhibited, it can, in some cases, control the rate of reaction.

Problems of the crystal-building step in electrocrystallization are in many respects identical with those of crystal growth from the gas phase. Crystal building can occur in any one of three possible ways.

Kinks and step growth. Kinks, naturally existing at any metal surface, form a suitable half-lattice position at which an atom is surrounded by one-half of the number of atoms that would surround it in the bulk of the metal; there, adatoms can be successively trapped and thus the crystal lattice is extended along a crystal edge and further on across the surface. This step growth mechanism is shown in Figure 3A. The mechanism, however, has a limited capacity for crystal growth. A step can move as far as the edge of a crystal, and step growth would lead to smoothing of the surface to perfection, but then further growth would cease.

Screw dislocations. Mechanisms associated with screw dislocations, or twinning edges, can provide for a continuous growth of crystals. The screw dislocation mechanism, shown in Figure 3B, is made possible by a specific fault often found in the crystal lattice that may be called a dislocation originating from a shift of one atom in the lattice with respect to a perfect arrangement. This shift may then result in the formation of a monoatomic edge projecting above the electrode surface at which new atoms can be stacked. The stacking produces a turning of the edge around the base atom as a centre, the process producing a spiral growth.

Stacking

Nucleation mechanisms. If growth sites are rare, or if the substrate at which deposition should take place is foreign to the depositing metal, the charge transfer results in an accumulation of adatoms to a concentration considerably larger than that which can exist there at equilibrium with the crystal lattice. This condition is termed supersaturation. In such a situation, agglomeration of adatoms to form crystal nuclei is favoured. Surface energy requirements show that at any degree of supersaturation, nuclei of certain dimensions are stable and can represent sites for further growth. The process is shown in Figure 3C.

The formation of deposits is controlled by the above mechanism as long as the discharge process supplies ample amounts of adatoms as building material over the entire surface. If the rate of deposition is increased, so as to produce near the surface considerable depletion of ions, uneven deposition will start. This is caused by the protrusions of a normally rough metal surface being closer to the bulk of solution than the recessed parts and, hence, getting a somewhat faster supply of the discharging species. Once such a situation is established, it tends to develop further. The faster growing points penetrate into ever richer layers of solution, and this penetration into fertile fields in turn results in an ever faster growth. Thus, a natural consequence of deposition under transport-controlled rate is the amplification of the original surface roughness and the appearance of protruding spikes, called dendrites, as deposits.

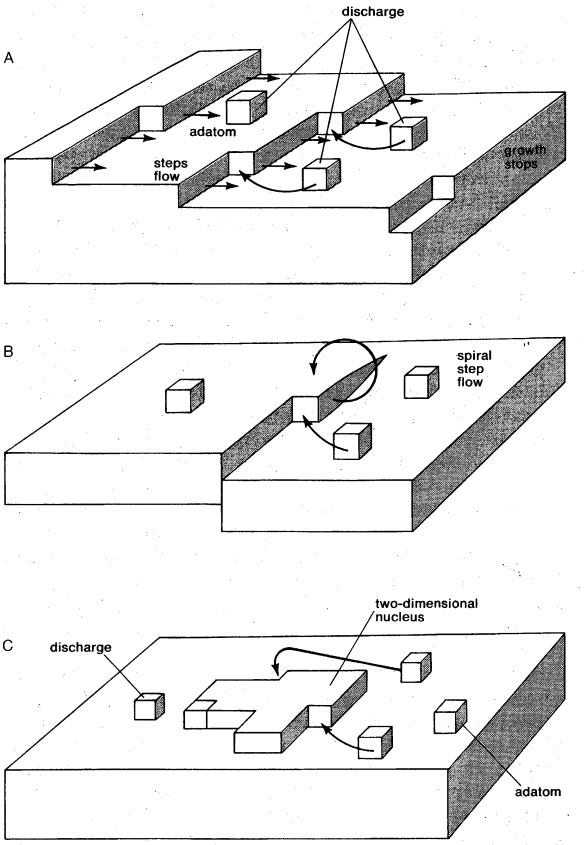

Figure 3: *Mechanisms of crystal growth.*
(A) Step growth, (B) screw dislocation, (C) nucleation.

Additives. A converse process is the smoothing of the original surface irregularities, which may occur when some foreign species, called an additive, is present in solution and adsorbs on the surface and inhibits the process of discharge. If those molecules are incorporated into a growing deposit, a situation may arise in which their supply to recessed parts of the surface becomes slower than to elevated parts. As a result, deposition becomes faster at recessed parts than at elevated ones and leveling of the surface occurs. This process has considerable technical application. Metal dissolution can sometimes be governed by a similar, transport-controlled mechanism, in which case a polishing effect is obtained. Electropolishing has found wide application in practice.

Organic electrode reactions. A very large number of electrochemical reactions involving organic molecules are known. An example is the oxidation of ethylene according to the equation:

$$\underset{\text{(ethylene)}}{C_2H_4} + \underset{\text{(water)}}{4H_2O} \rightarrow \underset{\text{(carbon dioxide)}}{2CO_2} + \underset{\text{(hydrogen ion)}}{12H^+} + \underset{\text{(electrons)}}{12e^-}.$$

Many chemical organic reactions can be made to function electrochemically, a general advantage being that the rate of the reaction is easily controlled by controlling the potential. A change of potential may change the path of the reaction and hence a certain product may be tuned in. In particular, polymerization reactions at electrodes can be stimulated; such a method is now used as a step in the production of nylon.

Electromechanical effects. Several properties of solid bulk metals turn out to be dependent upon electrochemi-

cal reactions. Thus, if the hydrogen atom concentration on an electrode surface exceeds a certain critical value, the hydrogen molecules (H_2) inside intrinsic voids in the metal's interior may exceed a critical gas pressure and cause the voids to open up and spread, thus causing the metal to lose ductility and become brittle. It is the electrochemical reaction, represented by the equation $H^+ + e^- \rightarrow H$ (hydrogen ion plus electron equals hydrogen atom) at the metal–solution interface that controls the surface hydrogen atom (H) concentration and, hence, the hydrogen molecules (H_2) present inside the metal. A limiting electrode potential which causes hydrogen atom concentration exists, above which a metal loses strength. This concept applies also to moist metal surfaces; *i.e.*, most practical metal surfaces, the electrolyte being in effect a surface moisture layer and the ions being produced from the dissolution of atmospheric carbon dioxide. Friction between solids involving moist or wet surfaces is also dependent on electrochemical factors.

Ductile and brittle properties

Multielectrode systems. So far, systems have been considered in which a single electrode process takes place. In principle, at any electrode potential all species present in the system fall into two categories: those that are stable, and those that undergo oxidation or reduction. The stable species are those that at the given electrode potential would not decrease their free energy by giving off or accepting electrons.

At any potential there should occur a codischarge of all unstable species. Thus, the system can be considered as a multielectrode system, consisting of as many electrodes as there are redox couples present. The rate at which different processes occur, however, can be so widely different that usually a single process is by far the dominant one. Systems at which two electrode processes occur at comparable rates are of considerable importance. If two kinds of metal ions are discharged simultaneously, an alloy is formed upon crystallization. The properties of the alloy would in most cases be those determined by the phase diagram (a plot of the temperature of melting versus the composition of the mixed system) for the ratio of quantities of discharged metals given by the rates at which the discharges take place. In many cases, nonequilibrium metal phases are formed giving unusual properties to the alloy.

Corrosion

If a process of metal dissolution (an oxidation process) can occur at a rate comparable to that of some reduction process on the same metal, a corrosion couple is established. Thus, zinc immersed in acid solution tends to establish a potential sufficiently positive for the metal to eject metal ions into the solution (oxidation). At the same time, it is also sufficiently negative for the reduction of hydrogen ions, present in any aqueous solution, to hydrogen gas. Hence, a spontaneous process of hydrogen evolution and of dissolution of the metal will take place. The rate at which this corrosion process occurs is governed by rate laws of the type given by equation (3) (see below *Calculations*). The mixed potential, spontaneously established by the corroding metal, is obtained by equating expressions for the anodic and cathodic currents of the two processes in the corrosion couple.

Corrosion can be prevented in two ways. One is by using an external source to make the potential of the metal sufficiently negative to bring it into the potential region in which the metal is stable, called cathodic protection; and the other is by provoking by some means the formation of a film on the surface that would slow the process. Such films could consist of an oxide or a layer of organic molecules that prevents dissolution and hence is called an inhibitor.

APPLICATIONS

Electrochemical processes are used in many ways and their use is likely to increase because they can replace polluting chemical situations with nonpolluting electrochemical ones. In many fields, however, applications have been profitable for some time. Major categories are listed below.

Metallurgy. All technologically important metals, except iron and steel, are either obtained or refined by electrochemical processes; for example, aluminum, titanium, alkaline earth, and alkali metals are obtained by electrode position from molten salts, and copper is refined by electrolysis in aqueous copper sulfate solutions.

Electroplating. One of the major ways of both decorating objects and improving their resistance to corrosion is by electroplating them. All major metal working industries, particularly the automobile industry, have large electroplating plants.

Chemical industry. Electrolysis of brine to obtain chlorine and caustic soda is an electrochemical process that has become one of the largest volume productions in the chemical industry. Modern processes cover a wide field, from the production of a variety of inorganic compounds to the production of such synthetic fibres as nylon. Intensive research in organic electrochemistry promises major developments in application, particularly with the prospect of greatly reduced electricity costs expected eventually to arise from the development of controlled fusion.

Batteries. Electrochemical storage of electricity is effected in batteries. Such devices are electrochemical cells and consist of two electrodes per unit. As the electricity to be stored is accepted on the plates of the cell, it converts substances on the plates to new substances having a higher energy than the old ones. When it is desired to make the electricity available again, the terminals of the battery are connected to the load and the substances on the battery plates retransform themselves to those originally present, giving off electricity as a product of their electrochemical reactions. The steadily rising production of the lead-acid battery is largely the result of its use for starting the internal-combustion engine, which has had an equally steady rise. Other electrochemical systems are also used as storers. The nickel-iron (Edison cell) and nickel-cadmium battery with alkaline electrolyte are both used in applications where longer lives than those of the lead-acid battery are needed; the silver-zinc battery is used to start airplane engines because of its high power per unit of weight. A variety of new systems is being investigated for covering other needs. One of the greatest challenges to electrochemists and electrochemical engineers is that of producing a battery with sufficient power and energy density to run an automobile the way gasoline (petrol) does. Even if the best hypothetical predictions for removal of polluting chemicals from automobile exhausts is realized, the cleanup will not be sufficient because the expected growth of the automobile population will increase the pollutant rate until by 1985 it will again become serious. Electrochemically-powered automobiles by that date seem to be a necessity.

Fuel cells. The energy of chemical reactions is converted into electrical energy in fuel cells. In these, the fuel (*e.g.*, hydrogen, hydrazine) is fed continuously to one electrode, while oxygen from the air is reacting at the other one. The efficiency of energy conversion in fuel cells is more than twice that attainable by conventional means, for example, by means of internal combustion.

Analytical chemistry. In analytical chemistry, most modern automated instrumental analysis is based on electrode processes; for example potentiometry, used to measure ionization constant.

Biological research. In biology the idea that many biological processes, from blood clotting to the transfer of nerve impulses, are electrochemical in nature continues to spread. The biological conversion of the chemical energy of food to mechanical energy takes place at an efficiency so high that it is difficult to explain without electrochemical mechanisms. Intensive research is developing in various directions in bioelectrochemistry.

CALCULATIONS

The three equations referred to above are stated in this section, and other mathematical considerations are also included. The rate of an electrochemical reaction in terms of oxidation and reduction reactions, the concentration of the reacting species, the electrode potentials and the current densities can all be related quantitatively according to equation (1):

$$i = \vec{i} - \overleftarrow{i} = \vec{k}C_{red}\exp\left(\frac{\alpha_a F}{RT}E\right) - \overleftarrow{k}C_{ox}\exp\left(\frac{\alpha_c F}{RT}E\right)$$

in which i is the net current density, $\vec{i}$ and $\overleftarrow{i}$ are the partial current densities of the oxidation and reduction respectively, C_{red} and C_{ox} are the concentrations of the reducing and oxidizing agents, respectively, $\vec{k}$ and $\overleftarrow{k}$ are the corresponding rate constants, while α_a and α_c are the so-called transfer coefficients; *i.e.*, specific constants giving a proper influence factor to the exponential dependence of rate on the potential, E. In the case of a simple one-electron transfer these factors are termed symmetry factors, for they, in a way, reflect the symmetry of the energy barrier. It can be proved that $\alpha_c + \alpha_a = n$, the number of electrons exchanged in a single act of an electrode reaction.

Nernst Equation. For a particular value of E the two partial current densities must become equal. This value of potential is the reversible electrode potential. From equation (1) one can deduce equation (2):

$$E_{rev} = \frac{RT}{(\alpha_c + \alpha_a)F}\ln\frac{\vec{k}}{\overleftarrow{k}} + \frac{RT}{(\alpha_c + \alpha_a)F}\ln\frac{C_{ox}}{C_{red}}$$

$$= E^\circ + \frac{RT}{nF}\ln\frac{C_{ox}}{C_{red}}.$$

This equation is known as the Nernst Equation; E° is the standard electrode potential (at $C_{ox} = C_{red} = 1$) characteristic of the given redox couple.

The standard electrode potential on the hydrogen scale is related to the thermodynamics of the electrode process. It reflects the standard free energy change of the redox reaction between the electron and the given redox couple, relative to the free energy change that takes place in the hydrogen electrode process.

Butler-Volmer Equation. The reversible electrode potential can be introduced into equation (1) and the potentials taken relative to its value. When so expressed, they are termed overpotentials and can be stated as $\eta = E - E_{rev}$; equation (1) then transforms to equation (3):

$$i = i_0\left\{\frac{(C_{red})_i}{(C_{red})_o}\exp\left(\frac{\alpha_a F\eta}{RT}\right) - \frac{(C_{ox})_i}{(C_{ox})_o}\exp\left(-\frac{\alpha_c F\eta}{RT}\right)\right\}$$

in which i_0 represents the value of either of the (equal) electron-emitting and electron-accepting partial current densities at the reversible potential and is termed the exchange current density. Equation (3) is called the Butler-Volmer Equation and represents one of the most fundamental relationships of electrochemistry.

As overpotentials, either positive or negative, become larger than about 5×10^{-2} volts (V), the second or the first term of equation (3) becomes negligible, respectively. Hence, simple exponential relationships between current (*i.e.*, rate) and overpotential are obtained, or the overpotential can be considered as logarithmically dependent on the current density. This theoretical result is in agreement with the experimental findings of the German physical chemist Julius Tafel (1905), and the usual plots of overpotential versus log current density are known as Tafel lines. The slope of a Tafel plot reveals the value of the transfer coefficient α for the given direction of the electrode reaction.

Difficulties in transport of reaction species. The above conclusions about the overpotential-current density relationship are valid as long as the ratios of concentrations at the electrode surface of the species involved at current density i, C_i and in the absence of current C_o stay close to unity. As the current density is increased, the concentration gradient needed to maintain a corresponding diffusion flux of the species concerned must begin to become appreciable. This condition is possible only if the concentration of the species at the surface starts to differ appreciably from the bulk value; *i.e.*, $(C_i)_i/(C_i)_o \neq 1$. The change in concentration of the discharging species at the electrode surface with time can, in principle, be obtained by using a second order partial differential equation (Fick's law), which, however, has explicit solutions only for a limited number of well-defined boundary conditions.

When significant concentration changes set in, no more exponential dependence of current density on potential can be obtained. It can be derived that, instead, a transition towards a limiting value takes place.

The important case is that in which the concentration of the discharging species at the electrode surface becomes equal to zero. The steady-state (*i.e.*, independent of time) current density obtained in such a case is the highest possible for the given set of conditions (diffusion limiting current density). The value of the concentration gradient in this case is directly proportional to the bulk concentration of the species involved and inversely proportional to the thickness of the diffusion layer (*i.e.*, the layer close to the electrode in which the concentration of the species differs from the species concentration in the bulk). This layer most often has a thickness fixed by hydrodynamic conditions in the solution surrounding the electrode. The definition used most often for the diffusion layer thickness is that of the German physical chemist Walther Hermann Nernst (1864–1941), according to whom this quantity is equal to the distance from the electrode at which the concentration would reach the bulk value if the concentration gradient were constant and equal to that at the electrode surface.

If a current larger than the limiting current is forced upon the electrode, the given electrode process will be able to sustain it only in the initial period in which the layer of solution close to the electrode is not completely exhausted of the discharging ions. As the concentration of ions tends toward zero, the electrode potential will change and another electrode process will start. The time at which the abrupt change of potential toward a new process takes place is termed the transition time. The relationship between transition time, current density, and concentration of the discharging species is given by Sand's equation:

$$\tau^{1/2} = \frac{\pi^{1/2}nFC_oD^{1/2}}{2i}.$$

Since τ is a well defined function of the concentration of the discharging species, the observation of the transition time can also be used as an analytical tool (chronopotentiometry).

Electromagnetic Radiation

Electromagnetic radiation is the propagation of energy through space by means of electric and magnetic fields that vary in time. In the absence of a material medium the velocity is a universal constant, c, the velocity of light. Electromagnetic radiation may be characterized, in accord with the wave theory, by the frequency with which it varies in time, or by its wavelength. Electromagnetic waves exhibit the properties of other forms of wave motion (*q.v.*), including reflection, refraction, diffraction, interference, and, because these waves are transverse (vibrating in a plane at right angles to the direction of propagation), polarization, as described below.

General characteristics. The orderly arrangement of radiation according to wavelength or frequency is called the electromagnetic spectrum, and is represented by the Table shown below, which charts the electromagnetic spectrum. The most familiar frequency range is light, that

narrow band of electromagnetic radiation to which the eye is sensitive, extending from violet on the high-frequency side to red on the low-frequency side, the neighbouring regions of which are consequently called ultraviolet and infrared. Infrared radiation is also known as radiant heat. Gamma radiation was first observed as emission from radioactive substances. The X in X-rays originated after the discovery of such radiation but while its nature was still unknown. Radio waves are also called hertzian waves, after the German physicist Heinrich Hertz, who in 1887 produced the first manmade electromagnetic waves and investigated their properties. Other terms have been applied outside the range of their initial meaning: the word monochromatic (literally "one colour") is applied to any radiation of one frequency, regardless of whether or not it is in the visible part of the spectrum. Microwaves developed for radar (see RADAR) during World War II are small only in comparison with radio waves; in comparison with light waves they are extremely long. The frequencies present in any wave disturbance are determined by the source of the wave, as shown in the following Table.

Essential features of electromagnetic radiation

The essential features of all electromagnetic radiation may be summarized rather briefly. The electric and magnetic fields in an electromagnetic wave act in planes that are perpendicular to each other and to the direction of propagation. According to electromagnetic theory, a changing electric field is accompanied by a magnetic field of a prescribed strength, and a changing magnetic field is accompanied by an electric field. Moreover, these relations maintain themselves as the disturbance spreads in a direction perpendicular to both fields, travelling with a velocity $c = 3 \times 10^{10}$ centimetres per second (approximately 186,000 miles per second) in free space. The energy density in space—that is, the energy per unit volume of an electromagnetic disturbance—and the flux of energy in the direction of propagation are equally divided between the electric and magnetic fields; both are proportional to the square of the field strengths. Momentum is also propagated by electromagnetic waves. Electromagnetic disturbances originate in the acceleration of electric charges, such as those in an oscillatory discharge (*i.e.*, a spark the charges of which alternate in their direction of flow) used by Hertz, and charge accelerations are produced when these disturbances are absorbed.

Radiation has corpuscular (particle-like) properties in addition to those characterizing wave motion. Radiant or electromagnetic energy is quantized in that for a given frequency ν (nu), its energy occurs as an integer times $h\nu$, in which h is another fundamental constant of nature, called Planck's constant after the German physicist Max Planck. A quantum of electromagnetic energy is called the photon. An ordinary particle in motion can be characterized by its momentum—its mass times its velocity. Likewise, the photon has momentum, but it has no rest mass; if a photon comes to rest by being absorbed, it ceases to exist and its energy is converted to some other form of energy. Because the photon energy is proportional to the frequency, the arrangement of radiation according to frequency is also known as its energy spectrum, and in the third column of the Table the photon energy is given. Its unit, the electron volt (eV), is the kinetic energy an electron would acquire in being accelerated through a potential difference of one volt. A photon of yellow light, as an example, has an energy of approximately 2 eV. Visible light and those parts of the spectrum adjacent to it are usually characterized by giving the wavelength, whereas radio and other long waves are more often specified by the frequency of the waves. The observation of extremely high-frequency radiation is made by detecting single individual photons, and its spectrum is described by giving the photon energy in electron volts or some multiple of that unit.

Wavelengths of the Electromagnetic Spectrum

	wavelength (cm)	frequency (sec^{-1})	photon energy (eV)
Cosmic ray photons	3×10^{-22}	10^{32}	4×10^{17}
	3×10^{-20}	10^{30}	4×10^{15}
	3×10^{-18}	10^{28}	4×10^{13}
	3×10^{-16}	10^{26}	4×10^{11}
	3×10^{-14}	10^{24}	4×10^{9}
	3×10^{-12}	10^{22}	4×10^{7}
Gamma rays	3×10^{-10}	10^{20}	4×10^{5}
X-rays	3×10^{-8}	10^{18}	4×10^{3}
Ultraviolet–visible light	3×10^{-6}	10^{16}	40
Infrared	3×10^{-4}	10^{14}	0.4
Microwaves	3×10^{-2}	10^{12}	4×10^{-3}
Radar	3	10^{10}	4×10^{-5}
UHF, VHF, FM shortwave, AM radio	300	10^{8}	4×10^{-7}
	3×10^{4}	10^{6}	4×10^{-9}
Longwave radio	3×10^{6}	10^{4}	4×10^{-11}
	3×10^{8}	10^{2}	4×10^{-13}

Different parts of the electromagnetic spectrum interact with matter quite differently. The Earth's atmosphere is almost transparent to waves in the visible and near infrared range and to radio waves; but it tends to absorb the rest except for extremely penetrating high-energy cosmic-ray photons. For astronomical observations, the atmosphere thus has only two "windows," for which optical and radio telescopes are designed, whereas X-ray astronomy, for example, depends on detectors in rockets and satellites that go outside the atmosphere. Glass can be made almost perfectly transparent to visible light, but it does not transmit the ultraviolet. Other dielectric (nonconducting) substances, such as pitch, are quite opaque to visible light but sufficiently transparent to microwave radar waves to be used for making lenses and prisms. The velocity of electromagnetic waves is lower in material media transparent to them than the free-space velocity by a factor called the index of refraction of the medium. The refractive index of any medium depends on the wavelength: the spectrum of colour can be produced by a glass prism because the short wavelength blue is slowed more in glass than the long wavelength red and thus is bent through a larger angle at each surface of the prism in emerging from glass into air. This phenomenon is called dispersion, and any medium in which the velocity of propagation depends on the wavelength is called a dispersive medium. The only truly nondispersive medium is a vacuum, but for some particular range of the spectrum a given medium may produce very little dispersion. A vacuum is also the only perfectly transparent medium, and all material media absorb strongly some regions of the spectrum.

Dispersive medium

The origins of radiant energy are also widely varied. The frequency range of electromagnetic radiation used for terrestrial communication is largely manmade, although the same frequencies are by no means uncommon in the universe as a whole (see RADIO SOURCES, ASTRONOMICAL). A radiating antenna is part of an electric circuit in which charge is caused to oscillate at a definite frequency, thus giving rise to electromagnetic waves of that frequency. A receiving antenna is part of a circuit tuned to, or in resonance with, the incoming wave. Except for the energy supply, the two circuits, radiating and receiving, are quite similar. Any system that emits radiation can absorb the same radiation. The wavelength characteristic of any emitter or absorber is related to its size, although often not in a simple way. The relatively long radio and television waves are radiated by large antennas, but visible light arises from oscillators of atomic dimensions. Careful analysis of the radiation from such natural emitters as atoms and molecules yields much of the detailed information known about atomic and molecular structure. Gamma rays are produced by accelerations inside atomic nuclei, whereas the most tightly bound electrons, those near the nucleus, may produce X-rays. Outer electrons of an atom give rise to ultraviolet and visible radiation, and molecular vibrations and rotations produce infrared. The energy per photon in line or band spectra corresponds exactly to certain aspects of atomic or molecular structure, and the pattern of frequencies emitted or absorbed serves as a clue to that structure.

This article is outlined as follows:

I. Classical theory of radiation

HISTORICAL DEVELOPMENT

Early work by Maxwell and Faraday

It may be said that the history of electromagnetic radiation began in 1865 with the publication of a paper by a British physicist, James Clerk Maxwell, proposing in summary that "we have strong reason to conclude that light itself (including radiant heat, and other radiations if any) is an electromagnetic disturbance in the form of waves. . . ."; or, at the earliest, when Michael Faraday of England published in 1846 the article "Thoughts on Ray Vibrations," following his discovery in 1845 of a connection between magnetism and light. (This was the Faraday effect: in the presence of a magnetic field a substance such as glass becomes optically active; *i.e.*, can rotate the plane of polarization of light.)

Early ideas about light. It is now recognized that light may be defined as visible electromagnetic radiation, and the science of light begins in antiquity. The rectilinear or straight-line propagation of light, a property of all electromagnetic radiation traversing empty space or a physically homogeneous transparent medium, was known to Euclid (a Greek mathematician) *c.* 300 BC, as was the law of reflection: at the boundary between two different media, radiation is reflected with the angle of incidence equal to the angle of reflection. Refraction, the change in direction of propagation of radiation in passing from one transparent medium to another, was recognized in antiquity, but the quantitative law of refraction was first discovered empirically in 1621 by a Dutch mathematician, Willebrord van Roijen Snell.

The law of refraction was actually published by René Descartes of France, who derived it on the basis of his theory that light is a kind of pressure transmitted through the all-pervading ether. According to this theory, light is propagated with infinite velocity, but in passing from a rarefied medium (air) to one more dense (glass or water), it behaves like a corpuscle the velocity component of which parallel to the interface is not affected, but which is speeded up in a direction normal to the boundary surface. The theory is neither correct nor logically consistent, but Descartes's derivation is based on measurable quantities, and is even scientific, compared with views current in the Middle Ages. It was widely accepted, but a contrary view was presented by a French mathematician, Pierre de Fermat, in 1657. In his celebrated principle of least time, he claimed that "Nature always acts by the shortest course." To the Greek geometer Hero of Alexandria (1st century AD) is attributed the theorem that reflected light traverses the shortest distance between two points compatible with meeting the reflecting surface. Fermat succeeded in deriving the law of refraction from the principle of shortest traversal time, but only on the assumption that the speed of light is smaller in a dense medium than in a rare one, contrary to Descartes's derivation. In the mid-17th century it was not yet known whether the passage of light takes any time at all, and Fermat's views were not widely accepted.

The finite velocity of light was first demonstrated by a Danish astronomer, Olaf Rømer, in 1675, from observations of the eclipses of Jupiter's satellites. He noticed that the period of the first satellite is apparently slowed as the Earth and Jupiter move away from each other, so that the eclipses occur later than expected when Jupiter is most remote. This difference is understandable if light requires a finite time to traverse the solar system. From the observations Rømer calculated the time required for light to travel from the Sun to Earth as 11 minutes. It is in fact more nearly eight minutes. In 1728 an English astronomer, James Bradley, announced the aberration of starlight, that apparent annual motion of the stars that is produced by the orbital motion of the Earth. From his observations Bradley computed the time for light to reach Earth from the sun as 8 minutes 12 seconds. Terrestrial measurements of the velocity of light, accurate to within a few percent, were first made in 1849 by the French physicists Armand-Hippolyte-Louis Fizeau and Jean-Bernard-Léon Foucault.

Wave theory of light. The theory that light originates as a vibratory motion and is transmitted as a wave disturbance in a medium was developed by an English scientist, Robert Hooke, and published in his *Micrographia* (1665). He introduced the idea of the wave front, but his wave front was not necessarily perpendicular to the direction of propagation in a homogeneous medium, and he thought the speed of light should be greater in an optically dense transparent substance. Hooke also discovered that light does not travel in perfectly straight lines but is found inside the geometrical shadow of an obstacle placed in its path. In this observation he had been anticipated by an Italian physicist, Francesco Maria Grimaldi, who named the phenomenon diffraction. The wave theory, however, is more justly attributed to a Dutch scientist, Christiaan Huygens, who explained reflection and refraction in terms of Huygens' principle, just as is done in modern elementary textbooks of physics. According to this principle (published 1690), each point on the wave front in the hypothetical ether is regarded as the source of a new disturbance that spreads out spherically, and the new wave front is the envelope of all the individual wavelets that originate from the old wave front.

Hooke's notion of a wave front

An important discovery concerning visible radiation was the observation of double refraction in Iceland spar (calcite), reported by a Danish physicist, Erasmus Bartholin, in 1669. A single ray of light entering the crystal emerges as two rays, the direction of an "extraordinary" ray in the crystal depending on the crystal orientation. Huygens gave a satisfactory account of this phenomenon on the basis of his principle by assuming secondary ellipsoidal wavelets in addition to the spherical wavelets of the ordinary ray. The ellipticity is produced by asymmetry of structure in the crystal. Huygens was not able, however, to explain his own significant discovery that the two rays obtained by double refraction in one crystal behave differently on entering a second crystal: if the crystals are oriented in exactly the same way (or at 180°), there is no further splitting of the rays; any other orientation produces four rays. Isaac Newton of England, considering this phenomenon in 1717, concluded from double refraction that light rays must have "sides"; *i.e.*, properties that depend on directions perpendicular to the direction of propagation of the radiation. Pressure waves, such as sound, are longitudinal and perfectly symmetrical about the direction of propagation. Much earlier, Newton had discovered the composite nature of white light, investigated the colours of thin films, and developed a theory of colour (see LIGHT). It was inconceivable to both

Huygens and Newton that light could be a transverse wave, vibrating at right angles to the direction of propagation, and the difficulties of interpreting the phenomenon of polarization led Newton to reject the wave theory of light.

Revival of the wave theory at the beginning of the 19th century came as a result of discoveries made by the physicists Thomas Young of England and Augustin-Jean Fresnel of France. Young's greatest theoretical contribution was the principle of interference, the description of a property that has come to be a definition of wave in distinction to corpuscle. Young explained his principle by analogy to sound and to surface waves on water and concluded that

> whenever two portions of the same light arrive to the eye by different routes, either exactly or very nearly in the same direction, the light becomes most intense when the difference of the routes is any multiple of a certain length, and least intense in the intermediate state of the interfering portions; and this length is different for light of different colours.

Fresnel carried both theory and experiment much further, explaining diffraction by straight edges, obstacles, and apertures by a combination of Young's principle of interference and Huygens' principle for constructing wave fronts. It may seem strange that the idea of interference did not occur to Huygens, but conceptually his waves were pulses, not periodic, and the association of wavelength with light escaped him.

Transverse vibrations

Acting on a suggestion from Young that light is a transverse wave, Fresnel developed a complete theory of light propagation based on the properties of an assumed elastic medium, the ether. He was able to explain the optics of crystals, both calcite (uniaxial) and the biaxial crystals that were discovered later to be more common. Detailed predictions of this theory were confirmed after his death in 1827, as were the Fresnel formulas, which describe the intensity and polarization of light reflected at the surface of a transparent medium.

Fresnel also investigated the effect of the Earth's motion on the propagation of light and suggested the experiment later carried out by Fizeau to measure the spread of light in a moving material medium, in this instance water. (Fresnel's suggestion of the decisive experiment to distinguish the wave theory from the particle hypothesis by comparing the velocity of light in air and water no longer seemed crucial when performed by Foucault and others in 1850, when evidence for the wave theory had become overwhelming.) It is difficult to do justice to Fresnel's creativity, both experimental and theoretical; almost all of his contributions to the theory of radiation have survived the transition from the assumption of an elastic solid ether to the propagation of electromagnetic fields in free space.

Except for historical interest the details of the elaborate ether theories that occupied many scientists in the 19th century are no longer relevant to the study of electromagnetic radiation. One general question, however, must be applied to all models of a medium designed to transmit light: is the ether affected by the motion of bodies through it? There were many attempts to answer this question experimentally, with inconsistent results. The most ingenious attempt was the experiment devised by the United States physicist Albert Abraham Michelson in 1881 and carried out with the collaboration of Edward Williams Morley, also of the United States, in 1887. Their apparatus was designed to compare the velocity of light in directions parallel and perpendicular to the Earth's motion and thus to measure the speed of the Earth through the ether. The results were negative: no difference could be detected. But by 1887 it was becoming evident that light is an electromagnetic wave, and it was necessary to include a much broader range of phenomena in any theory that might account for its transmission.

Relation between electricity and magnetism. As early as 1760 the celebrated Swiss-born mathematician Leonhard Euler suggested that the same ether that propagates light is responsible for electrical phenomena. In comparison with both mechanics and optics, however, the science of electricity was slow to develop. Magnetism was the one science that made progress in the Middle Ages, following the introduction into the West of the magnetic compass, but electromagnetism played little part in the scientific revolution of the 17th century. It was, however, the only part of physics in which very significant progress was made in the 18th century. By the end of that century the laws of electrostatics—the behaviour of charged particles at rest—were well known, and the stage was set for the development of the elaborate mathematical description first made by a French mathematician, Siméon-Denis Poisson. There was no apparent connection of electricity with magnetism, except that magnetic poles, like electric charges, attract and repel with an inverse-square law force.

Following the discoveries in electrochemistry (the chemical effects of electrical current) by the Italian investigators Luigi Galvani, a physiologist, and Alessandro Volta, a physicist, interest turned to current electricity. A search was made by a Danish physicist, Hans Christian Ørsted, for some connection between electric currents and magnetism, and during the winter 1819–20 he observed the effect of a current on a magnetic needle. Members of the French Academy learned about Ørsted's discovery in September 1820, and several of them began to investigate it further. Of these the most thorough in both experiment and theory was a French physicist, André-Marie Ampère, who may be called the father of electrodynamics. The magnetic effect of a current had been observed earlier (1802) by an Italian jurist, Gian Domenico Romagnosi, but the announcement was published in an obscure newspaper.

Connection between electric currents and magnetism

The list of four fundamental empirical laws of electricity and magnetism was made complete with the discovery of electromagnetic induction by Faraday in 1831. In brief, a change in magnetic flux through a conducting circuit produces a current in the circuit. Almost equal claim to priority could be made for a United States physicist, Joseph Henry and the significant observation that the induced current is in a direction to oppose the change that produces it, now known as Lenz's law, was formulated by a Russian physicist, Heinrich Friedrich Emil Lenz, in 1834. When the laws were put into mathematical form by Maxwell, the law of induction was generalized to include the production of electric force in space, independent of actual conducting circuits, but was otherwise unchanged. On the other hand, Ampère's law describing the magnetic effect of a current required amendment in order to be consistent with the conservation of charge (the total charge must remain constant) in the presence of changing electric fields, and Maxwell introduced the idea of "displacement current" to make the set of equations logically consistent. As a result, he found on combining the equations that he arrived at a wave equation, according to which transverse electric and magnetic disturbances were propagated with a velocity that could be calculated from electrical measurements. These measurements were available to Maxwell, having been made in 1856 by the German physicists Rudolph Hermann Arndt Kohlrausch and Wilhelm Eduard Weber, and his calculation gave him a result that was the same, within the limits of error, as the speed of light in vacuum. It was the coincidence of this value with the velocity of the waves predicted by his theory that convinced Maxwell of the electromagnetic nature of light.

The electromagnetic wave concept. Maxwell's theory predicted that the index of refraction of a transparent medium is equal to the square root of the dielectric constant (a measure of specific inductive capacity) of the medium. This relation was not consistently observed because the dielectric constant was not measured at optical frequencies, and the apparent discrepancy added doubts to the validity of the theory. Maxwell did not include any account of the origin of radiation; and although effects of oscillatory electrical discharges had been observed much earlier by Joseph Henry and others, the theory was not confirmed until after his death with the experiments (1887–88) of Hertz. Hertz produced electromagnetic waves, demonstrated their reflection, refraction, and interference in complete accord with Maxwell's results, and

also took steps toward a theory of radiation, relating waves to their sources. The concept of retarded potentials had been introduced earlier, in 1867, by a physicist, Ludvig Valentin Lorenz, of Denmark, but their relation to the waves predicted by Maxwell was not at first clear. Other predictions of Maxwell's theory, including the pressure of light, were verified in the years that followed.

Practical use of electromagnetic radiation for communication (radio, radar, television) dates from the demonstration of wireless telegraphy by a British physicist, Oliver Joseph Lodge, in 1894, but Lodge himself failed to foresee any practical implications of the experiment. The credit for devising wireless long-distance communication is properly assigned to an Italian engineer, Guglielmo Marconi who in 1901 achieved transatlantic radio communication. This long-range transmission of electromagnetic radiation had been considered impossible because of the Earth's curvature, and the scientific community was initially skeptical. In 1903 Oliver Heaviside of England, and Arthur Edwin Kennelly, an electrical engineer of the United States, postulated a region of the upper atmosphere, called by them the ionosphere, that reflects electromagnetic waves of long wavelength. The ionosphere itself at once became a subject for research.

The concepts of electric and magnetic fields, in the sense of forces filling space, began with Faraday, who visualized them as bundles of lines, and were developed mathematically by a British physicist, Lord Kelvin (William Thomson), and by Maxwell. Maxwell was fully aware of the energy density in the field, but a general theorem relating the energy flux at any point to the electromagnetic fields at that point was announced only in 1884, by an English physicist, John Henry Poynting, and independently by Heaviside. In 1859 Gustav Robert Kirchoff, a physicist of Germany, showed that the frequency distribution of heat radiation in a cavity surrounded by walls (a black body) depends only on the temperature and the frequency, or wavelength. An expression for this dependence was derived by a German physicist, Wilhelm Wein, in 1893 on the basis of thermodynamic principles, but later was found by experiment to be valid only for high frequencies. In 1900 an English physicist, Lord Rayleigh (John William Strutt), published a different formula, based on a theorem of statistical mechanics, that of equipartition of energy among the degrees of freedom of the system. This formula, known as the Rayleigh–Jeans law after Rayleigh and James Hopwood Jeans, states that the intensity of radiation emitted by a black body is proportional to the square of its frequency; but it also predicts infinite intensity for the high-frequency end of the spectrum, although it approaches the correct value for long wavelengths at the other end of the spectrum. The correct law, proposed in 1900 by Planck, initiated the quantum theory of electromagnetic radiation.

The quantum concept. Although Planck originated the quantum hypothesis and thus arrived at the perfectly satisfactory radiation law that bears his name, the quantum of radiant energy, or photon, as it was later named (1926), was the theoretical creation of Albert Einstein in 1905, postulated to describe the photoelectric effect (*q.v.*). The reality of the quantum of electromagnetic radiation, complete with momentum as well as energy, is exhibited still more clearly by the scattering of photons by free electrons (those not bound to nuclei in atoms), the Compton effect discovered in 1923 by Arthur Holly Compton, a physicist of the United States. Einstein, however, had already, in 1916, derived the fundamental equations for the exchange of energy between matter and radiation, introducing the concept of stimulated emission and showing that emission and absorption are directed processes, involving transfer of momentum as well as energy. The result was successfully applied to describe the scattering of light by an assemblage of atoms around 1924 by the physicist Hendrik Anthony Kramers of The Netherlands and Werner Heisenberg of Germany. Stimulated emission means that there will be inelastic scattering, with the production of frequencies that are linear combinations of some natural frequency of the atom with that of the incident radiation. Such radiation, called Raman emission, was discovered in 1928 by a physicist, Chandrasekhara Venkata Raman, of India.

Stimulated emissions

The quantum theory of the pure radiation field was first developed by an English physicist, Paul Adrien Maurice Dirac in 1927; and for treating the interaction of radiation with matter, the electron is represented by the Dirac wave equation. For an account of the quantum theory of radiation, the reader is referred to the final reference listed in the bibliography of this article.

SEMIQUANTITATIVE TREATMENT OF RADIATION

Properties of wave motion. In wave motion (*q.v.*), be it from sound, the undulation of the ocean's surface, or electromagnetic radiation, energy is transmitted through space or through a material medium as some sort of disturbance, without the transport of matter. The disturbance may be sudden, with a sharp onset, or have any other form of beginning. Continuous waves of any kind may be periodic, the form of the disturbance being repeated at regular intervals, and the simplest periodic waves are sinusoidal; *i.e.*, identical in space at any given instant with a sine curve (Figure 1). The frequency ([nu] ν = number of vibrations of the wave at a given point per unit time) of a periodic wave is imposed by the source of the disturbance, but the velocity (v) of the disturbance through space is in general determined by the medium and by the nature of the wave. The wavelength (lambda, λ) of a periodic wave depends on both the source and the medium; the product of the wavelength and the frequency is the wave velocity: $\nu\lambda = v$. Waves are reflected by a boundary between two different media and are refracted (changed in their direction) in passing from one transparent medium into another, where their velocity is different. Waves can be characterized by interference and diffraction, and all electromagnetic radiation exhibits these latter properties.

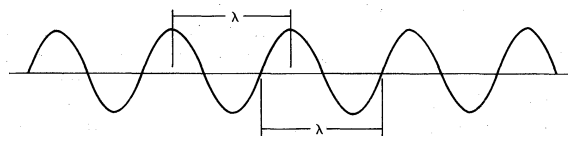

Figure 1: Sinusoidal waves in space, showing wavelength λ.

The distinction between interference and diffraction is not altogether sharp, but the term diffraction is usually applied to the deviation of waves from straight-line propagation, the occurrence of a disturbance in regions shielded from direct view of the source by opaque obstacles. The word interference, on the other hand, is most often used to describe the redistribution of energy in space or time because of the reinforcement and cancellation of parts of the disturbance. Two adjacent periodic sources of the same frequency, for example, reinforce to produce maxima in some parts of space, and cancel to produce minima, or nodes, elsewhere. Another example is provided by two sources with slightly different frequencies that interfere to produce beats, alternate reinforcements and cancellations that are periodic with time.

A surface of constant phase, such as a crest or trough of a periodic wave, is called a wave front. The wave front radiated by a single small source in three-dimensional space is a spherical surface. The energy transported in wave motion is proportional to the square of the wave amplitude (maximum periodic displacement). The energy transport per unit area perpendicular to the direction of wave propagation is the intensity, which for a spherical wave falls off inversely as the square of the distance from the source (and thus the amplitude falls off with the first power). This law follows from the fact that, in the absence of absorption, an undiminished amount of energy flows through any imaginary sphere surrounding the source, the area of a sphere being proportional to the square of its radius. Far away from a source where the radius is large, a resulting wave front will be approximately a plane, with energy transmitted undiminished in

the direction of wave propagation. Sunlight reaching the Earth is essentially plane.

Electromagnetic waves are transverse, and unlike longitudinal waves (as in the case of sound), the amplitude of vibration is perpendicular to the direction of travel; by analogy with mechanical waves, an elastic solid medium would be required to transmit them. Much effort of 19th-century physics was devoted to a study of the properties of this hypothetical medium that offers no perceptible resistance to the motion of planets and other bodies. This was called the ether. The laws of light and electromagnetism were based on the assumption of an ether stationary throughout the universe, with respect to which the laws were presumably valid in their simple form. The ether theories of the 19th century were based on Newtonian mechanics, and on this basis, if the Earth moves relative to the ether, it should be possible to detect its motion. The evidence seemed contradictory. Because of the motion of the Earth about the Sun, distant stars appear to move in orbits of about 41 seconds in angular diameter, a phenomenon that is quite consistent with a stationary ether. On the other hand, a difference between the velocity of light in the direction of the Earth's motion and at right angles to that direction, predicted on the basis of a stationary ether, was not observed in the famous Michelson-Morley experiment. Other experiments sought to distinguish between a stationary ether and an ether swept along by bodies passing through it, but none demonstrated the existence of any ether at all. The problem was resolved only in 1905 with Einstein's special theory of relativity. To trace the connection between light and electromagnetism, however, one must examine the laws of electricity and magnetism.

Distinction between interference and diffraction

Empirical laws of electricity and magnetism. There are four fundamental empirical laws of electricity and magnetism that in combination predict the existence of electromagnetic radiation. Moreover, electrical measurements yield an exact value for the velocity of propagation of this radiation. Using these four laws, the essential features of this synthesis of electromagnetism and light will now be reviewed.

The law usually written first in the list of four is Coulomb's law of electrostatics, which describes the force between two particles having an electric charge. The form of the law is the same as Newton's law of gravitation, with the substitution of charge for mass, except that there are two kinds of charge, positive and negative. Like charges repel and unlike charges attract, with a force that varies directly as the product of the charges and inversely as the square of the distance between them. From this law it is possible to define an electrostatic unit of charge as that which produces unit force on a similar charge at unit distance. The law itself can be stated as an action at a distance, just as the law of gravitation is usually stated, or in terms of an intermediate concept, the electric field. One charge, considered as the source, produces a field in the space surrounding it that can be measured as a force per unit charge by a positive test charge at any given point. The electric field is usually designated by the symbol $\boldsymbol{E}$, a vector quantity (a vector is a quantity for which direction and magnitude are implied; all vectors in the following discussions will be given in italic boldface type; magnitudes in italics only). The concept of field is essential for describing radiation but is merely a convenience in presenting the laws of electrostatics.

A second law deals with magnetism only. In terms of magnetic poles it is another inverse square law, but for fuller understanding it must be stated that isolated poles are nonexistent. Every magnetic pole is part of a dipole; *i.e.*, is accompanied by an opposite pole of equal strength. Experiments may be made with long dipoles, however, such as magnetized needles, and a unit pole is defined as one that produces unit force on a similar pole at unit distance. In terms of poles, a magnetic field may be defined at any point in space as the force per unit pole. Like the electric field, the magnetic field is a vector quantity, its direction being understood as the line along which its force acts.

A third law, known as Ampère's law, relates magnetism to electricity. An electric current, defined as moving charge, is accompanied by a magnetic field, the direction of which is in general at right angles to the motion of the charge. Consequently a current loop (such as a charge moving in a wire bent to a circular shape) is equivalent to a flat magnetic dipole, a "magnetic shell" the faces (opposite sides of the plane of the loop) of which have opposite magnetic polarity. In terms of the magnetic pole strength just defined, this equivalence between magnetic dipoles and a current loop yields a corresponding unit of current, defined as that current flowing in a loop of unit area that would be equivalent to a unit magnetic dipole. The charge conveyed past a point per second of time by this unit current is called the electromagnetic unit of charge and is defined quite independently of the static force it might exert on another charge.

Ampère's law

Analysis shows that this electromagnetic unit of charge does not even have the same dimensions (in terms of mass, length, and time) as the unit defined electrostatically: it is a constant c times larger, in which c has the dimensions of a velocity. The constant may be determined in many ways; the initial method used by Kohlrausch and Weber was to measure the discharge of a capacitor having known charge through the coil of a galvanometer that deflects magnetically according to the magnitude of the charge. The value of the constant is $c = 3 \times 10^{10}$ centimetres per second, to a good approximation. There is nothing, however, in the laws of electricity and magnetism thus far in this account that would suggest any association of the constant c with the propagation of radiation. Radiation depends on effects that vary in time and is not produced by static charges or steady currents.

The fourth fundamental law of electricity and magnetism is known as Faraday's law of electromagnetic induction. This law is the principle governing the behaviour of dynamos and generators, for its most apparent consequence is that an electric current is set up in a closed circuit by a changing magnetic field. The motion of charge in a conductor is the result of an electric field, and the law may be generalized to state that a changing magnetic field is accompanied by an electric field. The electric field so generated is at right angles to the change in magnetic field. The existence of this electric field does not require the presence of a conductor, and the relation holds in empty space, well away from all charges and currents that constitute the sources of magnetic field. (Because, by Ampère's law, magnets are equivalent to configurations of current, one need not include permanent magnets explicitly as sources of magnetic fields.)

Faraday's law concludes the list of fundamental principles of electricity and magnetism, except that the third, Ampère's law, is as an empirical relation not quite complete. According to Ampère, steady currents are accompanied by magnetic fields, but the law takes no account of the accumulation of charge that is possible with currents that vary in time. It is in fact not compatible with the conservation of charge, an axiom in accord with experience that the total charge of an isolated system is constant. This defect was remedied by Maxwell, who added to moving charge what is called the displacement current. The displacement current takes into account the accumulation of charge associated with time variations of the current, and also predicts that a changing electric field is accompanied by a magnetic field in space.

These four fundamental laws, when put into mathematical form, are called Maxwell's equations, and they will be considered explicitly in a later section. Maxwell's equations serve to trace quantitatively the electric and magnetic fields to their sources, the charges and currents. They also predict reciprocal relations between electric and magnetic fields as applied to empty space: that changes in either kind of field are accompanied by changes in the other kind of field, regardless of the specific sources of the fields. These interconnections may be expressed as circulation laws, involving the work done on a unit charge or on a unit pole. Faraday's law is readily written as a circulation law: the work done in

Maxwell's equations

taking a unit electric charge around a closed loop may be called the circulation of E. This work is equal to the rate of change of the total magnetic field through the surface bounded by the loop, the total magnetic field threading the loop. (The term threading comes from Faraday's analogy of the concept of a field to a bundle of lines, the number of lines per unit cross-sectional area representing the strength of the field.) The phrase "equal to" rather than "proportional to" implies the choice of a particular set of units. With the electric field expressed in electrostatic units and the magnetic field in electromagnetic units, a factor c must be included to ensure the correct numerical relationship: the constant c times the circulation of E referred to above is equal to the time rate of change of the magnetic field summed over the surface.

Ampère's law, as amended by Maxwell in the absence of real current sources, may be worded in an analogous way. The work done in taking a (hypothetical) unit pole around a closed loop is the circulation of the magnetic field B and is proportional to the rate of change of the total electric field threading the loop. Again, the factor of proportionality c must be included. If the choice of units is the same as above, Ampère's law states that the constant c times the circulation of B is equal to the rate of change of the total amount of electric field threading the loop. (For a uniformly changing electric field this is just the time rate of change of the electric field multiplied by the area of the loop.)

It can be shown in an elementary way, as appears in Figure 2, that certain mutually perpendicular electric and magnetic field configurations will be propagated through empty space in a direction transverse to the fields at the velocity c, as a result of these reciprocal relations. In this figure, E represents the electric field strength and B represents the magnetic field strength,

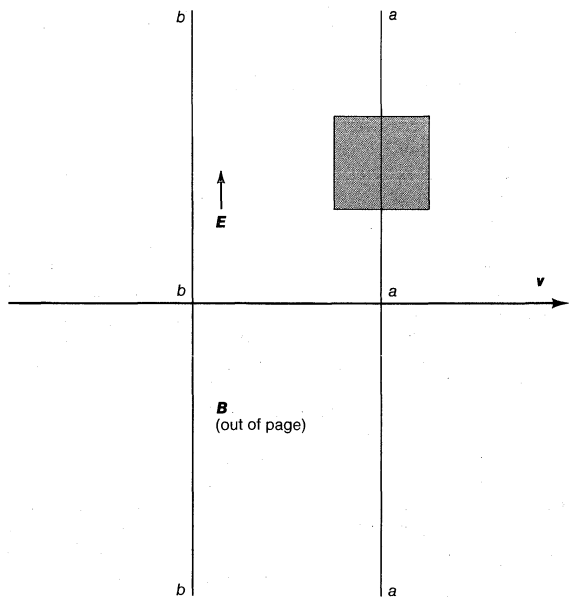

Figure 2: Slab of fields E and B, between planes *aaa* and *bbb*, moving toward right with velocity v as boundary crosses unit square (see text).

both being uniform in the region between two parallel planes *aaa* and *bbb*, with the field E directed toward the top of the page and the field B out of the page, as indicated. If this slab of field moves to the right with speed v, and the circulation laws are applied to stationary unit square loops, partly within and partly outside the field (one of which is shown as a shaded area), the circulation of E around this loop (work done on a unit charge) will be numerically equal to E, because no work would be done on a unit charge outside the field region, and the paths perpendicular to the field contribute nothing. The rate of change of total magnetic field threading this loop would be equal to the rate at which the magnetic field region is encroaching on the loop, namely v for a unit square, times the magnitude of the magnetic field, B. Thus the application of the first circulation law yields an expression in which the product of the constant c and the electric field strength is equal to the product of the velocity and the magnetic field strength, or $cE = vB$. If the square about which the circulation is to be taken is now turned at right angles to the plane of the page, and the circuital law for the field B is applied, there will result an equation analogous to the preceding; namely, $cB = vE$. Both these relations are satisfied for $v = c$ and $B = E$. The fields must have these relations to satisfy the circulation laws. Thus the orthogonal field configuration (electric and magnetic fields perpendicular to each other) will move at constant speed $v = c$ and will maintain itself undistorted; and a disturbance transferred in this way will constitute a pure wave. The conclusion is a consequence of the circuital laws that express the relationships between all magnetic and electric fields varying with time.

This result is entirely equivalent to the more formal mathematical analysis by which the equation for plane electromagnetic waves is derived in the section *Transmission of radiation in free space* (see below). The shape of the wave is arbitrary, and for many purposes it is more convenient to consider a sinusoidal disturbance (see Figure 3) of definite frequency and free-space wave-

Sinusoidal disturbance

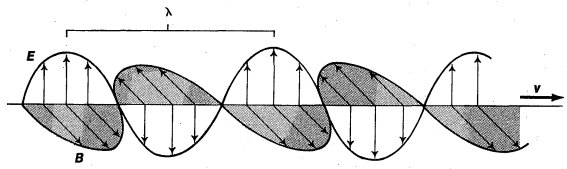

Figure 3: Radiation fields in which vectors E and B are perpendicular to each other and to the direction of propagation (see text).

length than a wave profile with such discontinuities as the one above. Here the electric and magnetic fields are transverse to the direction of propagation, and there is a definite relation between their magnitudes. The field vectors, E, B, and the direction of propagation, taken in the order stated, form a right-handed set of coordinates: if the index finger, second finger, and thumb of the right hand are extended at right angles to each other, they will represent, respectively E, B, and the direction of wave propagation. The reversal of both vectors E and B simultaneously does not change the direction of propagation, but the reversal of either E or B alone corresponds to changing the direction of the wave.

The radiation field. Within radiation fields, as in electric and magnetic fields generally, there is energy, with the energy density proportional to the square of the field strengths in question (E^2 or B^2). The relation between the fields in a progressive wave is such that the energy density is divided equally between the electric and magnetic fields at any point. The flux of energy, the energy crossing unit surface perpendicular to its flow per unit time, is called the Poynting vector and is equal in magnitude to the velocity c times the sum of electric and magnetic field energy densities. The radiation also carries momentum; the density of momentum is equal to the Poynting vector divided by c^2, or the energy density divided by the constant c.

Maxwell predicted the field relations, but he did not trace his predicted radiation to its sources. It is evident that neither static (stationary) charges nor steady currents can produce radiation fields, for the fields associated with such sources diminish rapidly in intensity as the distance from the source increases. Because electromagnetic energy density is proportional to the square of the field strength (electric or magnetic), the radiation field must be proportional to the inverse first power of the distance; for the wave intensity must obey the inverse square law to be actually transported away from the source. (This is because the area of a sphere is proportional to the square of its radius, and equal amounts of energy must be transported through successive spherical surfaces.) Such fields are produced by accelerated charges.

The simplest radiator is an oscillating electric dipole,

two equal and opposite charges vibrating in a straight line about a central point at the same rate but opposite in phase (that is, they are alternately moving toward and away from each other, passing at the central point). The dipole moment is the magnitude of one charge multiplied by its separation from the opposite charge at any instant, and in the oscillation the moment varies from its maximum value in one direction to its maximum value in the opposite direction, because, by convention, the direction of the field is from the positive charge to the negative charge, and the two charges are constantly interchanging positions. A dipole antenna may be represented in this way. The radiation field of an oscillating dipole is polarized, with the electric field vector at any point lying in a plane that contains the axis of the dipole itself; both the direction of propagation and the magnetic field vector are at right angles to this plane; because there are an infinite number of planes passing through the dipole, the magnetic field directions or lines are circles about the axis of the dipole. The radiation intensity depends on the angle between the dipole axis and the direction of propagation, having a maximum in the equatorial plane and a node (minimum) in the direction of the axis of the dipole. If the vibration frequency is fixed, the radiation is of course one wavelength, or monochromatic; but the radiation from accelerated charges generally can be analyzed into a spectrum of dipole radiation, and the strongest radiation from atoms and molecules is ordinarily of this kind.

Dipole radiation

Whereas a purely monochromatic wave is an idealization, any real wave may be represented by a superposition of disturbances having definite frequencies. The oscillating electric dipole is, strictly speaking, also an idealization of actual charge and current distributions, even though the dipole radiation pattern is often a good representation of actual radiation. A more complete description requires that the radiation field be expressed in terms of a series expansion, of which the dominant term is the electric dipole. Only when the configuration of charges is such that the dipole moment vanishes is the radiation not predominantly electric dipolar in character.

THE SPECTRUM OF ELECTROMAGNETIC RADIATION

All electromagnetic waves transport energy from a source to a receiver, as do mechanical waves, but unlike mechanical waves they do not require a material medium.

Electric current waves. Electric current waves, nevertheless, are commonly propagated along transmission lines, such as a pair of parallel wires or a coaxial cable. Transmission lines are in fact necessary to convey high-frequency electromagnetic energy from a generator to a load such as an antenna. The conductors are designed to have as little resistance as possible, and many features of typical transmission lines for high frequencies are those of an ideal line, for which the conductivity is infinite.

Figure 4 shows a cross-sectional view of a pair of long parallel wires fed at one end by a high-frequency alternating current generator. At the position of the cross section there is a difference of potential between the wires associated with their opposite charges, and therefore electric field lines extend from one wire to the other, as indicated. There is also a magnetic field between them associated with their opposite currents, magnetic field lines that crowd between the two wires, shown as dashed lines in the figure. These two fields, electric and magnetic, are perpendicular to each other and to the wires. It is possible to compute the capacitance per unit length of line (the ratio of the linear charge to the potential difference) in terms of the radius of each wire and their distance apart, and also to compute the inductance per unit length (the ratio of the inclosed flux per unit length to the current) in terms of the same dimensions. The application of simple circuit theory leads to a differential equation in the charge per unit length that is independent of the dimensions of the system and the frequency, a wave equation that predicts the charge disturbance will be propagated down the line with a velocity equal to the

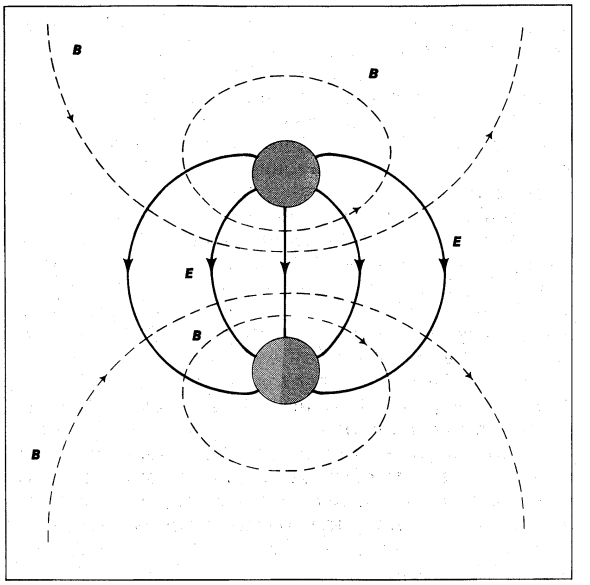

Figure 4: Cross section of a pair of wires (indicated by shading) carrying high-frequency current. Field lines ***E*** and ***B*** and wires are mutually perpendicular (see text).

velocity of light. (For the configuration shown in Figure 4 the wave is transmitted out of the page toward the reader.) Moreover, the distribution of the transverse electric and magnetic fields is exactly the same as if the charges were static and the currents were steady. The actual configuration of fields depends on the geometry of the conductors, but the identity of the fields with those produced under quasi-static conditions and the speed of transmission of the disturbance are quite general. For actual conductors having finite conductivity there must be a component of the electric field along the transmission line, but this component is small for good conductors.

Radio waves. Radio waves are ordinarily transmitted through space without benefit of wires, but they are produced and detected by electrical circuits. These disturbances have relatively low frequencies and consequently long wavelengths, as indicated in the Table. In empty space or a homogeneous medium, they would travel in straight lines and, because of the Earth's curvature, could not be useful in direct communication over long distances. It was this consideration that caused scientists to question Marconi's efforts to develop long-range radio, and Marconi's success, unexpected on theoretical grounds, led to the postulation of the Kennelly-Heaviside layer, or ionosphere. This region of free ions (positively charged particles) and electrons actually consists of more than one layer and fluctuates widely from day to night and from summer to winter.

The discovery of the ionosphere

Despite its fluctuation, the ionosphere has nevertheless been of great practical importance in radio communication. The range of direct communication, by means of what is called the ground wave, varies with wavelength but is something like 100 miles (160 kilometres) for waves 100 metres (330 feet) long, and little more for longer waves. Long-distance transmission depends on sky waves, waves that have been refracted by the ionized layers and are thus returned to Earth. Variations in signal strength are produced by fluctuations in the ionosphere and by interference of the ground and sky waves in regions where both may be received. The ionosphere absorbs appreciably only those waves whose free space wavelength is in the neighbourhood of 200 metres (660 feet). It is this frequency, about 1.5 megacycles, that corresponds to the cyclotron frequency of electrons caused by the Earth's magnetic field at that altitude. In general, the atmosphere is fairly transparent to radio frequencies, giving rise to the possibility of radio astronomy observations with terrestrial telescopes.

Microwaves. Microwaves may be defined as those with wavelengths between 1 millimetre and 30 centime-

tres, corresponding to frequencies between 3×10^{11} and 10^9 hertz (cycles per second). These wavelengths are comparable to the dimensions for which it is feasible to build apparatus, and highly directed beams may be produced by aperture antennas many wavelengths wide. This situation makes possible radar, the application of microwaves analogous to sounding in water navigation. A powerful beam of radiation may be sent out, much as a searchlight sends light, and detection of the reflected radiation gives information about the reflecting object. Because of their short length, microwaves give much better resolution and precision of information than could be obtained with longer wavelength radiation. These waves penetrate clouds of smoke, but they can detect rain because they reflect off water droplets, and so they are widely used in weather forecasting and the mapping of meteorological disturbances. Radar is particularly useful in the navigation of aircraft. Microwave apparatus is also a powerful research tool in the investigation of the properties of matter. Special devices for producing these high frequencies involve resonant cavities, and the energy is transmitted from source to transmitter by wave guides, or coaxial lines consisting of a central metal rod in a hollow conducting pipe.

Infrared waves. Infrared radiation comprises wavelengths from 1 millimetre to the longest wavelength visible light, about 7.5×10^{-5} centimetre. This range, also known as radiant heat, was discovered by the English astronomer Sir William Herschel in 1800. Herschel found, by putting a thermometer at various points in a prismatic spectrum, that ordinary light transmits some heat but that the effect is even more marked beyond the red end of the spectrum. Infrared radiation is readily absorbed by many kinds of matter and is thus effective in warming the substances on which it falls. Because it is more penetrating than visible light, such radiation lends itself to many kinds of practical applications, from physical therapy to detectors of military importance. The energy radiated by hot solids lies largely in this range. Infrared radiation is also characteristic of many natural frequencies of molecules, and by using a spectrograph and suitable photographic plates it is possible to photograph the lines and bands emitted by molecules. The atmosphere is almost completely transparent to a part of the infrared spectrum, in the neighbourhood of 10^{-3}-centimetre wavelength, and infrared photography takes advantage of this phenomenon to overcome the absorption of visible light by atmospheric haze.

Visible light. Visible light is the most familiar part of electromagnetic radiation and may be defined as that portion of the spectrum to which the eye is sensitive. This span is relatively narrow because the frequencies corresponding to violet are only about twice those that are characteristic of red. The observed wavelengths range from about 7×10^{-5} centimetre to 4×10^{-5} centimetre. The theory of light began in antiquity as a theory of vision, but a theory of vision involves many aspects of both physical and biological science. The physical science of light depends largely on instrumental receivers, such as the photographic plate. Visible radiation is produced by luminescence (fluorescence and phosphorescence) and by hot solids; its energy range includes many of the lines and bands characteristic of atoms and molecules, and historically much of our information concerning atomic structure has been derived from an analysis of atomic spectra.

White light includes a continuum of the range of visible wavelengths, which may be described mathematically as a distribution of simple harmonic waves of definite frequency, but it is in practice impossible to produce an infinitely long wave train and it is necessary to consider groups of waves. The phenomenon of interference, so crucial in determining the wave nature of light, can be observed only when the waves are mutually coherent; *i.e.*, when the interfering beams have a definite relation in phase and do not fluctuate independently of each other. If the two beams originate in the same source, they will be coherent unless the difference between their paths from the source to the interference region is too long. (It is of course possible to have partial coherence.) These arguments apply to all types of electromagnetic radiation, but for long waves the phase is more accessible to control than is generally true for optical frequencies, which are of the order of 10^{14} hertz.

Coherent beams

Ultraviolet light. Ultraviolet radiation lies on the short-wavelength side of the visible spectrum. It was reported in 1801 that the spectrum beyond the violet was capable of blackening silver chloride even more effectively than light. About the middle of the 19th century it was found that quartz is much more transparent than glass to ultraviolet rays, and ultraviolet spectroscopy developed rapidly. The detector may be a photographic plate or a fluorescent screen. In fluorescence, invisible radiation is absorbed, and radiation in the visible range is emitted. The maximum sensitivity of photographic emulsions lies in the ultraviolet, but the gelatin absorbs wavelengths shorter than about 2×10^{-5} centimetre, and the far ultraviolet was not at first accessible to investigation. The Earth's atmosphere also absorbs the short-wavelength ultraviolet and thus screens life from this kind of solar radiation.

X-rays. The discovery of X-rays by Wilhelm Conrad Röntgen, a German physicist, late in 1895 is often said to mark the beginning of modern physics. These rays were discovered by virtue of the fluorescence they produce, but their most significant feature was their penetrating power. Many kinds of substances that are quite opaque to visible light and ultraviolet light are transparent to X-radiation. In the flurry of research activity following this discovery, radioactivity was discovered and important new fields of science were opened; but the search for interference effects in X-rays was unsuccessful for nearly 17 years. In 1912 a German physicist, Max Theodor Felix von Laue, suggested that the regular arrangement of atoms in crystals might be equivalent to a ruled grating used to separate the wavelengths of visible light and might be of about the right spacing to make X-ray interference patterns. This prediction was confirmed, and X-ray crystallography was almost immediately developed further by the English physicists William Henry Bragg and his son, William Lawrence, and others. Since that time X-rays and crystal structure have remained closely related: crystal spectrometers are used to analyze X-ray spectra, and X-rays are used to determine the detailed structure of crystals. The definition of the range of radiation called X-rays is arbitrary, but the wavelengths are roughly from 10^{-7} to 10^{-11} centimetre. X-rays originate most commonly from the stopping or slowing of high-energy electrons and are usually detected by photographic plates. In the collisions of energetic electrons with heavy atoms, X-ray line spectra are also produced, definite wavelengths that are characteristic of the atoms, just as are the line spectra in the visible region.

Gamma rays. In addition to X-rays, there are other high-frequency electromagnetic radiations called gamma rays. The name originated in connection with radioactivity, gamma rays being that component of radioactive emission that is not affected by a magnetic field, in distinction to alpha- and beta-ray particles. Gamma rays are more penetrating than the particulate emanations from radioactive substances and more penetrating than longer wavelength electromagnetic radiation. Gamma rays are usually characterized by giving the energy per photon, $h\nu$, in electron volts (eV) or in millions of electron volts (MeV). They interact with matter in three principal ways: the photoelectric effect, the Compton effect (both discussed below), and in their transformation into electron–positron pairs (positrons are positively charged electrons). In order to create an electron pair, the gamma-ray photon must have an energy greater than twice the rest mass energy of an electron (the energy liberated if the combined mass of an electron and positron at rest is converted to energy); *i.e.*, more than 1.022 million electron volts. There is in principle no upper limit to gamma-ray frequencies, and all extremely high-frequency electromagnetic radiation, including the X-rays originating in space, is now classed as gamma radiation. The particle

Gamma radiation

(photon) properties of gamma rays are more pronounced than their wave properties, but their essential character is the same as that of other parts of the electromagnetic spectrum.

The mathematical formulation of the laws of electromagnetism is the set of four Maxwell equations, which may be written in a variety of ways. To appreciate the significance of Maxwell's equations and to understand the theory of electromagnetic radiation, however, simple algebraic equations will not suffice, and therefore vector analysis, a topic of advanced calculus, will be employed throughout the latter part of this article, *III. Mathematical formulation of electromagnetic theory*.

II. Quantum theory of radiation

ELECTROMAGNETIC RADIATION AS PARTICLES: THE PHOTON

Within a decade of the experimental confirmation of Maxwell's theory that light and electromagnetic waves are the same (Hertz, 1887–88), it became evident that the theory of radiation was unsatisfactory. The evidence came from several quite different phenomena, including the optical line spectra characteristic of atomic sources, which the classical theory could not explain. A more flagrant contradiction between experiment and apparently well-reasoned theoretical prediction arose in connection with the radiation from heated solids. It was this contradiction that led to the introduction of the quantum, a concept that has pervaded 20th-century physics.

Radiation laws. All solid substances emit and absorb thermal radiation, and for every particular wavelength each substance has the same radiant and absorbing power. (This relation between emission and absorption also holds for antennas, and its application to gaseous substances has made possible the study of the chemistry of interstellar matter.) Ordinarily the efficiency of absorption depends on the magnitude of the wavelength, but a perfect absorber, or black body, may be defined as one that completely absorbs all wavelengths. A cavity with perfectly absorbing walls, all at the same temperature, will contain radiant energy in thermal equilibrium with the walls, having a distribution of energy as a function of wavelength that depends on the temperature. This spectral distribution may be determined by analyzing the radiation that escapes from the cavity through a small hole. A satisfactory theory of radiation, coupled with the principles of thermodynamics, should yield a correct description of the result; but in fact two different laws were proposed in the late 19th century, neither of which was in complete accord with experiment. Both laws were valid asymptotically, that is, at the extremities of the black body spectrum, one for short waves and low temperatures, the other for long waves but not at all applicable to high frequencies. The correct law for the entire spectrum was supplied by Planck in 1900.

To trace the development of Planck's radiation law it is necessary to review briefly the basis for the incorrect laws that it supplanted. Much of this basis is quite sound and satisfies the detailed predictions that seemed to follow unequivocally from established principles. First one should note that the total energy density of radiation in a cavity is proportional to the fourth power of the absolute temperature; *i.e.*, to T^4. This result was found experimentally by Josef Stefan (1879), and derived theoretically by Ludwig Boltzmann (1884) from considerations of radiation pressure and the second law of thermodynamics; it is called the Stefan-Boltzmann law. Further thermodynamic arguments led to the conclusion by Wien (1893) that the distribution of radiant energy (dW) according to wavelength change ($d\lambda$) must have the form:

$$dW = W_\lambda d\lambda = C_1\lambda^{-5}f(\lambda T)d\lambda = C_1T^5\frac{f(\lambda T)}{(\lambda T)^5}d\lambda,$$

in which $f(\lambda T)$ is a function of the product of wavelength and absolute temperature (λT) only, and C_1 is a constant. The function W_λ must have a maximum, and the equation as to the nature of the distribution leads to a displacement law: the wavelength at which the energy distribution is a maximum (λ_m) multiplied by the absolute temperature (T) is a universal constant found to have the value:

$$\lambda_m T = 0.2898 \text{ centimetre-degree Kelvin.}$$

Wien's law

This law, like the Stefan-Boltzmann law proposed earlier, is fully confirmed by experiment. But the function $f(\lambda T)$ is not so susceptible to general arguments. Wien was able to derive a law (from consideration of a gas in equilibrium with thermal radiation), according to which the energy distribution falls off exponentially for high frequencies. This decrease agrees with observation for the high-frequency range of thermal radiation, but the formula is quite wrong for low frequencies. A more substantial argument, used by Rayleigh, begins by finding the number of modes of electromagnetic radiation (number of standing waves) per unit frequency range in a resonant cavity. In accord with the equipartition of energy theorem, which asserts that thermal energy is on the average shared equally by all possible modes of motion in an amount proportional to the absolute temperature, he assumed that each radiation mode could share equally in the total radiant energy. Each mode is thus equivalent to an elementary oscillator. The number of modes per unit frequency range is proportional to the square of the frequency (ν), and because $\nu = c/\lambda$, $\nu^2 d\nu$ is proportional in magnitude to $\lambda^{-4}d\lambda$, and the distribution should be given by $dW = CT\lambda^{-4}d\lambda$, in which C is a constant. It should be noted that this expression is consistent with the general conclusion of Wien with the function $f(\lambda T)$ simply equal to λT, but it becomes infinite in the limit of short wavelengths, and would predict that all of any finite amount of radiation should run to high frequencies.

The formula derived by Planck in 1900 would deny the equipartition of energy and substitute the assumption that the average energy of each oscillator of frequency ν is some integer times $h\nu$, and that the smallest amount of energy that can be emitted or absorbed is $h\nu$, in which h is a constant to be determined from experiment. The average energy per oscillator in an assembly of oscillators of this kind is $h\nu/(e^{h\nu/kT} - 1)$, and the radiation law becomes:

$$dW = \frac{8\pi ch\lambda^{-5}d\lambda}{e^{hc/\lambda kT} - 1},$$

which is in excellent agreement with the experimental results obtained earlier in 1900. (The constant k, called Boltzmann's constant, is well known in statistical mechanics and like the constant h is determined by experiment.)

The quantum hypothesis, which introduced Planck's constant h, yielded a solution to the paradox of black body radiation, but it was not at first applied to electromagnetic radiation in general. The light quantum was introduced as a theoretical concept by Einstein in 1905.

Photoelectric effect. Its first experimental confirmation was the evidence of its role in the photoelectric effect (*q.v.*). In this effect, discovered by Hertz, light is transformed into mechanical energy: electrons are given off when light of sufficiently high frequency strikes a metal surface, and the maximum kinetic energy of the emitted electrons is the difference between the photon energy ($h\nu$) and a work function (ϕ) that is characteristic of the metal, $E = h\nu - \phi$. This is Einstein's photoelectric equation; it means that light is absorbed in separate individual quanta, each of which may give its entire energy $h\nu$ to a single electron that must spend an energy ϕ to escape from within a metal where it is bound. There is thus a threshold frequency, $\nu_0 = \phi/h$, for the photoelectric effect. At frequencies higher than this threshold, the number of escaping electrons is proportional to the intensity of the incident radiation; but the energy per electron is a linear function of the frequency quite independent of the intensity, in accord with Einstein's equation. All features of the theory have subsequently been verified. The photoelectric effect cannot be explained by the classical theory of the absorption of electromagnetic radiation, according to which the energy necessary for electron emission would have to be accumulated gradually for low-intensity radiation, whereas no time delay is

Einstein's photoelectric equation

observed. The reality of the quantum of energy $h\nu$ and the equivalence of mass and energy leads to recognition of the fact that each quantum has momentum $h\nu/c$, or h/λ. This relation between energy and momentum is the same as in the classical theory of electromagnetic waves.

Compton effect. Compelling evidence of the particle nature of electromagnetic radiation is furnished by the Compton effect, which was announced in 1922. Compton found that in scattered X-rays there are lines of slightly lower frequency than that of the incident ray. The elementary theory of the effect is obtained by requiring both the conservation of momentum and energy in an elastic collision between a quantum of energy $h\nu$, having momentum $h\nu/c$, and an electron initially at rest. Figure 5 is

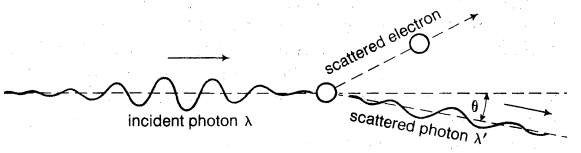

Figure 5: Elastic collision between photon and electron. Photon is scattered through angle θ with reduced frequency (ν) by an electron initially at rest (see text).

a diagram of the collision. It is necessary to use the relativistic formulas for the energy and momentum of the electron, which in the usual experimental arrangement is not observed. The result takes a simpler form in terms of wavelength rather than frequency. In terms of the scattering angle of the photon, the change produced in its wavelength is given by the product of Planck's constant divided by the mass of the electron and the velocity of the incident photon, and a quantity equal to 1 minus the cosine of the scattering angle:

$$\lambda' - \lambda = \frac{h}{mc}(1 - \cos\theta).$$

Here m is the mass of the electron, λ and λ' are the wavelengths of the photon before and after scattering, and θ (theta), the scattering angle, is the angle between the new path of the photon and the path the photon would have taken had it not been disturbed. The constant factor h/mc is called the Compton wavelength and has the value 0.0243×10^{-8} centimetre for electrons. A quantum of radiation with this wavelength would have an energy equal to the rest-mass energy of an electron.

Raman effect. The Compton effect is an example of an elastic collision between the photon and electron, but a photon may also be scattered inelastically, as in the Raman effect. This phenomenon was predicted by an Austrian physicist, Adolf Smekal (1923), and Kramers (1924), and observed in 1928 by Raman. (Equivalent observations were made almost simultaneously by G.S. Landsberg and L.I. Mandelstam in the Soviet Union.) The effect is that scattered light contains, in addition to the incident frequency ν, a series of other frequencies, all related to the original by the formula $\nu \pm \nu'$, in which ν' is a frequency observed in the absorption spectrum of the scattering material, or is equal to the difference of absorption frequencies. The Raman frequencies ν' are usually in the infrared, smaller than that of the incident visible light, so that the effect is the production of a band of lines in the neighbourhood of the incident frequency. If a scatterer is in its ground state (lowest energy state of the atoms or molecule), the scattered lines are all on the low-frequency side; but molecules already excited to higher states can add to the incident frequency, yielding visible light, although the intensity is in general stronger on the infrared side. The Raman effect has been a powerful tool in the study of molecular structure, because it brings evidence of infrared energy differences into the more easily observable visible region.

Wave–particle duality. These effects and others show that electromagnetic radiation is quantized; *i.e.*, consists of photons that behave as particles with energy $h\nu$ and momentum $h\nu/c$. Frequency, however, is a wave concept, having nothing to do with classical corpuscles. None of the phenomena of interference and diffraction that characterize a wave are invalidated by the particle aspect of radiation. Classical radiation theory, as surveyed here, is not actually incorrect, and it is quite sufficient to describe all effects except those that depend on the finite size of Planck's constant h. For long waves, and macroscopic radiators and receivers, quantum effects can ordinarily be entirely neglected, because the observed energy consists of a very large number of quanta. For all wavelengths the interference and diffraction patterns predicted by the classical theory are in accord with observation if the total effect of many quanta is observed. Thus electromagnetic radiation has a dual nature, appearing both as waves and as particles. The distribution of photons in a diffraction photograph, for example, is proportional to the intensity predicted by the wave theory. The incidence of each photon on the photographic plate is well localized; but in the neighbourhood of the diffracting obstacle, the radiation behaves like a continuous wave, impossible to localize within a wavelength at best. It should be noted that whereas a truly monochromatic wave would extend throughout all space, a narrow continuous band of frequencies may reinforce in a space with dimensions the size of a wavelength and cancel elsewhere. The lateral definition of a wave also requires a range of frequencies and phases. A wave packet with a slight spread of frequencies may exist in a definite region of space at a given time, and thus resembles a particle.

This wave–particle duality was extended by a French physicist, Louis-Victor de Broglie (1924), to apply to matter as well as to radiation. For a photon, its momentum (p) was established above, $p = h/\lambda$ (that is, its wavelength is $\lambda = h/p$); de Broglie's hypothesis is that every material particle is also a wave with a wavelength given by the same relation, which can be written $\lambda = h/mv$ inasmuch as a particle's momentum is equal to mass (m) times velocity (v). These waves of wavelength λ are not electromagnetic but are of a kind peculiar to matter. They do have periodicity, as do light waves, and an immediate consequence would be the possibility of diffraction for material particles. The diffraction of electrons was observed in 1927 by Clinton Joseph Davisson and Lester Germer, two physicists in the United States, and independently by George Paget Thomson, a physicist in Britain. The de Broglie hypothesis applies to all particles, and diffraction effects with helium atoms were found as early as 1930. Neutron diffraction is now an important tool for the investigation of crystal structure, supplementing the use of X-rays. An almost immediate theoretical consequence of the de Broglie hypothesis was the development of wave mechanics, one of two alternate formulations of quantum mechanics (*q.v.*).

Diffraction of material particles

In classical (Newtonian) mechanics the position and momentum of a particle may be known to arbitrarily high accuracy. This situation is not true for photons, and the de Broglie relation extends the limitation of precision to all particles. The uncertainty that is inherent in a wave packet makes possible an explanation of interference and diffraction in terms of photons, although the phenomena are conceptually more simple in terms of waves. Figure 6 shows an opaque shield with two openings A and B, called a double slit, and a white card acting as a projection screen. Parallel monochromatic light passing through the double slit will be found to produce on the screen an interference pattern, the intensity of which can be plotted as shown to the right. According to the wave theory, the field amplitudes at the screen cancel at any point, such as x_0, for which the respective distances to the slits A and B differ by half an odd number of wavelengths (*e.g.*, $\frac{1}{2}\lambda$, $\frac{3}{2}\lambda$, $\frac{5}{2}\lambda$, etc.).

The pattern owes its existence to the passage of part of the incident wave front through both slits. If the parallel homogeneous light is thought of in terms of photons, the description must be different, for each photon must go through either one slit or the other. Yet obstruction of one of the slits destroys the interference pattern—both slits must be open all the time. It was first thought that photons passing through the two slits interact with each other to interfere, but the pattern is produced even when

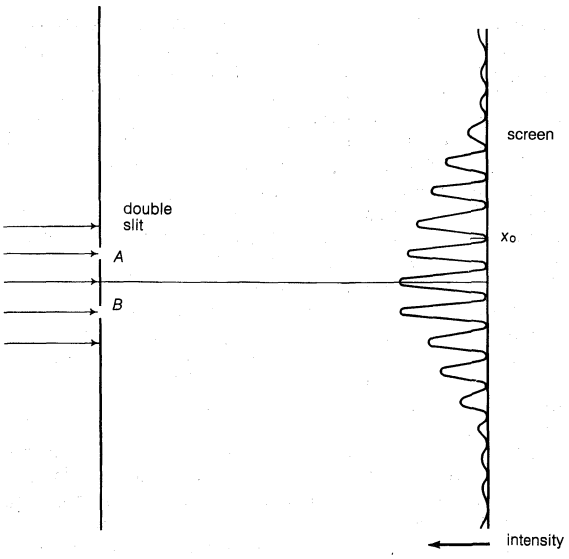

Figure 6: Light incident from the left on two equal slits forming a pattern on a distant screen. Intensity is zero at any point (*e.g.*, x_0) at which the contributions from *A* and *B* are out of phase (see text).

the intensity of the source is so low that not more than one photon is likely to be in the apparatus at any one time. The photon description of interference patterns can be satisfied in terms of probabilities. Probability amplitudes interfere in the same way that other wave amplitudes interfere, and the statistical occurrence of separate photon reception at the double slit yields the same intensity pattern as the classical wave theory. Any experiment that localizes the photon sufficiently to make it pass through a given slit destroys the pattern, just as closing the other slit would produce an alteration in electromagnetic wave intensity at the screen.

In atomic and nuclear systems, radiation occurs in the transition from one quantum state to another. A particle is described by a wave function, the mathematical representation of its equivalent matter wave. Quantized states are characterized by their parity, which is related to the symmetry of their wave functions in space. The parity transformation is inversion (reflection) in the coordinate origin (chosen as the centre of symmetry), defined by replacing the radius vector r with $-r$ whenever it appears. Parity is defined as odd, or $-$, for any function that changes sign under this transformation; and as even, or $+$, for one that does not change sign. Considerations of parity give rise to selection rules for the emission and absorption of electromagnetic radiation. In radiative transitions from one state to another, parity is conserved, so that in transitions between states of different parity the radiation field must be odd, and in transitions between states of the same parity the radiation field must be even. The parity of a particular kind of multipole field may be determined by examining the symmetry of the source, but it turns out that it is the same as the parity of the magnetic radiation field vector: electric multipole fields of order 2^n (in which n is a positive integer) have odd parity if n is odd (electric dipole, octupole) and have even parity if n is even (electric quadrupole). Because the corresponding magnetic multipoles are like the electric multipoles except that the fields are interchanged, it is evident that the opposite rule holds for them: magnetic multipole fields in order 2^n have even parity if n is odd (magnetic dipole, octupole) and have odd parity if n is even.

Selection rules

THE EFFECTS OF ELECTROMAGNETIC RADIATION

Wavelength dependence. All electromagnetic radiation interacts with matter. A beam of radiation is attenuated in passing through matter, so that its intensity decreases as its depth of penetration increases. The decrease in intensity (ΔI) in traversing a small increment of thickness (Δx) is proportional to the intensity itself (I) and to the increment of thickness, that is, $\Delta I = -\alpha I \Delta x$, and if the beam is monochromatic so that α (alpha) is constant, the intensity of the initial beam (I) after a finite penetration x is given by an exponential function $I = I_0 e^{-\alpha x}$. The attenuation may be due to elastic scattering (as discussed in the section of this article dealing with the scattering of radiation), various kinds of inelastic scattering in which the wavelength is altered, or outright absorption. Absorption is strongest at those frequencies that correspond to the resonance frequencies of the matter itself, those that are called ω_0 (omega) in the simple theory of scattering to be presented below. In fact, radiation propagates easily only through materials the atoms and molecules of which have natural frequencies that are quite different from that of the radiation. This resonance absorption may occur at any frequency; for example, the photon energies of visible and ultraviolet light, a few electron volts per photon, are comparable to those involved in chemical reactions, and these photon radiations are responsible for many photochemical reactions. Infrared radiation, or radiant heat, also produces chemical changes, such as burns and the processes that take place in cooking. Electronic ovens make use of longer wavelengths of the high-frequency radio band, usually the microwave range, so that the cooking of food is accomplished evenly by radiation that leaves almost unheated any nonconducting container for the food. (Microwaves do not penetrate metallic containers or wrapping, such as aluminum foil.)

Microwave heating

The relatively high frequencies of X-ray and gamma radiation are likely to change the internal structure of atoms, molecules, and solids (crystals), regardless of whether or not resonance is involved (see RADIATION EFFECTS ON MATTER). This effect is related to their great penetrating power; photons of this energy are not subject to surface scattering and reflection, such as is common with visible light at the boundaries of opaque materials. One should note that classification of high-energy photons according to their origin instead of their energy is becoming a thing of the past. Heretofore, by convention, radiations emitted from the deceleration of electrons or by transitions of electrons to inner atomic shells of atoms were called X-rays, and radiations caused by changes in nuclear energy states were called gamma rays. Part of the complication with earlier nomenclature arose with the recognition of annihilation radiation, photons of energy usually about 500,000 electron volts (0.5 MeV) emitted when a positive and negative electron combine. In this section, the term gamma ray will be used for any high-energy radiation, regardless of origin.

Absorption and scattering processes. Rayleigh scattering (see below) by tightly bound electrons in heavy elements is important for photon energies up to about 1 million electron volts, but Compton scattering is much more important and is the only observed scattering process for higher energies. The reason for this is that the binding energies of electrons in matter are much less than the high energy of hard gamma rays, and so all the electrons essentially behave as if they were free. As was seen earlier in Compton scattering, the scattered radiation has a longer wavelength and is less energetic than the incident ray, so that Compton scattering is accompanied by true absorption of energy by the material, unlike Rayleigh scattering. The attenuation of radiation through matter is then a combination of scattering and absorption in this process. In fact, Compton collisions are the most important absorption mechanism for photon energies in the range from 0.5 MeV to about 10 MeV, for all types of matter, and remain dominant for higher energy photons in materials made up of light elements.

At lower frequencies, and especially for heavy elements, the photoelectric effect is by far the most important absorption process. In this effect the quantum is absorbed as a whole, and an electron is ejected from the atom or molecule, as in Einstein's equation, except that the electrons have various binding energies, and the reaction is much more complicated than originally conceived. The dependence on atomic number is shown by the fact that

the photoelectric effect is the dominant mode of absorption in the element lead (atomic number 82) up to about 0.5 MeV, whereas it dominates the absorption in aluminum (atomic number 13) only for energies less than 0.1 MeV. There is no simple theory of photoelectric absorption because of the complications in the binding of electrons in atoms. Discontinuous jumps occur in the cross section for absorption—for example, at each resonance frequency corresponding to the ionization energy (energy required to completely remove an electron) of electronic subshells.

For gamma rays with photon energies above 1.02 MeV another type of absorption becomes increasingly important. This energy is just twice the rest-mass energy of the electron, and in the field of the nucleus a photon may be converted into an electron pair (an electron and positron; see below); their total energy, rest mass plus kinetic energy, is equal to the photon energy. The nucleus is necessary to the reaction to conserve momentum; because of its large mass, however, it receives practically none of the photon energy. For photon energies greater than four times the electron rest mass, an electron–positron pair may also be produced in the presence of an electron, and for extremely high photon energies the electrons in matter may become as effective as atomic nuclei in pair production. Pair production is the dominant mechanism for photon absorption for energies above about 5 MeV, except for the lightest elements. The positive electrons have no permanent existence: they interact with negative electrons to mutually annihilate each other, with the emission of their total energy as electromagnetic radiation, ordinarily two quanta of roughly equal magnitude, the annihilation radiation mentioned above. More rarely, in the field of a nucleus or another electron, this annihilation may result in a single quantum, a process that is the exact inverse of pair production. This radiation is indistinguishable from other electromagnetic radiation and is subject to the same scattering and absorption processes as is the primary beam of gamma rays.

Role of nucleus in pair production

The energy absorbed from gamma rays is almost entirely converted into the kinetic energy of what are called secondary electrons, and the effects of radiation on matter are produced almost exclusively by secondary electrons. Chemical and structural binding energies are of the order of a few electron volts, and the only permanent changes likely to be produced directly by a single high-energy photon are induced within the nucleus of the atom, a relatively rare event. The electrons that arise from the processes considered, however, dissipate their energy gradually, largely in the production of numerous pairs of ions within the material. These dislocations of external electrons and disruptions of chemical bonds resulting from a single high-energy photon absorption may be numerous. Each initial secondary electron may undergo a thousand collisions before being captured.

The action of radiation on complicated systems is the subject of much study (see RADIATION, BIOLOGICAL EFFECTS OF). Both theory and experiment are much simpler in treating materials consisting of a single kind of atom or of individual identical molecules than in determining what happens in inhomogeneous matter.

RELATION OF ELECTROMAGNETIC RADIATION TO QUANTUM THEORIES AND RELATIVITY

Classical mechanics as developed by Newton and others is relativistic in the restricted sense that it makes rest and uniform motion indistinguishable. This concept is in accord with everyday experience, for it is only the nonuniformities of motion that make a person conscious of travel with respect to the earth's surface, except as he sees objects move with respect to himself. Formally, the classical principle of relativity is stated as the law of inertia, according to which bodies maintain their state of rest or of uniform motion unless acted upon by an external force. The property of matter that measures this inertia is mass. Newton's laws of motion deal with forces and accelerations, departures from uniform motion. Mechanical waves are transmitted by material media that themselves have inertia, and the entire description of mechanical effects is self-consistent. All phenomena can be described classically in terms of a system of three-dimensional space coordinates, at rest or in uniform motion with respect to each other, and of a time scale that is universal, the same everywhere and for all kinds of motion. Any reference system in which the law of inertia holds is called an inertial frame of reference, and there is thus an infinity of inertial frames.

Relativity in the restricted sense did not extend to electromagnetic radiation as predicted by Maxwell and developed by others in the second half of the 19th century. The assumed medium of transmission (*i.e.*, the ether) constituted a unique frame of reference, corresponding to absolute rest. All efforts to detect motion through such a medium failed, however, and in 1905 Einstein proposed a new principle of relativity, with which the propagation of electromagnetic radiation with a universal velocity is compatible, and according to which absolute uniform motion is impossible to define. The revolutionary conceptual consequences of the special relativity theory include the fact that no signal, be it photons or material particles, can travel faster than c, the velocity of light and other electromagnetic radiation in free space; the equivalence of mass and energy; and the relativity of simultaneity—the fact that one's time scale depends on his frame of reference. In Maxwell's equations and the theory of radiation, however, no changes were necessary except in interpretation: the formal expressions of the laws of electrodynamics and the retarded potentials (see below for a definition of retarded potentials in the section *The relation of radiation fields to sources*) and fields remain unchanged, but according to special relativity they are equally valid in any and all inertial frames of reference. On the other hand, it was necessary to modify the laws of mechanics to bring them into conformity with this new relativity principle, and relativity theory extends the appearance of c, as a constant of nature, into all parts of physics. This constant enters the transformation equations that relate the space coordinates and time scale of one inertial frame to those of another, the so-called Lorentz transformation. The laws of electrodynamics are said to be Lorentz covariant, and the laws of mechanics must also be written so as to be Lorentz covariant if any velocities are involved that approach the velocity of light. Thus the theory that arose in response to an apparent failure of electromagnetic theory served instead as a basis for the reformulation of classical mechanics.

Einstein's theory of relativity

The classical theory of electromagnetic radiation, however, is correct only insofar as it is permissible to neglect all effects that arise from the finite size of h, Planck's constant. The introduction of the quantum and the accumulation of evidence for it has already been discussed. In the theory of quantum mechanics for particles, the quantization of radiation is a logically integral part. Quantum mechanics as initially developed by an Austrian physicist, Erwin Schrödinger, and Heisenberg, however, is a nonrelativistic theory, and even the relativistic wave equation formulated by Dirac in 1928 to describe the electron applies strictly only to a single particle. Moreover, the Dirac equation has solutions corresponding to negative energy that cannot be ignored but that could not be taken at face value. The interpretation of these states became quite clear with the discovery of the positron, a particle with all the attributes of the electron except for its positive charge. According to Dirac's "hole theory" all negative energy states are ordinarily filled up with electrons, a uniformity that is impossible to detect and that may be called the electron vacuum. A hole in the distribution of negative energy states constitutes the antielectron, with positive charge and positive energy. Charge is strictly conserved, and a positron appears only as a member of an electron pair. The transition of an electron from a negative energy state to one of positive energy results in the creation of a pair, and the reverse transition constitutes the annihilation of a pair. It is now known that there is an antiparticle for every kind of particle, (*e.g.*, there exists an antiproton having negative charge).

The quantum theory of the pure radiation field, excluding charges and other sources, was also first developed by Dirac and was generalized by Heisenberg and Wolfgang Pauli, an Austrian-born physicist. Complications arise that have no counterpart in classical theory, but it is possible to describe a vacuum radiation field in terms of quantized normal modes in such a way that Maxwell's equations are satisfied in the limit of Planck's constant approaching zero ($h \to 0$), in addition to Lorentz covariance as required by special relativity. These normal modes correspond to photons, which individually carry energy, momentum, and angular momentum (the property of a body associated with a resistance to a change in angular velocity).

In the actual physical world, however, electromagnetic radiation interacts with matter, and particles serve as sources and absorbers for photons. In fact, all physically observable effects of radiation result from such interactions. To describe these effects, coupling terms are introduced as additions to the pure radiation field and that of the charged particle. Many complications arise that have no counterpart in classical theory. As an example, the negative energy states of the Dirac theory are affected by the existence of an electromagnetic field, resulting in what is called the polarization of the vacuum. A constant field produces a constant polarization, which would be unobservable, but straightforward attempts to compute its magnitude have led to the embarrassing result that the effect is infinite. This defect and other divergences of the theory can be remedied by a procedure called renormalization of mass and charge. Inhomogeneous fields produce finite and observable effects that can be calculated. A series expansion is made, essentially in the quantity e^2/hc, the fine structure constant, but the renormalization may be extended to all orders of approximation, so that in principle all results may be obtained quantitatively, as corrections to the predictions of ordinary wave mechanics. The computation of these radiative corrections has been motivated by the experimental discovery of discrepancies between theory and observation on atomic energy levels and the magnetic moment of the electron. To the limit of present-day accuracy, the calculated effects are in complete agreement with experiment.

Vacuum polarization

But the situation cannot be considered satisfactory. In the words of Dirac,

> Physicists have constructed a method for handling the divergent integrals [infinities], the renormalization method, which is successful in many cases in leading to well-defined physical results that can be compared with experiment. However, the method can be considered only as a stopgap, since it does not follow logically from established physical laws.

A more logical theory may involve a revision of some of the fundamental laws of quantum mechanics or a reinterpretation of other basic concepts of physical theory. At present no satisfactory answer to these difficulties is in sight.

The general theory of relativity is a theory of gravitation and is not logically connected with the theory of electromagnetism. Quantum mechanics is also outside the scope of general relativity. General relativity is essentially concerned with the geometry of space-time, and gravitation is viewed as a geometric phenomenon, as time has the attribute of a fourth dimension. In electromagnetic theory and in the special theory of relativity, space and time are interrelated, but they play a purely passive role and are quite independent of the presence of matter and radiation. There have been many attempts to formulate a unified field theory comprising both electrodynamics and gravitation, but none has been successful. The velocity of light plays a role in general relativity, to be sure; and on a local scale the geometry is Euclidean, adequately represented by the inertial frames of the theory of special relativity. In the 1970s rapid advances were being made in general relativity, partly as a result of such significant discoveries in observational astronomy as quasi-stellar objects, pulsars, and exploding galaxies. These investigations of singularities in the theory, the prediction of gravitational collapse, leading to the "black hole" from which electromagnetic radiation cannot escape, are spectacular features of modern astrophysics, for which observational evidence is being sought. These are advances in cosmology and the theory of gravitation, however, and not in the theory of radiation as such. A relation between gravitation and electromagnetism must surely exist, but a full understanding of it seems at present even more remotely obtainable than the resolution of the logical difficulties in quantum electrodynamics.

Unified field theory

III. Mathematical formulation of electromagnetic theory

MAXWELL'S EQUATIONS

Before presenting the mathematical formulation of the laws of electromagnetism, it is necessary to adopt a system of units and dimensions in order to describe electromagnetic phenomena quantitatively, and the choice is sometimes a matter of controversy. The complication arises from the fact that electromagnetic theory, unlike classical mechanics, involves a fundamental constant of nature, c, the velocity of light *in vacuo*, as an essential feature of the theory. (Special relativity extends this feature to all of physics.) This velocity constant c occurs explicitly in some of the equations involving the Gaussian system of units, a system widely used in atomic physics and allied fields. The General Conference on Weights and Measures, which makes international decisions on the definitions of metric units, however, adopted in 1960 the International System of Units (denoted by SI), a system that incorporates technical units such as the ampere, the volt, and the coulomb. In fact, the ampere, a measure of current flow, is one of the basic SI units, and a basic unit of charge, the coulomb, is defined in this system as a secondary unit composed of current times time, or ampere-second. The SI system is particularly suitable for treating applications that involve both circuits and fields. As applied to electromagnetic theory, the SI system of units employs two constants, the dielectric constant of free space (epsilon ε_0) and the permeability of free space (mu μ_0), related by the velocity c, *i.e.*, $\mu_0\varepsilon_0 = 1/c^2$, and so only one of the constants is fundamental to the theory. Regardless of the system used, changing units or even dimensions does not affect the physical content of the equations. The numerical values of the constants involved depend on whether or not the equations are rationalized; the geometric factor 4π appears explicitly in equations implying spherical symmetry, if rationalized constants are employed; and is suppressed, for example, in the continuous source equations. Rationalized SI units will be employed in the sections to follow. It will be seen that all formulas are written so that they may be reduced to their Gaussian equivalents by the substitutions $4\pi\varepsilon_0 \to 1$ and $c\boldsymbol{B}_{\mathrm{SI}} \to \boldsymbol{B}_{\mathrm{Gaussian}}$, after using $\mu_0\varepsilon_0 = 1/c^2$ to eliminate the permeability of free space if it appears.

SI system of units

Written so as to apply to macroscopic charge and current configurations, the first of the fundamental empirical laws of electricity and magnetism is Coulomb's law of electrostatics, expressed in the form called Gauss's theorem (in the following equations, the symbol $\times$ indicates a cross product and the symbol $\cdot$ indicates a scalar product):

$$\int_{\text{closed}} \boldsymbol{E}\cdot d\boldsymbol{S} = \frac{1}{\epsilon_0}\int \rho dV = Q/\epsilon_0 .$$

in which the integral of the normal component of the electric field intensity $\boldsymbol{E}$ over a closed surface (scalar product of $\boldsymbol{E}$ and surface element $d\boldsymbol{S}$) is equal to $1/\varepsilon_0$ times the total charge Q inclosed by the surface; *i.e.*, the integral of the charge density (ρ) over the volume (V) inclosed by the surface. The field strength $\boldsymbol{E}$ is defined operationally as the force per unit positive charge, taken in the limit of a vanishingly small test charge so as not to perturb the measured field. The SI units of the field strength $\boldsymbol{E}$ are units of force per charge; that is, newtons per coulomb.

Because isolated magnetic poles have not been found to exist, the operational definition of the magnetic field

$\boldsymbol{B}$ is made in terms of force on a unit current element: a current I in an elementary line dl will experience a force ($\boldsymbol{F}$) given by the vector cross product of the elementary line and the magnetic field, $\boldsymbol{F} = I\boldsymbol{dl} \times \boldsymbol{B}$. The unit of the magnetic field $\boldsymbol{B}$ is thus a newton per amperemetre. The field $\boldsymbol{B}$ satisfies the relation that the integral of the normal component of the magnetic field over a closed surface is zero, namely, $\int \boldsymbol{B} \cdot d\boldsymbol{S} = 0$. In terms of magnetic poles, this is a statement of the inverse square law plus the fact that there are apparently no free poles.

The circulation laws

The relations between electric and magnetic fields are given by the circulation laws. The closed line integral of $\boldsymbol{E}$ about a loop is equal to the electromotive force given by Faraday's law of induction:

$$\oint \boldsymbol{E} \cdot d\boldsymbol{s} = -\frac{d}{dt}\int \boldsymbol{B} \cdot d\boldsymbol{S}.$$

The surface integral of $\boldsymbol{B}$ over any surface bounded by the closed path of the integral on the left is called the magnetic flux through the surface. Ampere's law may also be written as a circulation law: the line integral of the magnetic field about a closed path is proportional to the total current threading the loop,

$$\oint \boldsymbol{B} \cdot d\boldsymbol{s} = \mu_0 I = \mu_0 \int \boldsymbol{j} \cdot d\boldsymbol{S},$$

in which μ_0 is the permeability of free space, and the total current is equal to the integral of the current density $\boldsymbol{j}$ over a surface bounded by the path of the line integral of $\boldsymbol{B}$. This circulation law is valid for steady currents, but in the presence of time-dependent fields a term must be added to account for the conservation of charge.

By means of purely geometrical theorems, those of Gauss and Stokes, which relate closed surface and line integrals to the vector operators divergence and curl, symbolized by $\nabla\cdot$ and $\nabla\times$, respectively, these macroscopic integral laws may be transformed to differential relations between the fields, point by point. The result is the set of Maxwell's equations. As valid *in vacuo*, these relations may be simply written in terms of the electric and magnetic fields. The charge density (ρ) and the current density ($\boldsymbol{j}$) are assumed to exist in the absence of any continuous material media, and the four Maxwell equations are written

$$\nabla \cdot \boldsymbol{E} \equiv \operatorname{div} \boldsymbol{E} = \rho/\epsilon_0,$$

$$\nabla \cdot \boldsymbol{B} \equiv \operatorname{div} \boldsymbol{B} = 0,$$

$$\nabla \times \boldsymbol{E} \equiv \operatorname{curl} \boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t} \equiv -\dot{\boldsymbol{B}},$$

$$\nabla \times \boldsymbol{B} \equiv \operatorname{curl} \boldsymbol{B} = \mu_0\left(\boldsymbol{j} + \epsilon_0\frac{\partial \boldsymbol{E}}{\partial t}\right) \equiv \mu_0(\boldsymbol{j} + \epsilon_0\dot{\boldsymbol{E}}).$$

(The first and second time derivative of any variable, say x, will be written hereafter as $\dot{x}$ and $\ddot{x}$, respectively.) Here the permeability of free space $\mu_0 = 4\pi \times 10^{-7}$ kilogram-metre per coulomb^2, and the product of the permeability and dielectric constant of free space equals 1 divided by the velocity squared, or $\mu_0\epsilon_0 = 1/c^2$. It is thus evident that the permeability is defined in terms of an arbitrarily chosen electrical unit of current, and the dielectric constant is determined by this definition and the experimental value of the velocity of light, which is almost exactly 3×10^{10} centimetres per second.

These equations correspond to the four empirical laws listed in the section treating radiations semiquantitatively, the third equation here being Faraday's law of electromagnetic induction. The addition to the ordinary current density $\boldsymbol{j}$ in the fourth equation is the vacuum displacement current, and it is necessitated by the continuity equation expressing the conservation of charge,

Displacement current

$$\nabla \cdot \boldsymbol{j} \equiv \operatorname{div} \boldsymbol{j} = -\frac{\partial \rho}{\partial t}.$$

Unlike the true current density $\boldsymbol{j}$, the vacuum displacement current does not correspond to the motion of charge, but its presence makes possible a nonvanishing circulation of $\boldsymbol{B}$ in the absence of charges and currents, analogous to the circulation of $\boldsymbol{E}$ as given by the law of induction. In a dielectric (insulating) medium at rest, a volume electric polarization ($\boldsymbol{P}$; see below) is produced by the presence of an electric field, and the displacement current includes a term that corresponds to the motion of bound charge in a dielectric. The time rate of change of dipole moment per unit volume is dimensionally the same as a current density, and $\dot{\boldsymbol{P}}$ is quite literally a displacement current density. It is convenient to define another field quantity, called the displacement field, by the equation $\boldsymbol{D} = \epsilon_0\boldsymbol{E} + \boldsymbol{P}$, the first derivative of the displacement with time, or in terms of which the displacement current is simply $\dot{\boldsymbol{D}}$. In empty space polarization vanishes, and thus there is no distinction between $\boldsymbol{D}$ and $\epsilon_0\boldsymbol{E}$.

In magnetic materials, analogously, a second field quantity takes account of the volume magnetization, or magnetic dipole moment per unit volume, $\boldsymbol{M}$, the curl of which is the magnetization current. This field is denoted by $\boldsymbol{H}$ and may be defined by the equation

$$\boldsymbol{H} = \boldsymbol{B}/\mu_0 - \boldsymbol{M}.$$

The dielectric and permeability constants ϵ_0 and μ_0 do not appear explicitly in Maxwell's equations if the displacement field and the magnetic field $\boldsymbol{H}$ are introduced. Instead, they are simply

$$\operatorname{div} \boldsymbol{D} = \rho,$$

$$\operatorname{div} \boldsymbol{B} = 0,$$

$$\operatorname{curl} \boldsymbol{E} = -\dot{\boldsymbol{B}},$$

$$\operatorname{curl} \boldsymbol{H} = \boldsymbol{j} + \dot{\boldsymbol{D}}.$$

The equations in this form apply to material media as well as to empty space.

In the absence of all charges and currents the equations for vacuum electrodynamics take on a still simpler form:

$$\operatorname{div} \boldsymbol{E} = 0,$$

$$\operatorname{div} \boldsymbol{B} = 0,$$

$$\operatorname{curl} \boldsymbol{E} = -\dot{\boldsymbol{B}},$$

$$\operatorname{curl} \boldsymbol{B} = \mu_0\epsilon_0\dot{\boldsymbol{E}} = \frac{1}{c^2}\dot{\boldsymbol{E}}.$$

These last four equations lead at once to the prediction of electromagnetic waves that would traverse empty space with velocity c.

TRANSMISSION OF RADIATION IN FREE SPACE

The wave equation and electromagnetic waves. On eliminating the magnetic field by combining the two vector Maxwell equations written above, after taking their curl, one finds that

$$\operatorname{curl}\operatorname{curl} \boldsymbol{E} \equiv \operatorname{grad}\operatorname{div} \boldsymbol{E} - \nabla^2\boldsymbol{E} = -\frac{1}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2},$$

or

$$\nabla^2\boldsymbol{E} - \frac{1}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2} = 0,$$

as $\operatorname{div} \boldsymbol{E} = 0$ in the absence of charge. If the electric field is eliminated from the two vector Maxwell equations in an analogous way, it is seen that the magnetic field must satisfy the same equation

$$\nabla^2\boldsymbol{B} - \frac{1}{c^2}\frac{\partial^2 \boldsymbol{B}}{\partial t^2} = 0.$$

Homogeneous wave equations

This and the preceding equation are called homogeneous wave equations.

In Cartesian coordinates the homogeneous wave equation in the vector field $\boldsymbol{E}$ (x, y, z, t) may be written

$$\frac{\partial^2 \boldsymbol{E}}{\partial x^2} + \frac{\partial^2 \boldsymbol{E}}{\partial y^2} + \frac{\partial^2 \boldsymbol{E}}{\partial z^2} = \frac{1}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2}.$$

The meaning of this equation is readily exhibited if one assumes a plane wave in which the electric field is uniform over a plane. The coordinate system may be chosen such that this plane is perpendicular to the z-axis; then the electric vector is the same for all values of x and y for a particular value of z, and the derivatives with respect to these two coordinates vanish. The equation becomes

$$\frac{\partial^2 \boldsymbol{E}(z,t)}{\partial z^2} = \frac{1}{c^2}\frac{\partial^2 \boldsymbol{E}(z,t)}{\partial t^2}.$$

This second-order relation is satisfied by any vector function of the argument $(z \pm ct)$. The function f $(z \pm ct)$ represents a disturbance that travels in the direction of $\mp z$ with velocity c.

The first-order Maxwell equations must also be satisfied, of course, and because the divergence of the electric field is zero, it follows that the z component of the electric field vanishes except for uniform static fields. All these remarks apply equally to the magnetic field, and thus the wave is transverse, not longitudinal. The electric and magnetic fields, however, are not independent. It may be assumed without loss of generality that the wave is plane polarized, with the electric field vector $\boldsymbol{E}$ lying in the positive x direction in a given plane at a given time t. Then if $\boldsymbol{n}$ is a unit vector in the direction of positive z, normal to the wave front, Maxwell's curl $\boldsymbol{E}$ equation reduces to

$$\boldsymbol{n} \times \frac{\partial \boldsymbol{E}}{\partial z} = -\frac{\partial \boldsymbol{B}}{\partial t},$$

which is in the positive y direction. Thus the fields $\boldsymbol{E}$ and $\boldsymbol{B}$ are perpendicular to each other as well as to the direction of propagation. In fact, it follows generally that a plane wave moving in the direction of increasing z, for which the electric field has the form $\boldsymbol{E}(z - ct)$, has an accompanying magnetic field $\boldsymbol{B}(z - ct)$ such that $c\boldsymbol{B} = \boldsymbol{n} \times \boldsymbol{E}$.

The electric and magnetic fields and the direction of propagation, in that order, form a right-handed set of orthogonal vectors. The relative magnitude of the electric and magnetic fields in free space is $E = cB$ in these units. In Gaussian units the magnitudes of $\boldsymbol{E}$ and $\boldsymbol{B}$ are equal $(E = B)$.

Energy density

The energy density corresponding to an electrostatic field in free space is

$$\frac{1}{2}\epsilon_0 E^2 = \frac{1}{2}ED,$$

as may be computed in an elementary way from the energy stored in an idealized capacitor. Similiarly the magnetostatic energy density is $\frac{1}{2}B^2/\mu_0 = \frac{1}{2}HB$, as computed in an elementary way from the energy stored in an idealized solenoid (coil of wire). The two vector Maxwell equations may be combined by vector manipulation in the following way to give an energy integral that is interpreted in terms of the extension of these expressions to time-varying fields and the flux of energy carried by the radiation. Scalar multiplication of the curl $\boldsymbol{E}$ equation by $\boldsymbol{H}$, and of the curl $\boldsymbol{H}$ equation by $\boldsymbol{E}$, after which one is subtracted from the other, yields

$$\boldsymbol{H} \cdot (\text{curl } \boldsymbol{E} + \dot{\boldsymbol{B}}) - \boldsymbol{E} \cdot (\text{curl } \boldsymbol{H} - \boldsymbol{j} - \dot{\boldsymbol{D}}) = 0.$$

According to a general vector identity,

$$\boldsymbol{H} \cdot \text{curl } \boldsymbol{E} - \boldsymbol{E} \cdot \text{curl } \boldsymbol{H} = \text{div } (\boldsymbol{E} \times \boldsymbol{H}),$$

so that the equation becomes

$$\text{div } (\boldsymbol{E} \times \boldsymbol{H}) + (\boldsymbol{E} \cdot \dot{\boldsymbol{D}} + \boldsymbol{H} \cdot \dot{\boldsymbol{B}}) + \boldsymbol{j} \cdot \boldsymbol{E} = 0.$$

In this equation, the third term $\boldsymbol{j} \cdot \boldsymbol{E} = \rho \boldsymbol{v} \cdot \boldsymbol{E}$ is clearly the rate at which the electric field does work per unit volume on any charge density ρ, and from the relations $\boldsymbol{D} = \epsilon_0 \boldsymbol{E}$ and $\boldsymbol{B} = \mu_0 \boldsymbol{H}$ it follows that the second term

$$(\boldsymbol{E} \cdot \dot{\boldsymbol{D}} + \boldsymbol{H} \cdot \dot{\boldsymbol{B}}) = \epsilon_0 \dot{\boldsymbol{E}} \cdot \boldsymbol{E} + \boldsymbol{B} \cdot \dot{\boldsymbol{B}}/\mu_0$$
$$= \frac{\partial}{\partial t}(\boldsymbol{E} \cdot \boldsymbol{D} + \boldsymbol{H} \cdot \boldsymbol{B})/2$$

is the rate of change of electromagnetic energy density if the latter is identified with $(\boldsymbol{E} \cdot \boldsymbol{D} + \boldsymbol{H} \cdot \boldsymbol{B})/2$. The remaining term is the divergence of the vector $(\boldsymbol{E} \times \boldsymbol{H})$, which may be interpreted as the flux of energy per unit area through a surface normal to the direction of propagation. This flux vector is called the Poynting vector, and the equation relating its divergence to the time rate of change of the electromagnetic energy density is called Poynting's theorem. In a charge-free region, Poynting's theorem states the law of conservation of electromagnetic energy: the time rate of change of the field energy density is equal to the negative divergence of the energy flux.

In a plane progressive wave, with $\boldsymbol{E}$ and $c\boldsymbol{B}$ having the same magnitude, it is seen that the energy density is divided equally between the electric and magnetic fields, and the total energy density is equal to $\epsilon_0 E^2$ at any point. The Poynting vector is therefore $\boldsymbol{E} \times \boldsymbol{H} = c\epsilon_0 E^2 \boldsymbol{n}$, in which $\boldsymbol{n}$ is again the unit vector normal to the wave front. Electromagnetic radiation also possesses momentum in the direction of its propagation. A formula for the momentum density was derived by Maxwell on the assumption of stresses in the ether, but the simplest method to obtain the correct expression is to invoke the principles of special relativity. As has been shown, there is an energy density associated with the electromagnetic radiation fields, which may be denoted by W, and this should correspond to a mass density W/c^2 that is transmitted through space with velocity c. Thus there is also a momentum density of magnitude W/c, a vector quantity in the direction of propagation that in free space is equal to $\boldsymbol{E} \times \boldsymbol{H}/c^2$, the Poynting vector divided by c^2.

Radiation pressure

The momentum of electromagnetic radiation gives rise to radiation pressure. The magnitude of the force exerted per unit area of a material body depends on the reflectivity of the surface: the pressure on a perfect absorber normal to the Poynting vector is equal to W, the energy density, and that on a perfect reflector would be twice as great. Isotropic radiation, as in the ideal black body cavity, consists of randomly directed fields, and the radiation pressure is one-third the energy density on an absorbing probe or on the cavity walls. Radiation pressure is an extremely small effect under ordinary terrestrial conditions, but it plays an important role in the internal dynamics of stars.

An infinite plane wave of the kind being discussed would carry no angular momentum, even if the electric vector rotated periodically in the plane perpendicular to its propagation (circularly polarized light). The existence of intrinsic angular momentum in electromagnetic radiation would necessitate longitudinal field components, and it was shown above that radiation fields are transverse. A plane wave, the wave front of which is of finite extent, however, does involve small longitudinal components, and the angular momentum of a circularly polarized beam of light was measured by a United States physicist, Richard Alexander Beth, in 1936. The magnitude of the angular momentum density is related to the energy density and to the frequency of the light, and for circularly polarized light is in fact given by the energy density divided by 2π times the frequency, or $W/2\pi\nu$, in which ν is the frequency. Because angular momentum must be conserved, the effect can be detected by measuring the torque, or twist, on a half-wave plate, a thin slab of crystal that changes left-hand polarized light to right-hand polarized light, and vice versa; that is, it reverses the direction of rotation of the electric vector in circularly polarized light. The measured result was in accord with the theory to an accuracy of 10 percent. The concept of angular momentum is more useful as applied to spherical waves than to plane waves, as will be seen, and photons have intrinsic angular momentum related to their energy by the same factor, $2\pi\nu$, that is given by the wave theory of radiation.

The relation of radiation fields to sources. In order to relate radiation fields to their sources, accelerated charges, or changing currents, it is convenient to introduce potentials. The magnetic and electric fields can in general be derived from a vector potential (A) and a scalar potential (ϕ), which are functions of the space coordinates and the time, by the relations

$$\boldsymbol{B} = \operatorname{curl} \boldsymbol{A}$$

$$\boldsymbol{E} = -\operatorname{grad}\phi - \frac{\partial \boldsymbol{A}}{\partial t}.$$

The potentials are not completely defined by these equations, but the Maxwell equations that do not involve sources are automatically satisfied if the fields are expressed in this way. The other two equations become

$$\nabla^2\phi + \operatorname{div}\frac{\partial \boldsymbol{A}}{\partial t} = -\rho/\epsilon_0,$$

$$\nabla \times (\nabla \times \boldsymbol{A}) + \frac{1}{c^2}\frac{\partial \boldsymbol{A}}{\partial t^2} + \frac{1}{c^2}\operatorname{grad}\frac{\partial \phi}{\partial t} = \mu_0 \boldsymbol{j}.$$

The divergence of $\boldsymbol{A}$ and the time derivative of ϕ are not specified by their definitions in terms of the fields, and may be chosen so that

$$\operatorname{div}\boldsymbol{A} + \frac{1}{c^2}\frac{\partial \phi}{\partial t} = 0.$$

This is called the Lorentz condition on the potentials, after Hendrik Antoon Lorentz, a Dutch physicist. If this condition is satisfied, the potentials are solutions of the second-order inhomogeneous wave equations,

$$\nabla^2\phi - \frac{1}{c^2}\frac{\partial^2\phi}{\partial t^2} = -\rho/\epsilon_0,$$

$$\nabla^2\boldsymbol{A} - \frac{1}{c^2}\frac{\partial^2\boldsymbol{A}}{\partial t^2} = -\mu_0 \boldsymbol{j}.$$

The fields excited by the charge and current sources ρ and j are determined by differentiating the potentials, which are particular solutions of these equations.

Retarded potentials

It was first shown by Ludvig Valentin Lorenz, a Danish physicist, that solutions may be written formally as volume integrals over the source distributions evaluated at the retarded time, equal to the time (t) for which the field is described minus the distance travelled divided by the velocity, or $t' = t - r/c$, which would allow transmission of the fields from the source with velocity c; *i.e.*,

$$\phi(x, y, z, t) = \frac{1}{4\pi\epsilon_0}\int \frac{\rho(x', y', z', t - r/c)}{r}\,dV',$$

$$\boldsymbol{A}(x, y, z, t) = \frac{\mu_0}{4\pi}\int \frac{\boldsymbol{j}(x', y', z', t - r/c)}{r}\,dV',$$

in which r is the distance from a source point (primed coordinates) to the field point (plain coordinates). These are the retarded potentials; mathematically the advanced potentials, with the integrals evaluated at $t + r/c$, are equally acceptable, but in classical radiation theory no physical significance can be attached to such solutions.

A simple example will show that the retardation is responsible for the existence of radiation fields, which must fall off as the inverse first power of the distance, and not faster. If a charge e is restricted to a small region of space near the origin of coordinates, then, to a first approximation, the vector potential at a large distance r is simply

$$\boldsymbol{A}(x, y, z, t) = \frac{\mu_0}{4\pi}\frac{e\boldsymbol{v}(t - r/c)}{r}.$$

The relation $\boldsymbol{B} = \operatorname{curl}\boldsymbol{A}$ requires taking the space derivatives, each term of which would behave as $1/r^2$ at best except for the fact that the distance r is also involved in the retarded time. The radiation field is thus proportional to the time derivative of the velocity. In particular, if the motion of the charge is confined to the z axis in this simple approximation, the magnetic field is azimuthal, and given by

$$B_\varphi = \frac{\mu_0}{4\pi c}\frac{q\dot{v}}{r}\sin\theta = \frac{1}{4\pi\epsilon_0}\frac{q\dot{v}\sin\theta}{rc^3}.$$

Here θ is the angle between the z axis and the line r from source to observer. The corresponding electric vector is along the direction of change in angle θ and equal in magnitude to cB in these units.

The exact potentials corresponding to a point charge, in contrast to this approximation are not obtained by substituting the total charge for the volume integral indicated in the retarded potentials. The problem arises because of the finite velocity of field propagation, so that the integral of the retarded charge density over space is not in general equal to the total charge. The correct potentials for an electron of charge e are

$$\phi = \frac{1}{4\pi\epsilon_0}\left[\frac{e}{R - \boldsymbol{R}\cdot\boldsymbol{v}/c}\right],$$

$$\boldsymbol{A} = \frac{\mu_0}{4\pi}\left[\frac{e\boldsymbol{v}}{R - \boldsymbol{R}\cdot\boldsymbol{v}/c}\right],$$

in which $\boldsymbol{R}$ is the radius vector from the electron to the field point, v is the velocity of the electron, and the square bracket is used to denote the fact that all quantities are to be evaluated at the retarded time, not the time of observation. These are called the Liénard-Wiechert potentials. Before the advent of relativity theory they could not be justified for high-velocity electrons, because it was necessary to assume that Maxwell's equations were valid only in the reference frame of the observer, but the Liénard-Wiechert potentials are relativistically correct and also valid for the entire range of classical electrodynamics.

Liénard-Wiechert potentials

Historically, the radiation fields were first traced to their sources by Hertz, who assumed the existence of an infinitesimal oscillating electric dipole at the origin of coordinates. A vector expression for the fields of an arbitrarily oriented dipole may be written in terms of the dipole moment p, and $\hat{r}$, a unit vector in the direction of the radius vector r from the source to the point of observation:

$$\boldsymbol{B} = \frac{\mu_0}{4\pi}\left(\frac{\ddot{\boldsymbol{p}}\times\hat{\boldsymbol{r}}}{c^2 r} + \frac{\dot{\boldsymbol{p}}\times\hat{\boldsymbol{r}}}{cr^2}\right),$$

$$\boldsymbol{E} = \frac{1}{4\pi\epsilon_0}\left[\frac{\hat{\boldsymbol{r}}\times(\hat{\boldsymbol{r}}\times\ddot{\boldsymbol{p}})}{c^2 r} + \frac{2\hat{\boldsymbol{r}}(\hat{\boldsymbol{r}}\cdot\dot{\boldsymbol{p}}) + \hat{\boldsymbol{r}}\times(\hat{\boldsymbol{r}}\times\dot{\boldsymbol{p}})}{cr^2} + \frac{2\hat{\boldsymbol{r}}(\hat{\boldsymbol{r}}\cdot\boldsymbol{p}) + \hat{\boldsymbol{r}}\times(\hat{\boldsymbol{r}}\times\boldsymbol{p})}{r^3}\right]$$

Here $\ddot{p}$ is the second time derivative of the dipole moment, to be evaluated at the retarded time $t - r/c$. The initial terms comprise the radiation fields, and the Poynting vector is in the direction of increasing r,

$$\boldsymbol{E}\times\boldsymbol{H} = \frac{[\ddot{\boldsymbol{p}}^2 - (\hat{\boldsymbol{r}}\cdot\ddot{\boldsymbol{p}})^2]\hat{\boldsymbol{r}}}{16\pi^2\epsilon_0 c^3 r^2}.$$

Whereas the magnetic field has no component along r, the second term in $\boldsymbol{E}$ is partly in the direction of p. It is this term that can account for the radiation of angular momentum from a rotating dipole.

If the dipole is constrained to lie along the polar axis, both radiation fields are proportional to sine of the polar angle (θ), and the Poynting vector is simply

$$\boldsymbol{N} = \boldsymbol{E}\times\boldsymbol{H} = \frac{\ddot{\boldsymbol{p}}^2\hat{\boldsymbol{r}}\sin^2\theta}{16\pi^2\epsilon_0 c^3 r^2}.$$

The total energy radiated per unit time is the integral of the Poynting vector over a sphere of radius r,

$$\frac{-dU}{dt} = 2\pi r^2 \int_0^\pi N \sin\theta \, d\theta = \frac{\ddot{p}^2}{6\pi\epsilon_0 c^3}.$$

If the dipole moment is interpreted as the position of a charge e moving in the neighbourhood of a charge $-e$ fixed at the origin, $\ddot{p} = e\dot{v}$, and the rate of radiation may be written in terms of $\dot{v}$, the acceleration of the moving charge e,

$$\frac{-dU}{dt} = \frac{e^2\dot{v}^2}{6\pi\epsilon_0 c^3},$$

if U is the energy of the source. This last expression is the Larmor formula for radiation. The acceleration is to be evaluated at the retarded time, but it must be noted that this is not an unrestrictedly valid formula for the radiation from an accelerated charge. The general formula for the rate of radiation from a moving charge, as derived from the Liénard-Wiechert potentials, depends on the velocity as well as the acceleration,

$$\frac{-dU}{dt'} = \frac{e^2}{6\pi\epsilon_0 c^3} \frac{(\dot{v}^2 - (v \times \dot{v})^2/c^2)}{(1 - v^2/c^2)^3}.$$

Relativistically, the velocity is interpreted as the relative velocity of the charge e with respect to the observer, but t' is the retarded time, with respect to which the velocity and acceleration of the source are to be evaluated. The expressions for the electric and magnetic fields are complicated except for simple motions, but in all circumstances $B = r \times E/rc$, so that the magnetic field is always perpendicular to the electric field and to the retarded radius vector from the charge to the field point.

In accord with the principles of Fourier analysis, the solutions of the inhomogeneous wave equation may be constructed from components that are harmonic in time, so that the time dependence may be represented by the exponential coefficient $e^{-i\omega t}$. Here $\omega = 2\pi\nu$ is the angular frequency and i is an imaginary number $\sqrt{-1}$. This mathematical device has the advantage that introducing the factor $-i\omega$ is equivalent to taking the time derivative. This factor can be broken down by Euler's formula into the sum of two terms, one the real part and the other the complex part, so called because it contains the imaginary factor i. The actual fields are to be identified with the real part of the complex field expressions, as obtained by use of the Euler formula $e^{-i\omega t} = \cos\omega t - i \sin\omega t$, together with the real part of the corresponding formula for the complex factor in the spatial coordinates. To obtain instantaneous values of the energy density and other quantities that depend on the product of field strengths, it is necessary to write the real fields before multiplying, but it is a very simple matter to find the time average of such products. The time average of the product of the real parts of two vectors, both of which vary with the time as $e^{-i\omega t}$, is one-half the real part (Re) of the product of one vector and the complex conjugate of the other:

$$[(\mathrm{Re}\ \boldsymbol{E}) \times (\mathrm{Re}\ \boldsymbol{H})]_{\text{time average}} = \tfrac{1}{2}\mathrm{Re}\,(\boldsymbol{E} \times \boldsymbol{H}^*) = \tfrac{1}{2}\mathrm{Re}\,(\boldsymbol{E}^* \times \boldsymbol{H}),$$

for example. (The expression $\boldsymbol{H}^*$ denotes the complex conjugate of $\boldsymbol{H}$, obtained by changing the sign of i wherever it appears.) The product of a complex variable and its conjugate is entirely real. The time-averaging rule holds equally for scalar and vector products. With the time dependence given in this way, the plane wave solution of the homogeneous wave equation is written $E = E_0 \exp[i(k \cdot r - \omega t)]$, in which r is the coordinate or spatial vector of the field point and k is the propagation vector, directed along the direction of wave propagation and of magnitude $\omega/c = 2\pi/\lambda$. The space dependence of an outgoing spherical wave is asymptotically given e^{ikr}/r, with k now the magnitude of the propagation vector the direction of which is that of increasing r.

Propagation vector k

For a linear electric dipole of moment $p\, e^{-i\omega t}$, the spatial factors of the radiation fields are

$$E_\theta = \frac{-\omega^2 p \sin\theta}{4\pi\epsilon_0 c^2} \frac{e^{ikr}}{r},$$

$$H_\varphi = \frac{-\omega^2 p \sin\theta}{4\pi c} \frac{e^{ikr}}{r},$$

in which the subscripts indicate that the electric field is in the direction of changing θ, and that the magnetic field is in a plane at right angles to the propagation vector; *i.e.*, it is azimuthal. (In polar coordinates the polar axis is assumed to be in the direction of the dipole moment p.) In terms of the propagation vector k, which is along the radius vector r, the radiation fields may be written in vector form:

$$E = \frac{e^{ikr}}{4\pi\epsilon_0 r}[(p \times k) \times k],$$

$$H = -\frac{e^{ikr}}{4\pi r}(p \times k).$$

The electric field E also has a component along r that falls off as $1/r^2$, but the magnetic field is entirely azimuthal.

Because of the symmetry of the equations in the electric and magnetic fields, it is evident that an oscillating magnetic dipole would give rise to radiation having the same kind of distribution in space as does an oscillating electric dipole, except that the roles of the fields are interchanged. The electric field of a linear magnetic dipole is azimuthal, whereas the magnetic field has a radial component that falls off only as $1/r^2$ and can account for the radiation of angular momentum.

Only for a few special cases is it possible to perform exactly the volume integrals indicated formally in the expressions for the retarded potentials. For any finite source distribution that can be considered to remain in the neighbourhood of the origin of coordinates, however, a series expansion into multipole moments (dipole, quadrupole, octupole) can be made in which the variable involved is effectively $ka = \omega a/c$, a being a length characterizing the dimensions of the source. The complete radiation fields are then a summation of terms over standard distribution patterns in space, multiplied by coefficients that express the source strength of each distribution pattern. As might be expected, the angular distribution functions are just the spherical harmonics or their derivatives (solutions in terms of angular and radial components), and the radial dependence must be chosen to behave like e^{ikr}/r for large r to correspond to outgoing radiation. These are the multipole fields, which may be divided into two types: the electric multipoles, for which the magnetic field has no radial component; and the magnetic multipoles, for which the electric field has no radial component. The source strength depends on the nature of a source distribution; and because magnetic effects arise from currents, the magnetic multipole strength is generally smaller than the corresponding electric multipole by a factor ka, which for the harmonic time dependence assumed is equivalent of v/c. The radiation intensities are related by the square of this factor.

Multipole fields

It is evident from the dependence of the linear dipole fields on the factor $\sin\theta$ that there is no radiation along the axis of the dipole. Quadrupole radiation fields have two nodal cones where there is no radiation. Physically, electric quadrupole radiation would arise from a pulsating charge distribution of such symmetry that the dipole moment remains zero. The successive multipole moments ordinarily become important only if lower order moments of the source distribution vanish. Actually the integrals over the source need not be moments in the elementary sense; and if two or more moments contribute significantly, the source strength corresponding to each spherical harmonic should be represented by an integral over a more faithful representation of its distribution. In practice this integration is more often necessary in macroscopic antenna systems (the dimensions of which are not necessarily small in comparison with the wavelength of the emitted radiation) than in microscopic systems. In atomic or nuclear radiation the lowest order multipole possible is usually the only one observed.

WAVES IN SPACE BOUNDED BY CONDUCTORS

Boundary conditions. The patterns of radiant electromagnetic energy are affected by material media, whether the materials are transparent to the radiation or are opaque. The transparency of a substance to radiation depends on the wavelength of the radiation as well as on the nature of the substance, but metallic conductors reflect all electromagnetic waves except extremely high frequencies. Metallic surfaces may be made optically flat so as to reflect light in a regular way, but the most useful application of waves in regions bounded by conductors is in the microwave region of the spectrum. These applications include not only radar and other devices for communication, but are widely used as research tools in the investigation of the properties of matter.

Because of the boundary conditions imposed on the electromagnetic fields at the surface of a conductor, standing waves may be set up in a region within conducting boundaries, analogous to the one-dimensional standing waves of a vibrating string in which the wave form is stationary. A substance is called a conductor if charges are free to move within it, and in a perfect conductor there would be no resistance at all to the motion of charges. As a result of the application of external fields there are charges and the possibility of charge motion on the surface, but no fields penetrate the interior of the conducting medium. This property of real conductors is well-known in electrostatics, and its extension to fields that vary with time depends on the relation of conductivity to frequency: for good conductors such as copper and microwave frequencies (order of magnitude 10^{10} hertz), the geometrical representation of fields in cavities or wave guides corresponds to those obtained on the assumption of ideally conducting boundaries. To compute losses in cavities and the attenuation of transmitted waves, however, it is necessary to take the finite conductivity into account.

The boundary conditions on the electric and magnetic fields at the interface between two media of different electric and magnetic properties are inherent in Maxwell's equations for the fields. In the limit of high conductivity the fields are discontinuous at the surface of a conductor, but there are finite surface charges and surface currents that accompany the external fields. At the boundary the tangential component of the electric field vanishes, but there may be an electric field $\boldsymbol{E}$ normal to the surface and a magnetic field $\boldsymbol{B}$ tangential to the surface. The frequencies and field configurations that satisfy these conditions correspond to the normal modes of cavity resonators, regions of space bounded by conducting walls.

The analysis of cylindrical cavities may be immediately extended to wave guides, devices used to transmit electromagnetic energy at microwave frequencies. A wave guide, which usually has a rectangular or circular cross section, is simply a long metallic cylinder with open ends. Radiation may be introduced into wave guides by means of small loops or probes (see ANTENNAS AND WAVE GUIDES).

THE SCATTERING OF ELECTROMAGNETIC RADIATION

Matter is made up of charged particles, which by definition respond to electromagnetic fields. An electromagnetic wave periodic in time will produce periodic motion in the particles and thus produce radiation. In the process as a whole, energy is absorbed from the incident wave and re-emitted, thus scattering the electromagnetic wave. The details of the scattering depend on the nature of the scatterer and the wavelength of the radiation. First to be considered will be the scattering produced by electrons, which are forced to vibrate by an incident electromagnetic wave.

If the velocity of the electron is well below the velocity of light, the effect of the magnetic vector may be neglected. This approximation is valid for optical frequencies and even for soft (low-energy) X-rays. In the classical theory of scattering it is assumed that the electron is harmonically bound to a fixed position, so that it has a natural frequency that may be large or small compared with the frequency of the incident radiation. The forces acting on the electron comprise the binding force and a damping force corresponding to its reaction in emitting radiation, in addition to the external electric force field. If ω_0 represents the binding frequency and γ characterizes the damping, the equation of motion for the electron in the presence of an incident plane polarized electric wave field defined as $\boldsymbol{E} = \boldsymbol{E}_0 e^{-i\omega t}$, directed along x, is

$$\ddot{x} - \gamma\dot{x} + \omega_0^2 x = \frac{e}{m} E_0 e^{-i\omega t}.$$

The scattered wave has the same frequency as that of the incident wave, and a solution of this second-order differential equation, the time dependence of which is given by $e^{-i\omega t}$, corresponds to an acceleration,

$$\ddot{x} = \frac{e}{m}\left(\frac{-\omega^2}{\omega_0^2 - \omega^2 - i\omega\gamma}\right) E.$$

To find the corresponding radiation fields one simply substitutes $\ddot{x}$ in the formulas for radiation from an accelerated charge. The magnitude of the scattered electric field at a distance r from the electron is

$$E(r) = \frac{e\ddot{x}\sin\alpha}{4\pi\epsilon_0 rc^2},$$

in which α is the angle between the acceleration (or the electric vector of the incident field) and the direction of propagation of the scattered radiation; the same function accounts for the fact that no radiation is scattered in the direction of the incident electric field.

It is convenient to consider separately the various approximations to the complete scattering. For a free or weakly bound electron in which its damping force is negligible and its binding frequency is vanishingly small compared to the frequency of the incident, radiation ($\omega \gg \omega_0$), then $\ddot{x} = \frac{e}{m}E$ from the above equation, and the total radiation rate is given by substitution in the Larmor formula,

$$\frac{e^2\ddot{x}^2}{4\pi\epsilon_0 c^3} = \frac{e^4 E^2}{4\pi\epsilon_0 m^2 c^3}.$$

If this rate is divided by the intensity of the primary radiation, $I_0 = c\epsilon_0 E^2$, one obtains the effective scattering cross section per electron, the area from which the energy of the incident beam is removed by the scatterer. This is

$$\sigma_0 = \frac{8\pi}{3}\left(\frac{e^2}{4\pi\epsilon_0 mc^2}\right)^2 = \frac{8\pi}{3} r_0^2,$$

in which $r_0 = e^2/4\pi\epsilon_0 mc^2$, and is the classical electron radius. This result was first derived by Sir Joseph John Thomson of England, and classical free-electron scattering is known as Thomson scattering. It it noted that this cross section is a constant, the numerical value of which is $\sigma_0 = 0.665 \times 10^{-24}\ \text{cm}^2$. For electrons that are indeed weakly bound, the Thomson scattering formula represents the scattering of frequencies up to the X-ray region, but deviations become important for higher energy photons. The quantum mechanical calculation of the scattering cross section for free electrons gives the Klein-Nishina formula, which predicts that the scattered radiation is largely concentrated in the forward direction for extremely high frequencies. Moreover, the frequency of the scattered radiation is less than that of the incident radiation by an amount that depends on the scattering angle, as seen in connection with the Compton effect.

Thomson scattering

The general classical formula for the scattering cross section is

$$\sigma = \sigma_0 \frac{\omega^4}{(\omega_0^2 - \omega^2)^2 + (\gamma\omega)^2},$$

in which σ_0 is the Thomson cross section given above.

The cross section is a maximum for $\omega = \omega_0$, the natural frequency of the bound electron, and the resulting resonance scattering may be very large, because γ is small. For strong binding, on the other hand, such that $\omega_0 \gg \omega$, $\sigma = \sigma_0 (\frac{\omega}{\omega_0})^4$; that is, the cross section, and hence the scattering, varies as the inverse fourth power of the incident wavelength. The inverse fourth power law was first derived by Lord Rayleigh to account for the blueness of the sky and the reddening effect of the atmosphere at sunrise or sunset. Rayleigh assumed that the air molecules scattered randomly, so that intensities add, and with average empirical values of the natural frequencies of the atmospheric constituents, the result is in accord with observation. The formula for scattering per unit solid angle, with the incident beam unpolarized, is also in good agreement with the observed partial polarization of sky light.

For wavelengths long in comparison with the dimensions of the scatterer, the scattering cross section is much smaller than the geometrical cross section. The size of particles in atmospheric haze is of the same order as the wavelength of visible light, and infrared photography of a distant landscape is much clearer than that made with ordinary light. Particles with dimensions larger than the wavelength, however, scatter energy with a cross section independent of the frequency, and infrared light does not penetrate fog. The scattering from larger particles, such as water droplets and smoke particles, is called the Tyndall effect and is important in connection with colloidal solutions as well as in the transmission of light through atmospheric haze.

Tyndall effect

ELECTROMAGNETIC WAVES IN MATERIAL MEDIA

Matter is composed of charged particles that are affected by the application of an external electric field. Dielectrics differ from conductors in that they have no free charges that can move through the material, but there is a displacement of positive and negative charges relative to each other under the influence of an applied field. This charge separation, ordinarily small compared with atomic dimensions, is called polarization. Any configuration of induced bound charge is capable of producing electric fields, just as if they were free charges; but because the existence of any induced charge depends on the field itself, it is convenient to introduce another field quantity the sources of which are the free charges only. In terms of **P**, the dipole moment per unit volume, also called simply the polarization, this displacement field $\boldsymbol{D}$ is defined by the relation

$$\boldsymbol{D} = \epsilon_0 \boldsymbol{E} + \boldsymbol{P}.$$

In many dielectrics the polarization of the medium is proportional to the strength of the electric field, so that the displacement field is also proportional to it; that is,

$$\boldsymbol{D} = K\epsilon_0 \boldsymbol{E},$$

in which K is the dielectric constant of the medium, sometimes called the permittivity. This relation is not a principle of electromagnetism but a description of a limited class of matter, and it is called a constitutive equation. An analogous constitutive equation relates $\boldsymbol{B}$ to $\boldsymbol{H}$, but because in dielectrics and almost all conductors an applied magnetic field produces very little change in the charge configuration of the bound charge, one may assume that $\boldsymbol{B} = \mu_0 \boldsymbol{H}$, just as in empty space.

In the absence of free charges and currents, a combination of Maxwell's equations to eliminate the magnetic field leads to

$$\nabla^2 \boldsymbol{E} - \frac{K}{c^2} \frac{\partial^2 \boldsymbol{E}}{\partial t^2} = 0.$$

Exactly the same equation is obtained for the magnetic field $\boldsymbol{B}$. This is the ordinary wave equation, but the wave velocity (c') is now $c' = c/\sqrt{K}$. From the definition of the optical index of refraction, one obtains the Maxwell relation $n = c/c' = \sqrt{K}$, according to which the dielectric constant (K) should be at least approximately equal to the square of the index of refraction n. This relation is confirmed for long waves, and in some substances for the visible spectrum, but for many dielectrics it fails badly. Water is a notable example: the static dielectric constant is about 81, whereas the index of refraction is very nearly 4/3. The reason for these failures is that the polarization depends on the frequency; so that the transmission of electromagnetic waves of high frequency in dielectrics must be treated as a dynamic process, just as in conductors.

One should note that in a dielectric the vectors $\boldsymbol{E}$ and $\boldsymbol{B}$ are in phase and that the electric and magnetic energy densities are equal, just as in free space, although the instantaneous energy density is now $\epsilon_0 K E^2$. The average value of the Poynting vector is the wave velocity c' times the average total energy density.

All media absorb electromagnetic radiation to some extent. The simplest way to account for absorption is to introduce the conductivity σ and to assume that the current density $\boldsymbol{j}$ is proportional to the electric field in accord with Ohm's law: $\boldsymbol{j} = \sigma \boldsymbol{E}$. If the material is nonmagnetic, and if $\boldsymbol{D} = K\epsilon_0 \boldsymbol{E}$, the Maxwell equation corresponding to Ampère's law becomes

$$\nabla \times \boldsymbol{B} = \mu_0 \sigma \boldsymbol{E} + \frac{K}{c^2} \frac{\partial \boldsymbol{E}}{\partial t}.$$

Elimination of B between this equation and the Faraday induction equation then leads to the equation of telegraphy,

Equation of telegraphy

$$\nabla^2 \boldsymbol{E} = \frac{K}{c^2} \frac{\partial^2 \boldsymbol{E}}{\partial t^2} + \mu_0 \sigma \frac{\partial \boldsymbol{E}}{\partial t},$$

and $\boldsymbol{B}$ obeys a similar equation. Because of the dependence of the dielectric constant and the conductivity on the frequency, these equations are useful only for the Fourier components of the field, time variation of which may again be represented by the factor $e^{-i\omega t}$. Then

$$\nabla^2 \boldsymbol{E} + \left(K + \frac{i\sigma}{\epsilon_0 \omega}\right) \frac{\omega^2}{c^2} \boldsymbol{E} = 0,$$

in which the effective permittivity $\eta = K + i\sigma/\epsilon_0\omega$ takes the place of the dielectric constant in the wave equation. Because η is complex (has an imaginary part) there will be both absorption and a phase displacement between the electric and magnetic field vectors. There is correspondingly a complex index of refraction, which may be written $\sqrt{\eta} = n + i\kappa$.

The field variation of a wave traversing the medium in the x direction now depends on the exponential factor

$$\exp\left[-i\left(\omega t + \frac{nx}{c}\right)\right] \exp\left(-\omega \kappa x/c\right),$$

and κ is called the extinction coefficient.

The relative importance of the two terms in the differential equation for the electric field may be expressed in terms of a relaxation time $\tau = K\epsilon_0/\sigma_0$, in which σ_0 is the direct current conductivity. If this relaxation time is long compared with the period $2\pi/\omega$ of the radiation, the wave is propagated without much loss. For pure metals, however, the relaxation time is of the order of 10^{-14} second. Hence, for frequencies lower than those of the optical spectrum, an electromagnetic wave is essentially not propagated within a highly conducting medium. The extent to which the fields do penetrate the conductor depends on the frequency, and the "skin depth" is found by solving the equation with the assumption that the conductivity is extremely large compared to the product of the dielectric constant of free space and the frequency of the field; *i.e.*, $\sigma \gg \epsilon_0 \omega$. The square of the wave number k is then $k^2 = i\omega\sigma/\epsilon_0 c^2$; so that $k = (1 + i)/\delta$, in which $\delta = c\sqrt{2\epsilon_0/\sigma\omega}$ is the "skin depth," the depth to which the fields at normal incidence would decrease to $1/e$ (the logarithmic base $e = 2.7183$) of their values. Within the metal the electric and magnetic fields are no longer in phase, and the energy density is no longer shared equally by the fields but is largely magnetic.

For still higher frequencies a metallic conductor behaves like an ionized gas, in that the frictional forces corresponding to Ohm's law may be much less than the dynamical effect of the electric field on the free electrons. If there are N electrons per unit volume, each with mass m and charge e, the current density j is Nev, and the equation of motion $mv = eE$ may be transformed into

$$\frac{dj}{dt} = \frac{Ne^2E}{m}.$$

Formally, one may put $j = \sigma E$, and with the time dependence given by $e^{-i\omega t}$, it is found that $\sigma = iNe^2/m\omega$. In general it is necessary to add the displacement current $D = iK\epsilon_0 E$; so that

$$j_{\text{total}} = i\epsilon_0\omega(K - \frac{Ne^2}{m\omega^2\epsilon_0})E.$$

Clearly, there is a value of the frequency for which the total current vanishes, namely,

$$\omega_p = \sqrt{\frac{Ne^2}{m\epsilon_0 K}},$$

which is called the plasma frequency. Because the dielectric constant K is not far from unity, this frequency depends only on the density of free electrons and is given by $\nu_p = 8.98N^{1/2}$ cycles per second. For the ionosphere, ν_p is about three megacycles per second, whereas for copper it is 2.5×10^{15} cycles per second. At frequencies higher than the plasma frequency the displacement current is dominant, and therefore the conductor behaves as an insulator for such frequencies.

Plasma frequency

ANTENNAS

Electric dipole radiation is produced by any charge distribution that has a dipole moment that varies harmonically with the time. For application to real antennas, the formulas for radiation fields from an infinitesimal dipole given earlier must be integrated over the finite dimension of the radiating system. Short linear antennas, having length much smaller than the wavelength of the emitted radiation, require only the substitution of the current for the time variation of the charge. If the current I is written as $I_0e^{-i\omega t}$, and l is the length of the dipole, then $\ddot{p} = -i\omega lI_0e^{-i\omega t}$, and the time average of the square of $\ddot{p}$ is $\frac{1}{2}I_0^2l^2\omega^2$. The angular distribution of radiation from a short linear antenna is the same as for an oscillating linear dipole, given by the factor $\sin^2\theta$, with the angle θ measured from the dipole axis, so that no power is radiated in the direction of the axis. The time average of total radiated power ($\bar{P}$) is

$$\bar{P} = \frac{\pi I_0^2}{3\epsilon_0 c}\left(\frac{l}{\lambda}\right)^2,$$

in which $\lambda = 2\pi c/\omega$ is the free-space wavelength of the radiation. The power supplied to maintain this radiation is often expressed in terms of the radiation resistance, defined by analogy with the coefficient of the root-mean-square current, which gives the rate of joule (electrical) heating in a conductor, $\frac{1}{2}RI_0^2$. The radiation resistance is

$$\frac{\pi}{6\epsilon_0 c}\left(\frac{l}{\lambda}\right)^2 = \frac{\mu_0 c\pi}{6}\left(\frac{l}{\lambda}\right)^2 = 789\left(\frac{l}{\lambda}\right)^2 \text{ ohms}$$

for a short antenna in which the current is essentially constant over the length. This radiation resistance represents the power lost as radiation in an antenna supplied with a current $I_0e^{-i\omega t}$.

A somewhat more realistic antenna has dimensions that are not as small in comparison with the wavelength of its radiation. The half-wave antenna has a length $l = \lambda/2$, and is supplied with oscillating power at its centre. The current at any distance x from the centre is given by $I = I_0 \cos(2\pi x/\lambda) \cos \omega t$. Each element Idx of the antenna radiates as a short dipole, and the total fields are found by integrating over the length of the dipole. The angular distribution of the radiation from a half-wave antenna is similar to that from an infinitesimal dipole, but the intensity is somewhat more concentrated in the equatorial plane. The field intensities, and thus the Poynting vector, are independent of the frequency, and the total radiated power is simply proportional to the square of the effective current in the antenna. The radiation resistance of a half-wave antenna is 73.1 ohms. The assumption of the sinusoidal current in the antenna is not entirely justified, because the current distribution would be affected by the radiation losses; but the radiation field configurations are not significantly distorted by these deviations from the idealized half-wave distribution.

Antenna radiation pattern

The radiation patterns from linear antennas more than a wavelength long are more severely affected by the losses involved in the radiation. Linear antennas the lengths of which are an integral number of half wavelengths give rise to simple idealized patterns, symmetric about the axis of antenna, but with a number of lobes equal to $2l/\lambda$, the number of half wavelengths in the antenna. Ideally, the most intense lobe is one that makes the smallest angle with the antenna, but the decrease in current density along the wire produced by losses tends to reduce the intensity of these strong lobes relative to the weaker lobes near the equatorial plane. To radiate energy predominantly in some particular direction, it is more advantageous to use antenna arrays rather than long antennas.

The radiation patterns produced by arrays of dipoles are sensitive both to the separation of the dipoles in terms of the radiated wavelength and to the relative phase with which the antennas are driven, as well as to the length of each dipole. Simple arrays consist of half-wave antennas equally spaced in a direction perpendicular to their length. If the antennas are driven in phase, the radiation is emitted mainly at right angles to the orientation of the array—*i.e.*, broadside radiation. Antennas spaced a half wavelength apart and driven in alternating phases give fields that add constructively in the direction of the array, giving end-fire radiation.

Broadside and end-fire radiators

In engineering practice, antenna arrays have been designed to give a wide variety of radiation patterns. The arrays may be two- or three-dimensional; and by increasing the number of elements and decreasing their spacing, the limiting case of a continuous distribution is obtained. Particularly in the microwave region the energy is radiated by horns or by parabalidal reflectors. The directional characteristics of the radiation may be obtained by integrating over the fields in the radiating aperture because according to Huygens' principle each point on a wave front behaves like a secondary source. The whole process is very like that of describing diffraction effects in optics, except that in optics it is often possible to substitute a scalar field and neglect the orientation of the electric and magnetic vectors.

It is unnecessary to make a detailed separate analysis of receiving antennas to understand their operation. The transmitting antenna sets up a field that the receiving antenna must transform into a signal by means of a suitable detector. The receiving pattern of an antenna is identical with its transmitting patterns, although the receiver must be oriented properly for maximum reception of any particular signal. Maximum detected signal depends only on the direction from which the incident wave comes, but the effectiveness of antenna reception as a function of angular variables is the same as its gain as a transmitter in terms of angular variables with respect to its orientation.

In practice, neither transmitting nor receiving antennas are in free space, and the effects of both ground and the ionosphere must be taken into account. For certain frequencies the atmosphere itself affects the radiation. Depending on the frequency, the ground may be treated as a conductor or as a dielectric with a complex index of refraction.

Electron

The electron is the lightest stable elementary particle of matter known. Carrying a single negative charge, considered to be the basic charge of electricity, it is a constituent of ordinary matter and occurs free in space. For fundamental properties of the electron see below.

The antiparticle of the electron, the positron, has precisely identical properties except that it carries a positive charge. If it meets an electron both are annihilated in a burst of energy. Because electrons abound everywhere, positrons are rare on earth, being produced only in high energy processes (*e.g.*, by cosmic rays) and live only for brief intervals of time before annihilation by electrons.

Under ordinary conditions, electrons are bound to the massive, positively charged nuclei of atoms by the attraction between opposite electric charges, one of the four forces that affect elementary particles. (Particles with the same charge, such as electrons, repel one another.) In neutral (not electrically charged) atoms the number of electrons equals the number of positive charges on the nucleus of the atom, but any atom may have more or fewer electrons than positive charges and thus be negatively or positively charged as a whole; such charged atoms are called ions.

Within each atom and ion, the electrons are not at rest but seem to move in complicated orbits around the nucleus that holds them against their tendency to repel one another and fly apart; and thus orbiting they build a cloud of negative charge that occupies almost the whole volume of the atom, the positive nucleus being a tiny, heavy mass at the heart of this relatively weightless negative cloud. The size of an atom, and its response to other atoms, particles, light, and other electromagnetic radiation, such as X-rays, is thus determined by the arrangement of the orbiting electrons. Atoms combine to form larger structures, such as molecules. Since the discovery of the electron, the concept that atoms will combine with each other by transferring or sharing electrons has dominated chemistry in terms of the modern valence theory, based on atomic structure, and of the chemical bonding theory, based on the sharing of electrons by adjacent atoms. The attraction between electrons attached to one atomic nucleus and the nuclei of nearby atoms (called Van der Waals force) explains much of the mechanism of the formation of liquids and solids. In nonconducting solids, the electrons are permanently positioned among the nuclei. In semiconductors, metals, and electrolytes, the electrons can move through the whole sample; and if they are made to move in one direction by any of several methods, they create an electrical current.

Free electrons

Electrons may also occur free, not associated with atoms, in a gas or vacuum, and in such cases they can then be described, in the language of classical mechanics, as particles of matter. On the other hand, electrons in atoms and molecules, and in solids, have wavelike properties that require quantum mechanics for explanation. The quantum theory of the interaction of electrons with radiation and with other particles is now considered complete, although solutions of the equations for many-electron systems are still imperfect. In future applications of knowledge about the electron, considerable technical development may be expected in the control and use of electrons in solid-state and vacuum devices.

PHYSICS OF THE ELECTRON

Electrons in early theories of electricity. Although the electron as a concept was not developed until the end of the 19th century, earlier theories foreshadowed aspects of its nature. In the 18th century electricity came to be thought of as an elastic (*i.e.*, self-repulsive) fluid that, according to Benjamin Franklin (1747), consisted of "particles extremely subtile, since it can permeate common matter, even the densest metals, with such ease and freedom as not to receive any perceptible resistance." The characterization of vitreous and resinous electricity as two different fluids, positive and negative respectively (R. Symmer 1759), was made fashionable by C.A. Coulomb (1785), although this conjecture could not then be verified. By 1812 J.J. Berzelius was speculating that "the electricities" might be "matter, destitute of gravitation, but possessing affinity to gravitating bodies," to explain the disruptive effects of an electric discharge.

The atomicity of electricity was first strongly suggested by Michael Faraday's discovery (1833) that the mass of a chemical element liberated by electrolysis of a solution containing a compound of that element was inversely proportional to its chemical equivalent (*i.e.*, valency), and exactly proportional to the total electric charge that had passed through the solution: "there is a certain absolute quantity of the electric power associated with each atom of matter." It was natural, thereafter, to interpret the bond between atoms in a molecule in terms of the electrostatic force between charged atoms, or ions. Yet W. Weber's electrodynamics (1846), based on inverse-square forces at a distance between electric particles, was not widely favoured. For the next generation, speculation on the nature of electricity was dominated by the electromagnetic theory of James Clerk Maxwell (1864), who grounded his mathematical formulas on the notion of strains in a continuous ether, a theoretical substance then believed to fill the universe. As late as 1881, in his *Treatise on Electricity & Magnetism* (2nd ed.), Maxwell used the hypothesis of a "molecule of electricity" to explain electrolysis but remarked that it is "out of harmony with the rest of this treatise."

Electrons in cathode rays. In the 1880s interest was aroused in cathode rays, one of many mysterious phenomena observed in electrical discharges through gases at low pressures. The ray was an invisible radiation emanating from the negative electrode of a cathode tube and travelling in straight lines to produce a phosphorescent glow where it struck a glass envelope. Although the rays were deflected by magnetic fields, it was controversial whether these rays were vibrations of the ether or streams of charged particles. This question was at length resolved (1894–97) by the experiments of J.J. Thomson, who showed, using an apparatus (Figure 1) that was the prototype of the modern cathode-ray tube, that the rays travelled more slowly than light, transported negative electricity, and could be deflected by an electric field. The rays produced at the cathode C were defined as a beam by the slits A, B, and passed between the electrified plates D, E (or between the poles of a magnet), before striking the screen where the deflection could be measured. From the formula of H.A. Lorentz (1892)

First measurements of the electron

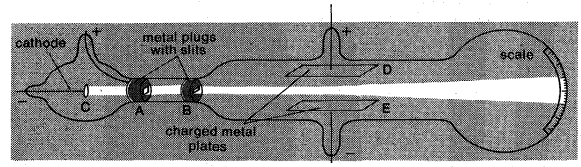

Figure 1: Device for detecting deflection of cathode rays by an electrostatic force acting between two charged plates (see text).

$$\dot{\mathbf{v}} = \frac{e}{m}\boldsymbol{E} + \frac{e}{mc}(\mathbf{v} \times \boldsymbol{H})$$

for the acceleration of a charged particle in the electric field $\boldsymbol{E}$ and magnetic field H, it was then easy to calculate by classical mechanics the velocity v and the mass/charge

ratio of the particle, m/e. This was found to be much smaller than for canal rays; *i.e.*, positive ions. This result meant that, since the unit negative charge exactly equalled the unit positive charge, the mass of the particle carrying the negative charge was considerably less than the mass of the particle carrying the positive charge. By measuring the mobility of ions (*i.e.*, any charged particle) in gases (or estimating the number on which cloud droplets had been nucleated), Thomson and his pupils demonstrated that the charge e was about the same as the charge carried by the hydrogen ion in electrolysis. By 1900 there was overwhelming evidence that electricity consisted of a flow of electric charges, in units of magnitude about 1×10^{-19} coulomb (this was the unit for which G.J. Stoney in 1894 had proposed the name electron) and that the mass of this corpuscle of negative charge was only about 1/2,000 the mass of a hydrogen atom.

Properties of the classical electron. Thomson's electrons were very soon identified as the cause of other natural phenomena. The electrical conductivity of air near a hot poker, observed in the early 18th century, was found to be due to thermionic emission of electrons from a hot metallic surface. Similarly, the photoemission of electrons from a metal plate illuminated with ultraviolet light was shown to be the cause of the photoelectric effect (dissociation of atoms into electrically charged particles resulting from the absorption of electromagnetic radiation). The beta rays emitted by many radioactive substances were found to be energetic electrons. Electrons were observed so universally in nature that any ionizing particle of obvious small mass or negative charge was taken to be an electron, an empirical generalization that was not proved false until the 1930s by the discovery of the elementary particles positrons and mesons in cosmic rays.

Measurement of negative charge

The magnitude of the negative charge e was obviously of basic importance and a scale parameter for the whole of atomic physics. Earlier estimates were superseded by R.A. Millikan (1916), who transformed the cloud droplet method into a precision technique. Through a microscope he timed the fall of a tiny drop of oil, whose size could then be deduced by Stokes' law for the motion of a sphere through a viscous fluid. He then switched on a vertical electric field: any charge on the drop could be calculated from the new rate of fall. From time to time this charge appeared to change abruptly by a constant amount, showing that the drop had captured, or lost, an electron. This direct observation of an atomic event seemed to give the value of e to within 0.1 percent.

Millikan's result was actually too low by about 0.6 percent. The correction came 20 years later by a roundabout route. Comparison of X-ray diffraction from crystals yielded absolute values of the spacings between their atomic planes. Avogadro's number could be calculated more correctly, and new measurements of Faraday's electrochemical constant then gave e to one part in 10^4. By that date similar precision could be obtained in measurements of e/m by a variety of techniques. But the values of e and m quoted below do not depend on any single experiment. These, and other fundamental constants, are now statistically adjusted for consistency with the observed values of the many different physical quantities in whose theoretical formulas they appear.

Electrons in the atom. By 1900, physicists knew that electrons came from inside atoms. What were they doing there? The sharp lines in optical spectra suggested that the electrons could vibrate in various ways with well-defined frequencies. Attempts to explain this action with stable electrostatic models—for example, with a model in which negative electrons are embedded like currants in a bun of positive charge—did not provide the right answers. Then came the alpha-particle-scattering experiments of E. Rutherford (1911), which showed that all the positive charge within an atom must be concentrated in a small, heavy nucleus, leaving all the electrons grouped somehow outside the nucleus. To this model N. Bohr (1913) added ideas from the quantum theory of M. Planck (1900). Each electron is supposed to move rapidly in a circular or elliptical orbit around the nucleus due to electrostatic attraction between it and the nucleus (Figure 2A). But only those orbits are permitted for which the angular momentum is an integral multiple of $\hbar$ (*i.e.* of Planck's constant h divided by 2π); light is emitted or absorbed as the electron acquires or loses energy and jumps from one orbit to another.

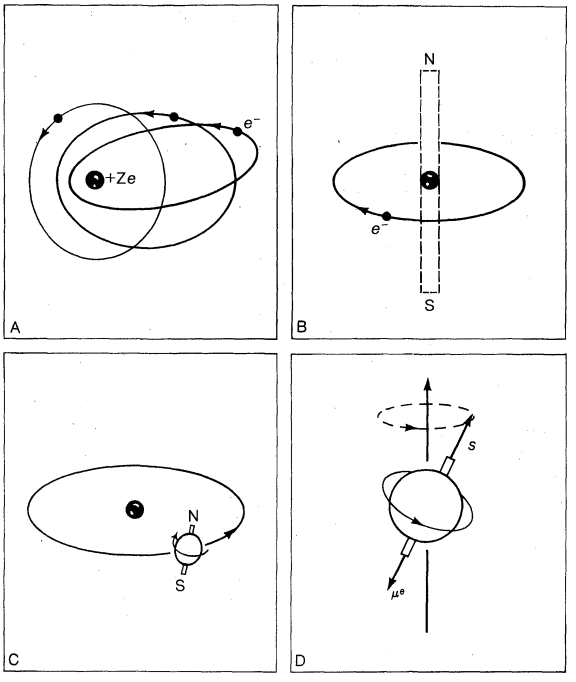

Figure 2: Orbital motion and spin of an electron in an atom, without regard to quantum mechanical concepts (see text).

The Bohr-Rutherford model

The Bohr-Rutherford model is the best classical picture of the electrons in an atom. In particular, it emphasizes their high kinetic energy. Indeed, the electron in the first Bohr orbit is travelling at an appreciable fraction of the velocity of light, c, a dimensionless number called the fine structure constant. It is given by the equation $\alpha = e^2/c\hbar = 1/137.0388(6)$. One of the successes of the model was A. Sommerfeld's prediction (1916) of fine structure in the hydrogen spectrum as a result of relativistic corrections to Newtonian planetary theory.

Electron magnetism and spin. A charged particle moving round and round a closed orbit is equivalent to a loop of electric current that behaves like a small magnet (Figure 2B). Each electron in an atom must therefore give rise to magnetic moment exactly proportional to its orbital angular momentum, which is quantized to the values $l\hbar$ ($l = 0, 1, 2 \ldots$). This contribution is easily calculated as an integral multiple, $l\mu_B$, of the Bohr magneton $\mu_B = e\hbar/2mc$. In an atom containing several electrons with orbits in various orientations, these contributions largely cancel out but could explain the existence of stable magnetized atoms such as iron. In an external magnetic field, H, the axis of each orbit would precess with the Larmor frequency $\omega_L = eH/2mc$. This frequency may combine with the frequency of an optical transition, giving rise to a Zeeman effect: the splitting of spectral lines in the radiation emitted by atoms in a magnetic field. Unfortunately for the simple Bohr theory, the Zeeman effect in many atoms was obstinately anomalous. As an empirical explanation, G.E. Uhlenbeck and S. Goudsmit (1925) conjectured that the electron might have an intrinsic angular momentum, or spin (Figure 2C), with an associated magnetic moment. Each electron is assigned an additional angular momentum, $s\hbar$, whose spin quantum number, s, takes only two values, $s = 1/2$ or $s = -1/2$. But the intrinsic magnetic moment is still of magnitude μ_B. If this is expressed as $\mu_e = g\mu_B s$ with $g = 2$, it is noted that the gyromagnetic ratio (*i.e.*, magnetic moment/an-

gular momentum) is twice as large for electron spin as for orbital motion.

This conjecture is confirmed by a variety of observations. Complicated atomic spectra are successfully calculated by the vectorial addition of orbital and spin moments. In most magnetic materials, the observed gyromagnetic ratio shows that the spin magnetic moment is dominant. A whole field of physics and chemistry deals with electron spin resonance, in which the Larmor precession frequency, $g\omega_L$ for a free electron spin in a magnetic field (Figure 2D), is detected directly by resonant interaction with a microwave field of the same frequency.

Electron radius

It is obviously tempting to picture an electron as a spinning sphere of electric charge whose radius is determined by the dimensional relation $e^2/a = mc^2$ at which the electrostatic self-energy of the charge distribution is comparable with the relativistic energy of the rest mass. This classical electron radius, $a = 2.81785 \times 10^{-15}$m, is an important scale parameter in physics; but the uniqueness of e, the arbitrariness of the quantization rules, and the difficulty of making it properly relativistic, forbid such a purely classical model.

The fundamental constants of the electron are as follows:

Mass: $m = 9.10908(13) \times 10^{-31}$kg
$= 5.48597(3) \times 10^{-4}$atomic mass units
Charge: $e = -1.60210(2) \times 10^{-19}$ coulomb
$= -1$ atomic charge
Spin: $s = \frac{1}{2}$
Magnetic moment μ_e
$= 9.2839(2) \times 10^{-24}$ joule per tesla
$= 1.001159622(27)$ Bohr magnetons

Electrons as waves. Electron theory was revolutionized in 1923 by L. de Broglie's hypothesis that an electron moving with velocity v might be accompanied by a periodic disturbance of wavelength $\lambda = 2\pi\hbar/mv$ (Figure 3A). This analogue of the photon concept (the unit of

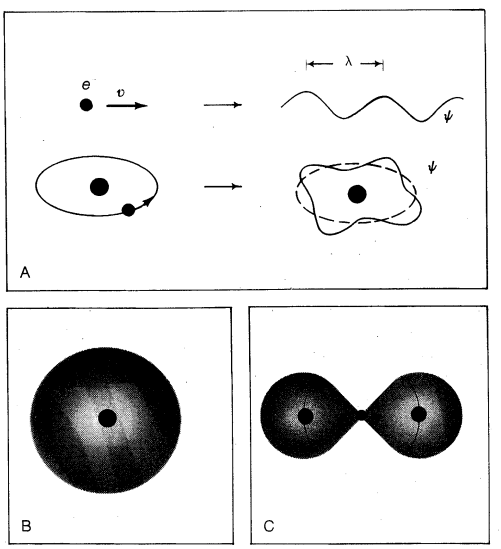

Figure 3: Cloud or probability concept of the electron according to quantum mechanics (see text).

electromagnetic energy that has no mass and no charge) was not, in fact, confirmed by direct observation (diffraction from crystal surfaces) until 1927, but the Bohr quantization rule could now be interpreted as the condition for a standing wave, with a whole number of wavelengths around the circumference of the orbit. In 1926, E. Schrödinger wrote down the partial differential equation for such a wave function (conventionally symbolized by the letter ψ) and showed that it had stationary solutions in the electrostatic field of a nucleus at exactly the energies predicted by the Bohr model. This equation is the basis of all subsequent theory for electrons at the atomic scale.

Of what is ψ a wave? At first it looks as if the electron charge has been spread out into a continuous cloud through the whole volume of the atom (Figure 3B). In fact, the value of $[\psi]^2$ at any point represents the density of probability of finding the electron, still a tiny indivisible particle, in that region. The uncertainty principle (M. Born; W. Heisenberg, 1927) permits only statistical notions of the whereabouts and velocity of the electron as it traverses the Bohr orbit, which thus becomes blurred into an orbital function. But the indefinite stability of such an orbital in time allows it to have a sharply defined energy, as required by spectroscopy.

Many-electron systems. As the number of positive charges on the nucleus increases with increasing atomic weight, the number of electrons increases equally. The arrangement of electrons around the nucleus follows a pattern that can be conceived as a balanced distribution among concentric shells. Each shell can accommodate up to a fixed number of electrons, and this pattern is expressed by the periodic law. The periodic law, therefore, can be interpreted as the filling up of successive closed shells of Bohr orbits, as electrons are added to neutralize increased nuclear charge. Strictly speaking, these wave mechanical electrons, being indistinguishable from one another, cannot be assigned individually to different orbitals in the same atom. But a fundamental postulate, that the many-electron wave function must be totally antisymmetric for the interchange of any two sets of particle coordinates, leads in simple cases to the exclusion principle of W. Pauli (1924): each quantum state can be occupied by only one electron at a time. For example, a given orbital function may not contain more than two electrons, which must then have opposite spins (Figure 3C).

Exclusion principle

Electron assemblies therefore obey Fermi-Dirac statistics. Whereas the molecules in a classical gas at low temperatures would all be crowded into the lowest state, the particles in a dense electron gas are forced to occupy a whole range of states up to the Fermi energy, E_F (Figure 4A). The average kinetic energy per electron remains as

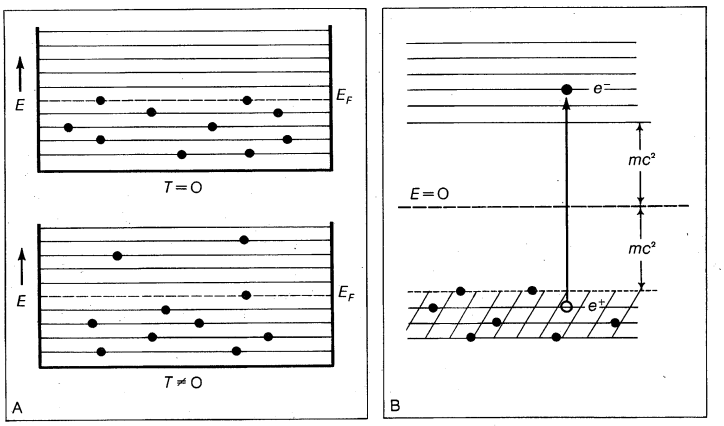

Figure 4: *Energy-level diagrams for the electron and positron.*
(A) Distribution of electrons among energy states: (top) at very low temperatures, (bottom) at higher temperatures.
(B) Formation of a positron by ejection of an electron.

large as if the gas were at an enormous degeneracy temperature, $T_F = E_F/k$ (k = Boltzmann's constant). When the assembly is heated, only a few electrons at the top of the distribution can take up energy by moving into empty higher levels, so that the specific heat is small. This phenomenon is extremely important in metals and in the interior of stars.

Even in a Bohr atom each electron would markedly perturb the orbits of others by mutual electrostatic repulsion. As a first approximation each orbital may be calculated as if the particle were moving in the average self-consistent field (D.R. Hartree, 1928) of its fellows. But many-electron wave functions are really much more complicated than antisymmetric combinations of quasi-independent orbital functions. Significant exchange and correlation factors which describe statistically the way in which electrons avoid one another in accidental encoun-

ters need to be included. The mathematical theory of these terms and of the physical phenomena to which they give rise is still incomplete.

Relativistic electrons and positrons. The unit of energy on the subatomic scale is the electron volt, the energy change of a charge moved through a potential difference of one volt. The relativistic rest mass, mc^2, of an electron is only 0.511×10^6 electron volts (*i.e.*, 0.511 Mev), which is easily exceeded in cosmic rays and in particle accelerators. What happens to the electron then?

As its energy increases, a point particle merely acquires additional mass, but a spinning sphere cannot easily be discussed relativistically. In nonrelativistic quantum theory one needs two wave functions, $\psi\uparrow$ and $\psi\downarrow$, to describe the electron in each of its spin states, together with rules for combining these functions as the spin axis changes direction. How do these functions behave at relativistic velocities? In a classic paper, P.A.M. Dirac (1928) showed mathematically that the wave function must have two additional components: $\bar{\psi}\uparrow$ and $\bar{\psi}\downarrow$. An electron in the state $\bar{\psi}\uparrow$ when accelerated to high energies acquires a proportion of the $\bar{\psi}\uparrow$ function, and so on. But a pure $\bar{\psi}\uparrow$ function seems to describe an electron in a state of negative kinetic energy, a new physical concept. Dirac suggested that these states are not normally observed because in a vacuum these states are all completely filled (rather like the states of an ordinary electron gas at absolute zero temperature). But given sufficient energy (*i.e.*, more than $2\ mc^2$) an electron could be knocked out of a negative energy state to leave a "hole" in the background continuum. Such a hole, being the negation of a particle of negative charge and negative mass, behaves electrically and dynamically exactly like an ordinary particle of positive charge (Figure 4B). A positron, as this hole came to be called, is thus said to be the antiparticle of an electron.

The positron

Without knowing of Dirac's theory, C.D. Anderson (1932), P.M.S. Blackett, and G.P.S. Occhialini (1933) reported the observation of just such particles in cosmic radiation where they could be distinguished from electrons by the opposite curvature of their cloud-chamber tracks in a magnetic field (Figure 5). When gamma rays (*i.e.*, high-energy photons) interact with matter, they can produce electron-positron pairs by exciting electrons out of the negative energy states of the vacuum. Each of these particles, in turn, can emit more photons, thus cascading into a cosmic-ray shower. The positron, however, has a short life in ordinary matter, for when it has been slowed down it meets an electron that drops into the vacant hole with the emission of another gamma ray; *i.e.*, the two particles mutually annihilate one another. Positrons are also emitted from certain artificially radioactive nuclei in the same manner as are beta rays.

Quantum electrodynamics. The motion of a charged body creates an electromagnetic field that reacts back to resist the motion. For the classical electron, a finite radius must be assumed if this self-energy correction is not to become infinite. Somewhat similar mathematical divergences were soon revealed in quantum theory. A moving electron polarizes the vacuum in its immediate vicinity: virtual photons and virtual electron-positron pairs are excited and then almost immediately destroyed, giving rise to infinite corrections, δm and δe, to the assumed mass and charge of the particle.

This difficulty again can be avoided by assigning to the electron a finite radius, but this arbitrary hypothesis cannot be made relativistically self-consistent. A partial solution was found, about 1950, in the renormalization scheme. Since the bare electron unaccompanied by virtual excitations can never be observed, δm and δe are treated as the physical mass and charge, disregarding the fact that the assumed parameters of the hypothetical bare particle would be infinitesimally small. Although obviously unsatisfactory as a fundamental physical theory, this procedure is relativistically respectable and correctly predicts several observed phenomena. For example, the vacuum close to a charged nucleus contains virtual photons that interact with an electron passing that way,

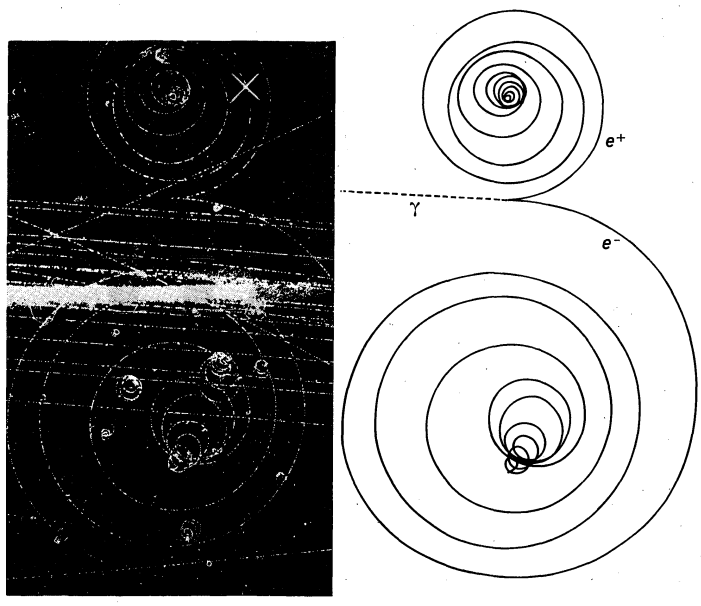

Figure 5: Cloud-chamber study of the spiral paths taken by an electron and a positron resulting from the passage of a gamma-ray photon through a sheet of lead. (The invisible path of the gamma ray is indicated with a dotted line in the diagram of the reaction on the left.) A magnetic field produces paths that are curved in a direction according to the positive or negative charge of the particle.

slightly changing the electron's energy. (This explains the Lamb shift [W.E. Lamb 1947] of about 1 GHz (gigahertz : 10^9 hertz) in some lines of the spectrum of atomic hydrogen.) The accompanying cloud of virtual excitations also contributes to the anomalous magnetic moment of the electron, whose g-factor is found to be slightly larger than the integral value 2 predicted by the basic Dirac theory.

Electrons in the nucleus. Since electrons are emitted as beta radiation in some radioactive transitions, it was assumed by Rutherford that they were present within the nucleus, neutralizing some of the protons making up the total mass of the nucleus. This is inconsistent with quantum mechanics because, by the uncertainty principle, an electron confined to so small a volume would have much too much kinetic energy to be bound. With the discovery of the neutron and of the fact that a nucleus consisted of a mixture of protons and neutrons, it became clear that beta decay was the spontaneous transformation of one of the neutrons in the nucleus into a proton and an electron, which could then escape from the nucleus. Similarly, a proton could emit a positron and change into a neutron, an event that also produces a more stable nucleus.

Beta decay

Beta decay is peculiar in that the energy of the emitted electron is not always the same but is spread over a wide range (Figure 6A). W. Pauli (1931) and E. Fermi (1934) explained this as the simultaneous production of another particle, the neutrino, which can carry away the rest of the energy but is undetected because it has zero charge and zero rest mass (Figure 6B). A further feature of this process was not suspected until 1956 when T.D. Lee and C.N. Yang showed that parity, one of the symmetry properties of elementary particles is not conserved. Experimentally, this can be observed in beta decay from a magnetically polarized nucleus, where the electrons are emitted preferentially into the hemisphere opposite to the spin vector of the nucleus, whereas if parity were conserved there would be no selectiveness.

The electron as elementary particle. J.J. Thomson's electron was the first to be discovered of a long list of elementary particles. Electrons are classified, along with muons and neutrinos, as leptons, showing that they are not affected by the strong interaction of nuclear forces but suffer the weak interaction that causes beta decay. These particles are all fermions; they obey Fermi-Dirac statistics, have spin $s = 1/2$, and have spinor-wave func-

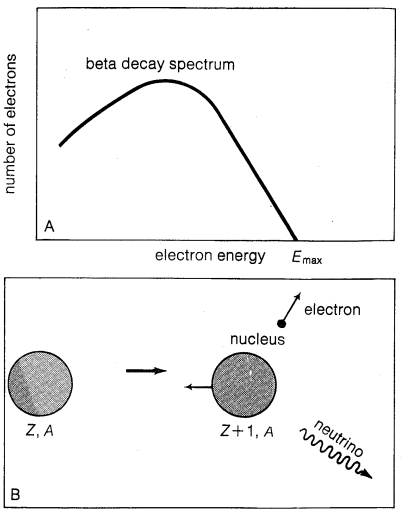

Figure 6: *Beta decay.*
(A) Curve showing how the number of electrons emitted in beta decay vary over a wide range of energies. (B) Schematic diagram showing production of a neutrino.

tions that satisfy the Dirac equation. Each particle has its antiparticle of identical mass but opposite charge. The most puzzling member of this group is the μ-meson or muon, which has all the properties of an electron except that it is much heavier (*i.e.*, $m_\mu = 207\ m$) and lives for only 2×10^{-6} second before decaying, with the emission of a neutrino and an antineutrino, into an ordinary electron. Is the muon, perhaps, merely a highly excited quantum state of the electron? Despite the precision with which the behaviour of these particles can be calculated in electromagnetic fields, up to enormous energies, an understanding of why electricity should occur in packets of exactly this strength, and why the negative particles, in the known universe, should have just this small mass is no nearer than it was for Thomson or Lorentz.

ELECTRONS IN ORDINARY MATTER

Atoms. In a neutral atom of atomic number Z, the Z lowest of all possible orbitals are occupied by electrons. Each orbital is a solution of the Schrödinger wave equation in the self-consistent field dominated by the number of positive charges ($+Ze$) on the nucleus. Each electron has four quantum numbers, denoting the total energy state of the electron; when classified according to their principal and orbital quantum numbers, n and l, the electron states group into shells that, when complete, are spherically symmetric and energetically stable.

Electron shells

The physical and chemical behaviour of an atom is largely, though not altogether, determined by the electrons in orbitals outside the core of closed electron shells. For example, the alkali metals, although widely varying in atomic weight and total number of electrons, have very similar properties because they each have only one electron in the outermost shell. This electron sees the nuclear charge $+Ze$ through the screen of $(Z\text{-}1)$ core electrons (Figure 7); it behaves rather as if it were in the field of a single proton and therefore occupies an orbital similar in energy and dimensions to those in a hydrogen atom, which has a single proton in the nucleus and a single electron. For atoms with two or more such valence electrons, the analysis is somewhat more complicated but easily explains the periodic law of chemistry, the regularities and complexity of atomic spectra, and the familiar fact that all atoms, regardless of atomic number, are roughly of the same size.

Gases. Energy is required to ionize an atom; that is, to remove or add an electron to a neutral atom. An outer electron, with ionization potential of only a few volts, may be ejected by interaction with ultraviolet light; core electrons in heavy atoms need electron impact or X-rays with energies of many kilovolts to be dislodged. In the

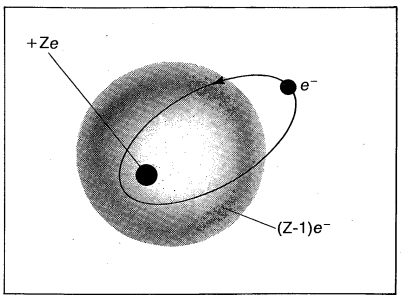

Figure 7: Representation of an atom with one electron outside a core of electron shells (see text).

long run the electron will be recaptured by a positive ion, but this recombination is impeded by dynamical and geometrical factors like those observed when the racked balls are broken in a game of pocket billiards: elastic scattering is easier than capture.

A gas at atmospheric pressure is not normally conductive because of the absence of free ions, but electrons emitted into a rarefied gas (as in a neon, mercury, or sodium vapour lamp) make infrequent collisions with atoms and may thus carry a discharge current. This action is accompanied by an arc or glow from atoms that have been excited into higher quantum states by electron impact. At higher voltages, the gas atoms may themselves be ionized by such impacts, producing more electrons that feed the current. At a critical breakdown voltage, even in a dense gas, the discharge may avalanche into a spark.

A plasma, a neutral gaseous mixture of electrons and positive ions, may thus be produced and maintained by a stabilized electric discharge or by a steady flux of ionizing radiation. Whether artificially produced in an electronic device or naturally occurring on the planetary, solar, or galactic scale, the electrical and magnetic properties of plasmas are due mainly to the electrons, which are vastly more mobile than the positive ions.

Plasma

Electronegative elements (typically the halogens, such as chlorine), which have one vacant orbital in their outermost shells, have an electron affinity of several volts and form stable negative ions. In an ionic solid or salt, such as sodium chloride, the outer electrons of the metal atoms are easily transferred to the halogen atoms (Figure 8A), forming an array of positive and negative ions bound together by their mutual electrostatic attraction (Figure 8B). The electrons all being in stable closed shells, these materials are normally electrical insulators.

But in a transparent alkali halide crystal, an electron at a vacant negative-ion site, or at a substituted metallic ion of higher valency (*e.g.*, a calcium ion [Ca^{++}] for a sodium

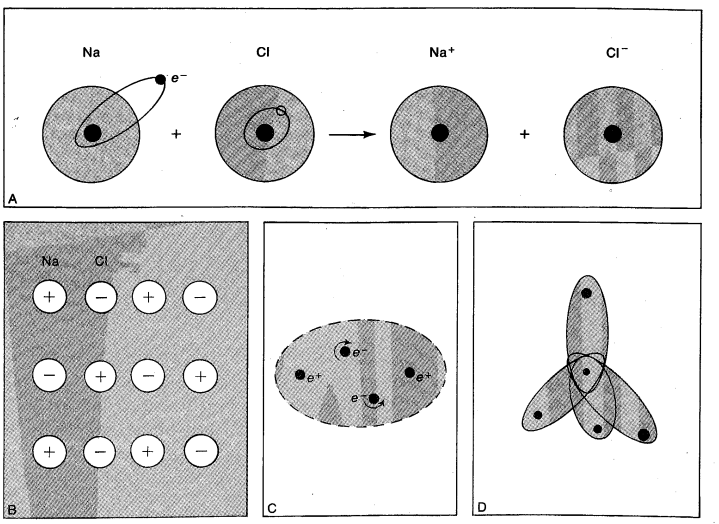

Figure 8: Sharing of electrons between atoms to produce bonding (see text).

ion [Na^+]), is only weakly bound to the local effective positive charge. The system has quantum states analogous to the hydrogen atom levels but much closer spaced in energy, and thus it gives rise to visible optical absorption in a so-called colour centre. A colour centre is readily ionized by a photon or energetic particle, releasing the electron to produce photoconductivity followed by other complex optical effects, such as fluorescence or luminescence, at other such centres.

Molecules. An electron moving through an ionic crystal of a salt is accompanied by a local polarization of the lattice, and this may substantially affect its apparent mass or mobility; such an electron is called a polaron. The behaviour of free electrons in molten salts is not well understood, but when the crystal is dissolved in water, or some other polar liquid, the electrons are taken up into negative ions, such as hydroxyl (OH^-).

Shared electrons

Shared electrons are the binding force in most chemical molecules. Consider two hydrogen atoms brought close together. In terms of reducing their total energy, it pays the electrons to merge their separate atomic orbitals into molecular orbitals that then enclose both nuclei. Two such electrons, by taking opposite spins (Figure 8C), may occupy the same bonding orbital building up a negative charge cloud between the two nuclei and thus binding them together electrostatically. The semiclassical model (G.N. Lewis, 1916) of the chemical bond as a pair of electrons held jointly by the two atoms was given this quantum-mechanical interpretation by W. Heitler and F. London in 1927.

This explanation of the valency rules in covalent compounds is fully justified theoretically and experimentally. Such familiar features as the rigidity of the tetrahedral arrangement of bonds about a carbon atom (*e.g.*, in methane, CH_4) follow immediately from the symmetry conditions on four molecular orbitals shared by a single nucleus (Figure 8D). But the convenient assumption that a pair of electrons is actually localized in each bond is not strictly correct; the true many-electron states are complicated combinations of wave functions extending throughout the molecule and much affected by correlation and exchange. This becomes significant in unsaturated molecules (*e.g.*, the benzene ring) where several, apparently equivalent ways of assigning electrons to bonds become mixed quantum mechanically (resonate) to produce a ground state of much lower energy than any single configuration.

The distribution of electrons in a molecule must take account of the differing electronegativities of the component atoms or subgroups, which may tend to polarize or stabilize the charge cloud or both. In many organic structures the electrons are relatively mobile, being able to

Electron transfer

transfer charge along or around the chains of atoms. Since chemical reactions occur between molecules or radicals with electrons to share or transfer, the rate of reaction depends critically on the electron distribution at the point where the link is made or broken. For example, nitration of an organic molecule occurs preferentially at places where the NO_2^+ radical can easily draw to itself an electron. The importance of electron transfer mechanisms in theoretical chemistry cannot be exaggerated.

Metallic cohesion. The chemical bond concept explains the cohesion of many solids that are no more than indefinitely extended molecules, whether regular crystals as in diamond or disordered networks as in silicate glasses. Since the electrons are all paired in saturated covalent bonds, these materials are basically electrical insulators, although they are easily made semiconducting by thermal excitation.

But an extended three-dimensional framework of directed bonds requires at least four bonds per atom. To make a condensed phase (solid or liquid) of a metal, such as sodium, with only one electron per atom, all the electrons must be set free to be shared by all the atoms. Metallic cohesion may be described as the most economical way of gluing together an assembly of impenetrable positively charged spherical ions with a fairly compressible negatively charged fluid of electrons, using purely electrostatic forces. Since this electron fluid is at a relatively high density, it is statistically degenerate and each particle has high kinetic energy. In the absence of specific quantum-mechanical forces, such as electron affinity for closed atomic shells, the electrons are not bound or localized in space and move rapidly throughout the whole sample. This picture is adequate to explain many of the properties of metals, such as their ability to form alloys over wide ranges of concentration, and many mechanical properties such as ductility and malleability.

Band structure of solids. By 1900, this picture of a metal was widely accepted as an explanation of high electrical conductivity. But a major contradiction, the absence of an electronic contribution to the specific heat, was not resolved until 1928 when A.H. Sommerfeld pointed out that Fermi-Dirac statistics would make this negligible at ordinary temperatures. In the quantum mechanical free electron model, each valence electron is assumed to occupy a distinct, free particle, de Broglie-wave state as if in an empty box bounded by the surface of the specimen (Figure 9A). Because of the Pauli exclu-

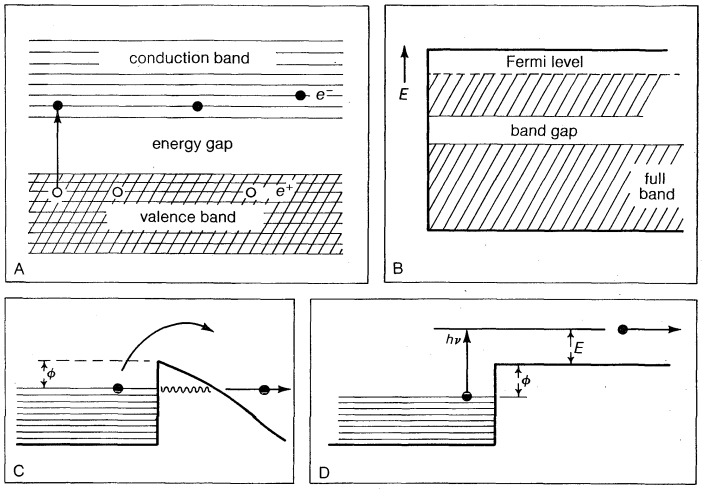

Figure 9: *Energy-level diagrams illustrating the band theory of solids.*
(A) Energy gap in a solid. (B) Transition of electron from valence band to conduction band. (C) Bound electron escaping from a metal. (D) Photoelectric effect.

sion principle, all the states up to the Fermi level are occupied so that only those electrons on the Fermi surface can respond to thermal excitation, or to external electric and magnetic fields. This model gives excellent semi-quantitative explanations of many basic metallic properties (heat conductivity, thermoelectric power, magnetic susceptibility, optical phenomena, etc.) and the answers are little affected by including the electron-electron repulsion in a complete many-electron calculation.

But, surely, the movement of each electron will be strongly resisted by collisions with the metallic ions. F. Bloch (1929) showed that the propagation of a quantum-mechanical electron through a regular crystal is really a problem in diffraction theory. An electron of given energy (*i.e.*, of given de Broglie wavelength) will either be transmitted without loss or it will suffer continual Bragg reflection and be unable to travel at all through the solid. The electron wave functions thus fall into allowed bands, with gaps between them (Figure 9A). The electronic band structure of these Bloch states is the analogue, for a solid crystal, of the atomic- or molecular-orbital structure of an atom or molecule; from it almost all the physical properties involving electrons may be deduced.

Conduction electron

For example, a conduction electron in an almost pure, almost perfect, metallic crystal at low temperatures may have a mean free path of many microns. In a suitably contrived setup with microwaves and magnetic fields, subtle phenomena may be observed showing exactly how the wavelength of the corresponding Bloch function varies with the direction of propagation through the crystal. The Fermi surface mapped in this way is often quite

similar to the spherical surface in the free electron model, implying that the electrons really are able to travel quite easily through the lattice in almost any direction. This can be attributed to the weakness of the pseudopotentials of many metallic ions; they do not have as much effect on the electrons as we should have supposed on classical grounds. Of course impurities and imperfections in the crystalline order, especially the inevitable thermal motions of the atoms at ordinary temperatures, scatter the electrons from one Bloch state to another, reduce the mean free path to a few microns, and produce the temperature-dependent electrical resistivity characteristic of metals. Surprisingly enough this nearly free electron picture survives in metals above the melting point, where all semblance of regular crystalline order has disappeared.

Superconductivity. In many metals the electrical resistivity vanishes completely below a critical temperature T_c of a few °K. This superconducting state, first observed by K. Onnes in 1911, did not seem to depend very much on the purity of the specimen, and the state was later discovered to have other physical properties that could be empirically correlated by assuming that the proportion of superconducting electrons to normal electrons increased as the temperature fell below T_c. But the basic mechanism of the transition remained quite mysterious until 1950, when H. Fröhlich drew attention to the coupling produced between conduction electrons through the electron-phonon interaction.

In nontechnical language, an electron passing close to an ion shifts it slightly by electrostatic interaction, and this changes the field seen by any other electron in the vicinity. The effect is very small but is magnified by a subtle quantum-mechanical coherence factor associated with the condensed state of the Fermi-Dirac gas. The result is to pair the electrons and to produce a small energy gap over the whole Fermi surface of the metal. An electric current, once established, cannot decay because there are no allowed states into which the paired electrons can be scattered. As the temperature approaches T_c, however, ordinary unpaired electrons are excited into states above the energy gap and behave as normal electrons. The essential coherence of the wave functions of paired superconducting electrons is eventually destroyed, either by thermal excitation or by a strong external magnetic field. It is noteworthy, however, that coherence persists when electrons tunnel quantum mechanically through a thin insulating film between two superconducting metals.

Magnetic metals. In a transition element, such as iron, two shells of atomic orbitals are simultaneously incomplete. The spins of the d-electrons in the inner shell tend to line up to give the maximum magnetic moment—*i.e.*, several Bohr magnetons per atom. Salts containing positive ions of these elements therefore show strong magnetic effects. But what happens to the d-electrons in the metallic state where the valence electrons are freed to form an ordinary conduction band? The appearance of permanent magnetization shows that the polarization of the spins within each ion still persists and that there is now a tendency for magnetic moments in neighbouring ions to align parallel with one another. On the other hand, optical evidence supports the general principle that the true electron wave functions must form a narrow d-band of Bloch states spread throughout the crystal. The problem of reconciling the localization of the magnetic moments with the extended character of the states, and of explaining the interactions between spins in neighbouring ions, has by no means been finally solved.

d-electrons

Semiconductors. In some crystalline solids, such as silicon and germanium, the valence electrons occupy a complete band (Figure 9B). In the equivalent chemical language, all the bonds are saturated so the material ought to be an insulator. But the energy gap to the next band may be small enough (*e.g.*, 1 ev) for a few electrons to be set free by thermal excitation. At room temperature an intrinsic semiconductor has an appreciable electrical conductivity that increases rapidly with temperature as more electrons are excited into the conduction band. Excess electrons may also be introduced by deliberately replacing an atom of the crystal by one of higher valency, thus producing n-type material.

But an unoccupied Bloch state near the top of the valence band also allows the movement of electronic charge through the solid. By analogy with the positron, this hole is a p-type carrier since it behaves electrodynamically like an ordinary particle with a positive charge. Since an excess of holes may be produced by doping the crystal with an element of lower valency, crystals containing both n-type and p-type regions are easily manufactured and form the basis of innumerable solid state devices.

An n-type carrier in the conduction band is not really at all like a free electron. Being strongly influenced by the regular crystal lattice, it may appear to have an effective mass very different from m, often depending on the direction in which it is moving. The same applies to the holes, whose dynamical properties may be very complex in detail. Although scattered by impurities and by lattice vibrations, both types may have quite high mobility as carriers of current and do not recombine very rapidly when brought into the same region. The choice of a semiconductor material for practical use obviously depends on such properties.

Surface emission. The conduction electrons in a metal are contained by a surface potential barrier of several volts, the work function, ϕ. They may be helped to escape by several means (Figure 9C). When the temperature is high enough, thermionic emission is observed. The classical formula of O.W. Richardson (1902) gives a rate of emission governed largely by the Boltzmann factor, $\exp(-e\phi/kT)$; since the escaping electrons come from the high energy tail of the Fermi-Dirac distribution, this is also valid quantum mechanically. Schottky emission is also thermally activated but is aided by a strong external electric field (~1V/m [*i.e.*, volts/metre]), which slightly lowers the effective work function. At much higher fields the barrier becomes thin enough to allow cold emission by tunnelling. Light of frequency ν causes photoemission of electrons (Figure 9D) whose maximum energy is given by the Einstein formula (1905) $E = h\nu - e\phi$ with a spectrum of energy depending upon the structure of the energy bands in the solid from which the electrons have been excited. An energetic electron striking a metal surface may also cause the emission of one or more secondary electrons, the basic mechanism of the photomultiplier tube.

Tunnelling

A source for the emission of electrons into a vacuum should obviously have the lowest possible work function. A photocathode surfaced with an alloy of alkali metals containing caesium ($\phi = 1.8$V) is sensitive into the infrared but cannot stand up to high temperatures. The most efficient thermionic source is the oxide-coated cathode, a refractory metal with $\phi \sim 4$V covered with an alkaline earth oxide (*e.g.*, BaO). The mode of action is not thoroughly understood, but seems to depend on excess metal from the oxide forming a very thin film of low work function on the surface.

ELECTRON CURRENTS AND BEAMS

Control. A current of energetic electrons within an evacuated vessel is a characteristic element of many technical devices of electronics and electrical engineering. The electrons are usually produced from a thermionic cathode and controlled by electrical and magnetic fields generated by voltages applied to various electrodes within the vacuum vessel or by currents in external coils. Many such devices contain an electron gun, a succession of apertures through which the electrons are accelerated by electrostatic fields into a well-defined beam of a few kilovolts energy. If much higher energies are required ($> 10^7$ ev), the electrons are made to travel in bunches along a tube or round and round in a magnetic field whilst being continuously accelerated by a synchronous electric field. Each electron then suffers a vast relativistic increase of mass and travels very nearly with the velocity of light.

Since the flow of electrons is always outward from the cathode, the simplest thermionic vacuum diode is a recti-

fier of alternating current. This current may be controlled by the voltage applied to a grid through which it passes on its way to the anode, yielding a triode, the prototype electronic valve device. Further grids are added to control space charge, the buildup of electrons in a region of the vacuum tube giving rise to fields opposing the entry of further electrons, and secondary emission of electrons from the anode. To obtain amplification or oscillation at very high frequencies, the electrons are formed into a beam and travel in bunches through a succession of resonant cavities in a straight line or bent around a magnetic field.

Electron microscopes

A succession of precisely placed cylindrical electrodes or coaxial coils, suitably energized, can focus a beam of electrons just as if it were a beam of light passing through a lens. In the transmission electron microscope the beam is directed through the object, a thin slice of, say, biological material, which stops a proportion of the electrons in the denser areas. Further electrode or coil lenses then produce an image at very high magnification, which may be observed photographically or on a fluorescent screen. Alternatively, in the scanning electron microscope, the beam is focussed into a tiny spot that plays over the surface of the specimen, in synchronism with the beam in a cathode ray tube, where variations of current through the specimen are recorded as a picture of the surface. For X-ray microscopy, the spot is focussed on an anode where it approximates to a point source for X-rays. In the electron microprobe analyzer, the characteristic X-rays produced by the electron spot beam on the surface provides identification of the chemical elements in the specimen at that locality.

Chemical and physical effects. A beam of electrons striking condensed matter gives rise to numerous chemical and physical effects. The phenomenon of electron diffraction is the analogue of X-ray diffraction and provides crystallographic and structural information about the material. The study of surfaces by low energy electron diffraction, reflection of electrons of 10–100 ev, is technically difficult but likely to be rewarding. Fluorescence and secondary electron emission are the mechanisms used for the transformation of variations of electron beam current into visual information.

As discovered by W.K. Röntgen (1895), energetic electrons produce X-rays when they strike a solid surface. At a few tens of kilovolts, the continuous spectrum due to the sudden stopping of the charged particle is predominant, although the fluorescence line spectrum emitted by atoms that have lost deep core electrons is of great importance as an identifiable characteristic of the element. In fact, only about $\frac{1}{1,000}$ of the kinetic energy of the beam goes into X-rays: the rest appears as heat as the electrons are scattered, slowed down, and stopped within a depth of a few hundred atomic layers. Electron beam heating is a clean technique for producing a very high temperature over a very small surface region, and it has innumerable applications in microelectronics and materials technology.

Electron beam heating

Electrons with energies in the MeV range can displace atoms in metals, producing vacancies, interstitials, and other defects. At higher energies again, various nuclear reactions can take place, as well as the copious production of gamma radiation.

But, since the electron does not have any strong interactions with nucleons, the elastic scattering of GeV electrons by, say, a target of liquid hydrogen depends essentially on the electric charge distribution within the proton. The classical notion of an elementary particle as a tiny sphere of electricity still has its place in a quantum-mechanical world.

Electronic Music and Instruments

In the broadest sense, any music produced or modified by electrical, electromechanical, or electronic means can be called electronic music. Some authorities prefer the term electrophonic music as being inclusive of those methods of sound production that are electrical but not technically electronic (*i.e.*, not dependent on devices utilizing the emission of electrons), but this name has not won acceptance in common parlance.

Definition and nature of electronic music

More narrowly, for a piece of music to be electronic, its composer must have anticipated the electronic processing that is subsequently applied to his musical concept, and the final product must reflect in some way his interaction with the medium he wanted to employ. This is no different from saying that a composer should have an orchestra in mind when he composes a symphony and a piano when he composes a piano sonata. When the definition is thus restricted, it becomes clear that a conventional piece of popular music does not become electronic music when played on an amplified guitar, nor does a Bach fugue become electronic music if played on an electronic organ instead of a pipe organ. Some experimental compositions, often containing chance elements and perhaps of indeterminate scoring, permit but do not necessarily demand electronic realization, but this is a specialized situation.

Electronic music in the narrower sense is produced from a wide variety of sound resources—from ordinary sounds and the sounds of musical instruments picked up by microphones to electronic oscillators (generating basic acoustical wave forms such as sine waves, square waves, and sawtooth waves) and complex computer installations —that are recorded on tape and then edited into a permanent form. Ordinarily, except for one type of performed music that has come to be called "live electronic music" (see below), electronic music is heard played back through loudspeakers either alone or in combination with ordinary musical instruments.

This article covers both early experimentation with electronic sound-producing devices—electronic music in the broad sense—and composers' subsequent exploitation of electronic equipment as a technique of composition. Throughout the discussion it should be clear that electronic music is not a style but rather a technique yielding diverse results in the hands of different composers.

Historically, electronic music is one aspect of the larger development of 20th-century music strongly characterized by a search for new technical resources and modes of expression. This search began very largely after World War II. Before 1945, composers sought to liberate themselves from the main Classical–Romantic tradition of tonal thinking and to reconstruct their thinking along new lines, for the most part either Neoclassical or atonal and 12-tone, in which a composition is built up entirely from a tone-row consisting of all 12 notes of the ordinary chromatic scale.

The pre-World War II period was accompanied by substantial experimentation with electrical and electronic devices. The most important outcome for the composer was the development of a number of electronic musical instruments (such as the Hammond organ and the theremin) that provided new timbres he could score into his compositions and that laid the technical foundations for the future development of electronic music proper—*i.e.*, composed with electronic techniques—from about 1948 onward.

Electronic music is represented not only by a wide variety of 20th-century works, most of them serious concert pieces, but also by a substantial literature of theatre, film, and television scores and, most recently, multimedia works that use all kinds of audiovisual techniques—and more besides. Electronic music for theatre and films seems to many an especially appropriate replacement for a disembodied, nonexistent orchestra heard from a tape or a sound track. Electronic popular music has also won adherents. This mostly consists of arrangements, often poor, of standard popular music for electronic synthesizers; the tentative use of electronic alterations by some of the more ambitious and experimental rock groups; and the preparation of recordings by studio techniques that are quite innovating and interesting.

HISTORY AND STYLISTIC DEVELOPMENT OF ELECTRONIC MUSIC

Beginnings. During the 19th century, attempts were made to produce and record sounds mechanically or electromechanically. For example, a German scientist, Hermann Helmholtz, traced the wave forms of regular sounds primarily to check results of his acoustical researches. An important event was the invention of the phonograph by Thomas Edison and Emile Berliner, independently, in 1877. This invention not only marked the beginning of the recording industry but also showed that all the acoustical content of musical sounds could be captured (in principle, if not in actuality at that time) and be faithfully retained for future use.

Cahill's pioneer work

The first major effort to generate musical sounds electrically was carried out over many years by an American, Thaddeus Cahill, who built a formidable assembly of rotary generators and telephone receivers to convert electrical signals into sound. Cahill called his remarkable invention the telharmonium, which he started to build around 1895 and continued to improve for years thereafter. The instrument, which was introduced in Holyoke, Massachusetts, in 1906, failed because it was complex, impractical, and could not produce sounds of any magnitude because amplifiers and loudspeakers had not yet been invented. Nevertheless, Cahill's concepts were basically sound. He was a visionary who lived two generations ahead of his time, and his instrument was the ancestor of present-day electronic-music synthesizers.

An Italian Futurist painter named Luigi Russolo was another ancestor of synthesized music. As early as 1913 Russolo proposed that all music be destroyed and that new instruments reflecting current technology be built to perform a music expressive of the industrialized present. Russolo subsequently actually did build a number of mechanically activated *intonarumori* (noise instruments) that grated, hissed, scratched, rumbled, and shrieked. Russolo's instruments and most of his music apparently vanished during World War II.

Between World War I and World War II, developments occurred that led more directly to modern electronic music, although most of them were technically, rather than musically, important. First was the development of audio-frequency technology. By the early 1920s basic circuits for sine-, square-, and sawtooth-wave generators had been invented, as had amplifiers, filter circuits, and, most importantly, loudspeakers. (Sine waves are signals consisting of "pure tones"—*i.e.*, without overtones; sawtooth waves comprise fundamental tones and all related overtones; square waves consist only of the odd-numbered partials, or component tones, of the natural harmonic series.) Also, mechanical acoustical recording was replaced by electrical recording in the recording industry in the late 1920s.

Invention of the electronic organ

Secondly, there was the development of electromechanical and electronic musical instruments designed to replace existing musical instruments—specifically, the invention of electronic organs. This was a remarkable achievement and one that absorbed the attention of many ingenious inventors and circuit designers. It should be stressed, however, that it was always the objective of these organ builders to simulate and replace pipe organs and harmoniums, not to provide novel instruments that would stimulate the imaginations of avant-garde composers.

Most electromechanical and electronic organs employ subtractive synthesis, as do pipe organs. Signals rich in harmonic partials (such as sawtooth waves) are selected by the performer at the keyboard and combined and shaped acoustically by filter circuits that simulate the formant-frequency, or resonant-frequency, spectra—*i.e.*, the acoustical components—of conventional organ stops. The formant depends on the filter circuit and does not relate to the frequency of a tone being produced. A low tone shaped by a given formant (a given stop) is normally rich in harmonics, while a high tone normally is poor in them. Psychologically, one expects this from all musical instruments, not only organs but also orchestral instruments.

Some organs operate on the opposing principle of additive synthesis, whereby individually generated sine waves are added together in varying proportions to yield a complex wave form. The most successful of these is the Hammond organ, patented by Laurens Hammond in 1934. The Hammond organ has odd qualities that have been overlooked by composers, mainly because it is so seldom heard to best advantage. The richness of its harmonic content does not diminish as the player goes up the keyboard. The German composer Karlheinz Stockhausen (in *Momente*, 1961–62), Arne Nordheim, the Norwegian composer (in *Colorazione*, 1968), and a few others have scored specifically for this instrument.

New instruments in the 1920s

Thirdly, there has been the development of novel electronic music instruments designed to supply timbres not provided by ordinary musical instruments. During the 1920s there was a burst of interest in building an extraordinary variety of such instruments, ranging from the practical and interesting to the absurd. The most successful of these new instruments are relatively few in number, are monophonic (*i.e.*, can play only one melodic line at a time), and survive because of their practicality and because some important music has been scored for them. These are the theremin, invented in 1920 by a Russian scientist, Leon Theremin; the Ondes Martenot, first built in 1928 by a French musician and scientist, Maurice Martenot; and the trautonium, designed by a German, Friedrich Trautwein, in 1930.

The theremin is a beat-frequency audio oscillator (sine-wave generator) that has two condensers placed not inside the circuit chassis but, rather, outside, as antennas. Because these antennas respond to the presence of nearby objects, the pitch and amplitude of the output signal of the theremin can be controlled by the manner in which a performer moves his hands in its vicinity. A skilled performer can produce all sorts of effects, including scales, glissandi, and flutters. A number of compositions have been written for this instrument since the 1920s.

The Ondes Martenot consists of a touch-sensitive keyboard and a slide-wire glissando generator that are both controlled by the performer's right hand and some stops controlled by the left hand. These, in turn, activate a sawtooth-wave generator that delivers a signal to one or more output transducers. The instrument has been used extensively by several modern French composers, particularly Olivier Messiaen.

The trautonium, like the Ondes Martenot, uses a sawtooth-wave generator as its signal source and a keyboard of novel design that permits not just ordinary tuning but unusual scales as well. Most of the music composed for this instrument is of German origin, an example being a *Concertino for Trautonium and Strings* (1931) by the German composer Paul Hindemith. In about 1950 a polyphonic version (capable of playing several voices, or parts, simultaneously) of this instrument was built by Oskar Sala, a former student of Trautwein and Hindemith, for preparing sound tracks in a Berlin film studio.

Tape music. With tape music the history of electronic music in the narrower sense of its definition begins. This history seems split into two main periods: an early (by now classical) period lasting from the commercial introduction of the tape recorder immediately following

Invention of the tape recorder

World War II until about 1960; followed by a second period, in which the tape medium has been dealt with less intensely for its own intrinsic properties, but rather in terms of the manner in which it fits into the musical and artistic environment. The invention of the tape recorder suddenly gave composers an exciting new musical instrument to explore, test, and use for new musical experiences. For more than a decade, fascination with the thing itself was bound to be the dominant motivation for composing electronic tape music. Also, musically, the 1950s, in contrast to the 1960s, were relatively introverted years: in all kinds of music, the focus of interest was technique and style, especially with the avant-garde. A composer whose concern centred not on these relatively neutral factors but on, for example, subjective expression or social activism was dismissed by the avant-garde as being out of touch.

In time, the medium became fairly well understood, the techniques for handling it became increasingly standardized, and a substantial repertory of characteristic and historically important compositions came into being. The burning issues were whether tape would replace live musicians; whether the composer was at last freed from the humiliations he so often endures to get his music into the concert hall; and whether a new medium of expression had been created, quite different from and independent of instrumental music, analogous, say, to photography as opposed to traditional painting.

It became increasingly evident, however, that there was no reason to think that the electronic-tape medium would eliminate instrumental performance by live musicians. Tape was increasingly regarded as something that could be—but did not need to be—treated as a unique medium. Thus the notion that the tape recorder could function as one instrument in an ensemble grew more and more popular, particularly in the concert hall. This conception obviated the visual monotony of an evening in an auditorium with nothing to look at but a loudspeaker. To this has been added a further stage of evolution, namely, live electronic music, in which the tape recorder and its tape is eliminated or greatly restricted in function, and transformations of the sounds of musical instruments are effected at the concert with electronic equipment. Not infrequently, this kind of performance environment also involves scores in which aleatory (chance, or random), improvisatory, or quasi-improvisatory musical guidelines for the manipulation of such equipment are supplied by a composer who prefers to let what happens just happen. Actually, it is open to question whether live electronic music is really an advance or a reversion to a more primitive state of the art, in the sense that it is the enhancement of the timbres of familiar instruments, rather than music conceived totally in terms of electronic media per se.

Establishment of electronic music studios

The first period of development is certainly one into which Europeans put the most consistent and sustained work. Tape music quickly gained recognition and financial support, and, before long, a number of well-equipped electronic music studios were established, primarily in government-supported broadcast facilities. Some important work was also done in the United States, but this was much more fragmentary, and not until after 1958 did Americans begin to catch up, either technically or artistically.

In 1948 two French composers, Pierre Schaeffer and Pierre Henry, and their associates at Radiodiffusion et Télévision Française in Paris began to produce tape collages (analogous to collages in the visual arts), which they called *musique concrète*. All the materials they processed on tape were recorded sounds—sound effects, musical fragments, vocalizings, and other sounds and noises produced by man, his environment, and his artifacts. Such sounds were considered "concrete," hence the term *musique concrète*. To this Paris group certainly belongs the credit both for originating the concept of tape music as such and for demonstrating how effective certain types of tape manipulation can be in transforming sounds. These transformations included speed alteration, variable speed control, playing tapes backward, and signal feedback loops. The engineers in this group built several ingenious special tape-manipulating machines. Schaeffer, however, was not interested in and in fact opposed the use of electronic oscillators as sound sources, claiming that these were not "concrete" sound sources, not "real," and hence artificial and anti-humanistic.

Two of the most successful and well-known *musique concrète* compositions of this early period are Schaeffer and Henry's *Symphonie pour un homme seul* (*Symphony for One Man Only*, 1949–50) and Henry's *Voile d'Orphée* (*The Veil of Orpheus*, 1953), extracted from a larger ballet score, *Orphée* (1953), written for the Belgian dancer Maurice Béjart. These and similar works created a sensation when first presented to the public. *Symphonie pour un homme seul*, a descriptive suite about man and his activities, is an extended composition in 11 movements. *Le Voile d'Orphée*, the finale of the ballet, is concerned with the descent of Orpheus into Hades.

The Paris studio has continued to flourish. The bias against purely electronic sounds gradually subsided, and compositions have been produced at a steady rate by a group of composers, including the Greek composer Yannis Xenakis.

The second event of significance was the formation of an electronic music studio at Cologne by Herbert Eimert, a composer working for the Nordwestdeutscher Rundfunk (now Westdeutscher Rundfunk, or West German Radio), who was advised in turn by Werner Meyer-Eppler, an acoustician from the University of Bonn. Eimert was soon joined by Stockhausen, who composed the first really important tape composition from this studio, the now famous *Gesang der Jünglinge* (*Song of Youth*, 1956). The Cologne studio soon became a focal point of the reemergence of Germany as a dominant force in new music.

Stockhausen's first tape composition

At Cologne, emphasis was immediately placed on electronically generated sounds rather than concrete sounds and on electronic sound modifications such as filtering and modulating rather than only on tape manipulation. Eimert and Stockhausen also published a journal, *Die Reihe* ("The Row"), in which appeared articles emphasizing the "purity" of electronic sounds and the necessity of coupling electronic music to serial composing (using ordered groups of pitches, rhythms, and other musical elements as compositional bases) that made no more sense than the Paris group's insistence on using only nonelectronic, non-serial material. This activity was part of the campaign of the 1950s that also brought about the collapse of Neoclassicism (a style that drew equally on 20th-century musical idioms and earlier, formal types), the emergence of the Austrian composer Anton von Webern as the father figure of the new music, and the development of total serialism, pointillism (a style making use of individual tones placed in a very sparse texture), intellectualism, and an emphasis on technique above all. The examples set by these two studios were soon widely imitated in Europe, with the sponsoring agencies being usually, as in these two original instances, government-owned broadcast organizations. This trend continued in the 1960s, with many more studios, from modest to elaborate, being set up in almost every major urban centre in Europe. As time passed, the techniques and equipment in the newer studios became more standardized and reliable, and the rather peculiar issue of concrete versus electronic sounds ceased to concern anyone.

In the United States, the production of electronic music, until 1958, was much more sporadic. The only continuing effort of this sort was the project of two U.S. composers at Columbia University, Otto Luening and Vladimir Ussachevsky, to create a professional tape studio and to compose music illustrating the musical possibilities of the tape medium. Luening and Ussachevsky often collaborated on joint compositions. They gained particular attention for the composition of several concerto-like works for tape recorder and orchestra. In 1959 Luening and Ussachevsky joined with another U.S. composer, Milton Babbitt, to organize, on a much larger scale, the Columbia-Princeton Electronic Music Center, in

which an impressive number of composers of professional repute have worked.

Varèse's *Déserts*

Other tape compositions in the early 1950s in the United States were largely those of individual composers working as best they could under improvised circumstances. One major composer who did so was Edgard Varèse, from France, who completed *Déserts* for tape and instrumental ensemble in 1954, and *Poème électronique*, for the Philips Pavilion at the 1958 Brussels World's Fair. Another was John Cage, an American, who completed the tape piece *Williams Mix* in 1952. Both Varèse and Cage had anticipated the electronic medium; Cage's *Imaginary Landscape No. 1* (1939) for RCA test records and percussion can well be regarded as a forerunner of current live electronic music.

Starting with the establishment of the Experimental Music Studio at the University of Illinois in 1958 by the U.S. composer Lejaren Hiller and the University of Toronto studio in 1959 by the Canadian composer Myron Schaeffer, the formation of facilities for both production and teaching began to move forward. The number of studios in university music departments grew rapidly, and numerous private studios also were established.

The number and variety of individual components of equipment may vary in a well-designed "classic" studio, but basically the equipment may be divided into five categories: sound sources such as sine-wave, square-wave, and sawtooth-wave generators, source for white noise (containing all possible sound frequencies), microphones for concrete sounds, and miscellaneous complex wave function generators; routing and control circuitry (patch panels and switching boards for coupling components together, adding circuits and mixers, amplifiers, output connections); signal modifiers (amplitude and ring modulators, frequency shifters, artificial reverberators, variable band-pass and third-octave or notching filters, variable-speed tape recorders, time compression–expansion devices, and other, more specialized, equipment); monitors and quality-control equipment (frequency counter, spectrum analyzer, VU metres that monitor recording levels from soft to loud, oscilloscope, power amplifiers with loudspeakers and headsets, and workshop facilities), and recording and playback equipment, including at least three high-quality tape recorders.

With this kind of equipment, the composer tape records sounds, both electronic and microphoned; modifies them singly or in montages by operations such as modulation, reverberation, and filtering; and finally re-records them in increasingly complex patterns. Inevitably, a major part of the composer's effort is involved in tape editing, unless he is satisfied with the crudest string of effects merely linked together in sequence. Like any other kind of music, the aesthetic merit of an electronic music composition seems to depend not only on musical ideas as such but also on the way in which they relate to one another and how they are used to build up a musical structure.

Integration of live instruments and tapes

The integration of the tape recorder with performance ensembles has become a rather popular form of chamber music, if not of symphonic music. Varèse's *Déserts* is an early example of this. It is scored for a group of 15 musicians and a two-channel tape and consists of four instrumental episodes interrupted by three tape interludes. In other works, the tape recorder is "performed" together with the remaining instruments rather than merely in contrast to them. The problems of coordination, however, immediately become overriding, for it is difficult for a group of performers to follow a tape exactly. Obviously, the tape dominates the situation, remorselessly moving along no matter what happens in the rest of the group. Balance of the tape loudspeakers with the group also has to be precisely adjusted, so as not to drown out the sound produced by the players and so that they can hear their cues.

Thousands of electronic-tape compositions were in existence by the early 1970s, many of ephemeral interest. It is relatively rare for a composer to have established his reputation solely as a composer of tape music. Pierre Henry perhaps is an example, but in general the important names in instrumental music of the 1950s and 1960s are the significant contributors in electronic music, too.

Stockhausen remained in the forefront of electronic-music composers with several important pieces following *Gesang der Jünglinge*. These included *Kontakte* (*Contacts*, 1959–60), for tape, piano, and percussion, and *Telemusik* (1966), a tightly organized piece for tape alone. Luciano Berio and Bruno Maderna, both Italians, worked for a while at the Radiotelevisone Italiana (at that time called Radio Audizioni Italia or RAI) studio in Milan. Besides *Différences* (1958–60), a composition for tape and chamber group, Berio's tape pieces include *Thema-Omaggio a Joyce* (*Homage to Joyce*, 1958) and *Visage* (1961), which exploit the unusual voice of American singer Cathy Berberian.

In the United States, the Columbia-Princeton Electronic Music Center has had the greatest output, a long list of composers besides Luening and Ussachevsky having used its facilities. Tape music from the University of Illinois studio includes Salvatore Martirano's *L's GA* (1967), a savage political satire for tape, films, helium bomb, and gas-masked politico. The University of Toronto studio, in spite of its technical excellence, has not been well represented on disks. One Canadian piece that is very amusing, however, is Hugh LeCaine's *Dripsody* (1955), all the sounds of which are derived from the splash of a single drop of water. John Cage's two principal tape pieces are *Williams Mix* (1952) and *Fontana Mix* (1958), both of which are complex tape collages.

Music synthesizers. Composing tape music by the classic method is neither easy nor free of technical pitfalls. A complex piece must be assembled from hundreds or even thousands of fragments of tape. Splicing all these sounds together consumes a vast amount of time and can also lead to an accumulation of errors and a deterioration of the sounds. Consequently, substantial efforts have been expended to reduce this work load and at the same time improve quality. Music synthesizers are the current product of these efforts. They cannot, however, be regarded as more than an intermediate technological development because of later computer technology to be reviewed below.

In contrast to Cahill's period, by the 1950s the means were finally at hand to construct full-scale music synthesizers, specifically, the RCA Electronic Music Synthesizers, designed by Harry Olson and Herbert Belar, research scientists working at the RCA Laboratories at Princeton, New Jersey. The first of two such machines was introduced in 1955. A second, improved model was turned over to the Columbia-Princeton Electronic Music Center in 1959.

The basic advance of the RCA synthesizer was an information input mechanism, a device for punching sets of instructions into a wide roll of punched paper tape. The composer had to know what the various coded punches would do and had to assemble his score sequentially from the beginning to the end of this tape; but he could, at any time during the programming process, interrupt this activity to listen to what he had punched, to make corrections, and to edit the material before making a final paper tape that then constituted the "master score" of the composition. The tape could be run at any desired speed; slowing did not lower the pitch of his sounds.

Contents of a synthesizer

The synthesizer contains a comprehensive assembly of signal generators, modulators, filters, and other components familiar from the electronic-music studio plus a few special circuits of its own, such as a glide generator. All those components are activated by the coded input prepared by the composer. The punches on the tape are decoded to yield a final product recorded on ordinary audio tape.

Although strong claims have been made that this machine can produce almost any sound of conceivable interest to musicians, it does have substantial limitations. It can produce at most only four sounds (four lines of music) at a time, and it lacks certain important functions, notably frequency modulation. The punched-tape input, and hence the master score, is valuable only so long as

the machine exists. The machine was also very expensive and was built with vacuum tube circuitry (electron tube), which requires substantial maintenance.

The composer whose name became particularly associated with the RCA synthesizer was Milton Babbitt. Among his compositions created with this machine are *Composition for Synthesizer* (1961), *Vision and Prayer* (1961), *Ensembles for Synthesizer* (1963), and *Philomel* (1964). Babbit had developed a precisely defined compositional technique involving total serialization (*i.e.*, of every musical element). When he became aware of the synthesizer, he was anxious to use it, because it gave him the opportunity to realize his music precisely rather than approximately, as had hitherto been the case.

In about 1960 a new circuit, the voltage-controlled oscillator (VCO), attracted the attention of engineers interested in electronic music because the frequency of its output signal is proportional to an independently generated input voltage rather than being internally set. The response is immediate because no mechanical couplings or controls are required. Also, these circuits can be built using transistor or integrated-circuit components, as opposed to vacuum tube circuitry, thus eliminating bulky configurations and high cost. An electrical engineer, Robert Moog, first designed and marketed several types of compact synthesizers of moderate price that supply a quite extended range of possibilities for sound manipulation. In addition to VCO's, which produce sine, square, sawtooth, and triangular waves, a Moog synthesizer contains white-noise generators, attack and decay generators (controlling a sound's onset and fading), voltage-controlled amplifiers, and bandpass filters and sequencers. One major advance in sound manipulation provided by VCO's is frequency modulation. If the input is a periodic function, the output frequency will vary periodically to provide tremolos, trills, and warble tones. Moog's synthesizer must now compete with several other synthesizers of essentially the same design, the Buchla Electronic Music Box, the ARP, and the Putney synthesizer. The last is an inexpensive instrument, apparently designed primarily for instructional use.

Design of the Moog synthesizer

Found in many music departments, these popular synthesizers eliminate much of the drudgery of tape splicing, but at a price. The range of timbres and processes is more limited because they operate by subtractive synthesis and impose transients that affect all partials (component vibrations) of a complex wave identically. A great advantage of a harmonic tone generator built by James Beauchamp, an electrical engineer at the University of Illinois, also from VCO's, is that it uses additive synthesis—*i.e.*, creating sound by combining signals for pure tones (sine waves)—instead of producing them by removing partials from a complex signal. It is so designed that each partial of a sound can have its own entry point, its own rise time, and its own decay time. The improvement in tone quality is enormous, because the ear normally expects nuances such as higher partials decaying faster than lower ones. Salvatore Martirano's *Underworld* (1965) is a good example of music in which the tape was made largely by additive synthesis.

A composer closely associated with synthesizers is Morton Subotnik, who has produced such extended pieces as *Silver Apples of the Moon* (1967). These pieces were created on the Buchla synthesizer, and any one of them demonstrates in relatively unmodified form the types of sounds one may obtain with these instruments.

A word may be said about realizations of instrumental music through synthesizers, notably an early, commercially successful album called *Switched-on Bach*, arrangements made by Walter Carlos on a Moog synthesizer. The record displays technical excellence in the sounds created and makes the electronic synthesis of music more intelligible to the general listening public, which is useful so long as it is realized that the materials on the record are arrangements of familiar music, not original compositions.

The success of *Switched-on Bach*

Computer music. The latest development is the use of electronic digital computers for both music composition and analysis. These can be used in five different ways: (1) routine data processing and information retrieval, including music library applications and abstracting; (2) processing of music notation and music printing; (3) acoustical, theoretical, and musicological research; (4) music composition; and (5) sound synthesis. In all these fields, considerable research and experiment was being carried out in the 1970s, with perhaps musicological research, the third way noted above, being the most widespread and advanced activity. But composition and sound synthesis, which are complementary processes because the first may lead to the second, are of most direct interest to composers. A composer may elect to use a set of compositional programs to produce a composition. He may then stop using a computer and print his results for transcription to instrumental performance. Alternatively, he may transfer his results directly into electronic sounds by means of a second set of programs for sound synthesis. Finally, he may desire only to convert an already composed score into sound. When he does this, he translates his score into a form that can be entered into a computer, say, by data cards, and uses the computer essentially as a data translator.

Use of electronic digital computers

The first point to understand about computer composition is that it is not a style but a technique. In principle, any kind of music, from traditional to completely novel, can be written by these machines. For a composer, however, the main appeal consists not in duplicating known styles of music, but, rather, in seeking new modes of musical expression that are uniquely the result of interaction between man and this new type of instrument.

At present, composers above all need a compiling language comprised of musical or quasi-musical statements and a comprehensive library of basic compositional operations written as closed subroutines—in effect, a user's system analogous to computer languages (such as Fortran) used by mathematicians. Incomplete attempts have been made to fill this need, one of which is Musicomp, worked on intermittently by Lejaren Hiller since 1963. But two major obstacles stand in the way of building up an effective musical computer language. The first is the obvious one of allocation of sufficient time, money, and other resources. The second is defining what goes into the subroutine library; *i.e.*, of stating with precision the smallest units of activity or decision making that enter into the process of musical composition. Unlike mathematics, in which traditional modes of thinking prepared the way for such a definition of subroutines, in music the defining of "modules" of composition leaves even sophisticated thinkers much more at sea.

The earliest example of computer-composed music is the *Illiac Suite for String Quartet* (1957) by two Americans, the composer Hiller and the mathematician Leonard Isaacson. It was a set of four experiments in which the computer was programmed to generate random integers representing various musical elements, such as pitches, rhythms, and dynamics, which were subsequently screened through programmed rules of composition. Several basic styles of composition—from traditional to experimental—were tested in an exploratory way, and the results were transcribed for instrumental performance. Even at this early stage, the composers realized that the best way of investigating computer composing was to proceed from random to orderly; that is to say, by programming what should be rejected.

Earliest example of computer-composed music

Two very different compositions, *ST/10-1,080262* (1962), by Yannis Xenakis, and *HPSCHD* (1968), by John Cage and Lejaren Hiller, are illustrative of two typical approaches to this technique. *ST/10-1,080262* is one of a number of works realized by Xenakis from a Fortran program he wrote in 1961 for an IBM 7090 computer. Several years earlier, Xenakis had composed a work called *Achorripsis* by employing statistical calculations and a Poisson distribution to assign pitches, durations, and playing instructions to the various instruments called for in his score, so that a uniform distribution of all these occurs during the course of the composition. He redid the work with the computer, retitled it, and at the same time produced a number of other, similar compositions. *HPSCHD*, by contrast, is a work of indeterminate

length scored for one to seven harpsichords and one to 51 tape recorders. When first performed in 1969, it was put on as a multimedia work and was allowed to run nearly five hours. For *HPSCHD* the composers wrote three sets of computer programs. The first, for the harpsichord solos, solved Mozart's *Musical Dice Game* (K294d), an early chance composition in which successive bars of the music are selected by rolling dice, and modified it with other compositions chosen with a program based on the Chinese oracle *I Ching* (*Book of Changes*). The second set of programs generated the 51 sound tracks on tape. These contained monophonic lines in microtone tunings based upon speculations by the composers regarding Mozart's melodic writing. The third program generated sheets of instructions to the purchasers of a record of the composition.

Basic techniques for producing sounds with a computer

The three basic techniques for producing sounds with a computer are sign-bit extraction, digital-to-analog conversion, and use of hybrid digital–analog systems. Of these, the first is cheap but limited, the second is the most sophisticated and expensive, and the third is the most recent, permitting synthesis in real time.

Sign-bit extraction has occasionally been used for compositions of serious intent—for example, in *Computer Cantata* (1963), by Hiller and Robert A. Baker, and in *Sonoriferous loops* (1965), by Herbert Brün—but more often it is an amusement indulged in around computer laboratories for playing Christmas carols and things of that sort. A number in the accumulator of a computer is really a sequence of binary digits (bits) that are physically represented by two different voltage levels. Consequently, if a position like the sign bit is caused to swing periodically from 0 to 1 (+ to −, arithmetically) by, for example, repeatedly adding a number to itself, and an electrical tap is taken from this spot, a square wave can be obtained. Because a square wave contains the odd partials of the harmonic series, it can be shaped, within reason, by filters and transients generators to provide a modest range of timbres.

Digital-to-analog conversion is by far the ideal technique for computer sound synthesis. This process was developed in the U.S. by Max Mathews and his colleagues at Bell Telephone Laboratories in the early 1960s. Its latest version is called Music V.

Digital-to-analog conversion (and the reverse process, analog-to-digital conversion, which is used to put sounds into a computer rather than getting them out) depends on the sampling theorem. This states that a wave form should be sampled at a rate twice the bandwidth of the system if the samples are to be free of quantizing noise (a high-pitched whine to the ear). Because the auditory bandwidth is 20–20,000 hertz (Hz), this specifies a sampling rate of 40,000 samples per second though, practically, 30,000 is sufficient, because tape recorders seldom record anything significant over 15,000 Hz. Also, instantaneous amplitudes must be specified to about 12 to 13 bits so that the jumps from one amplitude to the next are low enough for the signal-to-noise ratio to exceed commercial standards (55 to 70 decibels).

Music V is more than simply a hardware system, because it embodies an "orchestration" program that simulates many of the processes employed in the classical electronic-music studio. It specifies unit generators for the standard wave forms, adders, modulators, filters, reverberators, and so on. It is sufficiently generalized that a user can freely define his own generators.

PROBLEMS AND PROSPECTS

Science has brought about a tremendous expansion of musical resources by making available to the composer a spectrum of sounds ranging from pure tones at one extreme to random noises at the other. It has made possible the rhythmic organization of music to a degree of subtlety and complexity hitherto unattainable. It has brought about the acceptance of the definition of music as "organized sound." It has permitted the composer, if he chooses, to have complete control over his own work. It permits him, if he desires, to eliminate the performer as an intermediary between himself and his audience. It has placed the critic in a problematic situation, because his analysis of what he hears must frequently be carried out solely by ear, unaided by any written score.

In the future, certainly, more inexpensive synthesizers will be manufactured, especially many aimed at commercial exploitation and institutional use by music students. On a more sophisticated level, the further development may be expected of hybrid digital–analog systems for major electronic studio installations and, on a more modest level, as live-performance instruments. Better input systems may also be expected for entering musical and instructional information into computers for both composition and sound synthesis. Punched cards and tape and their equivalents will be replaced by optical scanners, light pens, and similar devices that trace a score directly onto a plate to which the computer is sensitive. One may hope that by the 1980s some really generalized and comprehensive programs for music composition with computers will begin to exist in a form that is transferable from one computer to the next. Another development will be more computer applications in the visual arts that can be coordinated to music, especially computer films and control systems for theatrical and intermedia presentations. The use of computer systems should increase in Europe, where little has been done so far (exceptions are the University of Utrecht studio directed by Gottfried Michael Koenig and the new Swedish Radio studio in Stockholm). Also, it is hoped that digitalized computer archives of important electronic music will be established, because audio tape seriously deteriorates with time, taking with it the present repertory.

It is important also that research in music acoustics be encouraged, not only for a better understanding of the objective physical sounds themselves, about which much has yet to be learned, but also for a better understanding of the subjective psychological response to all such sounds. The composer is no longer limited to using sounds that can be played by conventional instruments but only to those that can be perceived by the ear.

It is, of course, extremely hazardous to predict what will happen artistically. Perhaps the 1970s will prove to have been a period of consolidation of the technical discoveries and inventions and abstract systematic compositional systems of the 1950s with the much more uninhibited and flamboyant musical activities of the 1960s.

BIBLIOGRAPHY. The two most thorough histories of electronic music up through the 1950s are ABRAHAM MOLES, *Les musiques expérimentales* (1960); and F.K. PRIEBERG, *Musica ex Machina: Über das Verhältnis von Musik und Technik* (1960). Books that deal primarily with relevent aesthetic problems and artistic viewpoints include JOHN CAGE, *Silence* (1966); LUIGI RUSSOLO, *L'arte dei rumori* (1913; Eng. trans., *The Art of Noises*, 1967); K. STOCKHAUSEN, *Texte zur elektronischen und instrumentalen Musik*, 2 pt. (1963–64); and IANNIS XENAKIS, *Formalized Music* (1971). Electronic musical instruments and their components, many of which are also used for electronic music, are discussed in R.H. DORF, *Electronic Musical Instruments*, 3rd ed. (1968); ALAN L. DOUGLAS, *The Electronic Musical Instrument Manual*, 5th ed. (1968), and *The Electrical Production of Music* (1957); and WERNER MEYER-EPPLER, *Elektrische Klangerzeugung* (1949). A discussion of computer music may be found in H. BRUN, *Über Musik und zum Computer* (1971); HEINZ VON FOERSTER and J.W. BEAUCHAMP (eds.), *Music by Computers* (1969); L.A. HILLER and L.M. ISAACSON, *Experimental Music* (1959); L.A. HILLER, *Informationstheorie und Computermusik* (1964); H.B. LINCOLN (ed.), *The Computer and Music* (1970); and M.V. MATHEWS *et al.*, *The Technology of Computer Music* (1969). Periodicals that consistently printed important articles on electronic music include *Die Reihe* (German or English edition); *Electronic Music Review* (monthly); and *Gravesaner Blätter* (German and English); for current articles, see *Darmstädter Beiträge zur Neuen Musik* (German); *Source, Perspectives of New Music, Journal of Music Theory* (all three semi-annual); and the *Audio Engineering Society Journal* (monthly). Recordings of electronic music are now so numerous that it would be almost impossible to give a good list here. Consequently the reader is referred to HUGH DAVIES (comp.), *International Electronic Music Catalog* (1968); and to the *Schwann Long Playing Record Catalog* (both regular and supplementary editions) for listings.

(L.Hi.)

Electronics

The scope of electronics has grown so wide that older definitions of it are no longer adequate. Originally coined to describe the behaviour of free electrons in evacuated containers, the term was later made to include their behaviour in gases, liquids, and solids, and ultimately was applied to a particular branch of electrical engineering; and, yet, even electrical engineering, which is concerned with the movement of electrons along conductors, may with more logic be said to be a branch of electronics, which is concerned with electrons wherever they appear. The central fact in all of this is that, as the subject of electronics, the electron is so universal and so fundamental a constituent of matter that it is virtually impossible to limit the scope of the subject and the potential of the industry.

For a discussion of the theoretical aspects of electronics, see such articles as ATOMIC STRUCTURE; ELECTRICITY; MAGNETISM; ELECTRON; and SOLID STATE OF MATTER.

For a fuller discussion of the principal electronic applications, see such articles as BROADCASTING; COMPUTERS; ELECTRON TUBE; RADAR; RADIO; SOUND RECORDING AND REPRODUCING; TELEVISION; SEMICONDUCTOR DEVICES; and TELEMETRY.

In the 1970s electronics was one of the largest industries in the United States and was a major industry in several other countries. By the end of the century it may well be the largest industry in the world.

In the United Kingdom electronics output has risen by 80% since 1961 and the electronics industry is now overtaking the cotton industry. A similar story is repeated in Japan and the countries of Western Europe.

Electronics may be the key technology of the 1970s; its development may determine the direction of technology as a whole. Whatever major field of social activity or world industry is selected, it will be found that electronics is playing an increasingly dominant role in it. It is plausible that this is nowhere better illustrated than in the field of communications.

Sound and television broadcasting covers most of the earth's surface. Fourteen years after the first satellite was put into orbit in 1957, satellite communications (*q.v.*) linked most of the world with telephone and television circuits.

Electronics and communications

Electronics plays a key role in whatever aspect of communications is considered: submarine cable; automatic telephone networks; wide-band television circuits; and information processing, storage, and retrieval. Developments have come so fast that the major problem is how society can adapt to them.

Outside the communications field, electronics plays an increasing role in industry; for example, it can transform the situation in the machine shop. A modern milling machine is designed for the difficult and costly operation of machining complex shapes in three dimensions from solid lumps of hard metal. Now, this sequence can be directed by a digital computer and electronic control in which the programmer converts design data into a series of numbers representing the coordinates of sections through the solid component, together with instructions for feed and speed. The numbers are coded on punched tape that is read by a digital computer and recorded on magnetic tape in the form of instructions to the machine tool. The tape is then fed to the electronic control unit. Errors in the machining are automatically corrected. The machine can be programmed to produce one complex part after another or to repeat any part as often as required. The larger the number of components in a given batch, the greater the saving in machine time and cost when compared with the cost of skilled machinists. More than half of the large machine tools in some countries are now numerically controlled.

History

The word electron comes down from antiquity, having been derived from the Greek word for amber, which, as the ancient Greeks observed, attracts light bodies when rubbed. The character of the electron as a negatively charged particle in modern terminology owes something to Benjamin Franklin, whose kite experiment in 1752 demonstrated the "sameness of electrical matter with that of lightning." Franklin suggested that the "electrical fire" is present in all matter, and that an excess of the normal amount appears as a "positive" charge while less than the normal amount appears as a "negative" charge. To be consistent with this nomenclature, modern electronics has ascribed a "negative" charge to the electron, whose removal from neutral atoms leaves the atoms in the state Franklin described as positively charged.

The invention of the torsion balance, a magnetic needle suspended by a fine fibre, permitted accurate measurement of electrical forces and the important discovery (1785) that the action of the electric fluid, like that of gravity, was less as the distance between the charged bodies became greater. The invention of the voltaic pile, or battery, about 1800 was followed by a century of advance in knowledge of electricity and magnetism, which included the study of the behaviour of the new force in a vacuum. From these experiments came the conclusion that the particles whose activity was revealed were the basic substance of matter. A British physicist, J.J. Thomson, called them "electrons." A classic series of experiments during the opening years of the 20th century produced measurements of the mass and charge of the electron.

In the meantime, a curious phenomenon encountered by the United States inventor Thomas A. Edison in his development of the electric light led to an important discovery. Edison noted that under certain conditions of vacuum and voltage a bluish glow appeared in his lamp, indicating the existence of an unexplained current flowing between the lamp's two filament terminals in a direction opposite to that of the main current. Intensive research, especially that carried on by Thomson, revealed that the "Edison effect" was due to the passage of electrons from the negative terminal (cathode) to the positive terminal of the filament. One of Thomson's pupils worked out the theory of the physical process involved, which he called thermionic emission. Another British electrical researcher, Sir John Ambrose Fleming, who was scientific adviser to Edison's company in Britain, had the idea of using the Edison effect for the reception of radio waves. Preparing a vacuum tube with two metal plates, he heated the negative, or cathode, plate to incandescence by means of a battery, so that electrons were emitted in a continuous stream toward the positive, or anode, plate. When Fleming's tube was inserted in the circuit of a radio receiver, the anode became alternatively positive and negative according to the fluctuations of the incoming radio waves. Electrons were attracted to it when it was positive and repelled from it when it was negative, thus permitting the current to flow in only one direction. This rectifying process, also called detection and demodulation, produced a rectified output current that could be used to operate a telephone receiver or other recording device. The signals, however, were very weak. In 1907 a young American engineer, Lee De Forest, decisively improved Fleming's tube by adding a third electrode, shaped like a gridiron, between the cathode and anode. This controlling grid enabled the tube to deliver power without absorbing power and so made amplification of radio signals possible, and this led, through a number of intermediate steps, to the large-scale development of broadcast radio in the 1920s. One other major development took place in these early years, the invention by Vladimir Zworykin, a Russian-born American engineer, of the iconoscope, a device based on the photoelectric effect—*i.e.*, the ejection of electrons from metals by the action of light—which made possible the scanning and conversion of images into electric currents that is the basis of television.

Theory of thermionic emissions

The electronics industry was no more than on the verge of its major development when World War II suddenly mobilized the engineers and scientists of Europe, Japan, and the United States. By the end of the war, the U.S. and U.K. in particular had built up massive industrial resources for the production of electronic equip-

Invention of the transistor

ment. The invention of the transistor in 1948 provided a small, cheap, and simple substitute for the vacuum tube and gave a fresh impetus to the industry, especially by greatly facilitating development of the computer and opening new possibilities in industrial automation. With the introduction first of microcircuits and then of integrated circuits in the 1960s, electronics opened still further horizons in space, in the laboratory, and in industry.

Components

Modern electronic engineering encompasses a great variety of different kinds of component parts called "hardware," as opposed to "software," the name applied to the circuits and systems that use these components. A convenient method of classification is to divide the components into those that contain a source of power, called active, and those that do not, called passive.

ACTIVE COMPONENTS

Active components include such devices as electron tubes and transistors that serve as oscillators, amplifiers, and perform other specialized functions in electronic circuits.

Vacuum and gas-filled tubes. Fleming's crude diode of 1904 was the first of a vast family of electronic tubes that generate, rectify, amplify, modulate, and control electric signals. From 1905 to 1960 the production of these devices increased from a handful in a few laboratories to hundreds of millions a year in modern factories. The greatest rate of increase occurred after World War II with the rapid expansion of television, and this rate had only just begun to decline in the early 1970s under the impact of the advent of semiconductor devices.

From the point of view of circuit function and application, electron tubes can be grouped into four classes: General Purpose; Image; Photoelectric; and Microwave (see also ELECTRON TUBE).

General purpose tubes. Such tubes include all those whose basic functions are rectification, amplification, oscillation, frequency changing, and switching. They are called diodes, triodes, tetrodes, pentodes, hexodes, etc., according to the number of elements or electrodes they contain. In every case there is a cathode, or negative electrode, from which electrons are obtained, usually by heating the electrode and an anode or plate, the positive electrode. The introduction of a third electrode in the form of a grid constitutes a triode; a fourth produces a tetrode or screen grid tube; and so on.

The graphical symbol for a vacuum diode is shown in Figure 1A. Its function is primarily to rectify; *i.e.*, to change alternating inputs into direct pulsating outputs. Diodes are rated on the basis of their peak inverse voltage; *i.e.*, the maximum negative voltage that can be used on the plate without damaging the tube. Typical values for vacuum diodes are of the order of 1,000 volts but values as high as 25,000 volts can be attained by proper tube design.

The triode can amplify as well as rectify. The amplification capability is greatest when the space between grid and cathode is kept as small as possible. The spacing is minimized by the use of so-called frame grid construction, in which the grid is wound with very fine wire on a rigid framework and is spaced only about 0.002 inch (0.05 millimetre) from the cathode. The spacing between electrodes is also important in determining the time the electrons take to travel between electrodes, called the transit time; the upper frequency limit at which the tube will operate satisfactorily is determined by this time.

The tetrode includes a second (screen) grid whose function is to screen the control grid and cathode from the anode. This improves the performance but on the other hand electrons emitted from the screen grid tend to worsen the performance. The drawback is overcome in the pentode by introducing a third grid, called a suppressor grid, to repel the secondary electrons emitted from the anode. Very high amplification factors over extended frequency ranges can be obtained with modern pentodes.

Vacuum tubes having six or more electrodes, such as hexodes and heptodes, are used mainly as frequency changers. In such devices some of the electrodes are used to generate a local oscillation and others to combine this with the incoming signal frequency and so produce a number of new frequencies, called beat frequencies. Modern practice is to incorporate the two sets of electrodes in one envelope with a common cathode.

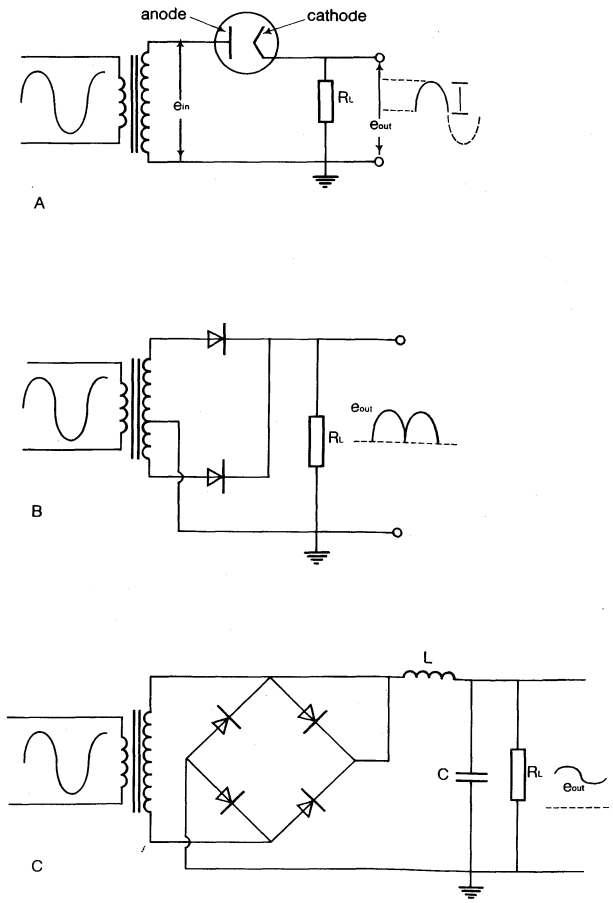

Figure 1: *Rectifier circuits.*
(A) Half-wave rectifier: vacuum diode. (B) Full-wave rectifier: semiconductor. (C) Bridge rectifier with LC filter circuit.

Image tubes. These tubes use the electrical input signal to generate and display a light image. This group includes cathode-ray oscilloscope tubes and television picture tubes. Their essential features are an electron gun for generating an electron beam; a means of deflecting and controlling the beam; and a screen that produces light when struck by the electron beam. The electron gun assembly is mounted in the neck of the tube and horizontal and vertical deflection of the beam is accomplished either electrically by passing the beam through two pairs of parallel charged plates, or magnetically by sets of coils wound round the neck. Modern cathode-ray oscilloscope tubes will respond to very small signals, and their speed of response is high. Using the best modern techniques, it is possible, for example, to display and photograph an event lasting only a thousand millionth (10^{-9}) of a second.

Features of an image tube

In the picture tube for television receivers, sometimes called a kinescope, magnetic deflection is provided by two pairs of coils formed round the neck and the absolute brightness of the spot produced by the electron beam is controlled by a grid in the electron gun. In the projection kinescope, used for theatre television, the very high intensity image in the tube is attained by accelerating voltages of up to 60,000 volts.

Photoelectric tubes. These tubes generate an electrical signal from an input of light energy. The simplest phototube consists of a cathode with a photoemissive surface (a surface which gives off electrons when struck by light) and an anode. Incident light produces electrons from the cathode which are drawn to the positive anode. Very low intensity light can be detected with a sensitive tube called a photomultiplier tube.

The most complex of the photoelectric tubes are the television camera tubes, in which the image of a scene focussed on the photosensitive surface is converted into an electrical signal—the video signal—which is transmitted to a television receiver where it is used to reproduce the original image.

Microwave tubes. Special tubes are required for the production and amplification of microwaves; *i.e.*, waves of very high frequency and short wavelength. The general principles are that the interelectrode spacings must be very small and that the inductance (opposition to the flow of alternating current) of the leads and interelectrode capacitances must be kept to a minimum. In the magnetron, the electron beam is controlled by crossed magnetic and electric fields. It is capable of generating pulses of extremely high power at frequencies up to about 1,000,000,000 (10^9) cycles per second (one gigahertz).

The klystron is a microwave receiving tube in which velocity control of the electron beam replaces the intensity control of the triode. The effects of transit time are reduced to a minimum by impressing the input signal on a part of the beam that has a very high velocity so that the transit time limitations are less serious than in a triode.

In the class of microwave tubes called travelling-wave tubes, the interaction between the signal wave and the electron beam occurs over the entire length of the tube.

Gas-filled tubes. The basic properties of gas-filled tubes depend on electric discharges in the gases. In a gas diode electrons emitted from the cathode collide with and ionize the molecules of a contained gas, such as neon, so that very large changes in current occur for very small changes in anode voltage. The gas diode can therefore be used to absorb very large changes in current with only small variations in its output voltage; *i.e.*, as a voltage regulator.

The thyratron is a gas-filled (hydrogen or mercury vapour) triode used for the control of high-power circuits. In the ignitron an electrode dips into a mercury pool that is the cathode and initiates a discharge between the ignitor and the mercury pool.

Semiconductor devices. Although semiconductor electronics (the study of materials that are neither good insulators nor good conductors) is a relatively recent development, semiconductor devices, in the form of crystal detectors, have been used since the beginning of the century (see also SEMICONDUCTOR DEVICES). The critical development was the invention of the point-contact transistor after half a century of theoretical advance in the physics of the solid state. This early device, in which contact was made to a semiconductor crystal by two closely spaced, pointed wires, was never a successful industrial product because its construction limited very severely the currents that it could handle, but it demonstrated the practical possibilities of electron flow in crystals and led to the development of the junction transistor.

Point-contact transistor

The junction transistor consists essentially of a sandwich made up of one layer of crystalline semiconductor, having an excess (called N-type) or deficit (P-type) of electrons, between two layers of semiconductor, which accepts (P-type) or donates (N-type) the electrons. It proved to have so many advantages over thermionic tubes that it led to an acceleration in the growth of electronics and to the development of a large family of active semiconductor devices that took over many of the functions of thermionic tubes.

The field-effect transistor is virtually a solid-state version of the thermionic triode and has many of the advantages of the thermionic tube without its disadvantages. It has replaced the tube in such applications as frequency meters, amplifiers, flip-flops (described later), timer circuits, and in applications in which a constant current is necessary.

The thyristor, a transistor having a thyratron-like characteristic, has been developed and is used for switching and controlling power of the order of megawatts.

Because the transistor does not need a heated cathode for its supply of active electrons, it is more efficient, smaller, lighter, and more robust than the thermionic tube equivalent. High-speed digital computers would not have been possible if transistors had not been available to replace the thousands of bulky tubes otherwise required for the large, powerful, machines.

Integrated circuits. Printed circuit techniques marked another stage in the general evolution towards smaller, more compact, and more reliable equipment. In these, solid-wire connections to individual components were replaced by printed connections on a flat circuit board on which the components were soldered. A density of 30 components per cubic inch was attained with these methods compared with about 10 per cubic inch that was the best attainable with miniature tubes and conventional equipment.

The next major development was to dispense entirely with individual containers, and transistors and their associated components, together with their interconnections, were formed in place, as thin films on glass or ceramic bases (substrates). The techniques used in producing these integrated circuits include diffusion, photolithography, etching, alloying, and metal evaporation and deposition (see also INTEGRATED CIRCUITRY). With increasing sophistication and know-how, the technique progressed to the point at which the packing density was increased to 1,000 per cubic inch by 1960 and to 100,000 per cubic inch by 1965. Packing densities up to several million per cubic inch are now possible, but these densities create a number of problems in practice, such as the dissipation of heat generated. Circuits formed in a single chip of silicon crystal are called monolithic and are now found in virtually every computer.

Components formed in place

As of the early 1970s, the latest development in this field was large-scale integration, also called array technology, in which the silicon wafer is covered with integrated circuits, which need not be identical. The circuits are tested by probes, the results are fed to a computer, and the optimum interconnection pattern for coupling the good circuits is obtained. Input and output connections are decided by the computer and added at the places indicated on the slice.

PASSIVE COMPONENTS

The important electrical characteristics of the passive components in an electronic circuit are those of resistance, capacitance, and inductance.

Resistance is a measure of the opposition a material presents to the flow of electric current. It is determined by many factors including the atomic structure of the material, its temperature, its impurity content, and the density of free electrons available to move under the influence of an electric field. The unit of resistance is the ohm, defined as the ratio of the voltage across a conductor to the current flowing through it. Thus, if an applied voltage of one volt produces a current of one ampere, the resistance is one ohm.

Capacitance, the ability to store a charge on a pair of conductors separated by an insulator, is measured as the ratio of the stored charge to the potential produced by the charge. The unit is a farad, a very large unit, usually replaced in electronics with microfarads (10^{-6} farad), or picofarads, formerly called micromicrofarads (10^{-12} farad).

Inductance, a magnetic property of conductors, is defined as the ratio of magnetic flux to the current required to produce that flux. The unit is the henry, or one weber per ampere. Both capacity and inductance depend upon the geometrical configuration of the conductors.

All conductors possess resistance, inductance, and capacitance. In circuit components, one or other of these is made to predominate, and the undesired properties are usually reduced to a minimum.

Basic properties of all conductors

Resistors. Resistors may be either fixed or variable, depending on circuit requirements. The principal forms of fixed resistors are carbon-composition, wire-wound, and metal-film. A cylindrical shape is convenient for fixed resistors and was used for most of them until the introduction of microcircuits.

In the carbon-composition resistor the resistive element is a cylinder of carbon with impurities added to control

the resistivity. The material is press-formed and wire leads are attached at each end and the assembly is encapsulated.

The metal-film resistor employs a very thin film of metal deposited on a glass or ceramic cylinder as the resistive element. Gold caps with leads attached are soldered to the film at each end and the unit is encapsulated. The effective length of the film may be varied before encapsulation by cutting a helix through the film on the circumference of the cylinder and so varying the length of the conduction path.

All these types of fixed resistors are usually colour-coded to indicate the nominal value of resistance and the allowable tolerance, or deviation, from this value.

Variable resistors are also either wire-wound or composition types. A sliding contact of some kind is mounted in such a manner that the contact position can be changed, thus varying the resistance.

From the circuit point of view, all resistors possess inductance and capacitance, which may be ignored at low frequencies but must be taken into account at higher frequencies. It is possible in resistor design to balance the effect of incidental inductance and capacitance over a limited frequency range; this provides the so-called non-reactive types.

Capacitors. The principal property of capacitors is their ability to store a charge. Generally speaking, in electronics they consist of two sets of metal plates separated by a vacuum, air, or a liquid or solid insulating material called the dielectric. For any particular dielectric, the capacitance increases as the area of the plates is increased and decreases as the distance between them is increased. Similarly, an increase in the dielectric constant of the insulating material increases the capacitance.

Mica, a mineral, has a high dielectric strength—*i.e.*, it resists high voltages—and a high dielectric constant, making it suitable for robust, compact capacitors. In these, metal foil is interleaved with layers of mica; leads are attached and the whole assembly encapsulated. For greater precision, a metal film can be deposited directly on the mica, as in the case of silver-mica capacitors. Mica capacitors are made in values from 10 to 5,000 picofarads and operating voltages from 500 to 20,000 volts.

Paper, film, and oil-filled capacitors all consist of alternate layers of metal and dielectric rolled into a cylinder. Leads are attached and the assembly encapsulated or suspended in oil.

In ceramic capacitors the dielectrics are ceramic materials such as titanates with high dielectric constant and strength. Physically small assemblies can provide quite high capacitances.

In wet electrolytic capacitors, the electrolyte, a solution of borax, phosphate, or carbonate, is used to form the dielectric and saturates the paper separating the conductors. In dry, or solid, capacitors a layer of tantalum or aluminum oxide is used to make possible extremely compact and small high-value capacitors: up to 3,500 microfarads with tantalum and 150,000 microfarads with aluminum oxide. Electrolytic capacitors have two important characteristics; the very thin dielectric restricts the maximum voltage and permits more leakage current than do thicker dielectrics, and the plate with the oxide film must always be kept positive with respect to the other plate or the capacitor will heat up and may even explode. They are, however, very useful where moderate temperatures and low voltages apply and space is limited, since high values can be obtained. Oil-filled capacitors are superior for high-voltage, high-capacitance applications.

Characteristics of capacitors

Variable capacitors are usually made with two meshing sets of metal plates, one movable and one fixed, with air as the dielectric, although this arrangement is bulky and presents mechanical problems. Variable capacitors from 10 to 500 picofarads can be made for voltages up to 5,000 depending on the separation of the plates.

Inductors. Inductance is a magnetic property and the design of inductors is based on the concept of energy as stored in the magnetic field which accompanies a current (see also MAGNETS AND ELECTROMAGNETS). Inductance depends on the geometry of the inductor, but for any given shape and cross-sectional area it is directly proportional to the square of the number of turns and the permeability (the ease with which lines of magnetic flux can pass through a material) of the core and inversely proportional to the length of winding. There is usually another important criterion, called the "Q," which is a measure of losses at any particular frequency. For direct current the losses depend on the effective resistance of the winding; as the frequency of the current is increased the losses will increase because they will occur in both the conductor and the core. The choice of ferromagnetic dust cores for higher frequencies minimizes losses in the core; the use of stranded wire reduces the effective resistance due to high-frequency current losses in the wire.

The simplest form of inductor consists of one or more turns of sufficiently heavy-gauge wire to be self-supporting so that air is the only insulator to be considered. At frequencies of the order of megahertz (10^6 hertz) it is easy to achieve Q's of 500 with this very simple design. For low frequencies, the greater inductance usually required necessitates a larger number of turns and therefore much smaller gauge wire. If this is wound as a single layer, it requires a cylindrical former or bobbin for mechanical support.

Much greater values of inductance can be obtained by using high-permeability magnetic material in the core, which, for radio frequencies, often consists of particles of magnetic powder (ferromagnetic dust) compressed into a doughnut shape, through which the wire is threaded. One advantage of this construction is that the magnetic field is confined almost entirely to the toroid. Inductances of about one millihenry to one henry are common with this design.

Very high values of inductance, up to 1,000 henries or so, usually for low or voice frequencies, can be obtained by increasing the size and number of turns and filling the core space with interleaved laminations of high-permeability silicon-steel alloy. Variable inductors are obtained either by moving a connection from one turn to another on the conductor so as to vary the effective number of turns, or by varying the position of a core of compressed magnetic powder mounted in the centre of the coil.

Transformers are special forms of inductors widely used in electronics to transform alternating power to one or more circuits at the same frequency, but usually with changed values of voltage and current. They operate on the principle of electromagnetic induction. All transformers consist of two or more windings so arranged that a change of flux in one winding induces a change of flux in the other. They are usually provided with a high-permeability material to increase the efficiency of the flux linkage and this material is laminated or otherwise divided to minimize the energy losses that would occur in solid material. Suitably designed transformers provide an accurate method of multiplying or subdividing voltages and currents since these are proportional to the ratio of the turns in the windings.

Transformers

Solid-state devices. In addition to the active semiconductor devices discussed above, electronics has produced a variety of passive solid-state devices.

Varistors. An important property of semiconductors is that a non-ohmic, or nonlinear, resistance can be obtained when a suitable contact is made between a semiconductor and a metal. Solid devices based on this behaviour, called varistors—*i.e.*, variable resistors—can be subdivided into symmetrical varistors—*i.e.*, those that have the same non-ohmic volt-current characteristics for both directions of applied voltage; and nonsymmetrical varistors—*i.e.*, those whose characteristics depend on the polarity of the applied voltage.

Nonsymmetrical varistors act as solid-state rectifiers that can be further subdivided into large-area rectifiers and point-contact rectifiers. Large-area rectifiers are generally made from either copper oxide or selenium. In the copper oxide devices, coin-shaped blanks punched from copper sheets are oxidized on one side with an oxide film, which acts as the semiconductor, and the units, after an-

nealing and drying, are assembled on a rod to form the finished rectifier.

Rectifiers. Selenium rectifiers are made by applying a thin layer of selenium to a backing washer of nickel or aluminum and heat-treating to convert the selenium to crystalline form. An outer contact of cadmium is sprayed on the free surface of the selenium layer. Selenium rectifiers are used in the small and medium power range.

Rectification can occur not only between the metal and the semiconductor but also at the contact between two semiconductors, and this is the basis of the germanium junction rectifier and the silicon junction rectifier, which have largely replaced the thermionic diode in electronics.

Zener diode as voltage regulator

A particularly useful variety is the Zener diode, in which the reverse voltage is very nearly constant for a wide range of reverse current; consequently, it can be used to provide a constant voltage where current demands vary.

Another interesting junction diode is the tunnel diode, which, owing to special characteristics, is a useful device as an amplifier or oscillator at high frequencies.

For high-power applications, silicon rectifiers consisting of units made from a mixture of silicon carbide, graphite, and ceramic applied between metallic electrodes are used. A silicon-controlled rectifier or thyristor is the solid-state equivalent of the thyratron and normally represents an open circuit but can be switched rapidly to the conducting state when an appropriate signal is applied to the control terminal. It has become popular as a fast solid-state switch over a very wide range of power.

Thermistors. A class of semiconductor devices that makes use of a large temperature coefficient of resistivity are the so-called thermistors, or thermally dependent resistors. These are made in a great variety of shapes and sizes by chemically preparing the desired mixture of semiconductors in powder form, molding the powder into a body of the desired size and shape, and heating until the grains are sintered into a compact, homogeneous mass. Metallic contacts are provided by firing on silver, gold, or platinum paint and soldering lead wires to the painted regions. The devices are enclosed in various forms of encapsulation. The resulting bead, rod, disc, or flake thermistors are sensitive to both voltage and temperature changes and have found numerous applications: in carrier-repeated amplifiers to compensate for temperature changes in the line; in microwave and high-frequency power meters; in signal limiters; in voltage regulators; in negative-resistance amplifiers; as time-delay devices; in medical thermometry; and in meteorology.

Photoconductive and photovoltaic devices. Another large field of devices, the photoconductive and photovoltaic devices, belongs almost entirely to the semiconductor area. The physical effect exploited in photoconductive devices is the liberation of extra electrons in the semiconductor by the absorption of light energy and subsequent change in the resistance. The usual method of making photoconductive cells is by preparing a film of the semiconductor over a metal or between metal electrodes. In the selenium cell a thin selenium film is applied over a metal layer and divided by a scribed line into two sections. In the lead-sulfide cell a thin film of lead sulfide is used between two electrodes and the unit is sealed into an evacuated glass tube. The point-contact phototransistor is similar to the conventional point-contact transistor but the activating electric charge is liberated by light rather than being introduced by another electrode. P-N junction and multijunction phototransistors can be produced with a current of only a microampere or so when not illuminated. They are often preferred to other cells in applications where a circuit must discriminate between "light-on" and "light-off."

Photovoltaic cells exploit the ability of semiconductor P-N junctions or rectifying contacts to generate a voltage when illuminated. The photoconductive devices described earlier also have photovoltaic properties and the design of photovoltaic cells amounts to maximizing these properties. A recently developed and most promising member of the family is the silicon solar cell, which achieves a conversion efficiency of more than 10 percent in converting sunlight into electric power.

Thermoelectric devices. Thermoelectric effects, the production of voltages between semiconductor junctions maintained at different temperatures, and the production of temperature differences by passing current through such junctions, are used in solid-state cooling units or thermal-battery devices.

Hall-effect devices. The Hall effect in semiconductors, the production of a voltage in a strip of the material carrying a current when it is placed in a magnetic field perpendicular to the current flow, permits the design of very sensitive measuring and indicating devices.

Ferrites. Magnetic properties are also involved in so-called ferroelectric and ferrite devices, which have applications as memory and storage components in computers, and as specialized components in high-frequency circuits (see also FERRITES).

SENSING DEVICES AND TRANSDUCERS

Transducers are devices that change energy from one form to another. Of principal interest are those in which either the input or the output is in the form of electrical energy.

Pickups for sound and vibration; microphones. The most familiar transducer, for converting sound waves and vibrations into electric signals, is the phonograph pickup, which is normally an electromechanical transducer actuated by modulations in the grooves of records and converting them into electrical outputs. These output signals, however small in amplitude or complex in waveform, can be reproduced at the required level with the help of amplifiers. Pickups for sound reproduction may be based on a variety of different elements; *e.g.*, piezoelectric crystals, capacitance variation, inductance variation, motion of an electrode in a tube, or a beam of light. Examples of piezoelectric crystals are: quartz, tourmaline, Rochelle salt, and the titanates; pickups embodying these crystals make it possible to measure noise and vibration, thus aiding the equipment designer in minimizing or eliminating these destructive properties.

Crystal pickups

Microphones, which constitute another well-known class of electro-acoustic transducer, respond to sound waves and deliver essentially equivalent electric waves. The many different types cover almost every conceivable application. The carbon microphone depends on the variation in resistance of carbon granules with pressure variation. The electronic microphone generates its voltages by the motion of one of the electrodes in an electron tube. The electrostatic microphone uses the variations in its electrostatic capacitance due to sound waves. The magnetic-armature microphone employs an armature to move a coil in a magnetic field to produce the electric waves. The ribbon microphone uses a moving conductor in the form of a ribbon that is directly driven by the sound waves. Standard microphones whose response is accurately known can be used to calibrate sound fields and pressures. Contact microphones can be actuated by mechanical contact of the diaphragm with the throat, as in the throat microphone; and the ear microphone is designed to fit in the ear. Extremely sensitive measurements and records of sound pressures can be made with such devices (see also SOUND RECORDING AND REPRODUCING).

Temperature sensors: thermocouples, resistance thermometers. The temperature sensors used in electronics are based on the fact that temperature changes alter electrical properties of the sensor. Thus the thermocouple is based on the thermoelectric effect, an electromotive force resulting from the difference in temperature between two junctions of dissimilar metals. A commonly used device, the vacuum thermocouple, consists of a rhodium-platinum alloy joined to a platinum wire and sealed with the leads in an evacuated tube. When a current is passed through the assembly, the thermocouple is heated and a voltage develops and can be calibrated to give the value of the current; if the value of the current is known, the difference of temperature between the hot and cold junctions can be calibrated on a meter scale. In a thermocouple thermometer the measuring junctions are placed in contact with the body whose temperature is to be measured.

The resistance thermometer, which depends on the variation of electrical resistance with temperature, utilizes a conductor that has a large change of resistance with temperature, in a form that can be placed in the region whose temperature is to be measured. The resistance must be measured independently of the leads and a bridge network is usually employed for this.

Thermistors are an example of semiconductor devices that have found increasing application as sensors for temperature changes and measurements (see also THERMOMETRY).

Stress and strain sensors: strain gauges. Pickups that convert mechanical stresses and strains into electrical currents or voltages are extensively used as the transducers in telemetry (*q.v.*). An electric strain gauge consists of a resistance wire or printed-circuit wound so that a change in stress produces a change in resistance. Electromagnetic strain gauges consist of a small armature and an iron-core coil whose spacing distance varies with the movement of the member in which the armature is fixed. Change in armature gap varies the inductance which in turn controls the frequency of a transmitting oscillator.

Stress changes resistance

Proximity sensors: capacity and induction types. Proximity sensors are based on the variation of electrical properties with the relative spacing of their constituent parts in relation to surrounding objects. Thus, the capacitance altimeter is a capacity proximity sensor in which altitude is measured by change of capacitance between two conductors on the aircraft that are affected by the distance to the ground. The redistribution of current in a conductor or coil brought about by the presence of another conductor can be used to indicate the proximity of the conductors. Variation of inductance can be made very sensitive to the proximity of a magnetic core or metal disc.

Chemical sensors—conductivity cells. The state of ionization of a solution—or its hydrogen-ion concentration—can be conveniently and accurately measured by the variation in its conductivity. For this purpose a conductivity cell, which is a liquid container with two electrodes, is connected into an arm of a bridge network and filled with the liquid to be measured. The conductivity can be measured and calibrated directly to yield the hydrogen-ion concentration, or it can be calibrated against a known standard cell.

Optical sensors: photocells, TV camera tubes. Optical sensors can now be effective over a great range from the long infrared part of the optical spectrum to the extreme ultraviolet. They are capable of very great sensitivity especially in conjunction with photomultipliers, and it is possible to select a suitable sensor for a specific part of the whole spectrum.

Practically any physical or chemical property can be converted into electron movement with a suitable transducer. Thus, transducers and electron devices have been developed for the investigation of high and low pressures, viscosity, turbidity, colour, flow-rate, humidity, hardness, roughness, polish, elasticity, and many others.

Circuitry

In this section some typical electronic circuits will be described in general terms.

POWER SUPPLY CIRCUITS

Rectifiers. Power supplies are found in virtually all electronic equipment. A power supply is usually the source of direct-current power in a circuit and thus requires the conversion of an alternating-current input to a steady direct current output. The usual methods involve a rectifier that converts alternating current into pulsating direct current and a filter unit that smooths the pulsations. Voltage regulators may also be used when accurate control of output voltage is required. The inverse process of obtaining alternating current from direct-current supplies involves inverters and vibrators.

Figure 1 shows how rectifier properties are exploited in power-supply circuits. The vacuum diode of Figure 1A is connected to the secondary winding of the transformer so that its anode is positive during the positive half cycle of the alternating voltage on the secondary winding. Thus the tube conducts during half of the cycle and current flows during this half from cathode to anode, leading to the term half-wave rectifier. A half-wave rectified voltage appears across the load resistance R_L in the output circuit.

Half-wave and full-wave rectifiers

Figure 1B illustrates a full-wave rectifier using two semiconductor diodes across the secondary winding, which has a centre-tap connected to ground. The resulting waveform across the load R_L is shown.

In Figure 1C four semiconductor diodes are used in a bridge rectifier. This arrangement has the advantage that for the same input voltage as Figure 1B, it produces about double the output voltage. The bridge rectifier produces the continuous rectified current with a superimposed alternating current—or ripple—as shown.

Filters. Filters are used widely in electronics to select or reject voltages of a given frequency or range of frequencies. They are illustrated here with reference to power supplies but they have many other important functions as well.

In Figure 1C the filter structure consists of the inductance (L), connected in series with the load (R_L), and the capacitor (C) shunted across the load. The unvarying part of the rectified current passes with relatively low loss (due to ohmic resistance in the inductor) to the load, while the alternating or high frequency part finds a relatively easy path to earth through the capacitor and does not appear in the load. Thus, the direct voltage appearing across R_L is smoother than it is at the bridge output. This process of filtering in a rectifier is called smoothing. With suitable combinations of R_L, L, and C, filter networks can be designed to accept or reject any band or range of frequencies. The band-pass filter, for example, consists of series and parallel, tuned R-L-C sections.

Voltage regulators. As noted before, gas diodes and Zener diodes have the ability to maintain a constant voltage over a large current range. This characteristic provides the most popular method of regulating the output of rectifier circuits within well-defined narrow limits. A suitable diode, such as a neon tube or a Zener diode, is connected in series with the output of the rectifier filter and the output voltage is taken from across the diode. A second method of voltage regulation is the use of vacuum tubes or transistors to sense small changes in the direct output voltage and compensate for these changes, thus keeping the final voltage constant.

Inverters and vibrators. Inverters were originally simple rotating machines which converted direct current into alternating current; such a conversion can now be achieved with thyristors, thus eliminating all moving parts. The basic unit consists of two thyristors with separate grid excitation connected either in series or in parallel with the load.

Vibrators are electromagnetic devices for turning continuous steady current into a pulsating current. Before the advent of transistors, they acquired some importance as alternating-current converters for equipment that was powered from a low-voltage battery (*e.g.*, a car radio) but their main use now is to act as choppers for low-value, direct-current signals, which can then be amplified with normal alternating-current techniques.

SWITCHING AND TIMING CIRCUITS

The functions of switching and timing can be performed electronically much better in many cases than by purely mechanical techniques, because of the greater accuracy, sensitivity, reliability, and speed of response. The ideal switch is either a perfect open circuit (infinite resistance) or a perfect conducting path (no resistance), which the ideal diode approximates. Such a diode conducts perfectly with one polarity and allows only a very tiny current flow with the opposite polarity. Switching operations formerly carried out by tubes are now largely performed by transistors and semiconductor diodes. The use of diodes as on-off switches amounts to selecting a diode with a suitable current and voltage range and selecting the operating point.

Timing and time delay circuits. These circuits are based on the ability of electronic systems to produce an

accurately controlled series of switched pulses of known frequency and duration. Thus, a circuit based on a quartz crystal that vibrates at a constant frequency can be stepped down with frequency dividing circuits to produce a low frequency of great accuracy. This is essentially the technique employed in international time standards, although the fundamental frequency is now that of a precisely measurable energy transition occurring in cesium atoms. The scope of electronics is nowhere better demonstrated than in the field of time measurement; the calibration signals from standardizing laboratories are radiated to an accuracy of one in 10^{13} and can be received within $\frac{1}{10}$ second in laboratories at opposite ends of the earth.

Time-delay operations can be carried out electronically quite simply; short periods can be timed automatically and repeated as often as desired. A large capacitor C (Figure 2) is connected in the transistor circuit in such a

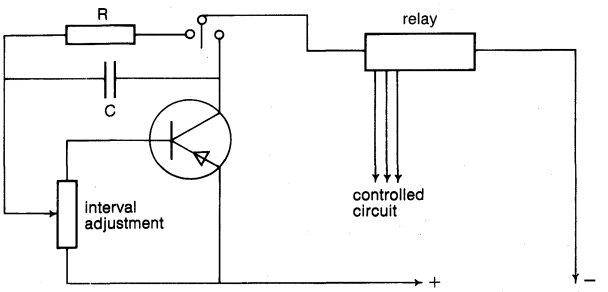

Figure 2: Interval timer.

way as to hold the relay armature down. When the current through the relay coil fails, the armature is released; the time of this occurrence can be altered simply by adjusting the potentiometer resistor.

Multivibrators. A useful source of all kinds of outputs at controlled frequencies is illustrated in the two-transistor network of Figure 3, called a multivibrator. When the circuit is running, one transistor drives the other and the frequency of the output pulses is largely controlled by the values of resistance and capacitance. The system has one stable state and one unstable state and tends to remain in the stable state until an appropriate trigger signal causes it to change. It is also called a flip-flop and is the basis of a very widely used binary counter.

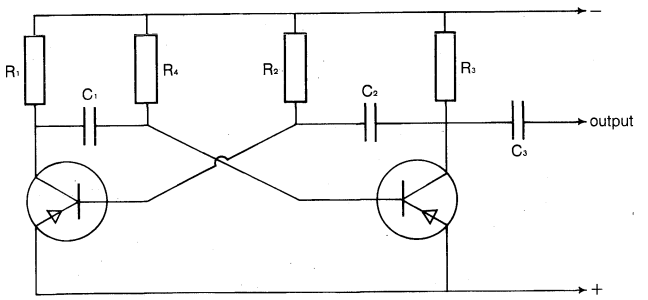

Figure 3: Multivibrator using two transistors.

Gating circuits. The logic processes in computers are arrived at by using binary counters of the type which change state at each input pulse. Large numbers of these circuits connected in chains and sequences carry out the logical operations of the computer and act as gates for the pulses passing through the chain. Thus, a so-called AND gate is one that produces an output only if all its inputs are energized and produces no output if one or more of its inputs are not energized. An OR gate is one that produces an output if any of certain selected inputs is energized but none if none of these selected inputs is energized. There are other types of gates but most logic systems may be constructed from AND and OR gate circuits together with a NOT inverter that produces the complement of the operating voltage; *i.e.*, its output is positive if input is negative and negative if input is positive.

Logic gates used in computers

AMPLIFIER CIRCUITS

The primary function of an amplifier is to increase the amplitude or power of a signal; the active elements used to do this are tubes and transistors. Amplifiers can be classified according to function, frequency range, and percentage of time of input cycle during which current flows in the active element (see Tables 1 and 2).

Table 1: Classification of Amplifiers by Frequency Range

type of amplifier	frequency range*
Subaudio frequency (VLF)	0–20 Hz
Audio frequency (AF)	20 Hz–20 kHz
Low frequency (LF)	20 kHz–300 kHz
Medium frequency (MF)	300 kHz–3 MHz
High frequency (HF)	3 MHz–30 MHz
Very high frequency (VHF)	30 MHz–300 MHz
Ultra high frequency (UHF)	300 MHz–3000 MHz
Microwave	above 3,000 MHz

*1 Hz = 1 cycle per second; 1 kHz = 1,000 cycles per second; 1 MHz = 1,000,000 cycles per second.

Coupling methods. The obvious method of obtaining any desired amplification from tubes or transistors is to connect them in sequence as required. Thus, the basic unit is the single-stage amplifier that consists of the active device and all the associated components that accompany such a stage. A series of units in sequence forms a multistage amplifier whose gain (or amplification) is approximately the product of the individual unit gains. In practice, input and output stages often differ from each other and from intermediate stages; the design is affected by considerations of cost, weight, size, stability, and so on. But a primary consideration is the technique for coupling the various stages together. These techniques can be divided into alternating-current coupling and direct-current coupling.

Table 2: Classification of Amplifiers by Percentage of Input Cycle in the ON Stage

class	percentage of input cycle tube or transistor is ON	grid voltage
A	100%	above cut-off
AB	between 50% and 100%	near cut-off
B	50%	at cut-off
C	less than 50%	below cut-off

In alternating-current coupling the link between the output of one stage and the input of the next includes either a capacitor or a transformer; although it may also include resistors and conductors there is no direct current path in the link. Thus Figure 4 shows resistance-capacitance-coupled, two-stage transistor amplifier. The frequency response of this amplifier would depend very largely on the relative values of C and R_6 but this amplifier would not be suitable for very low frequencies.

In direct-current coupling there is a direct-current path between stages, the coupling being made through a resistance network. This type of amplifier is useful for amplifying small changes in the level of small direct-current voltages and can also be used for alternating-current signals of low and medium frequency.

Main types of amplifier. The necessity of obtaining the maximum signal or power gain in a wide variety of conditions has led to a corresponding variety in the design of amplifiers.

Audio. Audio-frequency amplifiers, covering the frequency range 20 hertz to 20 kilohertz, usually have a nonselective response, and the frequency-gain characteristic is designed to be as constant as possible over the operating range. The preferred method of coupling is resistive, or inductive and resistive. The so-called high-fidelity amplifier—*i.e.*, one designed to amplify audio frequencies with a minimum of distortion—is only one link in a chain of equipment so that account must be taken of the wave shape and impedance (opposition to flow of alternating current) of the source and the impedance and character-

High-fidelity amplifiers

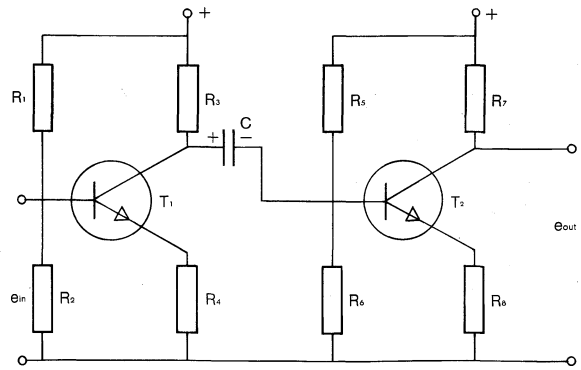

Figure 4: Amplifier using resistance-capacitance-coupled transistors.

istics of the speaker or other reproducer. Stability and reliability may entail the use of negative feedback (described later).

Video. Video amplifiers are wide-band amplifiers used to amplify the video frequencies in radar pulses and the periodic visual signals in television. The frequency range is about 30 hertz to five megahertz. As they are sometimes required to carry the direct-current component of the video signal, direct-current coupling is the method normally used.

Radio frequency. Radio-frequency amplifiers are generally selective in operation and are often tuned; *e.g.*, by tuning the grid or anode circuits or by including a band-pass filter in the coupling network. They generally use Class A for low power, Class B for high-power modulated waves, and Class C for high-power unmodulated waves (see Table 2).

Microwave. Microwave amplifiers, covering the frequency range from about 3,000 megahertz up to the infrared region where wavelengths are of the order of millimetres, employ special tubes, such as the klystrons and travelling-wave tubes mentioned earlier, and semiconductor diodes. Recent developments in electronics have led to great progress in this field. Lasers and masers (*q.v.*) use a completely new principle for the amplification of low-level high-frequency radiation by allowing it to react with electrons in such a way as to increase the energy of the radiation. This is the best available solution for amplifying faint signals from remote sources such as radio stars, without amplifying as well the thermal noise (a random noise generated in all components, its amplitude depending on temperature of the components) always present in ordinary amplifiers. The maser is operated at temperatures near absolute zero, where the inherent noise of components is negligible. Lasers represent the extreme limit of amplifying devices.

Special types. It is broadly true to say that vacuum-tube and field-effect transistor amplifiers act as voltage amplifiers with a relatively high impedance and junction-transistor amplifiers act as current amplifiers with a relatively low impedance. If a high input impedance combined with a low output impedance is required, a cathode follower—also called a grounded-grid circuit—may be used. In the case of a vacuum tube the input is applied between control grid and ground and the output is taken from an impedance between cathode and ground. In a field-effect transistor the drain electrode is grounded and for a junction transistor the collector is grounded. This is really a process of negative feedback used to achieve the desired result.

The so-called chopper amplifier mentioned above has become increasingly popular for amplifying low-value direct-current signals. Both mechanical and electronic devices are used to chop the direct-current signal into an alternating-current signal, then amplified with normal alternating-current techniques. Very low noise levels in relation to input may be obtained with these amplifiers.

Differential amplifiers have two similar input circuits connected so as to respond to the difference between two voltages or currents and effectively suppress voltages and currents that are alike in the input circuits.

The phase inverter or paraphase amplifier converts a single input into a push-pull output by combining cathode and anode coupling.

Magnetic amplifiers, which do not use tubes or transistors as amplifiers, can be employed to obtain large output power for a small input power. A direct-current or slowly varying alternating-current input or control current is made to control a large output power by changing the impedance of a coil in the output circuit. The magnetic circuit is designed to reach magnetic saturation so that both control and output windings are wound on a toroidal saturable core.

Feedback. The process of returning a fraction of the electrical or acoustical output of any stage in an amplifier to the input of that stage or of a preceding stage results in an increase or decrease in amplification depending upon the relative phase of the portion returned. This is called feedback: positive feedback if the return is positive with respect to the input signal, and negative feedback if it is negative.

Positive feedback will increase the amplification but will reduce the stability and introduce distortion. There is always a point beyond which positive feedback will result in oscillation. Thus, sufficient positive feedback in an audio-frequency system will produce an oscillatory condition known as howling.

Negative feedback will reduce the amplification but will increase the stability and bandwidth of the amplifier, and reduce distortion. It will also increase the input impedance and decrease the output impedance: the cathode-follower amplifier already described is essentially a method of negative feedback.

Negative feedback may be used in alternate stages in multistage amplifiers to improve gain stability. Each pair of stages is isolated from the other.

High-gain direct current coupled feedback amplifiers, called operational amplifiers, can perform a number of operations such as multiplication, addition, and integration of an input signal. They are widely used in measurement and control applications as well as in analogue computers. Feedback amplifiers are also used to stabilize the voltage output of a rectifier power supply to a greater extent than is possible with a simple Zener-diode circuit.

OSCILLATORS

Electronic circuits can generate alternating-current signals of every variety of waveform and over a wide range of frequency and can amplify them as well. The only convenient way of generating high-frequency voltages is with vacuum-tube or transistor oscillators, widely used for this purpose in signal generators for testing and measurement; in timing and counting equipment; in radio and television transmitters and receivers; for dielectric and induction heating; and in radar systems.

There are two broad classes of oscillator: harmonic oscillators and relaxation oscillators. Harmonic oscillators generate a nearly pure single frequency and employ resonant circuits such as tuned circuits of inductance and capacitance, microwave cavity resonators, and piezoelectric crystals. Relaxation oscillators generate complex waveforms such as square and triangular waves; they are less stable than harmonic types.

Variable frequency L-C and R-C oscillators. Positive feedback will produce oscillation; the frequency may be determined by a feedback network made up of variable inductance and capacitance or variable resistance and capacitance.

Figure 5 is a simplified circuit diagram of a typical variable frequency L-C oscillator: the transistor Colpitts oscillator. Positive feedback is achieved from the collector electrode via R_1, L, and C_1, C_2, with the emitter grounded. The inductance is tuned by the capacitor C_3 and the feedback ratio of the system is determined by the ratio of C_1 to C_2.

An example of a simple oscillator circuit employing a conventional amplifier stage and an R-C feedback network is the transistor phase-shift oscillator, in which the necessary phase shift is obtained by three sequential resistance-capacitance circuits.

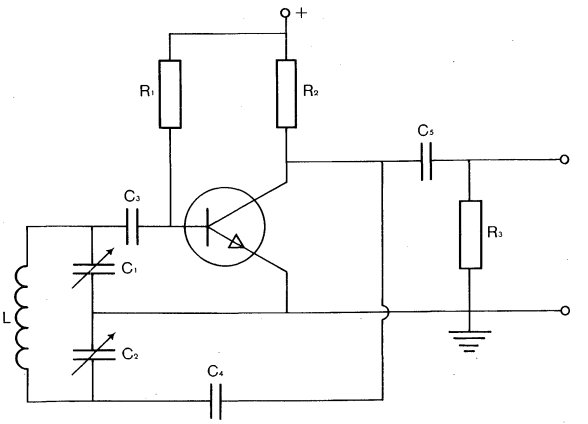

Figure 5: Colpitts oscillator circuit.

Relaxation oscillators. Circuits that employ the nonlinear or negative-resistance characteristics of the active element are termed relaxation oscillators. The neon-tube oscillator—using a gas-discharge tube—is a simple example. A capacitor connected across the tube is charged through a resistor and the voltage across it increases until the breakdown voltage is reached, at which point discharge begins and the voltage drops to a low maintaining voltage. The resistor is made too large to supply the current to maintain this discharge, so the tube turns off and the capacitor begins to recharge. Repeated cycles produce a sawtooth waveform.

A silicon-controlled rectifier, or thyristor, can produce results similar to those of the neon tube and the breakdown voltage can be adjusted by varying the gate (control) current.

Fixed-frequency oscillators. The usual form of fixed oscillator is the crystal oscillator that makes use of a piezoelectric device (*q.v.*); that is, a crystalline material that develops an electric charge or potential difference across some of its faces when the crystal is subjected to mechanical strain. Quartz is almost universally used because it is hard, robust, and strong and has a small temperature coefficient (small change in frequency as the temperature changes). The general principle is to connect the crystal in the feedback circuit. In a Pierce oscillator, the circuit is identical to that of the Colpitts oscillator of Figure 5 except that the crystal replaces the resonant circuit. Frequency stability of 100 parts per million (10^6) is typical and even greater accuracy and stability can be achieved by putting the crystal in a temperature-controlled oven.

Quartz crystal oscillators

Transit-time oscillator. The transit time of electrons in vacuum tubes—that is, the time required for the electrons to travel between tube elements—becomes of major importance in the generation of high frequencies. The corresponding motions of electrons in semiconductor solids can be exploited to produce microwave oscillators. Thus, the Read diode, developed in 1958, is used as a transit-time oscillator for microwave applications. Acoustic-wave amplifiers involve the use of a travelling-wave interaction between drift electrons and acoustic waves in a solid such as cadmium sulfide. The so-called Gunn effect has been utilized to produce microwave oscillations in bulk cadmium sulfide and, in addition, has led to the development of small, compact, robust microwave oscillators.

SPECIAL CIRCUITS

Mixer-modulators, frequency-changers, multiplexers. The mixing and separation of two or more signals or carriers is a fundamental requirement in radio (*q.v.*) and communication systems and in sound recording and reproduction (*q.v.*).

In the reception of radio signals with a heterodyne receiver, the incoming signal is mixed with the signal from a local oscillator to produce the intermediate-frequency signal. In vacuum-tube receivers special tubes are used to perform the mixing function. Frequency-converter tubes, widely used before transistor development, perform this function by including the local oscillator in the tube envelope. In transistor versions of these circuits the mixer or frequency changer may be one of two types. It may consist of a separately excited mixer requiring a second transistor as a local oscillator; or it may be a self-oscillating mixer in which a single transistor combines the functions of mixer and oscillator. The main advantage of the self-oscillating type is that it is cheaper.

Multiplexers are of two types: frequency-division multiplexers and time-division multiplexers. The first are designed to transmit two or more signals over a common path by using a different frequency band for each signal. Each channel is identified with a separate subcarrier frequency and each message modulates the subcarrier identified with its channel. At the receiver terminal the channels are separated by frequency selection and the subcarrier is filtered out, restoring the original message signal.

In time-division multiplexing (see TELEPHONE AND TELECOMMUNICATIONS SYSTEMS) different time intervals are used for different signals. The timing and channel operations may be obtained by a multivibrator ring circuit containing one modulator per channel, and all modulators are connected in tandem and fired by a triggering pulse.

Limiting and clamping circuits. A frequent requirement is to prevent a particular characteristic of the output of a circuit from exceeding a predetermined value, or to hold it at that value. Limiting and clamping circuits are used for these functions.

The widely used so-called Schmitt limiter or trigger is a pulse generator in which a pair of transistors with positive feedback produces an output pulse of constant amplitude as long as the input voltage exceeds a certain value.

One of the simplest limiter circuits is of the so-called neon-lamp type, which consists of a series resistor and a neon lamp. The output taken across the lamp never exceeds the breakdown voltage, so that the instantaneous values of amplitude above this value are clipped.

Figure 6 shows another simple example of the use of transistors and semiconductor diodes in chopping and limiting applications.

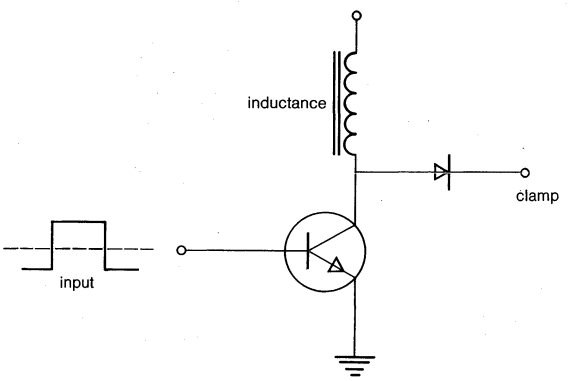

Figure 6: Transistor chopper.

Wave-shaping circuits. Circuits that generate pulses of current or voltage are of two basic types: (1) the self-contained generator, which includes a pulse oscillator; and (2)) one that acts on an input signal to produce a train of pulses at the output. A square-wave generator is useful in testing the response of video amplifiers and in switching applications in computers and telemetering testing. Sawtooth and triangular pulses can be generated by relaxation oscillators fed from a constant-current transistor.

Electron Tube

An electron tube is a device, usually in a sealed glass or metal enclosure, that generates and controls a stream of electrons in such a manner as to perform a useful function in an electronic circuit. This function can be the amplification of a very weak radio or audio signal, the generation of electrical oscillations such as audio tones or radio frequencies, the production of X-rays, or numerous other functions that will be discussed in the course of this article. Electron tubes include both vacuum tubes, in which the air or gas has been exhausted from the enclosure, and gas tubes, in which a small amount of gas has been introduced into the enclosure.

This article discusses the basic operating principles of electron tubes, the history of their development, how they are constructed and manufactured, and some of their applications.

BASIC TUBE OPERATION

All types of tubes operate under the same basic conditions, which can best be understood by looking first at a diode, a two-terminal device that conducts electricity more easily in one direction than in the other: voltage is impressed on the tube, normally between the plate (or anode) and cathode (see Figure 1A). If the plate is at a positive (+) voltage (potential) with respect to the cathode, electrons emitted by the cathode will be attracted to the plate and current will flow. If it is at a negative (—) potential, no current will flow. The diode thus serves as a sort of valve (the name given it in the U.K. and some other countries), permitting current to flow when the plate is positive and blocking current when the plate is negative. It can thus convert ac (alternating current, a flow of electricity that reaches maximum in one direction, decreases to zero, then reverses itself and reaches maximum in the opposite direction) to dc (direct current, current that flows in only one direction), a useful characteristic in many electronic circuits, as will be seen later.

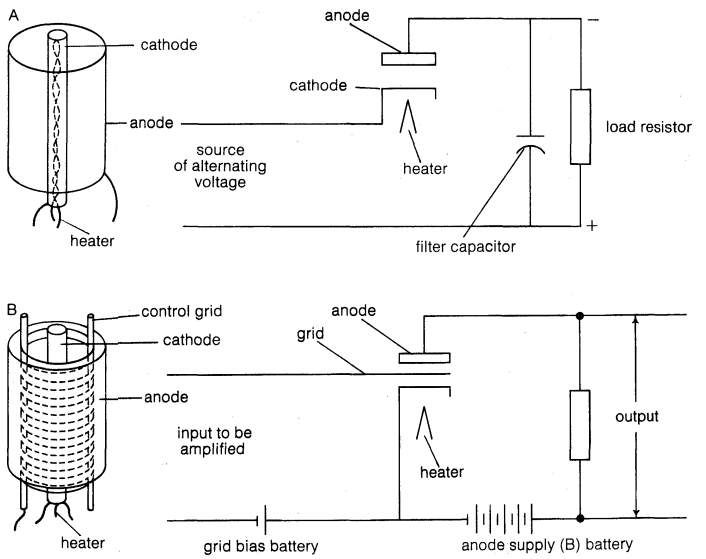

Figure 1: (A) Internal parts and schematic rectifier circuit of thermionic diode. (B) Internal parts and schematic amplifier circuit of thermionic triode.

If a third element in the form of a fine metal mesh or screen, called the control grid, is inserted between the cathode and plate, it can be used to control the flow of electrons (see Figure 1B). The resulting tube is termed a triode and is useful as an oscillator or amplifier. Other grids may be added for various operating refinements, producing what are called multi-element tubes. Tubes of this nature generally operate with a high vacuum. Gas-filled tubes are usually used as switches; for the tube to pass current (switch on), conditions must be such that the gas is ionized. When not ionized, current will not flow (switch off). Specialized tubes may use the stream of electrons for other purposes, as for the generation of X-rays in the X-ray tube, or to produce a visual display in the television picture tube.

DEVELOPMENT OF THE ELECTRON TUBE

Sir William Crookes, an English physicist of the mid-19th century, was the earliest pioneer of the vacuum tube when he experimented with the passing of high voltages across electrodes in an evacuated tube. Electron theory developed from his research with what came to be known as Crookes' tube. The Röntgen X-ray tube followed in 1895, and the cathode-ray tube in 1897. Thomas Edison also contributed to the vacuum tube, though he was not aware of it at the time. Working with the light bulb in 1883, Edison noticed that if he placed a metal plate inside the bulb and connected a positive voltage to the plate, current would flow to it when the lamp was lit. He also observed that if the plate was negative, current would not flow. Edison did not understand this effect and did not think it important, though he did record it in his journal. Some 16 years later, Sir J.J. Thomson of England experimented with the Edison effect, as it was called, and described what Edison had discovered: that current can be made to flow between two electrodes in a vacuum if one of the two is heated. He established that the particles in these experiments were indeed electrons, of a definite electric charge and mass, irrespective of their origin or the methods for their release.

Using the theory that Thomson developed, another Englishman, J.A. Fleming, constructed a workable, practical diode tube. His name for the diode—"valve"—came from his observation that the diode "acted as a valve, permitting current to flow or be shut off."

Development of the triode

Shortly thereafter, Lee De Forest of the U.S., working with Fleming's valve, sought to develop a tube that in addition to passing current in only one direction would amplify a small electrical signal voltage. His investigations led to the triode tube, consisting, as the name implies, of three elements. The third element, which De Forest called a grid, could, when placed between filament and plate, control the current flow through the tube. This single development may have had as much to do with the growth of electronics as any other discovery or invention. For the first time, signals could be amplified. De Forest originally called his tube the Audion, a name that soon fell into disuse.

The term filament, originally used to describe the emitter of electrons, took on a new meaning shortly after the development of the first tubes. It was found that some materials emit electrons more readily than others. Also, it was discovered that two different elements could be used, one to emit electrons (the cathode) and the other to supply the heat (the filament or heater).

MODERN TUBES

Electron emitters. In most modern tubes, electrons are produced by thermionic emission from a cathode. This is the name given to the process in which a suitable metal such as tungsten is heated to a high temperature. As the electrons in the heated metal become more excited, they acquire sufficient energy to escape from the metal surface. When pure tungsten is used as the cathode, it is heated to about 2,200° C (3,992° F) to emit electrons.

Cathode materials

Other materials besides tungsten can be used as electron emitters. With thoriated tungsten (tungsten with a thin layer of thorium on the surface), emission takes place at about 1,700° C (3,092° F). Such materials as strontium and barium oxides, used as coatings, begin to emit electrons at still lower temperatures, some as low as 700° C (1,300° F). These lower temperatures give higher efficiency.

In applications such as receiving tubes in radio and television sets, where large plate currents are not required,

oxide-coated cathodes are used almost exclusively. A separate filament heats the cathode, which usually consists of a nickel sleeve coated with oxides. There is no electrical connection between the two. This is called an indirectly heated cathode. When a filament serves as the cathode it is called a directly heated cathode.

One of the big advantages of the indirectly heated cathode is that the filament can be connected to an alternating-current source without introducing hum, as would happen if directly heated filaments were used. In a transmitter tube and other high-powered tubes, directly heated cathodes of tungsten are necessary, since oxides simply cannot produce the large quantities of electrons required.

Another type of cathode emitter is the photocathode used in photoelectric diode tubes (see Figure 2). The

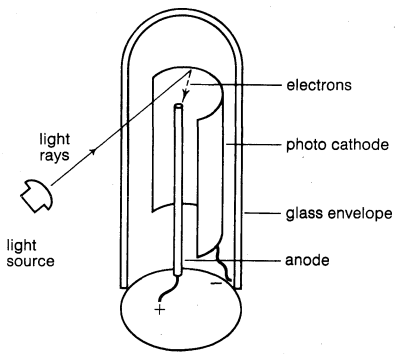

Figure 2: Basic photoelectric diode tube.

photocathode is coated with a material such as the element cesium that gives off electrons when light strikes it. No heat is required; such tubes are thus classed as cold-cathode tubes. Photoelectric cells or tubes are used for detecting or measuring light, as in light-beam burglar-alarm systems and in devices that measure light intensities. Cold cathodes are also employed in a special type called a field effect tube, in which a strong electric field draws electrons from the cathode. This type of tube is not very common; it was used as a rectifier tube in some of the very early ac-operated radio receivers.

Multi-element construction. Following the diode and triode, further developments led to the tetrode tube (four elements), in which a screen grid is inserted between the control grid and plate, and then the pentode or five-element tube, in which a suppressor grid is added between the screen grid and plate. Each of these tube types has its own advantages and disadvantages.

Tetrode. The tetrode has a major advantage over the triode: its screen grid serves as a shield between the control grid and plate, minimizing interaction between them and permitting much higher amplification than is possible from the triode. It has two disadvantages, however: it reduces the useful plate current when the plate and the screen grid are at nearly the same voltage, and it results in an increase in the effects of secondary emission. This is the term describing electrons that are knocked off the plate by an incoming electron striking it at high velocity. In the case of the triode, secondary emission is no particular problem, since electrons that are knocked off the plate simply return to it because of its high positive potential; but in the tetrode, the screen grid is nearby and also operating at a high positive potential, so that many of these secondary electrons are attracted to the screen grid and flow in its circuit, rather than in the plate circuit, where the output should flow for greatest circuit efficiency. Primarily for this reason, tetrode tubes are now seldom used, except in some transmitters. The high amplification factor and the lower plate-to-grid capacitance make the tetrode particularly useful as an amplifier of radio-frequency signals.

Pentode. The pentode tube represents a major improvement (see Figure 3). The pentode's fifth element, the suppressor grid, is at a negative voltage with respect to the plate and screen grid; therefore, any electrons that are knocked off the plate by secondary emission are repelled by this grid, forcing them to return to the plate. A few of the secondary-emission electrons may pass through the suppressor grid, but the numbers are so small that they do not affect the operation of the tube. Pentodes are used mainly as rf voltage amplifiers in radio and TV receivers. They are also suitable as power amplifiers, having greater amplification than triodes.

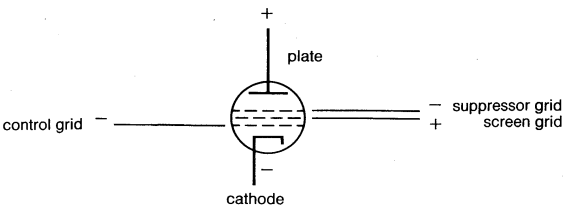

Figure 3: Pentode tube.

Function of the suppressor grid

Special tube types. *Multisection tubes.* In addition to the tubes described, electronic devices sometimes use other highly specialized tubes. Such is the pentagrid (five-grid) converter tube, used in most low-cost superheterodyne tube radio receivers as a combination oscillator-mixer and first detector—two important functions (see RADIO)—thus avoiding the necessity for two separate tubes and keeping the associated circuitry simple. In the superheterodyne receiver, the incoming modulated signals are amplified and then mixed (heterodyned) with an oscillator signal generated in the receiver. The frequency of this local signal is controlled by the tuning control so that it differs from the incoming signal frequency by a fixed amount, called the intermediate frequency. This intermediate frequency is further amplified and then detected (rectified) to recover the intelligence (audio, television, etc.) on the incoming signal.

Many versions of multisection tubes—more than one set of elements in the same physical envelope—have been developed, including dual triodes (two triodes in one envelope) and triode-pentodes. Some tubes, often called compactrons, have been introduced, though not widely used, containing three triodes in one envelope, or several pentodes and a triode, and other combinations.

Other specialized tubes, not used in receiving equipment, include high-power tubes used in transmitters. These must be cooled, either by air or water. High-power transmitting types that require water to keep them cool use metal envelopes. Openings allow the water to circulate around the outside of an inner envelope and out the other side of the tube. Such tubes have a double envelope, the inner containing a vacuum and housing the elements of the tube, the outer permitting the water to enter and circulate.

In the X-ray tube, another specialized type, a target of a heavy metal such as tungsten is bombarded by electrons and produces X-rays, which are used for X-raying teeth, broken bones, and the like.

Klystron and magnetron. The end of the 1960s saw a large increase in the number of special television, high-frequency, and high-power tubes, for example, the klystron and magnetron. These tubes operate on principles different from those of ordinary tubes. They are most useful for frequencies in the microwave region (above 1,000 megahertz, or 1,000,000,000 cycles per second), where they are capable of producing high output power. Both magnetrons and klystron tubes generate a very narrow bank of frequencies because the built-in cavity resonator acts as a tuned circuit for the operation of the tube; it can thus serve as a frequency control device. Regular tubes have external resonant (tuned) circuits so that the frequency can easily be changed. The size of the magnetron cavity establishes the resonant frequency.

The klystron, used to generate and amplify microwave signals for high-frequency communications systems, does permit some small adjustment of frequency. It contains an electron gun—a cylindrical electrode that produces a narrow beam of electrons—in place of a regular cathode (see Figure 4). The input radio frequency is connected to the input cavity and the output is taken from the output cavity. A beam of electrons, forced through the cavities

by an accelerating voltage, is allowed to drift in the space between the cavities. The input radio frequency produces a varying voltage on the first cavity, thus speeding up some electrons and slowing down others. This action produces a bunching effect in the drift space; the bunched electrons at the second cavity produce an amplified version of the radio-frequency input to the first cavity. When used as a generator or oscillator, some of the output signal is fed back to the input (positive feedback) in such a manner as to sustain oscillations.

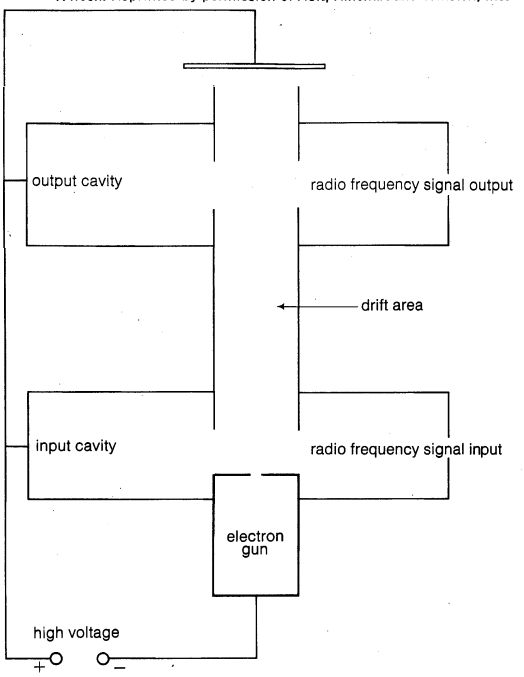

Figure 4: The klystron tube.

Although, for simplicity, the illustration shows only two cavities, it is possible to have a number of them—as many as six in a single klystron tube. Amplification is increased with extra cavity resonators, along with cost, size, and complexity.

The ignitron. Special tubes called ignitrons have been developed for use by industry as rectifiers for high-power applications, such as converting ac to dc for electric locomotives (see Figure 5). The ignitron is a mercury-pool rectifier in which the initial ionization is provided by an arc started between a special electrode, called the igniter, and a liquid pool of mercury, the cathode. The igniter must be used to start the arc, so that the tube can be controlled by small pulses of current to the igniter and hundreds of amperes can be controlled by a small input. The heavy currents are carried by the arc discharge through the ionized mercury, rather than by thermionic emission as in most of the lower power devices.

Other gas tubes, such as gas-filled diodes, are on a smaller scale. These tubes are similar to regular vacuum-tube diodes used in receiving equipment except that after the air has been evacuated, a small amount of mercury vapour is allowed to enter the envelope. Ordinarily a filament (to keep mercury vapour from condensing) and a plate are used, as in a regular diode tube. In these smaller gas diodes, ions of the gas, rather than electrons, carry the current.

Gas-tube diodes come in many sizes, from small receiver types to large types used in power supplies for radio and television. The type used is determined by the power requirements. In addition to handling heavier current, the gas-tube diode has an internal resistance lower than that of a vacuum tube; that is, less power is wasted within the tube itself.

The thyratron. Another type of gas tube is the thyratron. Basically this is a triode or pentode tube, with a

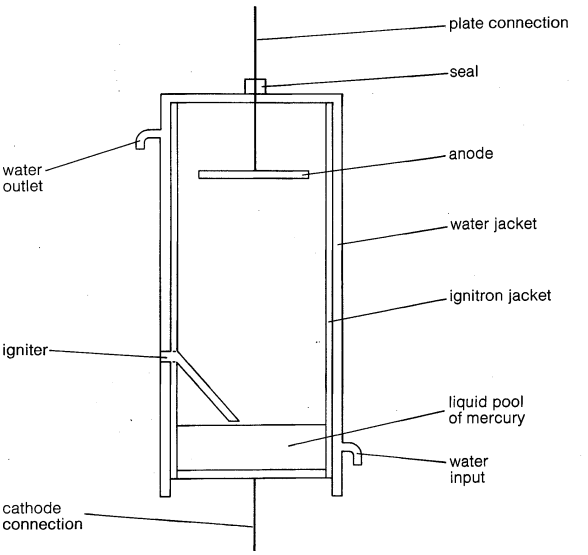

Figure 5: Cutaway view of ignitron construction (see text).

small amount of gas added. Though a triode gas tube has a cathode, control grid, and plate, the control grid does not exercise the same control as it does in a vacuum-tube triode. Once the control grid of the gas-filled triode allows current to flow, the tube conducts fully, regardless of any change in the voltage on the control grid. The only way current flow may be stopped is by reducing the positive voltage on the plate to near zero. For this reason, thyratrons and other gas-filled tubes are operated with alternating current rather than direct current on the plate. The alternating current shuts the tube off at the end of the positive half-cycle of each alternation. If the grid potential is adjusted so that the tube conducts as soon as the plate becomes positive, the tube conducts for approximately one-half, the positive half, of the input cycle.

If conduction for a lesser period of time is desired to satisfy a circuit requirement, a higher potential is impressed on the control grid, permitting conduction to take place only with a higher plate potential. The tube stops conducting when the positive half-cycle on the plate has passed, as before. In practice, it is possible to operate the tube so that it conducts from only a tiny fraction to almost half of its input cycle, thus providing a widely varying current for such applications as dc motor speed control. The grid can be operated with alternating voltage on it as well as on the plate. The phase of the grid voltage can be made adjustable so that the conduction time of the tube can be predetermined and the desired output current obtained.

Thyratrons are often used in arc welding equipment. Through their use, precise amounts of heat can be produced at the weld. If more heat is needed the thyratron can be adjusted to conduct for a longer portion of the positive half-cycle. When currents are required that are greater than the rating of a particular thyratron, larger devices can be used, controlled by the smaller.

Television tubes. With the advance of television in the 1960s, many tubes were designed specifically for television receivers, such as tubes for the rf amplifier. One such tube, only a quarter of an inch in diameter, is capable of excellent low noise amplification.

Another special tube utilizing the phenomenon of secondary emission to provide large amplification in television camera tubes and other applications is the photomultiplier (see Figure 6). Basically a phototube, the photomultiplier amplifies the signal produced at the photocathode up to 10,000,000 or more times.

Photomultiplier utilizes secondary emission

This tube operates through the use of a number of small plates called dynodes. Each dynode, starting at the cathode, is operated at an increasingly higher positive voltage with the collector (or final plate) the highest. Electrons from the cathode strike the first dynode plate, knocking

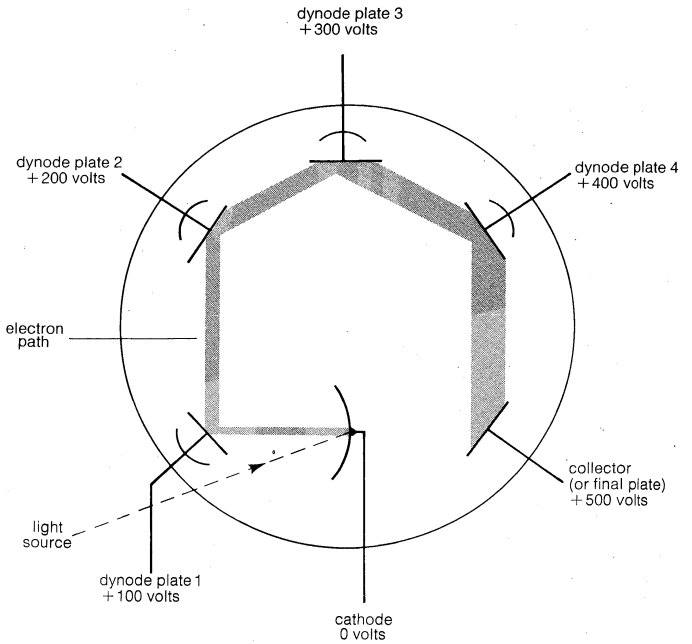

Figure 6: The photomultiplier tube (see text).
From *Basic Electronics* by Glade Wilcox. Copyright © 1960 by Glade Wilcox. Reprinted by permission of Holt, Rinehart and Winston, Inc.

out electrons by secondary emission. The plate material and circuit conditions are selected so that more electrons are knocked out at the plate than strike it, thus producing amplification. These electrons are attracted to the second dynode plate, where they knock out even more electrons, which are attracted to the next dynode plate, and so on until the final plate is reached.

Such tubes are particularly useful for the measurement of very small light intensities. Light so dim that it cannot be seen with the unaided eye can be measured using these tubes and associated equipment. They are available with various colour band sensitivities, from ultraviolet to infrared, so that any particular spectrum may be investigated by the researcher. Photomultiplier tubes are also often used in nuclear radiation-measurement equipment in which the radiation particle produces a very small flash of light or scintillation in a special type of crystal. The photomultiplier tube can be used to detect this light and amplify the resulting signal to a useful electronic pulse that can be recorded, counted, and analyzed to determine the characteristics of the material producing the radiation.

Electron-gun tubes. A very important group of tubes are those that belong to the electron-gun family. Included are cathode-ray tubes used in oscilloscopes, which display varying electrical voltages and currents as a function of time, and picture tubes used in television sets. An unusual type is a tube with a phosphor—the layer of luminescent material applied to the inner face of the tube—that has a long persistence; that is, it retains an image, or glow, a long time. Some of these long-persistence tubes are used in radar, others in computer memory units.

All cathode-ray tubes use an electron gun. Basically the gun resembles a regular electron tube with cathode, control grid, and several other elements, but without a plate. In the cathode-ray tube, however, the entire gun is used to accelerate the electrons from the cathode and focus them into a narrow stream. They leave the gun in just this form and end up striking a very small spot on the face or screen of the cathode-ray tube.

A major difference between the cathode-ray tubes used in oscilloscopes and those used in television sets is the way in which the electron stream is deflected to different areas on the screen. The oscilloscope type of cathode-ray tube almost always uses electrostatic deflection, a process in which two pairs of parallel metal plates are placed inside the cathode-ray tube, one pair horizontal and the other vertical. The electron beam passes between these plates and is deflected by any difference in potential between the two plates of each pair. In this way the beam can be moved in any direction so that it hits the desired spot on the face of the tube.

Television picture tubes use electromagnetic deflection; that is, the stream of electrons leaving the electron gun is deflected by a magnetic field derived from a horizontal and a vertical deflection coil, called a deflection yoke, positioned around the neck of the picture tube. Through the use of properly shaped voltage pulses to the yoke, the beam is deflected to the proper position on the screen.

Phosphor light colours

There are two differences between cathode-ray tubes and picture tubes. One is the colour of light produced by the phosphor, which in black-and-white picture tubes is white. In oscilloscopes, the phosphor generally produces green light, though other colours are sometimes obtained. The second difference is that of persistence mentioned above. Most, but not all, cathode-ray tubes for oscilloscopes have a short persistence. Television picture tubes have a longer persistence.

The colour picture tube has three different colour phosphors, green, blue, and red, arranged on the face of the picture tube in the form of tiny dots, placed with one colour at each corner of an imaginary triangle. Three electron guns, one for each of the three colours, shoot electron beams at the proper phosphors.

TUBE CONSTRUCTION AND MANUFACTURE

Common vacuum tubes are made up of a variety of parts and elements. The grid or grids are made on a special grid-winding machine. Cathodes are made of many different materials and combinations. Filaments are also made as a separate part of the tube, generally of fine tungsten wire. Similarly, the plate, or anode, of the tube is made of a suitable material, depending on the application.

Manufacturing of electron tubes is highly automated. The various elements are assembled with micra or other insulating material to provide proper spacing and rigidity, for the distance and tolerance between elements are often only a few thousandths of an inch. A jig holds all elements in place until they are ready to be placed inside the envelope. Often heat is applied to drive off gases from the finished product.

Removing residual gas

A getter—an alkali metal that reacts chemically with and eliminates any remaining gases—is also placed inside the tube. The elements are spot-welded to suitable pins that serve as connections through a header on the outside of the tube.

It is necessary that the base permit the pins to pass through it, allow no air to enter, and provide a good seal. For many years the manufacturing problem was extremely difficult, but today's methods of very close heat control, excellent tolerance control, special base glues, and automated equipment have brought the problem under control.

After the elements have been spot-welded to connection pins, the entire inner electrode assembly is heated and placed inside the envelope, which usually has an extended tubelike appendage at the top, bottom, or side, through which air is pumped out. This appendage is then heated and pinched off, making a permanent, vacuum-tight seal. The getter, if used, is then flashed (ignited) to combine with any remaining gases and produce a good vacuum.

A getter is not always used, for in very high frequency tubes it may increase the interelectrode capacities between the various elements and degrade tube performance. It is also often omitted in high-power tubes to prevent a short developing between elements.

During the entire manufacturing process, great care is exercised to keep the elements of the tube from being contaminated by dust, dirt, or chemicals. Gloves are used by personnel handling the internal parts of the vacuum tube.

The manufacture of large, high-powered tubes, or the special klystrons and other ultrahigh frequency devices, is not as automated. Much handwork is still necessary in the proper fitting and assembly of the parts.

Rugged-ized tubes for special needs

Several tube manufacturers make special versions that are rated as "long life," or "premium," tubes, most often used in applications in which breakdowns are likely, such as in the amplifier in an undersea cable, in a remote, unattended radio relay station, or in an industrial or military application where they are subjected to extreme shock and vibration. Apart from their ruggedized character and extreme care in manufacture, these premium tubes are often much like the regular versions of the same device. In some cases, the heater or filament is specially designed to be longer lasting than the regular version.

In the basing of tubes, many different forms are used. Early tubes used a screw-in base, but since about 1930, tubes, except for high-power and high-frequency types, have generally been of the plug-in type. The most common bases today are the seven- and nine-pin miniature types, which have small wires emerging from the glass envelope through a glass base. These small pins enter a socket that serves to hold the tube in place, to permit connections to be made, and to allow it to be easily replaced.

Other types of bases include the earlier octal basing, which was a standard eight-pin socket. The tube was placed in a bakelite plug, with fine wires emerging from the base of the glass envelope. These wires were placed in metal prongs on the bakelite socket and soldered in place. The bottom of the glass envelope was then glued to the bakelite. Many television picture tubes still use this type of basing, though new equipment is no longer designed for its use.

Special receiving tubes may have different types of base. Materials are used that do not absorb energy at high frequencies to minimize losses.

APPLICATIONS AND FUTURE PROSPECTS

From its beginnings, the electronics industry has built its devices around the versatile electron tube, whose applications today assume staggering proportions. Low-power tubes are found as rectifiers, amplifiers, oscillators, and in other special applications. The great majority of television sets are still exclusively tube types. The average colour television set uses 20 to 30 tubes, the number often being a measure of the quality of the set.

Radio transmitters of broadcast quality employ large numbers of electron tubes, serving basically the same function as they do in the receiving equipment. In fact, many of the smaller, regular tubes are used in transmitters as well as receivers. In addition, transmitters utilize high-powered amplifier tubes (generally tetrodes and pentodes) to provide the necessary power output. Gas-filled diodes are commonly used as rectifiers to provide the high-voltage, high-current dc required by the high-power amplifier stages.

High-power and special tubes find applications in many other devices, such as industrial controls, radar, computers, radio-frequency heating, weather equipment, and automation of factories.

The transistor (see SEMICONDUCTOR DEVICES) has in many cases changed the nature of electronic equipment, such as the computer, enabling it to be made much smaller and with much less heat dissipation. Transistorized radios are now made in enormous numbers. Yet the "end of the tube," once thought to be in sight, now seems further off. The transistor has been best able to supersede the electron tube in applications where small power is required, small size is imperative or desirable, or in applications in which the transistor can do the job more cheaply.

The transistor versus the tube

The time will no doubt come when the tube-operated television set will be a thing of the past. Special problems exist, however, in some of the television circuitry that makes transistor application difficult. All-transistor colour sets have achieved some success, however, in the early 1970s.

In applications in which higher powers are required, transistor inroads have been slow for many reasons. In high-frequency applications, very low capacities and inductances are required. Transistors, when fabricated to meet this requirement, are expensive. When high powers are needed at high frequencies, as in transmitters, transistors are inadequate because they cannot provide sufficient power while operating in the upper frequency range. Transmitters that have lower power outputs, such as those used in mobile equipment, have transistorized receivers (for low battery drain and dependability) but often have tube type transmitters, or a combination of tubes and transistors, with tubes doing the high-power work.

On the other hand there has been great progress in solid-state diodes. The tube rectifier is rarely used in receiving equipment any longer. Even in high-current applications, solid-state diodes are supplanting the vacuum tube. It is now conceivable that solid-state diodes will completely take over the diode rectifier tube market in the near future.

Yet the impact of transistors and other solid-state devices on electron tubes has not been nearly as great as predicted. Much of the reason for the continued health of the electron tube lies in the great increase in black-and-white and colour television sets all over the world. Where old-fashioned radio receivers used only 5 or sometimes 6 tubes, the television set, even black-and-white, uses 12 to 15 tubes, with colour sets using 20 to 30 tubes. Stereophonic radios, tape recorders, and other devices also continue to create a market for tubes, though the transistor is rapidly taking over.

The market for tubes

In the case of the klystron, magnetron, and other special-purpose tubes, no real challenge has yet been forthcoming from transistors. The nature of these tubes and their uses make competition from the transistor unlikely for some time. Transistors available today can operate at frequencies of several hundred megahertz (million cycles), but klystrons operate at 20,000 to 30,000 megahertz. The tube designed specificially for this operation promises to remain unchallenged for some time.

Electroplating

Electroplating is the act of coating with metal by means of electric current. Plating metal may be transferred to conductive surfaces (metals) or to nonconductive surfaces (plastics, wood, leather), after the latter have been rendered conductive by such processes as coating with graphite, conductive lacquer, electroless plate, or a vaporized coating.

While some metal coating procedures date back to ancient times, modern electroplating started in 1800 with A. Volta's discovery of the voltaic pile, or battery, which made noteworthy quantities of direct current electricity available. At about the same time, the battery was employed to deposit lead, copper, and silver. After a nodule of copper had been deposited on a silver cathode, the copper could not be removed. In the same year, zinc, copper, and silver were deposited on themselves and on a variety of basis metals (the metals on which the plating is applied), such as gold and iron.

Figure 1 shows a typical plating tank containing copper sulfate ($CuSO_4$) solution. A dynamo supplies electric current which is controlled by a rheostat. When the switch is closed, the cathode bar, which holds the work to be plated, is charged negatively. Some of the electrons from the cathode bar transfer to the positively charged copper ions (Cu^{++}), setting them free as atoms of copper metal. These copper atoms take their place on the cathode surface, copper plating it.

Concurrently, as shown in the drawing, the same number of sulfate ions (SO_4^{2-}) are discharged on the copper anodes, thereby completing the electrical circuit. In so doing, they form a new quantity of copper sulfate that dissolves in the solution and restores it to its original

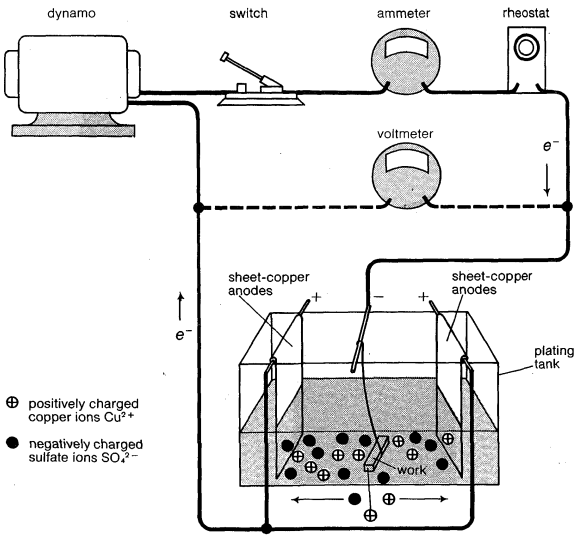

Figure 1: Electroplating circuit.

composition. This procedure is typical of nearly all ordinary electroplating processes: the current deposits a given amount of metal on the cathode and the anode dissolves to the same extent, maintaining the solution more or less uniformly. If this balance is perfect and there are no side reactions or losses, a 100 percent cathode efficiency and 100 percent anode efficiency could possibly be realized.

Cathode and anode efficiency

If the metal surface of the cathode is chemically and physically clean, the discharged atoms of copper are deposited within normal interatomic spacing of the atoms of the basis metal and attempt to become an integral part of it. In fact, if the basis metal is copper, the new copper atoms will frequently arrange themselves to continue the crystal structure of the basis metal, the plate becoming more or less indistinguishable from and inseparable from the basis metal.

Cleaning and pickling. If the surface of the basis metal is contaminated by a film of grease, oil, rust, or oxide, or even if the surface is strained or smeared by cold working, the plating will cover these intervening materials. The adhesion then may vary widely from completely adherent to completely nonadherent. It is thus necessary to clean the basis metal perfectly before plating. Films of oil and grease are removed by such methods as vapour degreasing, hot-alkaline cleaning (soak, cathodic, or anodic), or scrubbing with pumice. Rust and oxide films are removed by acid dipping or pickling (soaking in acid), and, if possible, a thin layer of metal is dissolved away by etching to remove surface strains and expose a fresh surface.

Plating processes. If suitable solutions of different metals are mixed, it is possible to plate a wide variety of alloys of metals. By this means plated brass can be made more or less indistinguishable from cast brass. It is also possible, however, to deposit alloys or compounds of metals that cannot be produced by melting and casting them together. For example, tin–nickel alloy plate has been used commercially for its hardness and corrosion resistance, which are superior to that of either metal alone. The deposit consists of a tin–nickel compound (Sn-Ni), that cannot be produced in any other way.

Other common alloy plates include bronze, and gold, with varying properties, such as different colours or hardnesses. Magnetic alloy plates of such metals as iron, cobalt, and nickel are used for memory drums in computers. Solder plate (Sn-Pb) is used in printed circuit work.

Electroplating on a commercial scale was begun around 1840–41 and was accelerated by the discovery of cyanide solutions for plating silver, gold, copper, and brass. A cyanide–copper solution, for example, gave adherent deposits of copper directly on iron and steel. It is still used for this purpose and also for the initial plating on zinc die castings. The copper sulfate solution described above corrodes these metals, giving nonadherent deposits.

Nickel plating

Nickel plating on a commercial scale was introduced in Boston, in 1869. It required pure anodes and salts and a neutral or slightly acid nickel solution. Previous workers had used alkaline nickel solutions in which the nickel anodes did not dissolve properly and which provided only thin films of metal. Nickel plating achieved immediate popularity, and an important American railroad became known as the Nickel Plate Road as a symbol of luxury and efficiency.

While there were many attempts to discover a dependable chromium plating process, they were unsuccessful until 1924. Most of the early work had involved the simple trivalent and bivalent salts of chromium. It took a long time to discover dependable and practical conditions for chromium plating from chromic acid solutions, with insoluble lead anodes and a catalyst of sulfate ion equal to 1 percent by weight of the chromic acid. In this case, the solution is maintained by chromic acid additions and not by means of soluble anodes.

Many innovations were introduced into electroplating practice around the turn of the century. Electrolytic cleaning and the bulk plating of small parts in tumbling barrels were introduced. Zinc plating iron parts for rust protection gradually established itself, followed by cadmium plating for the same purpose around 1920. Tin plating was well known from the middle of the 19th century onward, but it was not until the World War II period that both acid and alkaline baths came to be used on a large scale for the plating of steel strip for tin cans, thus economizing on the amount of tin required compared to hot tinning.

Electroplating is a large and growing industry with sophisticated engineering and equipment requirements. The metals that can be readily plated from aqueous solutions at high current efficiencies near 100 percent can best be surveyed from Figure 2. It shows these metals in a single

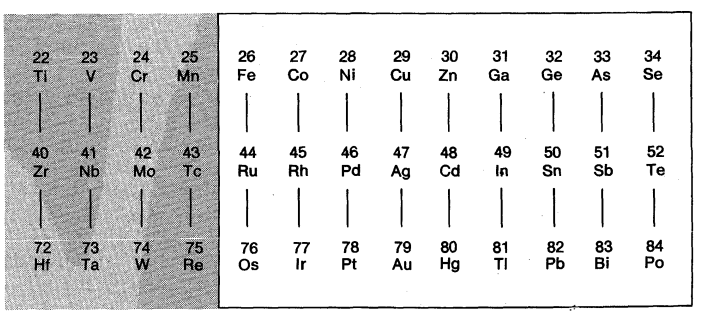

Figure 2: Periodic chart of metals readily plated.

rectangle in their proper relationship to each other. The only metal in common use outside of the rectangle is chromium, which is commonly plated at low current efficiencies of about 10–20 percent. Of the 27 metals inside the rectangle, about 15 are more or less common in plating, specifically, iron, cobalt, nickel, copper, zinc, ruthenium, rhodium, palladium, silver, cadmium, tin, iridium, platinum, gold, and lead. The others can be deposited easily but have not found much use in this way either due to cost or availability or lack of useful properties.

A few metals outside of the rectangle are sometimes used for plating or electroforming purposes. Thus aluminum is frequently deposited in this way from organic or nonaqueous solutions and also fused salt baths. Some of the refractory metals (molybdenum, tungsten, tantalum, and niobium) have also been applied in this way by workers using fused (melted) salt baths.

To obtain a smooth, bright finish it was formerly necessary to polish and buff both the basis metal and the plate. The cost of this processing was generally as much as or more than the cost of plating. The trend has accordingly been to the constantly increasing use of bright plating solutions and even "levelling" deposits (especially of cop-

per and nickel) that actually fill in scratches and other defects in the basis metal and make possible the production of bright finished articles with little or no buffing or polishing. While occasional use was made of bright plating solutions after the initial use of carbon disulfide to brighten silver plate around 1847, it was only with the introduction of bright nickel plating in the 1930s that the period of intensive developments in this direction began. Another development giving similar results, particularly with copper, was the use of periodic reverse current for electroplating. Intensive work on "levelled" deposits dates from the introduction of semibright nickel plating in the early 1950s.

Bright plating solutions

The introduction of chromium plating in 1925 had stimulating repercussions all through the plating industry. Chromium was essentially a bright plate and retained its brightness indefinitely. Chromium plate found a ready market in the automotive and appliance fields, in which the merits of the combination plate nickel–chromium or copper–nickel–chromium were soon proven. The requirements for closer control procedures in bath composition, temperature, and current density were reflected in better control and development of other processes.

The so-called hard chromium plating likewise created a new way of improving wear resistance of machine parts and improved operation due to good frictional and heat resistance properties. Worn or undersized parts were built up with chromium plate. The success of chromium plating increased the field for engineering applications of other metals such as nickel, copper, silver, and gold.

The Manhattan Project for the production of the atomic bomb in World War II could not have succeeded without a durable nickel plate lining in the pipes and valves for handling the uranium hexafluoride vapours. Nickel was required and there simply was not enough nickel available to make solid nickel pipes.

The success of hard chromium plating is partly due to several intrinsic properties of the process. If the solution is heated to the proper temperature of about 50° C (122° F) or more, it does a great deal of its own cleaning and produces deposits of a very high degree of adhesion under almost all conditions. The chromium deposits also "heal" torn places and machining defects in the surface of the basis metal to which they are applied, due to excellent smoothing or levelling ability. Part of the decreased friction on these deposits results from this property.

The low current efficiency of chromium plating baths was nearly doubled (though it remained in the range of 15 to 25 percent) by the use of combined catalysts of both sulfate and complex fluoride ions (for example, silicofluoride, SiF_6^{2-}) in self-regulating high speed (SRHS) baths described in 1950. These baths also gave harder and brighter chromium deposits of increased utility.

Chromium plating has been unique in the extremely wide variety of deposits that are produced for different purposes by altering the bath composition, temperature, current density, and post treatment of the deposit. Ordinary deposits are cracked unless extremely thin (less than 0.00002 inch; 0.000508 millimetre) but are completely adherent, and the cracks heal and fill in completely as deposition proceeds, while new cracks form on the surface. Use is currently being made of this pattern of extremely fine cracks to obtain decorative plates of improved corrosion resistance, described as microcracked or microporous chromium plate.

Microporous chromium plate

A dull, crack-free chromium plate was introduced in 1953, and a bright, crack-free plate in 1957. Porous chromium plate is a type of heavy chromium plate, generally more than 0.004 inch (0.1016 millimetre) thick, used in diesel engines and other internal combustion engines for oil retention and to get good "breaking in" qualities by etching or otherwise roughening the chromium surface and then finally honing or polishing it prior to use.

While decorative chromium plate has for a long time been specified to be about ten-millionths of an inch thick and commonly requires several minutes plating time to produce, a large-scale use has been found for radically thinner chromium coatings: to replace the tin on tin cans. This development originated in Japan. A rapidly moving strip-steel can stock is plated with about 0.0000003–0.0000005 inch (0.0000076–0.0000127 millimetre) of chromium in about one-third of a second, a coat that provides a good basis for an adherent coat of lacquer. The product is called tin-free steel (TFS), used predominantly for beverage cans. About 10 percent of all "tin" cans in the early 1970s were being made of TFS, and the proportion was expected to rise to about 30 percent.

While nonmetallic materials have been plated since the mid-19th century, a period of rapid growth in the utilization of electroplated plastics began in 1963 with the introduction of ABS plastic (acrylonitrile-butadiene-styrene), which was readily plated. Thus the utilization of plated plastics grew from 9,000,000 pounds in 1968 to about 35,000,000 pounds in 1970. The plastic part is first etched chemically by a suitable process, such as dipping in a hot chromic acid–sulfuric acid mixture. It is then sensitized and activated by first dipping in stannous chloride solution and then in palladium chloride solution. It is then coated with electroless copper or nickel before further plating. A useful degree of adhesion is obtained (about 5 to 30 pounds per inch; 1 to 6 kilograms per centimetre), but in no way comparable to the adhesion of metals to metals.

Applications. Copper plating is used extensively to prevent case hardening of steel on specified parts. The entire article may be copper plated, and the plate ground off on the areas to be hardened. Silver plating is used on tableware and electrical contacts; it has also been used on engine bearings. The most extensive use of gold plating is on jewelry and watch cases. Zinc coatings prevent the corrosion of steel articles, while nickel and chromium plate are used on automobiles and household appliances.

Elementary and Secondary Education

As nations and peoples develop their language, codify their law, and create new patterns of work, their educational systems tend to become increasingly complicated in terms of levels and programs. In keeping with the specialized demands of modernizing societies, the educational system provides a source for the human resources and the knowledge necessary for continuing development. The educational system also assists in the preparation for specific occupational tasks and attempts to promote commitments to (and, ideally, constructive criticisms of) the values of society. In contemporary nations three major educational levels have emerged, each of which may be subdivided into numerous types of institutions.

Definitions of primary, elementary, and secondary education

The terminology used to identify the educational stages, however, may be confusing. The first major stage of the formal education system, for example, is called primary education in some countries and elementary education in others. Historically these terms have had quite different meanings. Thus during earlier periods in Europe, when highly selective educational systems existed, primary schools frequently referred only to those lower schools preparing students for advanced education. By contrast, elementary schools were terminal institutions that provided literacy and some general education for larger groups of children. Currently the choice between the phrases elementary education and primary education is largely a matter of national preference. The earlier distinction has largely disappeared, since most nations now have a single system for the first stage of schooling. In the United States, for example, the term elementary school is widely used, whereas the term primary school (in its various linguistic equivalents) is more common in western Europe.

Secondary schooling likewise presents certain definitional problems. Not only do most nations have a number of distinct kinds of secondary schools but also the demarcation of secondary schools from lower or higher institutions varies from nation to nation. Thus the sixth form in English education is typically considered part of secondary education, yet the academic study at this level would be more equivalent to the introductory years of American universities. Moreover, as part of secondary education there may be general secondary schools, various vocational secondary schools, and teacher-training schools. Any of these types may be considered terminal or as preparatory for higher education. They may emphasize arts, language, or science, or they may offer little specialization. Vocational secondary schools may provide only a single course of study, such as agriculture, or they may prepare pupils in any of a number of vocational skills. Teacher-training schools—for preparation of teachers in lower grades—is conducted at the secondary level in many nations. The trend, however, is to require postsecondary school training for future teachers.

SOME MAJOR MODELS IN EDUCATION

As the foregoing suggests, generalizations about the structure of elementary or secondary education may be misleading. National traditions, ideological preference, influences of climate and terrain, the level of industrialization, and other ecological considerations all influence the organization and control of education, the school program, and even the schedule for attendance. Certain influential models have existed historically, however, and it is well to identify these before entering into a discussion of recent trends (see also EDUCATION, HISTORY OF for a discussion of the historical roots common to much of European education as well as education in other areas).

Although the patterns of elementary and secondary schooling everywhere have taken on distinctive national colourations, cautious generalizations may be made about those systems found in certain regions. In western Europe, for example, the first stage of schooling is usually only four to five years in length, followed by a much longer period of secondary education. Traditionally these two levels have been separated by a rigorous and decisive examination. Secondary education usually consisted of a variety of terminal vocational institutions and one (or one public and one private) clearly demarcated academic path providing preparatory work for universities. Increasingly, however, with the extension of compulsory education and under egalitarian pressure for postponement of commitment to a particular course of study, the lower years of secondary education are being opened to all. Further, the fees formerly charged in secondary schools have now been largely abolished.

Because of their wide influence throughout the world, it is appropriate to sketch briefly the educational patterns of a few major European nations and the United States. For Europe an examination of France, Germany, England, and the U.S.S.R. should suffice.

The French system. Contemporary France has a first cycle of education for all children 6 to 11 years of age. Much has been written about the belief of the French people in the principle of national culture. The task of the French elementary school is to lay the foundation for the perpetuation of national culture by providing all children, through a common language, with knowledge of the common heritage of the nation.

Following this five-year period of general education, children enter one of a variety of secondary education programs. During the first two to three years of secondary schooling, however, children are in an orientation or observation stage. This period is used to determine which type of further education is most appropriate for the pupil. For the least academically talented boy or girl a three-year terminal program in general education is offered that will carry the pupil until the end of his compulsory education at age 16. A second group of pupils, having passed an aptitude test at the age of 11, are assigned to a short course in general education leading to a variety of vocational courses. The most academically talented boys and girls at the age of 11 enter *lycées*, where they specialize—with various options in classical languages, modern languages, and the sciences. Each program of studies at the secondary level awards its own diploma, certificate, or degree. The most prestigious of these is the *baccalauréat* offered only to students in the *lycées* upon successful completion of a series of examinations. The *baccalauréat* thus caps secondary education; however, it is also considered the first university degree and is a requirement for entrance to most programs of higher education. The *baccalauréat* bears some similarity to the *bachillerato* offered in Spanish-speaking nations at the end of general secondary education. This degree, however, should not be confused with the bachelor's degree offered in American and British universities.

Lycées

The West German system. In West Germany, schools are the responsibility of the governments of the states, or *Länder*, and the structure of elementary and secondary education is not entirely consistent throughout the nation. In all states, however, the period of elementary education covers eight or nine grades. All children spend the first four to six years in a neighbourhood elementary school. After this period, three basic options are available to the pupils. They may, after counselling by the elementary school teacher and upon the request of the parents, be placed in a *Realschule*, a *Gymnasium*, or a *Hauptschule*, the last representing a continuation of elementary education.

Those pupils attending the *Hauptschule* proceed with their study of language, arithmetic, geography, history, science, music, art, and physical education. Industrial arts for boys and home economics for girls are usually offered. After completion of a program of studies at the *Hauptschule*, which lasts four or five years, the pupil typically enters apprenticeship training.

In Germany, the term secondary school refers to institutions offering courses leading to the "Certificate of Maturity" (the *Reifezeugnis*), a qualification for entrance to an institution of higher education. The *Realschule* offers pupils further general education, some prevocational courses, and English-language study. At the age of 16, pupils conclude their program of studies and transfer to a vocational school or enter apprenticeship training.

If academically qualified, the pupil may also transfer to the *Gymnasium*.

Gymnasium

The *Gymnasium*, the third alternative for German youth, offers rigorous academic preparation for higher education. Like the *lycée* in France and the grammar school in England, the *Gymnasium* is designed for those pupils who have shown the most academic promise; and its curriculum emphasizing languages, mathematics, natural sciences, and social sciences requires a high degree of diligence throughout all of the nine grades. Unsuccessful pupils in the *Gymnasium* may be transferred to the *Hauptschule*. At the age of 16, moreover, pupils may terminate their academic studies and enter a vocational school.

Students in the *Gymnasium* must pass an examination, the *Abitur*, entitling them to the Certificate of Maturity, if they are to be admitted to a German university. The content of the *Abitur* is adjusted to the focus of studies, such as classical languages, modern language, or mathematics-science, chosen earlier by the student.

The English system. In England, the first stage of education is called primary education and includes pupils from ages 5 through 11. The great majority of these pupils pass through a sequence of infant and junior schools that together comprise the full system. Primary education is concerned with physical, spiritual, and moral development as well as the intellectual growth of children. The infant schools in particular tend to provide a relatively unstructured learning atmosphere for the child to experience and experiment with the world around him. The junior schools attempt to provide a sound introduction to disciplines as a preparation for further learning. These schools, however, have been moving in the direction of becoming more child centred, with increased emphasis on activity and greater accommodation to the interest of the children.

England, since World War II, like most other European nations, has increased the variety of secondary school programs available to adolescents. The allocation of pupils completing their primary education to different types of secondary schools takes place largely by means of an examination given at the age of 11 or shortly thereafter. The majority of students attend the secondary modern school, which offers a broad, general education until the age of 15. On the basis of their scores on the "eleven-plus" examinations, pupils may enter secondary technical schools and prepare to become skilled technicians.

The third school in the English tripartite system of secondary education is the grammar school, traditionally the most prestigious of the secondary institutions and the one most associated with university preparation.

Comprehensive schools

Some attempts have been made to incorporate the programs associated with modern, technical, and grammar schools in multilateral or comprehensive schools. (Indeed, the structure of secondary education has become both a pedagogical and a political issue of some magnitude in England.) This reform of educational structure is sometimes viewed as a move in the direction of the American-style comprehensive education. It should be noted, however, that a single comprehensive school for adolescents is not merely an American phenomenon; it is also well developed in Sweden and is under consideration in a number of other nations.

The students seeking university entrance must successfully complete a series of examinations that result in the General Certificate of Education. These examinations have two levels: ordinary and advanced. Entry to a university requires a prescribed combination of passes on the ordinary and advanced level in such subjects as English, foreign language, science, and mathematics. The sixth-form curriculum is largely oriented toward preparation for the advanced level examination and provides intense specialization.

In England a separate and highly significant group of independent schools exists. These primary and secondary schools are financially self-supporting. The best known of the independent schools are the "public schools," some of which, notably Eton and Harrow, have long maintained a distinguished international reputation. These schools for centuries have prepared students academically for higher education, typically at Oxford or Cambridge University, and ultimately for leadership in English life. Although a controversial element in English education and frequently accused of reinforcing invidious social distinctions, these institutions remain popular.

The Soviet system. Contemporary U.S.S.R. has an educational pattern that differs distinctively from that just described. The first stage of education takes place in an eight-year general-education school. This school offers the usual core subjects of language, mathematics, science, history, and geography. Work in art, music, and physical education is also provided. A unique feature is the provision of labour experience in order that pupils may acquire simple skills in working with wood and metal, so that they may become involved in socially useful work.

After graduating from the eight-year school, Soviet youth, if qualified, have a number of secondary schools open to them, including polytechnical or general secondary schools and various vocational or technical schools. Although in previous times there existed in the U.S.S.R. the same sharp division between the first (universal) and second (highly selective) stages of education common in other parts of Europe, in recent years the selection process has been extended over a number of years. The object now is to provide prolonged guidance for the pupils and place them into increasingly differentiated programs of study throughout the last few years of the elementary school and the first two or three years of secondary school. Many of those leaving the elementary school go directly into an occupation. Most critical for students wishing to continue their education is the selection at 17 or 18 years of age for higher education. The universities and higher institutes admit only 15 to 20 percent of the graduates of the secondary level institutions. Most graduates of the polytechnical or general secondary schools are required to take jobs for two or three years, after which those qualified may proceed to higher education. For those not admitted to regular educational programs at the secondary or higher levels there still are opportunities for continued education through a vast network of part-time educational programs.

Further comment needs to be made regarding polytechnical education. Polytechnical education is not the same as the Western vocational education in the Soviet view, for the latter is seen as referring to a much narrower set of experiences. Polytechnical education as understood by Soviet educators and political leaders is part of general education or citizenship training because all citizens are ideologically viewed as "workers." Thus all students must acquire both theoretical and practical training in the fundamentals of production in some agricultural or industrial pursuit. The specific educational programs that should comprise polytechnical education are, however, subject to continuing discussion and debate.

The U.S. system. The United States also offers a distinctive educational pattern—one that some observers see as representing, at least structurally, the trend in most industrialized societies. Without heritage of a distinction between primary education and elementary education (in the senses noted at the beginning of this article), the United States historically has had a single system of elementary and secondary education for the great majority of its students.

In the United States, education is the responsibility of the individual states; therefore some variation in structure exists. Typically, however, children at the age of six enter a neighbourhood school. Depending on the preference of the community, elementary education may extend from six to eight years. Although great variation exists, the elementary schools in the United States tend to provide a more relaxed learning environment and a more informal relation between pupil and teacher than found in most other parts of the world.

Comprehensive high schools

In the United States, over 80 percent of the secondary age groups attend secondary school. The American goal for decades has been to provide secondary education for all within a single type of institution popularly referred to as the comprehensive high school. Although the precise meaning of this term is frequently not clear, comprehensive schools usually include a broad program of general and specialized curricula and accommodate a wide range in the academic abilities of the pupils. Thus in the same American secondary school some students plan to pursue university study and others seek terminal secondary education. At times, however, this distinction is more apparent than real, for American schools are strongly influenced by residential patterns, which in some communities make for a high degree of homogeneity in the aspirations of parents and students.

Even though the principle of secondary education for all youth is well accepted in the United States, criticism is made regarding the academic standards in the secondary schools. Some persons have urged the schools to strive harder for academic excellence and have pointed to European secondary schools as models.

Students, at least those anticipating a university education, in the future may expect more stringent requirements in the basic disciplines. In spite of continuing controversy, however, there appears to be little possibility that a substitute will be created for the comprehensive school.

FACTORS AFFECTING EDUCATIONAL CHANGE IN THE 20TH CENTURY

A number of factors have influenced educational change in the 20th century, probably the most important of them being (1) the extent and rapidity of technological change, (2) the rate of population growth, (3) the growth in concern for equity, and (4) the increasing popularity of long-range, comprehensive planning.

Technological change. Technological developments during the 20th century have produced industrialized societies in many parts of the world and a few emerging postindustrial societies. With its more complicated division of labour, industrialization has meant a growth in the number of occupations requiring extensive formal educational preparation. The number of people who must be able to manage and to manipulate the technical and bureaucratic apparatus in an industrial society is large and requires a constant flow of literate persons and a stream of technically competent persons.

Relation between the occupational and educational structures

In the more advanced nations the occupational structure has already changed from a triangular shape, with little room at the top for highly skilled and professional tasks, to a diamond shaped structure, with a reduction in the demand for bottom-level unskilled labour and a large growth in the need for middle-level skills. Some observers see the most technologically advanced nations already moving toward an occupational structure shaped like an inverted triangle with the great bulk of occupations requiring advanced educational preparation. The direction of change in this occupational structure implies growth at every level of the educational system and indeed hints at the need for organized schooling for learning throughout one's life. To the extent that the schools react to or anticipate employment needs, the trends suggest that schools will be continually revising curriculum, adjusting facilities, and retraining teachers.

In the less developed nations technical skills frequently are in short supply. In the early stages of industrialization, consequently, rapid expansion of secondary and higher education may be called for. On the other hand, social demand for schooling may, at the same time, effect a rapid expansion of elementary schooling. Given sparse resources, the choice of educational priorities—that is, the choice of the best educational investment in terms of national goals—is indeed critical. Unfortunately, given the limited knowledge about the complex processes of economic and social development and the equally limited insight into the functioning of educational systems, there are few guidelines for these nations.

In the processes of economic and social development it is generally assumed that providing the requisite knowledge as well as the necessary certification for advanced skills will be the task of the educational system. In quantitative terms, therefore, the trend everywhere is toward expansion of educational enrollments at the secondary and higher levels. To a large extent the trend also is toward increased specialization in preparation for any of a growing number of technical and professional fields. The difference in rate of economic and technological change between the developed and underdeveloped nations, moreover, is significant. Educational expansion in the less developed nations has frequently outstripped the occupational opportunities for graduates. Generally, in western Europe and North America, on the other hand, the output of the educational systems has not kept abreast of the expanding technical and professional demands of the economies.

The swiftness of technical change requires not only new and increased amounts of technical knowledge but also great flexibility regarding its transmission. In a relatively static society, learning is comparatively fixed and limited. The transmission of knowledge from one generation to the next is thus a comparatively easy task. Under conditions of technological and social change, schools must adapt quickly to new demands. The rapid obsolescence of skills and knowledge, moreover, means that learning and formal instruction must take place during much of one's lifetime and cannot be limited merely to childhood and adolescence.

Demographic change. A second major influence on contemporary education is the nature of demographic change, more particularly the rate of population growth. It is obvious that the structure, size, and growth of a society's population directly affects education. If, for example, population is growing at a rate more rapid than the rate of expansion of educational plants and personnel, the enrollment ratios, literacy rates, median-school years completed, and other measures of educational attainment will tend to fall.

Population growth and education

The effects of population growth on education, though visible in most parts of the world, are most dramatic in the less developed nations. In Latin America, for example, the average population growth rate is more than 3 percent a year, while that in South Asia exceeds 2.6 percent. Due to improved health measures that have reduced infant mortality, moreover, the youth population is growing more rapidly than the population as a whole. Thus, merely to maintain, in the coming years, the present proportion of children and youth in school will require great efforts, particularly on the part of the nations of Asia and Latin America. Further, even if in the near future birth-rates are forced to drop, little immediate relief can be expected because the children who will attend the elementary and secondary schools for the next several years have already been born.

Rising expectations. Quantitative changes in education are also being strongly influenced by the phenomenon of increased social demand—a phenomenon widespread in contemporary societies. Rising expectations among the parents and the youth of less developed societies, stimulated by glimpses of the wealthier outside world or by the privileges of the small, educated groups at home, have given rise to an intense desire for education. In the more advanced societies, the expanded social demand for education may be traced to the growth in the affluence of large segments of the population and to the increased propensity of the privileged and less privileged alike to view education as a requisite for respectable status and a good job.

Egalitarianism

Associated with the increased demand for education is an egalitarian overtone—at times a dominant force, at times merely a subtle pressure. In much of Europe and North America, for example, many of the "educational reforms" have been a direct outgrowth of social reform aimed at extending social opportunities. The possibilities for status and success in the society are viewed as being closely related to the kind and level of education attained. This realization has led many nations, particularly the more industrialized ones, to seek to promote equality in educational opportunity. At a minimum, equity in schooling has come to mean an extended period of participation by all children and youth in a common educational culture.

Need for planning. The rapidity of technological and social change, the growing faith in man's ability to predict the consequences of such change, and the desire to make optimum use of limited human and natural resources have given great stimulus to planning in education. As in national planning, views of educational planning may be placed along a continuum. At one end of the continuum lies educational planning as the process of fulfilling explicit manpower targets established by the central government, and at the other end of the continuum

lies educational planning as a system of loose guidance to facilitate the individual's vocational and other choices. Although there remains a certain vagueness about the term educational planning, it may be distinguished from educational administration by (1) comprehensiveness of coverage, (2) a longer time perspective, and (3) more attention to economic and social supports and constraints on education.

The major elements taken into consideration in educational planning may be classified under four categories: (1) population change, (2) economic growth and economic development, (3) social demand, and (4) social equity. All nations do not give these elements equal emphasis. Many of the less developed nations concerned with limited resources are most concerned with adapting education to satisfy the needs of economic development for new knowledge and skills. The more industrialized nations, on the other hand, view as priorities the desires of all parents and students for more education and the demand among disadvantaged groups for greater equality of educational opportunity. Regardless of preferences, however, the increased interest in educational planning represents a growing optimism that the educational system is manipulable and manageable. Such confidence has led some reformers to use the educational system as a means of achieving planned economic and social change.

In summary, the most visible educational changes in the 20th century are (1) the diffusion and expansion of schooling and (2) the increasingly significant role of formal education in social and economic change. Technological change has demanded ever increasing levels of education for the population. Social pressure has resulted in mass education becoming at least the long-range goal of every contemporary nation. Although in the poorer nations universal schooling is as yet an unfulfilled goal, rudimentary schooling is being offered to large numbers of young children who in earlier periods went unschooled. In the more advanced nations of western Europe, and in Australia, Japan, Canada, and the United States nearly all children are provided free education at least through the lower grades of secondary school. In these nations literacy approaches 100 percent.

SCHOOL OBJECTIVES, CURRICULA, AND TEACHING METHODS

In most of the less developed nations the formal education of the majority of citizens ends after a few years of elementary education. It has been estimated that half the world's adult population remains illiterate despite the many continuing national and international efforts to cope with this problem. Only in the more industrialized nations has some portion of secondary education customarily become part of the common schooling of the majority of citizens.

Basic and elementary education. Despite the many cultural and political differences among nations, the objectives and curriculum at least of elementary education tend to be similar. Nearly all nations are officially committed to mass education, which is viewed as eventually including a full elementary education for all. An increasing agreement may therefore be found among nations to the effect that preparation for citizenship is one of the major objectives of elementary education. In terms of curriculum this objective suggests an emphasis on language competence, arithmetic skills, and basic social studies and science. The proportion of school time devoted to each of these areas may vary from nation to nation, but taken as a whole they typically comprise the bulk of the curriculum.

Some observers viewing the less developed nations have suggested that such a curriculum does not cover enough ground and that community or vocational skills should be included. Many innovations in this direction have been attempted. Local crafts are taught in the basic schools of India, for example; agriculture has been introduced in some of the primary schools of Uganda, Kenya, and Tanzania; and introductory skills in wood and metal working are included in the curriculum of mainland China. The specific reasons for teaching hand skills in the elementary school vary from nation to nation. In a few nations such teaching is viewed as providing vocational or prevocational skills; in some nations it is hoped that the products of the children's work will be marketable and hence defray the expenses of schooling; and in still other nations handwork is seen as a way of instilling an appreciation for labour. Objections have been voiced to these changes, however, by some parents and students who fear that the introduction of "practical" subjects may lessen the possibility of entrance to secondary schools—a widely held pupil aspiration.

Experiments in elementary curricula and methods

Perhaps more experimentation and innovation in curriculum and teaching methods have taken place at the elementary level than in secondary education. In the more progressive schools throughout the world attempts are being made to synthesize subjects previously taught separately. Examples of this are efforts to combine reading with literature and history with geography. In North America and western Europe, innovations such as team teaching, the use of more teachers' aides or clerks, and the establishment of ungraded schools have been tried. Most significant and pervasive, however, has been the widespread and growing acceptance of the principle that elementary education should focus on activity and experience as well as on subject matter. This principle as yet is reflected only in some of the elementary schools of a few nations but may well lead to a worldwide movement involving more informality in the learning environment, more student-initiated projects, and a greater variety in the content of elementary schooling.

Although not in any way opposed to the trend noted above, one remarkable similarity may be noted among the world's educational systems in the general sequence of learning. Elementary schools in most nations introduce the child first to the local environment and then systematically bring him into contact with larger environments. The way in which this is done, the relative emphasis on factual knowledge, the relative attention to the concept of culture, and the degree of pupil involvement in the design of the learning experiences may vary greatly from nation to nation or even between educational systems. Nevertheless, the principle that a child's learning should move from the immediate and familiar to the distant and unfamiliar appears to be widely accepted.

A special comment should be made on the Communist educational model, which offers somewhat unique objectives and curriculum. Although most nations of the world, in principle at least, share a concern for mass education, the fervour of Communist nations for infusing ideology and skills throughout all age groups, young and old, is rarely equalled. A dramatic case in point is offered by the example of mainland China, which claims to have moved the literacy rate of the Chinese people from 20 percent to approximately 90 percent between 1950 and 1970. In China, and also in Cuba, the curriculum even from the earliest grades is also linked to work, more particularly to manual labour. In addition to the usual reading, writing, arithmetic, and ideological lessons, elementary school children tend school gardens, care for the school buildings, and construct and repair simple furniture and home devices. Older children are involved in more complicated work projects in the school and community. Older children are, moreover, likely to spend their vacation working in farming areas—at the same time bringing literacy training to rural adults. To further enhance the status of work, teachers may be required to participate in harvests, and skilled farmers and craftsmen may in turn be used in the school to teach their respective skills.

Great variation then exists intranationally and internationally regarding such characteristics as the degree of stress on textbook content, the extent of teacher domination of classroom learning, and the relation between teachers and pupils. Some of these distinctions will be further elaborated later when considering a classification of types of schooling.

Secondary education. It is at the secondary level that the greatest contrast in objectives and curricula may be

found. Secondary schooling tends to be selective and therefore, with some exceptions, is not viewed as a part of citizenship preparation. Rather, secondary education typically is viewed as preparation for middle-level vocational and technical positions or as intellectual training for admittance to higher education. The *Gymnasium* of Germany, the *lycée* of France, and the grammar school of England, with their tradition of high-quality literary and scientific preparation, have greatly influenced the patterns of secondary education in Asia, Latin America, and Africa.

Subject-matter organization

Curriculum in general secondary education is strongly influenced by the academic disciplines, and most subjects offered in secondary schools could be easily classified under the humanities, social sciences, and natural sciences. Somewhat less attention is typically given to the fine arts, music, and physical education. There is, however, great variation among nations in the level of specialization required of students. The academic curriculum of the secondary schools in several European nations, for example, demands rigorous and extensive study in the chosen course. Scholarship is traditionally defined as competence within prescribed subject-matter boundaries. Teachers are viewed, and view themselves, as specialized scholars and thus have more in common with university professors than elementary schoolteachers.

The same orientation, if not the same level of academic accomplishment, may be said to exist in much of Latin America, Asia, and Africa. In Latin America, for example, most general secondary schools are called *liceos* or *colegios* and offer academic programs similar in nature to, although somewhat briefer in length than, those found in the general secondary schools of western Europe. One exception to this pattern may be found in Chile, which has lengthened the period of elementary schooling by moving the seventh and eighth grade from the secondary school to elementary education. The similarity between this reform and those attempts in western Europe to prolong the period of common education is quite apparent.

The model of secondary education that contrasts most strikingly with this pattern again is to be seen in the communist nations. The polytechnical concept of secondary education as found in the U.S.S.R. has already been mentioned. A more drastic attempt to link instruction and work is found in China, where a respect for labour and a suspicion of the humanities and empirical social sciences has led to a rejection of the traditional academic model. Most of the secondary school population in China attends part-time, vocationally-oriented middle schools. Secondary school students may operate small factories and experimental farms producing a variety of goods and foods for the nation. Even the general middle schools, which are the most academic in orientation, expect all students to involve themselves regularly in approved work projects.

Changing views of "intellectual" and "academic" education

Recent years have seen other modifications and occasionally the outright rejection of the intellectual objective of secondary education. In the United States, secondary education increasingly is becoming part of common education and therefore serves general citizenship objectives as well as preparation for advanced education. In western Europe, at least the lower years of secondary schooling are seen in much the same light. Furthermore, in the less industrialized nations there is dissatisfaction with the seeming remoteness of academic curricula in the secondary schools. Here proposals have been forthcoming to streamline curriculum by eliminating some of its historical and classical content and to define more broadly "intellectual" and "academic" to include experiences directly related to employment.

In the industrialized nations the direction of secondary education is clearly toward a unified pattern, which will represent at least a partial realization of the objectives of the European educators who for years have promoted the idea of *école unique* and *Einheitsschule*. The United States and Sweden have pioneered in promoting comprehensive secondary schools, where all students and all curricula would, in effect, be under one roof. Other European nations are experimenting with their own variants of comprehensive schooling. Alternatives to this approach may be found, for example, in the French *cycle d'orientation*, which provides for students, in their early secondary schooling, a guidance and diagnostic period before they must select the path for further education.

Methodology. Teaching techniques and teaching styles reflect variations in objectives and curriculum. The American educator Lawrence Thomas, in classifying types of schooling, has suggested the following categories: (1) memorizing, (2) training, (3) developing intellect, and (4) problem solving.

These types may be viewed as characterizing, or at least having implications for, the entire educational process. They are perhaps most useful, however, in offering perspective on methods of instruction and the selection and use of curricular materials.

Following the interpretation of Thomas, schooling oriented toward memorizing tends to place heavy reliance on this sequence: lecture–recitation–examination. The threat of failure is the chief source of motivation, and all learning activities are dominated by the teacher. The academic schools in many of the developing nations appear to fit this pattern. Schooling characterized as training usually implies that the teacher serves as a model, conducts drill, and supervises assignments or the exercise of prescribed skills. Most secondary vocational schools reflect this pattern. Schooling for developing the intellect features the teacher dominating the learning process through lecturing, presenting demonstrations, questioning the student about his ideas, and in turn inviting questions and debate. The student is expected to analyze predefined problems. The *Gymnasium*, *lycée*, and grammar schools of Europe are good examples of this pattern. Schooling as problem solving emphasizes experiences that provide students with the skills and attitudes to locate, define, and analyze problems found in school materials or in community life. Extra class activities, such as student clubs and student government, are considered vital if they serve to reinforce problem-solving skills. A few of the elementary schools of the United States and England illustrate this approach, as do experimental programs in science teaching in a number of nations.

Other classifications could be devised for the various methods of instruction employed in the classrooms of elementary and secondary schools throughout the world. Within the same school, different teachers or even the same teacher might employ a variety of teaching techniques. Nevertheless, the four types described serve well as frames of reference for understanding what is expected of children and youth in their schooling and, to some extent, in later life.

Summary. There has been a multiplication of objectives for elementary and secondary education in contemporary times. In addition to preparing pupils for advanced education, elementary and secondary schools increasingly provide a general education for a large proportion of the world's future citizens. These schools also provide youth with a growing array of vocational skills as the educational systems continually seek a degree of congruence with the needs of employment. Clearly these objectives may, at times, be in conflict. Institutions of higher education want only students who have demonstrated a high level of academic ability; the labour market seeks the most skilled or the most trainable young persons. Thus, regardless of the principle of equal opportunity in education, selection remains an important characteristic of the schools.

Although the general objective of providing a secondary education for all youth has not been fully achieved in any society, the wider participation of the various social strata is slowly being accomplished. How a student body representing a spectrum of social backgrounds and measured aptitudes may affect the design of curriculum and teaching methods is not, however, entirely clear. The concept of the curriculum not as a fixed body of traditional knowledge but as a changing set of experiences, skills, knowledge and values is achieving popularity. The view

of the teacher not as the fount of specialized knowledge but as a companion in the exciting but often confusing adventure of learning is gaining many adherents but is not yet widely reflected in elementary and secondary schools throughout the world.

CURRENT AND EMERGENT TRENDS

Viewed globally, several of the factors already described as having influenced the pattern of education earlier in the century continue to be potent determinants of educational change. One factor is represented by the expansion of enrollments resulting from population growth and increased public desire for the fruits of schooling. A second factor, most apparent in the industrialized societies but visible in most other nations, is the social pressure for equalizing educational opportunity between social classes, ethnic and racial groups, rural and urban populations, and the sexes. Planning through the use of new managerial techniques, systems analyses, and operations research constitutes a third factor. A fourth factor, arising partly in response to the three already mentioned and partly a product of educational theory and research, involves curriculum and pedagogical changes. Related to such changes but representing a fifth factor of a different magnitude is the dissatisfaction voiced by a few social critics with any of the existing models of formal education and the call for the initiation of new structures, programs, and financial arrangements for education.

There is little to add to earlier comments on the quantitative effects of population growth on elementary and secondary schooling. It should be noted, however, that education as a means of population control is receiving increased attention. Extraschool instruction in fertility control appears to be successful in several of the developing nations, for example, particularly those with relatively high levels of literacy. This has led to recommendations that in nations with rapid population growth fertility education should become an important part of the curriculum for girls in elementary and secondary schools.

Efforts toward social equity

Trying to create an educational system to satisfy the goals of social equity continues to cause difficulty. The complexity of the idea of equality of opportunity is, perhaps, only now being fully understood. As applied to the educational system, for example, should equality mean (1) providing a free education up to a certain level; (2) providing a common curriculum for all children; (3) providing equivalent inputs in terms of per-pupil expenditure, school plant, and the like; or (4) providing a racial and ethnic composition in the schools proportionate to that found in the greater society? Until recently it was widely assumed that expansion of enrollment and extension of the period of compulsory education would automatically reduce differentials in amount of schooling associated with social classes or with racial or ethnic groups. Experience has shown, however, that at least up to a point, educational expansion benefits the middle and upper classes much more than it does the lower classes or disadvantaged social groups.

As the definitions of equity vary, so will the ameliorative policies. Current knowledge is not yet adequate, however, to design programs to meet many of the possible objectives of equity. Many nations still hope that an increase in the rate of school participation of poorer segments of the population can be achieved largely through curriculum and structural changes in the schools. A few nations—the best example is perhaps the United States—have initiated large-scale efforts at extraschool compensatory education for certain of the more disadvantaged elements of the population. Work with preschool children from poor families in the United States suggests early instruction in conceptual and language skills may somewhat improve the ability of these children to cope successfully with the skills and knowledge taught in elementary schools. Unfortunately, studies appear to indicate that unless extraschool compensatory education is continued, paralleling regular schooling, the relative academic advantage of the children from the more privileged social groups is quickly reasserted.

In terms of planning and evaluating education for an assumed or desired future, some rather formidable tools are being developed. Economic models and high-speed computers allow intricate simulation models to be employed and permit the examination of large quantities of data regarding educational inputs and desired outputs. The utility of these and other managerial and analytic techniques is hampered, however, by a lack of insight into the dynamics of educational systems. It is difficult, for instance, to plan for certain outputs or to evaluate the consequences of a particular educational policy without more understanding of the teaching–learning process, the effects on learning of different administrative styles, the potentials and limitations of instructional technology, and the functioning of the peer group. Although progress is being made in these directions, no one can yet predict the results on the learner of a given combination of inputs in the educational system.

Efforts toward new curricula and methods

Although innovations in curriculum and in teaching techniques are too numerous to describe in detail, a few proposals can be identified that suggest the general directions of change. One of the newer approaches in curriculum and in instructional techniques has been called the inquiry or discipline approach. In this approach the function of instruction is to help the pupil develop several modes or styles of inquiry rather than acquire a store of information per se. The proponents of this approach argue that, given the rate of increase in knowledge, it is extremely difficult for a teacher to attempt continually to update content or information; moreover, the explosion of knowledge creates an impossible burden of subject matter on the student. Thus, instead of teaching the discipline directly, some argue that the methods or style of inquiry of the discipline should be taught to the student. Students, in effect, would learn science by acquiring the scientific method, would learn history through the historical method, and so on. This approach has acquired many supporters, particularly among the teachers of mathematics and the sciences in the United States. One of the major advantages of focussing on the structure and methodology of the discipline lies in the ability of pupils to develop skills of analyzing and explaining phenomena. Limitations, however, are significant: to teach the methods of scientific inquiry that currently exist may frustrate a person's ability to learn new methods as they arise. Further, a focus on method and style of inquiry does not deal directly with the real substantive problems and issues of life.

It is this latter point that conflicts with the demands of young radicals in many parts of the world. The call by youth for relevance in education has most dramatically affected the universities but nevertheless is being heard at lower educational levels. In the United States, for example, many young blacks are demanding programs of black studies in the secondary schools as well as in the colleges. At every level the more vocal pupils are asking the schools to give greater attention to social issues. But the radicals are not seeking rational, disciplined analyses of contemporary problems. Such formal study will, many of them argue, only lead to social paralysis. Education to be relevant must be personal and intuitive and must deeply involve the student.

Whether or not a disciplinary approach is used in the selection and study of subject matter, the trend is toward more active student involvement in the learning process. The idea that children and youth must engage in the act of discovering knowledge for themselves is gaining support among educators and teachers.

Trends toward newer technologies

The idea of discovery may be related to the more general trend toward individualizing and personalizing instruction. Techniques such as team teaching, flexible scheduling, and the provision of individualized instructional technology (headphones for language tapes, programmed learning, desk computers, and so forth) support this trend. Yet, the innovations in curriculum and teaching methods being described have not been widely implemented even in the wealthier nations. High costs, inadequate teacher preparation, and lack of appropriate ad-

ministrative leadership are among the many obstacles to implementation. Many educators and teachers, moreover, remain committed to schooling as an accumulation of a rather clearly defined body of knowledge, and such persons are unconvinced that the newer instructional approaches do indeed lead to the attainment of such an objective.

Improved educational technology may lead to greater efficiency in achieving the objectives of elementary and secondary education. Advocates of a greater use of technology in the schools point out that educational systems make less use of media, computers, and other applications of technology than other sectors of society. Advocates point out that, far from being a dehumanizing force, technology can free the teacher from the more routinized work. Through instructional technology, pupils proceeding at an individual rate may acquire the basic skills, diagnose their own difficulties, and evaluate their own progress. The teacher can then become a coordinator of learning activities rather than a distributor of knowledge. Through the wise use of technology, furthermore, the teacher can be provided the opportunity to concentrate on the more advanced intellectual, aesthetic, and ethical objectives.

In terms of the final trend—namely, the consideration of alternatives to formal education—the reasons for dissatisfaction with present structures and programs are relatively clear; the nature of the needed substitutes, however, is more difficult to discern. By way of illustration, some U.S. administrators and economists concerned both with rising educational expenditures and with the general lack of efficiency in the educational process have argued that vocational and professional education, and perhaps all of formal schooling, should become, in effect, a private business. Education assumed to have high community benefits might be financed by the government, but other education would be privately financed. Thus, vouchers would be distributed to parents and children based on the cost per child of that amount and kind of education deemed beneficial to society. Critics of this proposal have pointed out (1) the difficulty, if not impossibility, of separating out those aspects of education that have primarily societal effects and (2) the likelihood that such an arrangement would lead to even greater racial and social-class segregation. In any case, all schemes for the direct purchase of professional services for education have thus far largely remained matters of academic discussion.

In western Europe and North America a few drastic innovations in schooling have moved from the drawing board into operation. These vary greatly in organization, curriculum, and teaching methods but tend in the direction of creating a very permissive environment with maximum opportunity for children to experience the world about them in their own way. In the less developed nations the dissatisfaction of political leaders with current educational arrangements generally lies less with the possible constraints on individual expression or even on individual creativity than with the failure of educational investment to result in rapid economic growth. As a result, some nations are examining the agressive policy of China in linking formal schooling with productive work. Although ideological differences may keep many nations from adopting the Chinese educational model, work-study and study-work programs are on the increase. Particularly in the less industrialized nations, the educational systems tend to be poorly adjusted to the changing needs of employment. Consequently, there is an increase in experimental programs for training youth within business and industry and an increase in arrangements linking industry and the educational system in partnership. The point of view appears to be growing that, although elementary and secondary education may provide certain prevocational skills and possibly certain generalized vocational skills, specific occupational training best takes place on the job.

The future is likely to bring numerous and often radical experimentation and innovation in elementary and secondary education. Some nations and communities may relegate a number of the current educational functions to other agencies. In some cases, for example, the responsibility for the teaching of certain skills may be removed from the schools and given to the place of employment, the peer group, or specified tutors. In any case, forceful steps will most assuredly be taken in many nations to ensure more equitable representation of the less privileged social groups in the educational process. And, regardless of which arrangement is chosen, the notions of relevance, efficiency, and flexibility will serve as major guides.

BIBLIOGRAPHY. Among the recent standard descriptive works on comparative education treating elementary and secondary education are J.F. CRAMER and G.S. BROWNE, *Contemporary Education*, 2nd ed. (1965); E.J. KING, *Other Schools and Ours*, 3rd ed. (1967); and I.N. THUT and D. ADAMS, *Patterns of Education in Contemporary Societies* (1964).

Since most scholars in comparative education specialize in one or more geo-cultural areas, the resulting studies, while often not explicitly comparative, offer some of the best factual descriptions and some of the more penetrating insights into education. These publications range in focus from the Handley factual country reviews sponsored by the U.S. OFFICE OF EDUCATION to the more elaborate field investigations represented in P.J. FOSTER, *Education and Social Change in Ghana* (1965); and A.M. KAZAMIAS, *Education and the Quest for Modernity in Turkey* (1966). The series on "Education in Europe," prepared by the Council for Cultural Co-operation of the Council of Europe, provides a useful guide to the structure and curriculum of elementary and secondary education.

Concern for more meaningful comparisons of education across cultures has given rise to attention to methodology. The first book in the field devoted entirely to method was G.Z.F. BEREDAY, *Comparative Method in Education* (1964). Recent writings in comparative education increasingly have emphasized the empirical and social sciences. Examples of this trend are H.J. NOAH and M.A. ECKSTEIN, *Toward a Science of Comparative Education* (1969); and J. FISCHER (ed.), *The Social Sciences and the Comparative Study of Educational Systems* (1970).

Elements, Geochemical Distribution of

Knowledge of the geochemical distribution of elements involves elucidation of the relative and absolute abundances of the chemical elements in the Earth and in its various parts—the crust, interior, atmosphere, and hydrosphere. This comprises a major part of the science of geochemistry, which is the study of the distribution of the chemical elements in space and time and the laws governing this distribution (see GEOLOGICAL SCIENCES). Basic knowledge in this area was largely accumulated during the 19th century. The concept of a limited number of chemical elements had been established by 1800, and the appearance of the periodic table (*q.v.*), or system, in 1869 provided a new insight into the limitations on the number of elements. Concurrent with these advances in chemical understanding, from about 1850 onward there was a steadily increasing output of analytical data on the Earth's rocks, minerals, and waters, mainly from laboratories in Europe and North America. The output from North America was materially increased following the establishment of the United States Geological Survey in 1879 and the appointment of Frank W. Clarke as chief chemist in 1884.

Basic work of Clarke and Goldschmidt

Clarke's name will always be linked with the study of the geochemical distribution of the elements—indeed, the term clarke was proposed as the unit for the average percentage of an element in the Earth's crust by Soviet scientists and has been generally adopted. In 1889 Clarke wrote the first of his many publications on the geochemical distribution of the elements. He assembled many chemical analyses of rocks from different continents, calculated average values, and showed that the overall chemical compositions of continental areas are remarkably similar. By combining these averages he obtained values for the abundances of the commoner elements in the continental crust of the Earth, values that have not been materially changed in spite of the vast increase of available data since that time. He also estimated abun-

dances for many of the less common elements; these estimates were based in many instances on very limited and imprecise data and subsequently have been improved.

A further development of great significance was the assemblage of comprehensive data on the abundances of individual elements in terrestrial materials and in the cosmos (based on solar and meteorite abundances) by the Norwegian geochemist Victor Moritz Goldschmidt during the 1930s. Goldschmidt's tables provided the basis for modern research on the geochemical distribution of the elements, and his compilation of data on cosmic abundances was the key to later theories on element synthesis in stars and supernovae.

Goldschmidt also contributed to the understanding of elemental distribution within the Earth through his geochemical classification of the elements into lithophile, siderophile, chalcophile, and atmophile. Lithophile elements are those with a strong affinity for oxygen; they are concentrated in the crust or lithosphere as silicate and oxide minerals. Siderophile elements are principally metals that alloy readily with iron; Goldschmidt explained their scarcity in the Earth's crust by their concentration in the nickel–iron core (the siderosphere). Chalcophile elements are those with strong affinity for sulfur; they occur mainly as sulfides. And atmophile elements are gases, such as nitrogen, argon, and other rare gases, which are unreactive and hence accumulate in the atmosphere. (Goldschmidt also proposed a group of biophile elements, for those that concentrate in living matter—essentially carbon, hydrogen, oxygen, nitrogen, sulfur, and phosphorus.)

This article treats the distribution of chemical elements in the Earth's core, mantle, and crust, with specific reference to the principal groups of rocks, ore deposits, mineral fuels, and soils. It also covers the geochemical distribution of elements in the Earth's atmosphere and hydrosphere. The significance of the data on element abundances that are presented is enhanced by inclusion of information on the cosmic or absolute abundance of elements at the outset. For further information on the chemical composition of extraterrestrial bodies, see MOON; METEORITES; and articles on the individual planets. For additional detail on the Earth's interior, see EARTH, STRUCTURE AND COMPOSITION OF. And see the articles OCEANS AND SEAS; OCEANS, DEVELOPMENT OF; FRESHWATER, GEOCHEMICAL PROPERTIES OF; ATMOSPHERE; and ATMOSPHERE, DEVELOPMENT OF, for discussion of the chemistry and chemical processes of the Earth's shells of air and water.

ABSOLUTE OR COSMIC ABUNDANCES OF THE ELEMENTS

In order to understand the processes whereby elements are distributed or concentrated in specific environments or regions, it is necessary to have some knowledge of what may be called their absolute abundances, namely, their overall abundances within the entire universe. Such knowledge cannot be obtained from the analyses of terrestrial rocks. The rocks of the Earth's crust are extremely varied in composition, and they represent the end-products of a long series of chemical differentiation processes from the primordial matter that aggregated to form the Earth. Even this primordial matter, if it could be sampled, would not give the absolute abundances of the chemical elements; it already was enormously depleted in hydrogen and helium with reference to the universe as a whole. The best source of information in this regard is the composition of the Sun, other stars, and the Moon.

The Sun and other stars. Goldschmidt derived his table of absolute abundances from a careful evaluation of spectrographic data (emitted light that is correlative with chemical composition) on the Sun and other stars, combined with analyses of meteorites, which he recognized as probably being a good average sample of the nonvolatile (nongaseous) matter of the solar system. More recent work has largely confirmed these premises; in particular, it has been shown that elemental abundances in a specific group of meteorites, called the Type I carbonaceous chondrites, are in excellent agreement with abundances determined in the Sun. It is important to note that more than 99 percent of the mass of the Sun —and probably of the universe as a whole—consists of hydrogen and helium.

When the cosmic abundances of the elements are plotted against their atomic numbers (Figure 1), a number of significant relationships can be observed. The abundances show a rapid decrease for elements of lower atomic number (to about atomic number 30), followed

From L.H. Ahrens, *Distribution of the Elements in Our Planet* (1965); McGraw Hill Book Co.

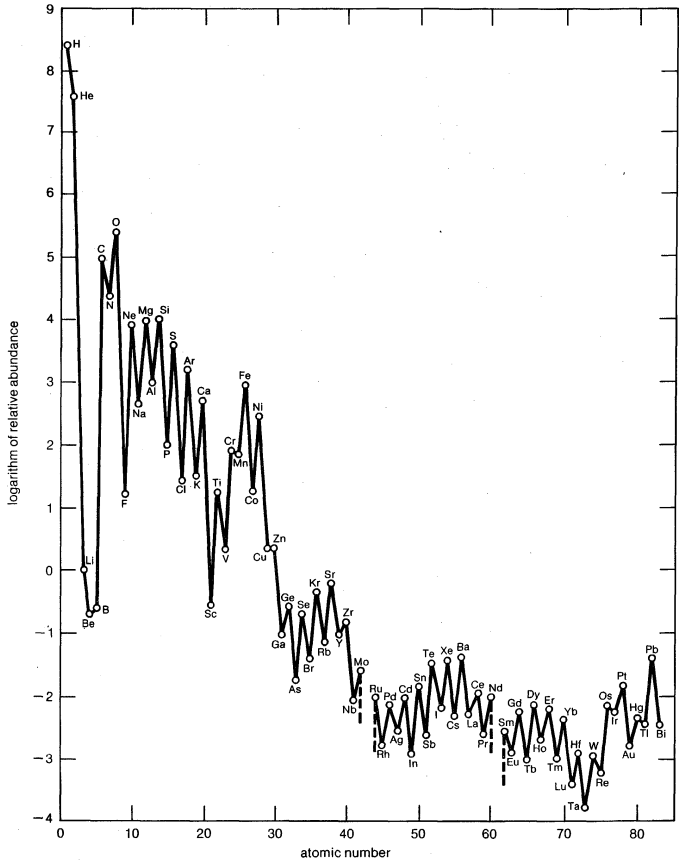

Figure 1: Relative abundances of the elements.

by fairly uniform abundances for the heavier elements. Elements of even atomic number are more abundant than their neighbours of odd atomic number on either side; this regularity was first observed in analyses of terrestrial rocks in 1914 and 1917. Only ten elements—hydrogen, helium, carbon, nitrogen, oxygen, neon, magnesium, silicon, sulfur, and iron, all of which have atomic numbers less than 27—show appreciable abundance; of these, hydrogen and helium far outweigh the other 8. These relationships indicate that the absolute abundances of the elements depend on nuclear rather than chemical properties and are related to the inherent stability of their atoms. On this basis the decrease in relative abundances with increasing nuclear complexity can readily be explained. The absence of elements 43, 61, 85, and 87 from the Earth is due to an almost complete instability of any nuclear arrangement for these atomic numbers (note that they are all odd-numbered). The remarkably low abundances of lithium, beryllium, and boron among the low-numbered elements can be explained by the ready disintegration of atoms of these elements under bombardment by high-energy particles, such as takes place in the Sun and other stars.

Element abundances on the Moon. Until recently, more was known about element abundances in distant stars than in the Earth's nearest neighbour, the Moon. The lunar landings have provided samples that have been intensively analyzed in many laboratories throughout the world. The data for the Apollo 11 material, collected in

the Sea of Tranquility (Mare Tranquillitatis), are given in Table 1. Analyses of Apollo 12 collections are similar for most of the elements. Comparison of the analytical data with those for carbonaceous chondrites (a type of meteorite that provides a good average sample of nonvolatile solar system material) shows that the lunar material has undergone marked geochemical fractionation (segregation of elements). Lithophile elements, those with an affinity for oxygen, are markedly enriched in the lunar material, whereas chalcophile and siderophile elements (with affinities for sulfur and iron) are markedly depleted. Although the lunar data have been obtained from only a few sites, they suggest that the material of the Moon has undergone a complex geochemical history.

TERRESTRIAL DISTRIBUTION OF THE ELEMENTS

The study of earthquake waves passing through the body of the Earth has shown that the interior is not uniform;

it consists of distinct shells separated by concentric discontinuities at which the velocities of the passing waves change. The two major discontinuities that are universally recognized are the Mohorovičić Discontinuity, which divides the Earth's crust from its underlying mantle, and the Wiechert–Gutenberg Discontinuity, which separates the mantle from the core. The latter discontinuity exists at a depth of 2,900 kilometres (1,800 miles); it is marked by a sudden increase in density, from about 5.7 at the base of the mantle to 9.7 at the top of the core. The only reasonable interpretation of this discontinuity is that the mantle consists of silicates and oxides of the common elements (largely magnesium and iron), and the core consists of metallic iron alloyed with minor amounts of other elements (analogous to the nickel-iron in meteorites). The Mohorovičić Discontinuity varies in depth from place to place; it averages about 33 kilometres (20 miles) below the continents and about 8 kilometres (5 miles) below the bottom of the deep oceans. It too is marked by a density increase from crust to mantle—a comparatively small one, from about 3 to 3.3.

To the three spherical divisions—crust, mantle, and core—two more should be added: the hydrosphere, which is the discontinuous shell of fresh and salt water, on and within the crust; and the atmosphere, the ocean of air that surrounds the Earth, gradually thinning into the vacuum of outer space. The principal characteristics of these "geospheres" are set forth in Table 2.

Table 2: Volume and Masses of Earth Shells

	thickness (km)	volume ($\times 10^{27}$ cm^3)	mean density (g/cm^3)	mass ($\times 10^{27}$ g)	mass (percent)

Crust	20 (mean)	0.010	2.8	0.029	0.5
Mantle	2,880	0.897	4.5	4.010	67.1
Core	3,471	0.175	11.0	1.936	32.4
Whole Earth	6,371	1.083	5.52	5.976	100.00

Correlation with density and other physical properties

The Earth's core. The evidence for the composition of the core is all indirect because no means have yet been devised for directly sampling the deep interior of the Earth. The moment of inertia of the Earth indicates that there is a concentration of mass around the centre, and seismic data have shown that below the Wiechert–Gutenberg Discontinuity the density of the material is high, ranging upwards from 9.7. The only heavy element with high cosmic abundance is iron, and because an iron–nickel alloy is an important meteorite component, it is reasonable to conclude that the Earth's core consists largely of metallic iron with a minor admixture of other elements. This conclusion is supported by geophysical evidence that indicates that the mean atomic number of the material of the core is about 22. The atomic number of iron is 26, so this implies that the core also contains an admixture of elements of lower atomic number. Sulfur, with atomic number 16, and carbon, with atomic number 6, are relatively abundant in meteoritic matter, and the presence of minor amounts of these elements in the core would effectively reduce the mean atomic number. Some authorities have advocated silicon (atomic number 14) as the major alloying component in the core, but this seems less likely; if silicon were the sole alloying element, then the core would have to contain more than 30 percent silicon in order to reduce its mean atomic number to 22. In addition, free silicon requires extremely reducing conditions (lack of oxygen), and the presence of ferrous iron in the mantle is inconsistent with this requirement.

With present information it is not possible to give definite figures for the abundances of the elements in the Earth's core. It is certainly made up largely of metallic iron, however, probably with some nickel, a little cobalt, and appreciable amounts of such lighter elements as carbon and sulfur.

The Earth's mantle. The mantle comprises that part of the Earth between the Mohorovičić and the Wiechert–Gutenberg discontinuities. It makes up 83 percent of the volume of the Earth and 67 percent of its mass and is thus of decisive importance in determining the bulk composition of the planet. In estimating elemental abundances in the mantle, however, the same difficulty as with the core arises: direct sampling is not feasible. Much more geophysical data are available for the mantle, however, and some volcanic eruptions have brought rock fragments to the surface that have certainly been derived from this zone. The most remarkable of these materials are the diamond-bearing inclusions found in the famous pipes, or volcanic necks, that are mined in South Africa and Siberia. The presence of diamond, the high-pressure form of carbon, implies a depth of origin of at least 100 kilometres, but these inclusions are rare. The common type of mantle-derived inclusion is peridotite, a silicate rock consisting largely of olivine, $(Mg,Fe)_2SiO_4$, with minor amounts of orthopyroxene, $(Mg,Fe)SiO_3$, and diopside, $CaMg(Si_2O_6)$.

Implications of the occurrences of diamond

Geophysical information indicates that below a depth of about 1,000 kilometres the mantle behaves as an essentially homogeneous material, but above this level its physical properties are more varied, and there is evidence for second-order discontinuities. This region above 1,000 kilometres is frequently referred to as the upper mantle, and in recent years has been the object of a concentrated research effort by geologists and geophysicists all over the world. The significance of the upper mantle is that processes originating there have dramatic effects on the surface—in the form of volcanic eruptions and some earthquakes—and less dramatic but equally important effects within the crust, such as the introduction and concentration of some elements, possibly leading to the formation of ore deposits. Increased knowledge of the upper mantle thus has both scientific and economic appeal.

Geophysical data on the properties of the upper mantle suggest that it must consist essentially of magnesium-iron silicates, probably largely olivine in the region immediately below the crust. Olivine is not stable under very high pressures, however; it is converted to a different phase of about 10 percent higher density and with a structure like the mineral oxide spinel ($MgAl_2O_4$). This conversion would occur in the mantle at depths of around 400 kilometres, and a second-order discontinuity at that depth can plausibly be ascribed to this conversion. Pyroxenes also undergo transformations to phases of greater density at the high pressures within the mantle. Thus the mantle, although composed of material of familiar chemical composition, consists, in its lower part at least, of different minerals than those in the upper part.

Many estimates of the composition of the upper mantle have been made in recent years; some of these are presented in Table 3. On the whole, the similarities are more important than the differences. All agree that the principal components are oxides of silicon, magnesium, and iron. The differences are mainly in the minor components such as aluminum oxide, calcium oxide, and the alkalies, and are determined largely by theoretical considerations and the weight given to specific aspects of the geophysical and geochemical data.

Although fairly reliable estimates exist for the abundances of the major elements in the mantle, little is known of minor and trace elements. Knowledge of the crystal structure of possible mantle minerals indicates that many minor and trace elements will not be readily incorporated, however. They are therefore likely to concentrate in liquid material in the mantle and be carried upward in solution, eventually being transported into the crust. It is thus probable that the mantle is relatively depleted, and the crust relatively enriched, in minor and trace elements. This is certainly true for uranium and thorium, because the amount of these elements in the crust is almost sufficient to account for the total amount of heat flowing out of the Earth.

The Earth's crust. The crust is a comparatively thin shell on the surface of the Earth and makes up less than 1 percent of its total mass. Its geochemical significance is only marginally related to its bulk, however. It has been

subjected to extensive investigations, and it provides the raw materials on which civilization depends. It is the most diverse of the geospheres, being a complex mosaic of many rock types—igneous, sedimentary, and metamorphic—each with a wide variety of chemical and mineralogical compositions. The surface is veneered with soils, related in composition to the rocks from which they formed, but with important modifications because of the smaller grain size, the presence of organic matter, and an intricate complex of living organisms. Ultimately, man's welfare and indeed his survival depends on the wise utilization of the materials in the crust. Modern civilization has been erected upon the exploitation of fuels and ore deposits, which are simply geochemical concentrations of useful elements.

Igneous rocks. Clarke estimated that 95 percent of crustal rocks are of igneous origin (formed from molten silicate masses, or magmas). Sedimentary rocks occur as a thin veneer on an igneous or metamorphic basement, except where locally thickened in mountain belts. The primordial rocks of the crust must have been essentially igneous, and the first sedimentary rocks were derived from them by processes of weathering and erosion. Metamorphic rocks are formed from both sedimentary and igneous rocks by transformations due to heat and pressure at depth in the crust; unless very intense, these transformations do not totally obliterate the primary igneous or sedimentary features. Igneous rocks show a wide range of composition; the principal component, silica (SiO_2), ranges from about 35 percent to 80 percent among the commoner igneous rocks, and other components also show a wide variation. They thus illustrate some quite extensive geochemical fractionations of the elements, the fractionations that may have economic significance if they bring about the findings of workable ore deposits.

Geochemical distinction between oceanic and continental crust

In 1924 a comprehensive review of igneous rock composition based on compilation of over 5,000 superior analyses was published. This was in many respects the ultimate refinement of Clarke's initial review of 1889. It confirmed that the averages of analyses from different continental areas are essentially identical. It also revealed significant geochemical differences between the continental and oceanic crusts. The average of igneous rock analyses from the oceanic islands is notably lower in silica and alkalies, and higher in magnesium and calcium oxides, than the continental averages. This is simply a reflection of the fact that most oceanic islands, such as Hawaii, consist almost entirely of basalts (averaging about 50 percent silica), whereas continental areas include large granitic masses, with silica contents around 70 percent. In terms of volumes, igneous rocks consist predominantly of two great types, granitic and basaltic. The former essentially are confined to the continents and the latter occur in both continents and ocean basins. The other types of igneous rocks, while many and varied, are quantitatively insignificant and hardly affect the averages. Thus, for the major elements, the average of over 5,000 analyses of igneous rocks is not significantly different from the simple average of two individual rocks, a granite (G-1) and a basalt (W-1). This can be seen from Table 1, by comparing G-1 and W-1 values with those in the column headed "Earth's crust."

The figures for the specific granitic (G-1) and basaltic (W-1) rocks are included in Table 1 because they have been analyzed for practically all the elements in different geochemical laboratories throughout the world. The rock G-1 was a granite from Westerly, Rhode Island, and W-1 was a basaltic rock (specifically a diabase) from Centerville, Virginia. Several hundred pounds of each of these rocks were crushed to a fine powder in the laboratories of the U.S. Geological Survey and samples distributed to analytical laboratories throughout the world, in order to obtain as many analyses as possible. The results were then critically examined, and the figures given in Table 1 are considered to be the best available in terms of accuracy and precision. G-1 and W-1 are undoubtedly the most thoroughly analyzed rocks and now serve as basic geochemical standards. It must be borne in mind that they are individual rocks, however, and cannot be considered to be averages of all granites and all basalts. Indeed, it is clear that G-1 is unusually rich in some trace elements (*e.g.*, thorium).

The eight principal components of the crust

Perhaps the most significant feature of the composition of the earth's crust is that it is dominated by comparatively few elements. Only eight—oxygen, silicon, aluminum, iron, calcium, magnesium, sodium, and potassium—are present in amounts greater than 1 percent, and these eight make up almost 99 percent of the whole. Of these, oxygen comprises almost 50 percent by weight. The dominance of oxygen is even more marked when weight percentages are converted to atomic percentages, as follows: oxygen (weight percentage, 46.6; atomic percentage, 62.2), silicon (27.7; 21.2), aluminum (8.13; 6.47), iron (5.00; 1.92), calcium (3.63; 1.94), magnesium (2.09; 1.84), sodium (2.83; 2.64), potassium (2.59; 1.42). This comparison, of course, merely emphasizes the fact that the crust consists almost entirely of oxygen compounds,

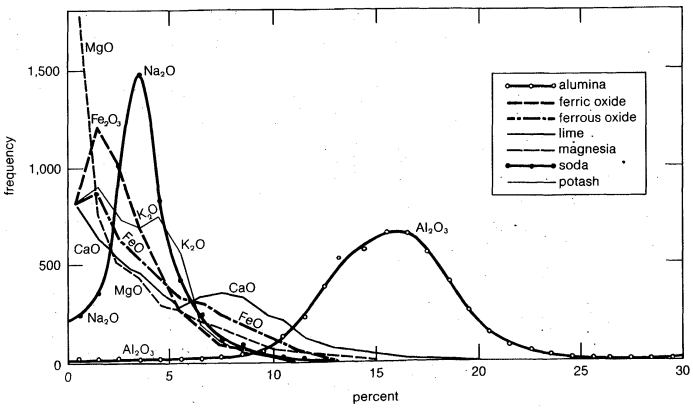

Figure 2: Frequency distribution of the major oxides in analyses of igneous rocks.

mostly silicates and aluminosilicates of iron, calcium, magnesium, and the alkali metals. As Goldschmidt remarked, the lithosphere may well be called the oxysphere. Clarke and his collaborators calculated that the average mineralogical composition of igneous rocks is: quartz 12.0%, feldspars 59.5%, pyroxene and hornblende 16.8%; biotite 3.8%, titanium minerals 1.5%, apatite 0.6%, and other accessory minerals 5.8%.

So far only the major elements have been discussed, those present in amounts greater than 1 percent by weight. Consideration must now be given to the minor and trace elements. The data are given in Table 1, and are presented diagramatically in Figure 3.

A cursory examination immediately reveals some intriguing features in the abundance pattern. The predominance of the even-numbered elements over the neighbouring odd-numbered ones is still apparent but not so regular as in the cosmic abundances. Chemical fractionations taking place during the evolution of igneous rocks from primordial matter have clearly modified this basic relationship. The odd–even relationship is most prominent in the rare-earth elements (atomic numbers 57–71), which are chemically so similar that they are little fractionated by geochemical processes.

Minor and trace elements

A particularly noteworthy feature is that some unfamiliar elements, such as rubidium, are relatively abundant, whereas others, such as most of the industrial metals except iron and aluminum, are actually of very low abundance. Thus boron, familiar to every housewife in the form of borax cleansers and boric-acid antiseptics, and well-known in the ancient world, is an element of extremely low abundance, much lower, for example, than zirconium, and lower even than hafnium, an element first discovered as late as 1923. Mercury, another element known to the ancient Greeks and Romans, is also of extremely low abundance. On the other hand, the so-called rare-earth elements are not extremely rare. Evidently one must make a clear distinction between abundance and availability. Some elements may be of low abundance but are readily available, because geochemical processes result in their concentration in specific deposits which can be commercially exploited. Other elements that are relatively abundant may be widely dispersed in small amounts and seldom or never occur in concentrated large deposits. A typical example is titanium, which is present in practically all igneous rocks in amounts ranging up to several percent, but which, in spite of its useful properties as a metal, is still not widely used. This is partly because of its dispersed nature and partly because of the technical difficulties in extracting the element from the minerals in which it occurs.

The distribution of minor and trace elements in igneous rocks, for those of lithophile affinity, is largely controlled by their ionic radii or size. Minor and trace elements with radii similar to those of major elements can substitute for these elements in the common minerals of the igneous rocks. The crystal structures of these minerals act as sorting mechanisms, accepting those atoms of appropriate size and rejecting others. Thus rubidium, with a radius of 1.47Å (one angstrom [Å] = 10^{-8} centimetres) is incorporated in potassium feldspar, $KAlSi_3O_8$, because its radius is close to that of potassium (1.33Å). The next-higher alkali element, cesium, with a considerably larger radius (1.67Å), is not accepted into the feldspar structure; it remains in the igneous liquid during the crystallization of the major minerals until its concentration increases to such an extent that it can form the independent mineral pollucite ($CsAlSi_2O_6$).

The factor of ionic size, coupled with geochemical affinity (lithophile, chalcophile, or siderophile) is a key to the distinction between abundance and availability. Elements that are similar in size and geochemical affinity to major elements are dispersed in small amounts in common minerals; *i.e.*, rubidium in potassium feldspar, gallium in aluminum minerals, and germanium in silicate minerals. Elements that do not readily enter the common minerals of igneous rocks remain in the residual melt as crystallization proceeds. Fractional crystallization of magmas (igneous melts) normally results in a residual liquid of granitic composition. Under suitable conditions this residual liquid solidifies as a coarse-grained rock known as a pegmatite. Pegmatites are famous for their content of rare and unusual minerals, which contain many of the minor and trace elements. They are the commercial sources of lithium, beryllium, scandium, yttrium, the rare earths, cesium, niobium, and tantalum, all elements that concentrate in the residual liquid because of their specific geochemical properties.

Chalcophile elements are all of rather low abundance, and the minerals that they form, mainly sulfides and some arsenides, are not stable at the high temperatures of igneous crystallization. Sometimes these elements are found in granites and pegmatites—molybdenite (MoS_2) is a typical example. More frequently they are removed from the crystallizing magma as hot aqueous solutions and are deposited as metalliferous veins in the surrounding rock. Sometimes they may reach the surface as components in thermal springs; mercury has been deposited (as native mercury and as cinnabar, HgS) by some of these springs, occasionally in sufficient amounts for profitable mining.

Concentration of elements by sedimentary processes

Sedimentary rocks. The decomposition of pre-existing rocks by weathering, the transportation and deposition of the weathering products as sediments, and the eventual formation of sedimentary rocks might be expected to produce a gross mixture of materials, thereby working against further geochemical differentiation of the elements. This is not the case; sedimentary processes frequently produce remarkable concentrations of the elements, leading to almost pure deposits of certain minerals. Some sandstones, *e.g.*, contain over 99 percent quartz and some limestones over 99 percent calcium carbonate. The ultimate is reached in salt deposits, with extensive beds of anhydrite ($CaSO_4$), gypsum ($CaSO_4 \cdot 2H_2O$), halite (NaCl), and other compounds. Goldschmidt compared the sedimentary process with a quantitative chemical analysis, involving the successive separation of specific elements or groups of elements.

Quartz (SiO_2) is highly resistant to weathering and accumulates as deposits of sand. When consolidated these deposits form sandstones, an important group of sedimentary rocks. Under special conditions almost any mineral may be deposited in sand-sized grains, but most minerals are eventually decomposed by weathering. A few resistant ones may survive and be sufficiently concentrated to form economic deposits known as placers; the most familiar are probably the gold-bearing sands, important sources of this element, but sand deposits may have economic concentrations of zirconium (as the mineral zircon, $ZrSiO_4$), titanium (as rutile, TiO_2, and ilmenite, $FeTiO_3$), tin (as cassiterite, SnO_2), and others.

The aluminosilicates of igneous rocks, mainly the feldspars, $(K,Na)AlSi_3O_8$ and $(Na,Ca)(Al,Si)_4O_8$, are relatively easily decomposed by weathering. The alkali elements and calcium are largely carried away in solution, whereas the aluminum and silicon are quickly redeposited as insoluble clay minerals. When consolidated, these minerals form shales and mudstones. The ferromagnesian minerals undergo a more complex decomposition, sometimes leading to the deposition of iron-rich sediments consisting largely of hydrated ferric oxide; such sediments are valuable iron ores in many countries.

Calcium is carried away in solution mainly as calcium bicarbonate, $Ca(HCO_3)_2$. Most of it eventually reaches the sea, where it is utilized by a vast variety of organisms as skeletal material in the form of calcite and aragonite (polymorphs—different forms—of $CaCO_3$). Accumulation of skeletal materials after death of the organisms has formed extensive deposits of limestone throughout geological time. Magnesium in seawater can react with calcium carbonate to form dolomite, $CaMg(CO_3)_2$, and in this way some magnesium is removed from solution and deposited in sediments.

Much of the magnesium, however, remains in seawater, which is essentially a dilute solution of magnesium, calcium, sodium, and potassium chlorides and sulfates, with many other elements in small amounts (Table 1). Under special geological circumstances bodies of seawater can be cut off from the open ocean, and under arid conditions the water will evaporate and extensive salt beds be deposited. Such conditions have occurred in different regions throughout geological time, and the resulting salt deposits are economically important as sources of sodium, potassium, calcium, magnesium, chlorine, and sulfur (see EVAPORITES).

The three major groups of sedimentary rocks are sandstones, shales, and the carbonate rocks (limestones and dolomites). Much less geochemical research has been devoted to sedimentary rocks than to igneous rocks, and the data for their contents of minor and trace elements are therefore less extensive. The figures in Table 1 show that the minor and trace elements generally tend to be more concentrated in shales than in the sandstones and carbonate rocks.

Average composition of sedimentary rocks

The problem of arriving at an average composition for all sedimentary rocks is still largely unresolved, largely because of uncertainty in the relative amounts of shales, sandstones, and carbonate rocks. From geochemical arguments Clarke estimated the relative percentages of these three groups as 80:15:5, respectively. Actual measurements of sedimentary rocks suggest that these figures overestimate the amount of shales and underestimate that of limestones, however. Thus, a compilation of the recorded amounts of shales, sandstones, and limestones in over 700,000 feet of sedimentary rock formations gave relative percentages of 46:32:22, respectively. The identification of a formation as a limestone, a sandstone, or a shale, however, is likely to be gross; shales usually contain considerable sand, sandstones may carry much clay, and the term limestone is applied to many rocks with 50 percent or less of carbonate. It does appear that limestones are more prominent in the geological record than might be expected from geochemical calculations, however; this probably reflects the fact that shallow-water environments are the great places of carbonate deposition, whereas the ocean deeps are the repository primarily of clay-rich sediments.

Metamorphic rocks. Comparatively few investigations have been made of the elemental composition of metamorphic rocks. Many of these rocks retain the geochemical features of their parent igneous or sedimentary materials, and their bulk composition has been little changed despite complete recrystallization and the production of new minerals and structures in some instances. Some metamorphic rocks, however, have been markedly modified by the removal of some components and the addition of others.

The Canadian Shield

The Geological Survey of Canada has performed a comprehensive study of a large area of the Canadian Shield, a region of complex geology largely made up of metamorphic rocks. From a collection of more than 8,000 bedrock samples, the average abundances of all the major elements and a number of minor and trace elements were determined; the figures are given in Table 1. As might be anticipated, the average composition is not very different from the average composition of igneous rocks. It does show a somewhat higher silicon content, probably reflecting a preponderance of granitic over basaltic rocks and a relative abundance of quartz-rich sedimentary rocks in the original makeup of the Canadian Shield. The general validity of these abundance figures for metamorphic rocks has been confirmed by a similar study of the average composition of metamorphic rocks in the U.S.S.R., which has given closely comparable results.

Ore deposits. An ore deposit, in its simplest terms, is a portion of the Earth's crust from which some industrial raw material can be extracted at a profit. As such, its characteristics are as much economic as geochemical. Nevertheless, its formation required the operation of geochemical processes to produce the concentration of a specific element or elements in a particular place. Economics decide whether this concentration is rated as an ore deposit or merely as a deposit of scientific interest. The economics may change with time, depending upon price, availability of transportation, cost of labour, and other factors.

Some general principles can, however, be enunciated. Proceeding from the average abundance of an element in the crust, and the minimum abundance that can be profitably exploited under normal circumstances, a factor of enrichment necessary to produce an ore deposit can be derived (Table 4). The economic control is immediately evident in the approximate relation between the factor of enrichment and the price of the product sought. The most extreme example of this is in diamond mining, where the product sought may be present in the rock mined in as low a concentration as 1 part in 50,000,000. Ease of extraction, of course, plays an important role in this. Diamonds are readily separated from the great mass of waste rock by a relatively simple and inexpensive process. Magnesium is commercially extracted from seawater, where its concentration is 0.13 percent, rather than from the common rock dunite, where its concentration is about 25 percent, because of the ready availability of seawater and the cheapness of the extraction process.

Table 4: Concentration Factors for Ore Bodies of the Commoner Metals

metal	percent in Earth's crust	minimum percent profitably extracted	enrichment factor necessary for an ore body
Aluminum	8.13	30	4
Iron	5.00	30	6
Manganese	0.10	35	350
Chromium	0.02	30	1,500
Copper	0.007	1	140
Nickel	0.008	1.5	175
Zinc	0.013	4	300
Tin	0.004	1	250
Lead	0.0016	4	2,500
Uranium	0.0002	0.1	500

Ore deposits may be found in all types of rocks—igneous, sedimentary, and metamorphic—and seawater

is also a significant source of such elements as sodium, chlorine, magnesium, and bromine. There are many possible processes of geochemical enrichment leading to the formation of ore deposits, and they are often the end result of a complex series of such processes acting over a long period of time. The economic importance of ore deposits has ensured their thorough study by all techniques of geological and geochemical research, but much controversy still exists regarding the origin of many of the more complex deposits.

The most readily understood ore deposits are those of sedimentary origin. They have been formed at the surface of the Earth by processes that can usually be observed operating at the present time and that can readily be simulated in the laboratory. Salt deposits are one kind whose origin is clearly amenable to such an approach. As long ago as 1849 an Italian scientist initiated laboratory studies on the evaporation of seawater and elucidated the sequence of crystallization of the different salts. Comparison of the results with the mineralogy of salt deposits revealed gross similarities but also important differences; these differences can be explained by a variety of mild metamorphic reactions resulting from burial of these deposits under overlying sediments.

Sedimentary iron-ore deposits

Some sedimentary deposits are not readily explicable by such an approach, however. The most extensive and economically important are the vast Precambrian iron-ore deposits, which are a major source for the hundreds of millions of tons of steel produced annually. They occur on all the continents (except perhaps Antarctica) and are uniformly of great age (about 1,900,000,000 years or older). Probably the most extensive and best exposed of these are in the Hamersley Range of Western Australia, where individual beds of iron ore are continuous over hundreds of square miles in a horizontally bedded sequence of iron ore and quartzite thousands of feet thick. The conditions that gave rise to these deposits were apparently unique to this early period in Earth history, because similar deposits are not known in younger geological formations. It has been argued that the explanation lies in an oxygen-free reducing atmosphere in early geological times, under which iron could readily be transported in solution as ferrous compounds to the ocean or large lakes, where deposition eventually took place, perhaps through the agency of primitive organisms. As soon as free oxygen appeared in the atmosphere, 1,000,000,000 to 2,000,000,000 years ago, the geochemical cycle for iron was profoundly modified, and this type of transportation and deposition ended forever.

Processes other than fractional crystallization from igneous melts also give rise to magmatic ore deposits. Economic deposits of the oxide mineral chromite ($[Fe,Mg][Cr,Al]_2O_4$), for example, occur almost entirely as bands or lenses in magnesium-rich igneous rocks. Chromite evidently crystallizes early from a magma, and, being of higher density than the liquid, it sinks to the bottom of the magma chamber and becomes concentrated as almost pure bodies of this mineral. Some accessory minerals of igneous rocks are important sources of metallic elements, but the rocks cannot be mined directly because the grade is too low. If these minerals are chemically and mechanically resistant, weathering and transportation may eventually concentrate them into workable deposits. A large proportion of the world's zirconium, hafnium, rare earths, and thorium, and some iron and titanium, come from such deposits in river and beach sands.

A large number of important ore deposits occur in metamorphic rocks. The ultimate origin of these deposits is frequently obscured by the complex processes they have undergone. If it can be established that the enclosing metamorphic rocks were of sedimentary origin, the question then arises whether the ore material was deposited along with the sediments or was introduced by circulating solutions during the metamorphism or possibly at some later time. The answer is seldom clear-cut, and such deposits continue to excite lively controversy among geochemists and economic geologists.

Mineral fuels. The mineral fuels—coal, petroleum, and natural gas—may be described as a special type of economic deposit. Geochemically they represent the concentration of carbon and hydrogen by processes that were initially biological in nature. Coal is essentially the product of accumulation of land plants in large amounts, and petroleum and natural gas are the products of marine organisms (although the origin of some petroleum and natural gas under nonmarine conditions cannot be entirely excluded). The origin of petroleum and natural gas presents a more difficult problem than coal because they are fluids and thus are free to migrate from their place of origin.

Formation of coal

The formation of coal is a relatively straightforward geochemical process that can readily be traced through its successive stages. The first requirement is a geological one—the rapid accumulation of plant material under conditions that inhibit its decomposition, followed by its burial under inorganic sediments such as shales and sandstones. The great coal-forming period in the Northern Hemisphere followed the Devonian Period (345,000,000 to 395,000,000 years ago), when abundant land plants first appeared, and has been named the Carboniferous Period (280,000,000 to 345,000,000 years ago). During this period, large areas in North America and Europe were evidently low-lying swamps that supported a lush vegetation. This vegetation died, accumulated in successive layers, and was partly decomposed by bacteria and other organisms to form peat. Burial of peat deposits under inorganic sediments brought an end to the period of bacterial decomposition, and the further changes to coal were essentially a mild metamorphism caused by an increase in temperature and pressure.

Chemically, this mild metamorphism was in large part the expulsion of carbon dioxide and water from the coal-forming substance. The main trend in the change from peat through lignite to bituminous coal and anthracite is the decrease in oxygen content and the increase in carbon (Table 5). If carried to its ultimate conclusion the product would be pure carbon in the form of graphite. This occurs comparatively rarely, but evidence for it is the presence of small amounts of graphite in many metamorphic rocks.

Table 5: Average Composition of Fuels

	carbon	hydrogen	nitrogen	oxygen
Wood	49.65	6.23	0.92	43.20
Peat	55.44	6.28	1.72	36.56
Lignite	72.95	5.24	1.31	20.50
Bituminous coal	84.24	5.55	1.52	8.69
Anthracite coal	93.50	2.81	0.97	2.72

Source: Clarke, *The Data of Geochemistry.*

Coal also contains inorganic material that appears as ash when it is burned, and some coal ashes show a remarkable concentration of unusual elements. This was demonstrated by Goldschmidt in 1933, when he found appreciable amounts of germanium in some coal ashes. The Hartley Seam of the Durham Coalfield in England contains so much germanium that the ash has a brilliant yellow colour because of the presence of the oxide (GeO_2).

The source of these minor and trace elements (Table 6) and their mode of incorporation in the coal are still not fully understood. There are three possibilities: (1) these elements were taken up by the plants during growth; (2) they were carried into the coal swamp as a component of the inorganic sediments; or (3) they were absorbed during or after the coal-forming processes from circulating solutions. The first possibility is not favoured, because growing plants seldom incorporate appreciable amounts of nonorganic elements. The second possibility also is unlikely, because there is no correlation, or rather an inverse correlation, between ash content and trace element concentrations. This leaves the third possibility as the most likely one. The presence of a large amount of carbonaceous matter means that the coal-forming environment is a highly reducing one, which will favour the precipitation of some elements; the presence of hydrogen

sulfide and sulfide ions will cause the precipitation of chalcophile elements (with affinity for sulfur); and complex organic compounds are noted for their absorptive, or chelating, capacity for metallic ions. Thus several individual reactions are potentially available for the fixation of foreign elements in the coal substance.

Table 6: Rare Elements in Coal Ash

	average content in coal ash (g/ton)	average content in Earth's crust (g/ton)	factor of enrichment
Boron	600	10	60
Germanium	500	1.5	330
Arsenic	500	2	250
Bismuth	20	0.2	100
Beryllium	45	2.8	16
Cobalt	300	25	12
Nickel	700	75	9
Cadmium	5	0.2	25
Lead	100	13	8
Silver	2	0.1	20
Scandium	60	22	3
Gallium	100	15	7
Molybdenum	50	1.5	30
Uranium	400	2.7	150

As pointed out above, the origin of petroleum is not as readily elucidated as the origin of coal, because petroleum can migrate from the region in which it was formed. Indeed, the very occurrence of a commercial oil field probably implies the concentration of the petroleum from a large volume of source rocks into a relatively much smaller reservoir.

The fact that petroleum is almost always found in marine sedimentary rocks has long been a basic argument in favour of a marine origin for this material. It is certainly true that some oil has been found in igneous and metamorphic rocks, but migration from a sedimentary source bed is a reasonable explanation for these occurrences. Proof of a marine origin has been forthcoming in recent years by the sensitive analyses of recent marine sediments, which show that they contain small amounts of petroleum hydrocarbons, evidently generated either directly by marine organisms or by their subsequent decomposition.

Composition of petroleum

Natural petroleum is a complex mixture of hundreds of different hydrocarbons, but its bulk composition is remarkably constant, about 85 percent carbon and 15 percent hydrogen. It may include small amounts of organic compounds containing oxygen, sulfur, and nitrogen. Its content of other elements is exceedingly small. Petroleum ash, unlike coal ash, is not noted for its trace element content. Some petroleum ash contains appreciable amounts of vanadium, however, and has been utilized as a source of this element. A class of nitrogen-bearing organic compounds known as porphyrins include a metal atom in their molecular structure; usually this atom is iron, but other elements in this region of the periodic table, especially vanadium, nickel, and copper, may play a similar role. The vanadium content of some petroleum ash probably originates as a vanadium porphyrin in some of the organisms involved in petroleum formation.

Petroleum is always accompanied by natural gas, but many natural gas fields have no petroleum associated with them. This can probably be ascribed to greater possibility for migration for a gas as compared to a liquid. It is also possible that some natural gas is generated from coal deposits. Natural gas consists largely of methane, but small amounts of more complex hydrocarbons may be present, and it may also contain unwanted components such as nitrogen, carbon dioxide, and hydrogen sulfide. Natural gas containing hydrogen sulfide is known as "sour gas" and for long was an undesirable material because of the noxious nature of this compound; recently, however, it has been found profitable to extract the hydrogen sulfide by converting it to sulfur and then utilize the hydrocarbons.

Natural gas is the sole source of one element, helium, the industrial demand for which has steadily increased in recent years. Comparatively few occurrences of natural gas contain sufficient helium for the extraction to be commercially profitable. Currently, the Western world's need for helium is largely met by its extraction from wells in western Texas. The explanation for this local concentration of helium in some natural gas fields is still a matter for discussion; the only reasonable source is from the disintegration of radioactive elements in the crust, but the mechanism of concentration remains something of an enigma.

Helium in natural gas

Soils. Soil is a thin veneer that forms a discontinuous cover on the land areas of the Earth. Its volume and its mass are small in comparison to the major geospheres, but it is of vast importance to man. Superficially it might be considered merely as comminuted (pulverized) and decomposed bedrock; however, this viewpoint takes into account only its inorganic components and completely neglects the complex of organic compounds, living organisms, water, and included gases that gives the soil its characteristic properties and its value as the abode of life. Comminuted bedrock alone is not soil in any real sense; the Antarctic continent, where not ice-covered, has a surface of comminuted bedrock, as does the Moon, but neither material can properly be termed soil.

Soils result from the weathering of rocks, and hence their composition might be expected to reflect the composition of the rocks from which they were formed. This is true only in a very broad sense, however. Environmental factors play an important part in soil formation. The same parent rock may give rise to very different soils under different conditions. Climate, topography, vegetation, biological activity, and time are all important factors in determining the nature of a soil. Climate is probably the most important of these, as can be demonstrated by contrasting the soils developed on the same rock type under tropical and temperate conditions. In general, the soil in the humid tropics will be different in texture and composition and much less fertile, as a result of the intense leaching brought about by high rainfall, high temperatures, and the almost complete removal of organic matter by micro-organisms.

The complex of inorganic compounds, organic compounds, water, and air that makes up the soil is in a continual state of change. Water tends to dissolve and remove the relatively soluble elements such as calcium, magnesium, sodium, and potassium, and the comparatively insoluble elements—aluminum, iron, and silicon—are thereby relatively enriched in the soil. The enrichment of iron is frequently manifested by a red-brown or yellow-brown colour caused by an accumulation of iron oxides. The most reactive part of the soil is the complex of clay minerals and organic matter, which is largely responsible for its agronomic characteristics. True soil does not exist without the presence of colloidal and organic matter. The relative absence of soils in desert areas reflects the fact that chemical and physical weathering of rocks alone does not necessarily result in soil formation. Most soil processes are directly or indirectly biological in nature. Organisms and organic compounds produced by their vital activities or their decomposition are effective agents for dissolving and extracting many elements from the inorganic constituents of the soil, thereby making them available for plant growth.

Minor and trace elements in soils

Although soils do differ in composition, the range of variation in the major elements is rather small. Minor and trace elements may show considerably greater variability, as is illustrated by Figure 4. The importance of certain trace elements in the soil for the healthy growth of plants, and through the plants, of the animals that graze on them, has become increasingly apparent in recent years. Most soils contain these trace elements in sufficient amounts, but when deficiencies are present, puzzling diseases appear, which in the past have rendered large areas of otherwise suitable land unavailable for farming. On a large area in the North Island of New Zealand, for example, although it grew satisfactory pasture, sheep and cattle failed to thrive and eventually died if not removed. As a result, much of this area was given over to afforestation. It was eventually discovered that

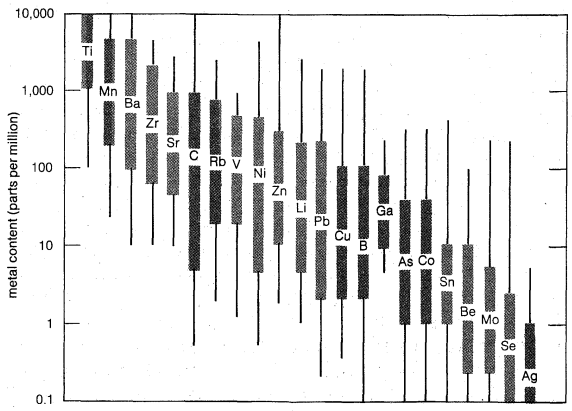

Figure 4: Range of the content of some minor elements in normal soils. Thin lines indicate ranges of more unusual values.

From *Chemistry of the Soil* by Firman Bear. Copyright 1964 by Litton Educational Publishing, Inc.

cobalt, in the amount of a few parts per million, would completely eliminate the disease when applied in fertilizer or administered directly to the animals. The ultimate explanation is the need of animals (but not plants) for vitamin B_{12}, which contains an atom of cobalt in its structure.

Occasionally, an excess of a specific element may have a deleterious effect on plant growth. Most obvious, of course, are the alkaline or saline soils of desert and coastal areas on which only an impoverished vegetation exists. Magnesium-rich soils are notably infertile; such soils develop on areas of ultrabasic igneous rocks consisting largely of olivine, $(Mg,Fe)_2SiO_4$, and the boundaries of these areas can frequently be readily mapped from aerial photographs by the marked change in vegetation. Sometimes plants take up available trace elements in amounts deleterious to animals grazing on them. A well-known example is *Astragalus racemosus* (locoweed), which in some areas of the western U.S. contains sufficient selenium to be poisonous to grazing animals.

The possible correlation between soil geochemistry and the geographical distribution of disease is thus a field of extreme significance which as yet has been insufficiently studied. The problem is a complex one, in large part because of the difficulty in isolating the numerous factors involved.

The hydrosphere. The hydrosphere is the discontinuous shell of water—fresh, salt, and solid—on the surface of the Earth. As such it comprises the oceans and the connecting seas and inlets, the lakes, rivers, and streams, the groundwater that feeds them, and the snow and ice cover of high altitudes and high latitudes. The mass of the ocean waters far outweighs the other parts of the hydrosphere. Goldschmidt estimated that there are 273 litres of water in all its forms for every square centimetre of the Earth's surface made up as follows:

	Litres	Kilograms	Total mass
Seawater	268.4	278.1	1.4×10^{18} tons
Freshwater	0.1	0.1	5.1×10^{14} tons
Continental ice	4.5	4.5	2.3×10^{16} tons

Seawater thus makes up over 98 percent of the total mass of the hydrosphere, and its composition (Table 1) essentially can be taken as giving the average composition of the hydrosphere.

Research during the past century has demonstrated that the composition of seawater is essentially uniform and that the relative proportions of the various ions are practically constant. In the open ocean the salinity (approximately the total weight of dissolved solids per kilogram) averages about 35 parts per thousand, but may rise to 40 parts per thousand in regions such as the Red Sea and the Persian Gulf, where rainfall and inflow are low and evaporation high. Sodium chloride is the dominant compound of the salts in solution and comprises about three-quarters of the whole; the remainder consists largely of chlorides and sulfates of magnesium, calcium, and potassium.

Though many data on minor and trace elements in sea water (Table 1) are available, the interpretation of these data is subject to some uncertainties. The concentrations of these elements are probably more variable than for the major elements and may depend to some degree on the sampling location. This is particularly true for the elements that are utilized by marine organisms. Phosphorus is a good example; it is markedly depleted in surface and near-surface waters by biological activity, but it enriches the deeper parts of the ocean through the dissolution of dead organisms. Silica is brought into the ocean in large amounts in solution in river water, but most of it is soon removed to become the skeletal material of diatoms, radiolaria, and sponges.

Chemical composition of sea water

Seawater also contains dissolved gases in variable amounts. Seawater of normal salinity at 0° C (32° F) in equilibrium with the atmosphere will contain about eight millilitres per litre of dissolved oxygen and 14 millilitres per litre of dissolved nitrogen. Dissolved nitrogen is essentially an inert constituent, but dissolved oxygen plays a fundamental role in the growth and decay of organisms and so varies greatly in concentration from place to place. In stagnant regions that are rich in decaying organic matter the water may be completely depleted in free oxygen, and a considerable concentration of hydrogen sulfide may be present. Much of the Black Sea below a depth of a few hundred metres is in this condition.

Another dissolved gas of prime importance for biological activity is carbon dioxide. The conditions controlling its concentration are quite complex, however, because in solution it can be present as free carbon dioxide, as undissociated carbonic acid, as carbonate ions, and as bicarbonate ions. The concentration of these ions will also be affected by biological activity and by the precipitation or dissolution of calcium carbonate.

The circulation of water through the hydrosphere is controlled in large part by the reservoir effect of the oceans. Evaporation from the ocean surface is precipitated as rainfall. Of that falling on the land, some is directly re-evaporated, some is absorbed into the reservoir of groundwater, and some flows off directly into rivers and streams. The total annual rainfall on the Earth is estimated to be 123×10^{18} grams, and the total annual runoff to the oceans 32×10^{18} grams.

Even the purest rainfall contains some material in solution, not only dissolved gases but also nonvolatile material. Rainfall near seacoasts always contains some sodium chloride and small amounts of other marine salts, the concentration of which falls off generally with distance from the ocean. Rainfall in industrial regions may of course contain a variety of pollutants; in many areas it is essentially a dilute sulfuric acid solution. Such material may also be carried far beyond the place of origin; acid rainfall in the Scandinavian countries probably originates in part from England and Germany.

Elements carried in solution by rivers

The runoff from the land contains additional material in solution, picked up during its circulation through the crustal rocks. River water averages about 120 parts per million dissolved solids, but the range is great, from about 10 parts per million up to several thousand parts per million. Commonly, the range is from 50 to 200 parts per million; contents greater than 200 parts per million are usually the result of human activities or of drainage from soils containing soluble salts, as in desert regions.

With an average content of 120 parts per million dissolved matter, the rivers of the world deliver 3.9×10^9 tons of material in solution to the sea each year. The average concentration of the important constituents (in parts per million) is: bicarbonate, 58.4; sulfate, 11.2; chloride, 7.8; nitrate, 1.0; calcium, 15.0; magnesium, 4.1; sodium, 6.3; potassium, 2.3; iron, 0.67; and silica, 13.1. Although these ten constituents account for most of the dissolved material, many other elements have been detected in river and lake waters. Comparatively little information is available for these elements, but the results of an extensive study of the large rivers of North America is summarized in Figure 5. The figures are in micrograms per litre—that is, in parts per thousand million.

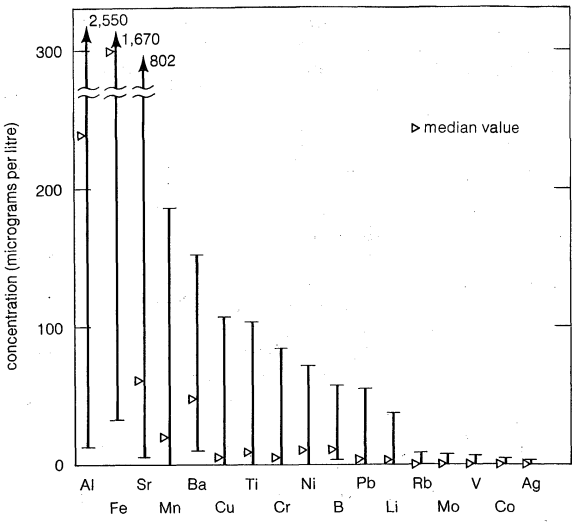

Figure 5: Concentrations of minor and trace elements in river waters of North America.

From W.H. Durum and Joseph Haffty, *Geochimica et Cosmochimica, Acta*, vol. 27 (1963); Pergamon Press

The 3.9×10^9 tons carried annually in solution to the oceans are but a small fraction of the total amount of material in solution in the oceans. Nevertheless, when integrated over the whole of geological time, more than 4×10^9 years, it greatly exceeds the present material in solution. Some of the material, especially sodium chloride, is of course cyclical, being circulated from the oceans to the land as aerosols and incorporated in marine sedimentary rocks and ultimately in large part being returned to the oceans in runoff.

Goldschmidt made an interesting calculation on the geochemical balance in seawater. From the amount and composition of sedimentary rocks he estimated that erosion during geological time had amounted to about 160 kilograms of igneous rock per square centimetre of the Earth's surface. Combining this figure with the amount of seawater per square centimetre, 273 kilograms, he derived a figure of 600 grams of igneous rock eroded per kilogram of seawater. Assuming this 600 grams had gone fully into solution (obviously a gross simplification but a limiting one), he drew up a balance sheet between the amounts of different elements potentially supplied to the oceans and the amounts actually present. Some of these figures are presented in Table 7. Despite the imperfections of the method, the results are certainly significant in a qualitative sense. Some elements—chlorine, bromine, boron, and sulfur—are present in seawater in amounts far in excess of those that can have been derived by erosion. The source of these "superabundant" elements has probably been volcanism and related magmatic activity. Halides, sulfates, and borates are deposited by volcanic gases and carried in solution in hot springs. The relative depletion of fluorine with respect to chlorine in seawater can be ascribed to the precipitation of highly insoluble fluorine-bearing compounds, mainly apatite (calcium fluophosphate). Sodium clearly remains in solution to a much greater extent than potassium; the latter element reacts with sedimentary materials to form insoluble potassium-bearing silicates such as illite and glauconite, which have no sodium-bearing analogs. Calcium is removed from solution much more effectively than strontium, evidently because it is utilized by organisms. Goldschmidt pointed out that many highly poisonous elements, such as arsenic and selenium, have been potentially supplied in dangerous amounts. Their concentration remains very low, however, presumably because of efficient processes of removal as insoluble compounds. Adsorption on colloidal particles of clay and iron oxides is a likely process.

Table 7: Geochemical Balance of Some Elements in Seawater

element	potential amount supplied to oceans (g/ton)	amount present in seawater (g/ton)	percentage in solution
Lithium	39	0.17	0.4
Boron	2	4.5	250
Fluorine	540	1.3	0.2
Sodium	16,980	10,800	64
Magnesium	12,540	1,290	10
Phosphorus	708	0.09	0.01
Sulfur	312	904	290
Chlorine	188	19,400	10,300
Potassium	15,540	392	2.5
Calcium	21,780	411	1.9
Arsenic	3	0.003	0.1
Bromine	0.97	67	6,900
Rubidium	186	0.12	0.06
Strontium	180	8.1	4.6
Iodine	0.18	0.06	33
Cesium	4	0.0003	0.008
Barium	150	0.02	0.01

Steady state of oceanic composition

The geological and geochemical evidence indicates that the ocean waters are, and have been for a long time, in a steady state of essentially unchanging composition. The addition of material by runoff from the land is adjusted by reactions within the ocean waters or between the ocean waters and sedimentary materials whereby the concentrations of the individual elements remain essentially constant. How far back in geological time this steady state has persisted remains something of an open question. The existence of most forms of marine life from the Cambrian to the present indicates a uniformity of marine conditions over the past 600,000,000 years; how far back into the Precambrian this uniformity extended is more difficult to elucidate. The earlier discussion of Precambrian iron formations suggested the possibility of very different atmospheric composition some 2,000,000,000 years ago, and the considerable interdependence of atmospheric and oceanic composition indicates that this might have resulted in marked geochemical differences in the ocean waters.

The atmosphere. The atmosphere is the most homogeneous and thus the most easily studied of the geospheres. Its mass is readily determined from the product of the average height of the mercury barometer in centimetres, the density of mercury (13.6 grams per cubic centimetre), and the area of the Earth (5.1×10^{18} square centimetres). Recent calculations give 51.17×10^{20} grams for its total mass.

The composition is also relatively simple, although a considerable number of gases may be present in small amounts (Table 8). Almost 99 percent consists of oxygen and nitrogen, with argon making up most of the remainder. Carbon dioxide, essential for plant life, is present in an extremely small amount. Some gases not listed in Table 8 may be present as local or even regional pollutants—city dwellers are becoming increasingly aware of oxides of sulfur as atmospheric pollutants, and the scientific study of smog is largely concerned with reactions taking place between hydrocarbons, oxides of nitrogen, oxygen and ozone.

Table 8: Average Composition of the Atmosphere

gas	composition by volume (ppm)*	composition by weight (ppm)*	total mass ($\times 10^{20}$ g)
Nitrogen	780,900	755,100	38.648
Oxygen	209,500	231,500	11.841
Argon	9,300	12,800	0.655
Carbon dioxide	300	460	0.0233
Neon	18	12.5	0.000636
Helium	5.2	0.72	0.000037
Methane	1.5	0.94	0.000043
Krypton	1	2.9	0.000146
Nitrous oxide	0.5	0.8	0.000040
Hydrogen	0.5	0.035	0.000002
Ozone†	0.4	0.7	0.000035
Xenon	0.08	0.36	0.000018

*ppm = parts per million. †Variable, increases with height.

The atmosphere gradually thins out into the vacuum of outer space, and its upper limit can conveniently be

placed at about 600 kilometres. An important zone in the stratosphere is known as the ozonosphere, a diffuse layer characterized by an increase in the concentration of ozone, O_3. This zone is highly important for life on Earth because it absorbs most of the ultraviolet radiation from the Sun; if this penetrated to the Earth's surface it would act as a potent sterilizer, fatal for most forms of life. It also helps to maintain a more uniform surface temperature by reducing the loss of heat by radiation to space—the so-called greenhouse effect.

History of the atmosphere

The geochemical history of the atmosphere has been a complex one. Scientists agree that the present atmosphere is quite different from the original one. It is certainly quite different from those of the other planets. It is reasonable to conclude that this reflects, in part at least, the Earth as the abode of life. The Earth's atmosphere differs from those of its neighbours in the Solar System probably in large part through the action of photosynthesis, a complex biological process which was probably preceded by a lengthy period of organic evolution.

The nature of the Earth's primitive atmosphere is still a subject of some speculation. Some scientists, reasoning by analogy with the larger planets such as Jupiter, have argued for an original atmosphere consisting largely of methane and ammonia. Others have considered that present-day volcanic gases may indicate the nature of the primitive atmosphere, in which case it contained carbon dioxide, possibly carbon monoxide, nitrogen, and water vapour. In either case, free oxygen was absent. If the evolution of the atmosphere is traced backward in time through the geological record, then extensive terrestrial photosynthesis is indicated by an abundance of land plants in Devonian times, about 400,000,000 years ago. Marine photosynthesis, however, is much older, since practically all the major groups of marine organisms were established by the beginning of the Cambrian period, some 570,000,000 years ago. As discussed earlier, the extensive Precambrian iron formations suggest an oxygen-free atmosphere which was terminated about 2,000,000,000 years ago. This evidence has been translated into estimates of oxygen content of the atmosphere of about 1 percent of the present level 2,000,000,000 years ago, about 10 percent of the present level at the beginning of the Cambrian Period, and essentially the present content by Devonian times.

Although it is not yet possible to know the quantitative composition of the primitive atmosphere, the geochemical processes that have operated to modify its composition during geological time can be evaluated. These processes can be summarized as a series of gains and losses. Additions to the atmosphere comprise: (1) gases released by igneous activity; (2) oxygen and hydrogen produced by the photochemical dissociation of water vapour; (3) oxygen produced by photosynthesis; (4) helium produced by the radioactive breakdown of uranium and thorium; and (5) argon produced by the radioactive breakdown of potassium. Atmospheric losses include: (1) oxygen removal by oxidation of ferrous to ferric iron, sulfur compounds to sulfates, hydrogen to water, and similar reactions; (2) carbon dioxide removed by the formation of coal, petroleum, and the death and burial of organisms; (3) carbon dioxide removed by the formation of calcium and magnesium carbonates; (4) nitrogen removed by the formation of oxides of nitrogen in the air and by the action of nitrifying bacteria in the soil; and (5) hydrogen and helium by escape from the Earth's gravitational field.

Photosynthesis has certainly been the most significant process in controlling atmospheric composition during much of geological time. Through this process carbon dioxide and water are converted to carbohydrate, with the accompanying release of oxygen. Much of this carbohydrate is consumed by animals and reconverted to carbon dioxide and water by respiration, and oxidative decay leads to the same result. Some, however, is incorporated into sediments; part may go to form exploitable deposits of coal and petroleum, but most of it remains as disseminated carbonaceous material; the average carbon content of sedimentary rocks is about 0.4 percent.

Quantitatively, more significant amounts of carbon dioxide have been removed from the atmosphere in the form of limestone and dolomite. Most of this removal has been effected by marine organisms, especially algae and corals, but direct inorganic precipitation may occur, especially in warm tropical waters. Judging from the vast deposits of limestone and dolomite throughout the sedimentary record, this process has operated with a remarkable degree of uniformity throughout geological time. Extensive limestone formations are possibly less common in older Precambrian rocks, indicating a slower beginning of carbonate precipitation. It is truly remarkable that so much carbonate rock has been deposited during geological time, with the carbonate being ultimately derived from an atmosphere which may never have contained a much higher concentration of carbon dioxide than is present today. It has been pointed out that reactions like the decomposition of calcium silicate—$CaSiO_3 + CO_2 = CaCO_3 + SiO_2$, in which $CaSiO_3$ is calcium silicate, CO_2 is carbon dioxide, $CaCO_3$ is calcium carbonate, and SiO_2 is silicon dioxide, which tends to go toward the right at ordinary temperatures—will act as buffering mechanisms to keep the carbon dioxide concentration of the atmosphere at a continuously low level.

Removal of carbon dioxide

If the carbon dioxide concentration has remained essentially constant, and yet this compound has been continuously extracted to form carbonates and organic compounds, then clearly a balancing source of "new" carbon dioxide is required. This evidently has been provided by volcanism and other igneous activity. The Earth is steadily being degassed, in the sense that gaseous compounds contained in the mantle are escaping to the surface. The presence of carbon dioxide in the mantle has been demonstrated by the presence of microscopic inclusions of liquid carbon dioxide in the minerals of the peridotite xenoliths (rocks contained within other rocks) brought up in some volcanoes. Along with carbon dioxide, much water and small amounts of other volatiles are being added continuously from sources in the mantle. Ultimately, the hydrosphere, as well as the atmosphere, is the product of the degassing of the Earth's interior.

Of the remaining atmospheric gases, argon presents some intriguing features. Argon is by far the most abundant of the inert gases on Earth, whereas in the universe as a whole it is much less abundant than either helium or neon. In addition, its isotopic composition is quite distinct, consisting almost entirely of argon-40, whereas in the cosmos argon-36 is the most abundant isotope. The reason for these anomalies is that atmospheric argon is almost entirely radiogenic, the product of the decay of the potassium-40 isotope of potassium.

Similarly, the helium in the atmosphere is probably entirely the product of the radioactive decay of uranium and thorium. Actually, the atmosphere contains only about 10 percent of the total amount of helium generated from these sources during geological time. Some of this helium remains occluded in the rocks where it was formed, some has escaped from the upper atmosphere. Helium (and hydrogen), consisting of light atoms, can escape from the gravitational field of the Earth, whereas heavier gases cannot. A minor source of atmospheric oxygen throughout geological time is probably the photochemical decomposition of water vapour in the upper atmosphere, with the subsequent loss of the hydrogen to outer space.

Some oxygen has been removed from the atmosphere by oxidative reactions, of which the most significant has been the conversion of ferrous to ferric iron. In igneous rocks the average ferrous-to-ferric iron ratio (FeO/Fe_2O_3) is greater than unity, whereas in sedimentary rocks the proportion is reversed, ferric iron being dominant over ferrous iron. Other oxidative reactions are the conversion of manganous compounds to manganese dioxide and of hydrogen sulfide to free sulfur and sulfate. Nitrogen is almost inert geochemically, but a little is fixed as oxides of nitrogen by lightning, and somewhat more by the action of nitrifying bacteria in the soil. Most of this nitrogen is ultimately returned to the atmosphere by the decay of the organisms. Oxides of nitrogen formed in the atmosphere are removed in rain as nitrite and ni-

trate. Nitrogen does not accumulate in the soil, however, except perhaps under extremely arid conditions, as in the deserts of northern Chile, the locale of the unique nitrate deposits.

THE GEOCHEMICAL CYCLE

The preceding discussion has shown that at the time of formation of the Earth the chemical elements already had been considerably fractionated: the universe consists almost entirely of hydrogen and helium, probably with less than 1 percent of the heavier elements. The Earth, on the other hand, consists almost entirely of the heavier elements. Helium is a very rare element on Earth, so rare in fact that it was first discovered as an unidentified line in the Sun's spectrum in 1868, some 30 years before it was detected on Earth. Hydrogen is moderately abundant on Earth, largely because it combines with oxygen to form water, whereas helium is an inert element.

Significance of inert gases

The rarity of helium and the other inert gases neon, krypton, and xenon on Earth is good evidence that the Earth formed by the accretion of small solid objects, or planetesimals. (Argon is a special case, since most of the Earth's argon has been formed within the planet by the radioactive decay of potassium.) These planetesimals had no atmosphere, and the atmosphere of the Earth has been derived by the outgassing of combined and occluded gases within these planetesimals. This process has operated throughout geological history and is probably still continuing; volcanic activity not only brings up solid material from the Earth's interior but also large amounts of gases, principally water vapour, carbon monoxide and dioxide, and nitrogen. The oxygen in the present atmosphere is almost entirely the product of photosynthesis, whereby carbon dioxide and water are converted to carbohydrate and free oxygen.

Direct information on the composition of the Earth's crust is available in the form of thousands of analyses of individual rocks, the average of which provides a reasonably precise estimate of the bulk composition. For the mantle and the core the information is indirect and thus much less precise. The origin of the Earth by the accretion of planetesimals is a well-founded hypothesis, however, and meteorites are probably examples of planetesimals that have survived from the preplanetary stage of the solar system. It thus seems likely that the Earth formed by the accretion of solid bodies with the average composition of stony meteorites. The accretion process, however, led to massive segregation of the elements. Much of the iron was reduced to the metallic state and sank to the centre to form the core, carrying with it the major part of the siderophile elements. Lithophile elements, those with a greater affinity for oxygen than iron, combined as oxide compounds, mostly silicates, and provided material for the mantle and crust. Chalcophile elements would tend to form sulfides; however, few sulfides are stable at the high temperatures of the Earth's interior, so the fate of the chalcophile elements during the early history of the Earth is somewhat uncertain.

This primary geochemical differentiation of the Earth can be interpreted in terms of the system iron–magnesium–silicon–oxygen–sulfur, because these five elements make up about 95 percent of the Earth. There was insufficient oxygen to combine with the major metallic elements iron, magnesium, and silicon; because magnesium and silicon have a greater affinity for oxygen than iron, these elements combined completely with oxygen, and the remaining oxygen combined with part of the iron, leaving the remainder as the metal iron and iron sulfide. As indicated above, the metal sank to form the core, carrying with it the major part of the siderophile elements. The iron sulfide phase probably incorporated much of the chalcophile elements; it does not seem to have formed a distinct shell within the Earth and probably remains primarily in disseminated form through the mantle and the core.

This primary geochemical differentiation was largely controlled by two independent factors, the geochemical affinity of the individual elements and the density of the principal phases. It is significant that the density of the individual elements is irrelevant in this context. Uranium and thorium, for example, are very heavy elements; nevertheless, they are concentrated in the crust, not in the core, because of their lithophile character (affinity for oxygen).

Separation of crust from mantle

The separation of crust from mantle has involved rather different geochemical processes than those of the segregation of the core. The core represents the physical separation of a high-density metallic liquid immiscible with the silicate material of the mantle and crust, whereas the separation of crust from mantle has resulted from more subtle geochemical processes. The mantle is made up very largely of the magnesium-iron silicates olivine and pyroxene (or their high-pressure equivalents). As discussed earlier, these minerals act as sorting mechanisms for other elements, accepting those of ionic size comparable to magnesium and iron and rejecting those much larger or smaller. The crust differs from the mantle in being enriched in those elements that do not readily enter the crystal structures of olivine and pyroxene. The common elements include the alkali metals (except lithium), aluminum, and calcium to some degree. These are combined in the crust in the form of the feldspar minerals, and one of the principal differences between crust and mantle is the dominance of feldspar in the former and its absence in the latter.

The differentiation of the crust from the mantle and core permits consideration of the outer part of the Earth as a distinct geochemical system. The distribution and migration of the elements within the crust (and in the hydrosphere and atmosphere) are the results of processes of magmatism, sedimentation, and metamorphism. The fate of an element during magmatic crystallization is primarily a function of its ionic size. If of appropriate size it enters the structure of one or other of the major minerals; otherwise, it tends to remain in the magmatic liquid until its concentration increases sufficiently for it to form specific minerals in which it is a major component. Volatile elements and compounds in the magma (principally water, carbon dioxide, nitrogen, and sulfur compounds) escape and are added to the atmosphere and hydrosphere.

Sedimentary processes lead to further geochemical differentiation. Liquid water is the medium in which these processes largely operate, and the solution chemistry of the individual elements is the key to their geochemical behaviour. The atmosphere and hydrosphere interact importantly with the lithosphere. Water and carbon dioxide are incorporated in sedimentary minerals; soluble ions, especially sodium, are added to the hydrosphere. Processes involving living organisms are intimately associated with sedimentation; indeed, some abundant and widespread sedimentary rocks, such as coal and limestone, are essentially biological in origin. These biological processes thus have had significant geochemical results. Photosynthesis also has been responsible for the present composition of the atmosphere.

Effects of metamorphism

Metamorphism tends in some degree to reverse the geochemical differentiation of the elements produced by igneous and sedimentary processes. In general, metamorphism promotes a more uniform distribution of the elements and tends to erase compositional differences within large rock masses. Unlimited metamorphism would result in a situation in which the whole lithosphere reached a uniform composition; such a trend is exemplified by the comparatively monotonous chemical and mineralogical composition of many extensive areas of metamorphic rocks.

This overall picture of the migration of the elements in the outer part of the Earth is the basis for the concept of the geochemical cycle (Figure 6). The geochemical cycle may be considered as beginning with the crystallization of a magma, which may produce a variety of igneous rocks and which adds volatile materials to the atmosphere and hydrosphere. Weathering decomposes the igneous rocks, and erosion eventually transports the decomposed rock to the oceans, partly as solid matter to form sedimentary rocks and partly as material in solution. Crustal movements may transport sedimentary and igneous rocks to deeper levels in the crust, where the

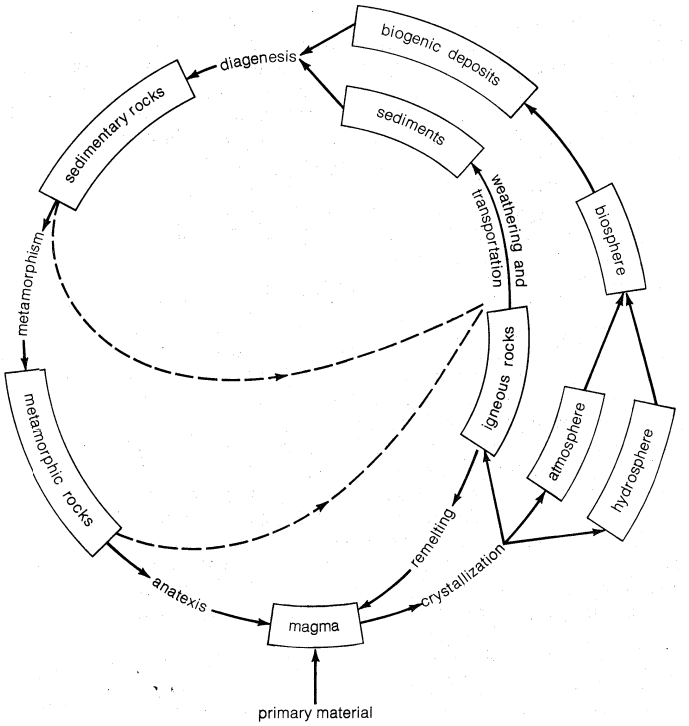

Figure 6: The geochemical cycle.
From B. Mason, *Principles of Geochemistry*, 3rd ed. (1966); John Wiley & Sons, Inc.

combined effects of heat and pressure induce metamorphism. If the temperature rises above the melting point of some of the rock material, magma is regenerated, and the cycle is complete. Such a geochemical cycle seldom goes to completion; at some stage it may be indefinitely halted or its direction reversed. Nor is the cycle a closed one, either materially or energetically. The crust receives "primary" magma generated in the upper mantle, bringing with it additional material and energy in the form of heat. The surface of the Earth receives an increment of meteoritic matter from outer space, insignificant in amount but nevertheless detectable in deep-sea deposits, where the rate of sedimentation is very low.

The geochemical cycle provides a useful conceptual framework for considering the course followed by an individual element in proceeding through the different stages. For a specific element, a complete understanding of its behaviour throughout the cycle is one of the major objectives of geochemical research. An element may tend to concentrate in a specific type of deposit at a particular stage in the cycle, or it may remain dispersed throughout the entire cycle. The geochemical cycles of a few elements have been elucidated in considerable detail, but for many of them knowledge is still fragmentary.

Elements, Physiological Concentration of

The physiological concentration of an element may be defined as the accumulation of that element in concentrations greater than those in the surrounding environment by the physiological processes of an organism. Concentration is usually compared, in the case of land organisms, with the content of the soil or of the Earth's crust in general and, in the case of aquatic organisms, with the concentration of elements in the surrounding water. Operating in conjunction with physical and chemical processes, biological processes may concentrate an element as much as 1,000,000 times the average abundance of that element in nature. One example of physiological concentration is illustrated by the distribution of the element carbon, which makes up about 0.03 percent of the Earth's crust. Carbon tends to combine with oxygen, principally producing the gas carbon dioxide, which then rises to the Earth's surface and is emitted in volcanic gases. Plants then concentrate this carbon, through photosynthesis, as a major constituent in their tissues. Some carbon is also concentrated in the production of calcium carbonate skeletons. A great deal of the carbon in the Earth's crust is therefore concentrated by organisms and preserved in their fossilized remains. More than 26 percent of the carbon that has been at the Earth's surface is thought to be preserved as organic material in sediments and sedimentary rocks; 73 percent is preserved in carbonate rocks that have organically produced skeletons as a major constituent.

Elements may concentrate in two basically different forms: as constituents of either organic compounds or mineralized skeletal materials; for example, a clam may concentrate carbon either in its soft tissues or in its calcium carbonate shell. The element concentrated may be a major constituent of the organism, as in the case of carbon, or it may be a trace element, such as iodine in some algae. Many, perhaps most, of the elements are concentrated by some group of organisms, but certain ones of greater importance have been more thoroughly studied and will be emphasized in this article. The reason for the concentration is not always known. The element forms part of a structural component of the organism in some cases, or it may serve a metabolic function.

Effects of physiological concentrations

Physiological concentration of elements is important in the distribution of the element in the Earth's crust, as in the case of carbon, and may also be of economic importance, as, for example, in the formation of coal deposits from carbon initially concentrated by plants. The concentration of elements is also important to human health. Saltwater fish concentrate iodine in their tissue, and man concentrates the iodine in his thyroid gland by eating these fish, thus preventing the development of goitre. On the negative side, fish also concentrate mercury, which is poisonous to man above a certain minimum level; cows concentrate strontium in their milk, including radioactive strontium 90, which may cause damage to persons who drink the milk and concentrate the strontium 90 in their bones. Because some plants concentrate certain metals, such as zinc and lead, one method of prospecting for mineral deposits utilizes chemical analysis of plants growing on the soils overlying the mineral deposit. Geologists have used the concentration of certain elements in fossilized skeletons to study the temperature and chemistry of ancient oceans.

More than 60 elements have been identified in analyses of organic matters, and the selective concentration of elements by many organisms has been established (see Table 1). Among elements consistently present in plants and animals in greater concentrations than in the environment are: carbon, nitrogen, phosphorus, calcium, magnesium, potassium, sodium, chlorine, and sulfur. In general, the most impressive and thoroughly studied and documented examples of physiological concentration of elements are the concentrations by marine organisms that will be discussed in this article. For information on the general distribution of elements in nature, see ELEMENTS, GEOCHEMICAL DISTRIBUTION OF; see also OCEANS AND SEAS and MARINE SEDIMENTS for the chemistry of seawater and sediments. The nature of the marine organisms discussed here is covered in FOSSIL RECORD.

Concentration of major seawater constituents. In terms of the amount of material involved and the permanence of the product, marine invertebrates are the most im-

Table 1: Concentration Factor for Some Metallic Elements in Marine Organisms*

	concentration factor

*With respect to seawater; concentration factor given as dry weight for total organism. †These figures probably are too low.

portant physiologic concentrators of elements. Many marine invertebrates have mineralized skeletons in which various elements have been concentrated from seawater. These skeletons may be fossilized and thus take large quantities of material out of circulation. Even the soft organic tissue may not entirely decompose on death of the organism but may be buried in marine sediment and partially preserved in rocks formed from sediment.

Precipitation of calcium carbonate. Many different groups of organisms concentrate calcium from seawater in the formation of calcium carbonate skeletons (see Table 2). Calcium constitutes about 0.04 percent of seawater and about 40 percent of calcium carbonate skeletons, representing a 1,000-fold enrichment. Calcium carbonate in invertebrate skeletons is precipitated in one of two mineral forms: calcite or aragonite; some organisms form skeletons composed of a combination of the two. The process by which organisms precipitate calcium carbonate skeletons is complex and is still imperfectly understood. As indicated by Table 2, practically every major phylum of organisms has members that form calcium carbonate skeletons. Further, practically all species of many of these phyla, such as the mollusks, brachiopods, and bryozoans, have calcium carbonate skeletons. Some groups of organisms, such as the vertebrates and arthropods, form skeletons of calcium phosphate, thus concentrating calcium in a different mineral form. Phosphates are quantitatively much less important than carbonates as skeletal material among marine invertebrates.

Table 2: Distribution of Skeletal Mineral Types Among Important, Skeletal-Bearing Phyla

	mineral substances concentrated					
	calcite	aragonite	calcite and aragonite	opaline silica	phosphates	other

*Brucite? †Iron oxide, celestite. ‡Gypsum. §Fluorite, iron oxides.

In most places the oceans are saturated or even supersaturated (*i.e.*, calcium and carbonate ions are present in solution in sufficient or more than sufficient concentrations to react and produce calcium carbonate, $CaCO_3$) with respect to calcium carbonate, but relatively little inorganic precipitation occurs, practically all calcium being removed in the formation of skeletons. Much of the calcium carbonate skeletal material accumulates in the marine sediment; in fact, the sediment is often composed almost entirely of accumulating skeletal material. Such sediment is formed in many parts of the world in shallow, tropical waters, such as the Bahama Banks, Florida Keys, Persian Gulf, and the Great Barrier Reef of Australia. Deep-sea sediments also often consist largely of the skeletons of free-floating species of a protozoan group, the foraminiferans. Marine sediments tend to be rich in calcium carbonate skeletons in areas remote from sources of land-derived sands and muds. Such sediments may eventually become rocks and form limestone that is elevated by tectonic forces (*i.e.*, structural disturbances of the Earth's crust) to become part of the land. Calcium may thus be removed from further circulation for periods of millions of years. Weathering and erosion eventually return the calcium to solution, and it re-enters the cycle. Much of the calcium in the Earth's crust has been concentrated in the formation of limestone, largely as a result of organic processes.

Abundance of calcium carbonate

Occurrence of magnesium. Although no mineral in which magnesium is the principal metallic constituent is known with certainty in the skeletons of marine organisms, magnesium is common in the skeletons of marine invertebrates. Magnesium is chemically similar to calcium and is readily substituted for it in many minerals, including calcite (magnesium may be substituted for up to 30 percent of the calcium atoms in organically formed calcite). The presence of magnesium in the skeleton can range from barely detectable amounts to approximately 8.5 percent by weight; amounts of about 3–4 percent are common. The highest concentrations of magnesium are found in the calcite secreted by certain groups of calcareous algae, which may contain up to 8.5 percent magnesium by weight. Some of the calcareous algae are thought to contain small amounts of the mineral brucite (magnesium hydroxide) mixed with calcite, but the evidence for this is not considered conclusive. The echinoderms (starfish, sea urchins, crinoids, etc.) are also high in magnesium, containing as much as 4.7 percent. Marine mollusks with aragonite skeletons contain the lowest concentrations of magnesium, as little as 0.04 percent.

Magnesium in calcite

Although magnesium is the fifth most abundant element in seawater, it comprises only about 0.135 percent by weight; thus, the foregoing cases represent concentration by a factor of 50 or more in invertebrate skeletons. In most if not all groups of organisms, the concentration of magnesium is temperature dependent. In the echinoderm class Echinoidea (sea urchins and sand dollars), for example, specimens from cold waters usually contain only about 1.5 percent magnesium, whereas those from warm, tropical waters may have as much as 4.6 percent. On the basis of this relationship, it has been suggested that the magnesium content of fossils be used to determine the temperature of the oceans in the geologic past. The magnesium content of fossils is almost always altered, however, in the fossilization process. When invertebrate skeletons become buried in marine sediment and elevated above sea level, contained magnesium is readily leached out by groundwater. Some geochemists believe that the magnesium may then be further concentrated inorganically in the form of the mineral dolomite (*i.e.*, calcium-magnesium carbonate), one of the most common minerals in sedimentary rocks.

Strontium concentration. Rarely found in the form of a separate strontium mineral, strontium is nevertheless a fairly common constituent of invertebrate skeletons. An exception to the general occurrence of this element is the acantharian radiolarians, which have skeletons composed of the mineral celestite (strontium sulfate). Strontium is also chemically similar to calcium and is readily

substituted for it, especially in skeletons made of the mineral aragonite. Strontium concentrations are highest in aragonite corals and calcareous algae, which may contain as much as 1.0 percent strontium by weight, and probably lowest in calcite mollusks, which may contain only a trace (0.05 percent). The strontium content of seawater is only about 0.0008 percent; thus, organisms with high strontium skeletons concentrate this element by a factor of more than 1,200. In the celestite radiolarians the concentration factor is about 60,000.

Temperature dependent concentration

The strontium concentration in the skeletons of some marine organisms varies with the temperature at which the organism lives, and strontium offers more potential as a method of determining ancient marine temperatures, because it is not as readily altered in fossils as is magnesium. The ratio of strontium to calcium in the high-strontium forms is slightly higher than in seawater, indicating that the organisms concentrate strontium in their skeletons slightly more than they do calcium. According to studies of fossils, the amount of strontium in seawater has probably been nearly constant for at least the last 280,000,000 years; calcium and magnesium also appear to have been constant for at least that long. The strontium balance has probably been maintained largely by organisms removing it from seawater as fast as it is supplied by the weathering of rocks on land.

Concentration of minor seawater constituents. *Silicon.* One of the most abundant elements in the Earth's crust, silicon is present in seawater in very small but quite variable amounts (about 0.0003 percent by weight) and is concentrated by some marine organisms in the form of hydrous silicon dioxide (opaline silica). Diatoms, microscopic algae with cell walls that are usually strongly impregnated with silica, are among the most abundant of organisms on the Earth. In certain places their accumulated skeletons comprise the major portion of thick sediment. Diatomaceous earth, which is composed of diatom skeletons, has important applications as a filter material and as an insulator. Microscopic single-celled radiolarians, although not as abundant as diatoms, are widespread in the seas, and their delicate siliceous skeletons are a major constituent of marine sediments over large areas of the sea floor. Certain varieties of sponges also concentrate silica; the delicate and beautiful Venus's-flower-basket sponge from the deep sea is an especially spectacular example of a "glass sponge." The effect of the removal of silicon from the seawater by these organisms, especially the diatoms, is so great that surface waters of the seas are much depleted in silicon relative to deeper waters, where lack of light prevents growth of diatoms.

Occurrence of phosphate skeletons

Phosphorus. In a few groups of organisms phosphorus is concentrated in skeletons made of calcium phosphate minerals. The vertebrates, including the fish, are the most important group of marine organisms with phosphatic skeletons; the only nonphosphatic portions of the fish skeleton are the otoliths, or ear bones, which are calcium carbonate. Arthropods, especially the crustaceans, are important producers of phosphatic skeletons, and a few species of brachiopods, a minor phylum of shelled marine organisms that was important in the geologic past, also produce phosphatic skeletons. Biological concentration of phosphate in rocks formed from marine sediments is sometimes extensive enough to be economically important as a local source for fertilizer and other commercial products.

In addition to being concentrated in the skeletons of some organisms, phosphorus is important to all plants and animals as an essential constituent of phosphoproteins, nucleoproteins, and phospholipids. Phosphorus is present in seawater in very small and variable amounts (about 0.000009 percent), in part because it is rapidly removed by organisms and thus tends to be depleted from surface waters by organisms and concentrated in deeper waters, where there are fewer forms of life because of the lack of light. Areas where deeper waters come to the surface are likely to be very rich in life, in part because of the abundance of this important nutrient.

Iron. A very minor constituent of seawater (about 0.0000004 percent), iron is concentrated by many organisms as a constituent of certain organic molecules; its presence in the respiratory pigment, hemoglobin, is a well-known example. The skeletons of a few animal groups also contain iron minerals, and an amorphous form of iron oxide is found as the cementing agent between sand grains in the shells of some foraminiferans. Certain snails and chitons make a more spectacular use of iron minerals: as cappings for radular elements with which they scrape food (algae) from hard substrates. The iron minerals used in the radula, including magnetite and goethite, are very hard, an asset to an animal that utilizes an animated file.

Iodine. Extremely small amounts (0.000006 percent) of iodine are present in seawater; in fact, the element was discovered in marine algae long before it was detected in seawater. Concentration of iodine by marine plants is so effective that seaweeds were formerly a source for commercial iodine. Iodine is present in many organisms and ranges to 1 percent of the dry weight in the brown algae, a concentration almost 200,000 times that in the seawater. Among the brown algae, *Laminaria* and *Fucus* are especially rich in iodine. Iodine content is highest in brown algae of the temperate zone of the Northern Hemisphere and lowest in the tropics. The concentration also increases with water depth and has been observed to vary during the year, usually being highest in winter. Many other organisms also concentrate iodine: sponges, alcyonarians, and portions of fish, especially the thyroid gland and liver oil, are especially high in the element. The form and function of concentrated iodine is unknown, but it seems to exist both in organic compounds and as inorganic salts.

Vanadium. Concentration of vanadium by certain tunicates (sea squirts) is perhaps the most spectacular example of the concentration of an element from seawater. Although vanadium is extremely rare in seawater (about 0.0000002 percent, or two parts per 1,000,000,000), it may constitute several percent of the respiratory pigment of certain tunicate species (especially species of the Ascidiidae), a concentration on the order of 10,000,000 times. The bulk dry tissue of some tunicates often contains 0.1–0.2 percent of vanadium. Because the concentration of vanadium in seawater is so low, it was first thought that the tunicates obtained vanadium from some other source, perhaps from marine sediments suspended in seawater, but it has been established that the tunicates do in fact obtain vanadium from seawater. In at least one tunicate species the vanadium content of tropical specimens is considerably higher than in those from cold water, suggesting a temperature effect.

Copper. Another element highly concentrated in invertebrates, especially in the mollusks, is copper. Although it comprises only 0.0000001 percent of seawater, copper may be as high as a few tenths of a percent in some cephalopods (octopuses and squid) and clams (especially oysters). In those organisms, the element is a constituent of the respiratory pigment hemocyanin. The copper content of edible clams (oysters and mussels) has been the subject of especially extensive investigation. So-called green oysters, which are poisonous, are rich in copper. Certain of the arthropods, especially the crustaceans, also use hemocyanin as their respiratory pigment and are thus rich in copper.

Fluorine. Fluorine, another minor seawater constituent, is found in the gizzard plates in a few gastropod species in the form of the mineral fluorite (calcium fluoride).

BIBLIOGRAPHY. The literature on this topic is quite diverse; the following treatments constitute the best general sources of information: A.P. VINOGRADOV, *The Elementary Chemical Composition of Marine Organisms* (1953; orig. pub. in Russian, 1935–44), the most valuable single source of information in this field reviewing all literature through about 1950; H.A. LOWENSTAM, "Biologic Problems Relating to the Composition and Diagenesis of Sediments," in T.W. DONNELLY (ed.), *The Earth Sciences: Problems and Progress in Current Research*, pp. 137–195 (1963), the most thorough modern review of skeletal geochemistry; and E.D. GOLDBERG, "Biogeochemistry of Trace Metals," in the GEOLOGICAL SOCIETY OF

AMERICA, *Treatise on Marine Ecology and Paleoecology*, pp. 345–357 (1957), a review of the interrelationship of the chemistry of marine organisms and seawater.

(J.R.D.)

Elevator

An elevator, or lift, is a car that moves in a vertical shaft to carry passengers or freight among the levels of a multistory building. Most modern elevators are propelled by electric motors, with the aid of a counterweight, through a system of cables and sheaves (pulleys). By opening the way to higher buildings, the elevator played a decisive role in creating the characteristic urban geography of many modern cities, especially in the United States, and promises to fill an indispensable role in future city development.

History. The practice of lifting loads by mechanical means during building operations goes back at least to Roman times; the Roman architect-engineer Vitruvius in the 1st century BC described lifting platforms that used pulleys and capstans, or windlasses, operated by human, animal, or water power. Steam power was applied to such devices in England by 1800. In the early 19th century a hydraulic lift was introduced, in which the platform was attached to a plunger in a cylinder sunk in the ground below the shaft to a depth equal to the shaft's height. Pressure was applied to the fluid in the cylinder by a steam pump. Later a combination of sheaves was used to multiply the car's motion and reduce the depth of the plunger. All these devices employed counterweights to balance the weight of the car, requiring only enough power to raise the load.

Prior to the mid-1850s, these principles were primarily applied to freight hoists. The poor reliability of the ropes (generally hemp) used at that time made such lifting platforms unsatisfactory for passenger use. When an American, Elisha Graves Otis, introduced a safety device in 1853, he gave birth to the passenger elevator. Otis's device, demonstrated at the Crystal Palace Exposition in New York, incorporated a clamping arrangement that gripped the guide rails on which the car moved when tension was released from the hoist rope. The first passenger elevator was put into service in the Haughwout Department Store in New York City in 1857; driven by steam power, it climbed five stories in less than a minute and was a pronounced success.

The first passenger elevator

Improved versions of the steam-driven elevator appeared in the next three decades, but no significant advance took place until the introduction of the electric motor for elevator operation in 1889. This installation, in the Demarest Building in New York City, utilized an electric motor to drive a winding drum in the building's basement. The introduction of electricity led to two further advances: in 1894 push-button controls were introduced, and in 1895 a hoisting apparatus was demonstrated in England that applied the power to the sheave (pulley) at the top of the shaft; the weights of the car and counterweight sufficed to guarantee traction. By removing the limitations imposed by the winding drum, the traction-drive mechanism made possible taller shafts and greater speeds. In 1904 a "gearless" feature was added by attaching the drive sheave directly to the armature of the electric motor, making speed virtually unlimited.

With the safety, speed, and height problems overcome, attention was turned to convenience and economy. In 1915 so-called automatic levelling was introduced in the form of automatic controls at each floor that took over when the operator shut off his manual control within a certain distance from the floor level and guided the car to a precisely positioned stop. Power control of doors was added. With increased building heights, elevator speeds increased to 1,200 feet (365 metres) per minute in such express installations as those for the upper levels of the Empire State Building (1931) and reached 1,800 feet (549 metres) per minute in the John Hancock Center, Chicago, in 1970.

Automatic operation, widely popular in hospitals and apartment buildings because of its economy, was improved by the introduction of collective operation, by which an elevator or group of elevators answered calls in sequence from top to bottom or vice versa. The basic safety feature of all elevator installations was the hoistway door interlock that required the outer (shaft) door to be closed and locked before the car could move. By 1950 automatic group-supervisory systems were in service, eliminating the need for elevator operators and starters.

An early attempt to minimize the sacrifice of floor space in elevator installations in tall buildings was the basis of the idea of the double-deck elevator, first tried in 1932. Each elevator consisted of two cars, one mounted above the other and operating as a unit, serving two floors at each stop. The technique is being increasingly adopted. Automatic double-deck elevators in the Time-Life Building, Chicago, were operating in 1971, and installations in the John Hancock Tower, Boston; the Standard Oil Company (Indiana) building, Chicago; and the Canadian Imperial Bank of Commerce, Toronto, were under construction in 1971.

Double-deck elevators

Modern elevators. Modern elevators are made in a variety of types for many purposes; in addition to ordinary freight and passenger operations they are used in ships, dams, and such specialized structures as rocket launchers. Heavy-lift, rapid-descent elevators are employed in high-rise construction operations. Practically all are electrically propelled, either by cables, sheave and counterweight, by a winding-drum mechanism (still used in many low-rise freight elevators), or by an electro-hydraulic combination. Multiple cables (three or more) increase both the traction surface with the sheave and the safety factor; cable failure is rare.

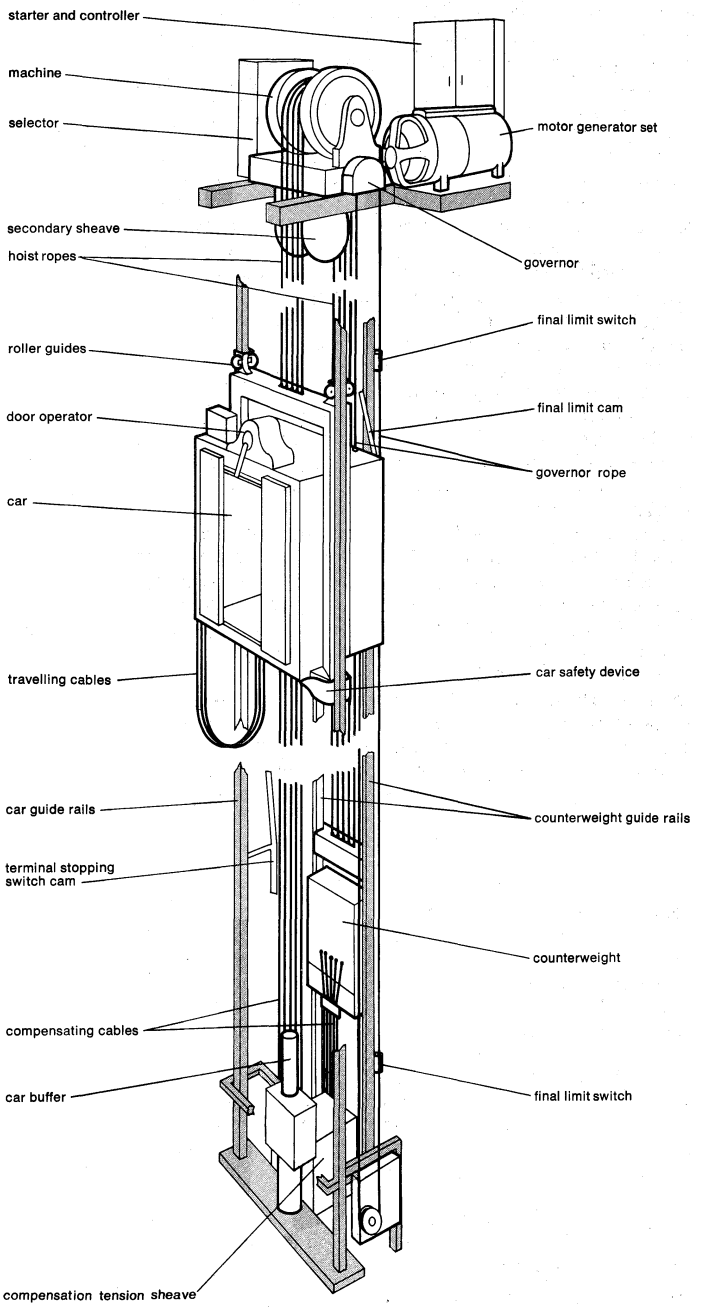
The drive motor is usually alternating current for slower speeds and direct current for higher speeds. With the direct-current motor, the speed is varied by varying the field strength of a direct-current generator, and direct connection of the armature of the generator with the armature of the drive motor. For high-speed operations, a gearless arrangement is used, usually with the cables wrapped twice around the sheave. The traction elevator may have an unlimited rise; however, rises exceeding 100 feet require compensating ropes—*i.e.*, ropes from the bottom of the car to the bottom of the counterweight; as the car rises, the compensating rope weight is transferred to the car, and as it descends, more is transferred to the counterweight, keeping the load on the drive machine nearly constant (see illustration).

Hydraulic elevators. Hydraulic cylinders and plungers are used for low-rise passenger elevators, and for heavy duty freight elevators. The plunger pushes the platform from below by the action of pressurized oil in the cylinder. A high-speed electric pump develops the pressure needed to raise the elevator; the car is lowered by the action of electrically operated valves which release the oil into a storage tank. Specialized types of hydraulic cylinder and plunger arrangements, including horizontally placed elements, are used for unusual applications. For instance, the roped, or "geared," type of hydraulic elevator common around 1900, with plunger and cylinder fitted with sheaves at each end, is employed on aircraft-carrier elevators to lift heavy loads short distances. As pressure is applied to the plunger, the distance between the sheaves increases and the ropes wrapped around the sheaves pull up the elevator.

Safety devices. Elevators lifted by hoisting ropes are required to have platform "safeties," devices designed to clamp onto the steel guide rails upon activation, quickly braking the elevator to a halt. The safety, usually mounted below the car platform, is actuated by a speed governor through a rope. The rope pulls the safety to the on position in the event of governor overspeeding and continued downward motion of the car. The device first cuts off elevator power; if overspeed continues, it applies the safety brake.

Automatic control system. Most modern elevators are automatic, using various control systems to operate elevators individually or in groups.

The earliest automatic control system, single-automatic-push-button, gives a rider exclusive use of the car for a



Electric passenger elevator for automatic service.
By courtesy of Otis Elevator Co.

trip. It is used in small apartment buildings and for freight elevators.

Collective operation is popular for use with a single elevator in a building. The car answers all calls in one direction in sequence and then reverses and answers all calls in the opposite direction. It is used in larger apartments, hospitals, and small office buildings. A variation, called two-car or duplex collective, permits two cars to operate together and share calls between them.

Group-automatic operation

Group-automatic operation controls two or more cars as a group, keeping them spaced within a specified operating interval. Group-automatic operation is used if traffic is heavy and two or more elevators are operating as in hospitals, department stores, and offices.

Doors. Separate outer doors and car doors are essential parts of modern elevator systems. The two usually employ the same type of operation—*e.g.*, centre-opening, two-leaf, single-slide. Doors are opened and closed by an electric motor on the car. Door speed in closing is regulated to avoid injury to persons caught in the closure. A sensor electrically reverses the door if it strikes an object in closing. Photoelectric controls and electronic proximity devices are also employed to control door reversal. Hoistway doors are designed so that they are always closed before the elevator can operate.

For freight elevators, vertically sliding, biparting doors are common. Such doors consist of an upper and lower leaf, mechanically linked so that the bottom half drops to floor level while the top half rises above the cab roof. A protective inner gate is often required.

Communication systems. In isolated locations, especially in private residences, a telephone to an outside exchange is often required by law. In many buildings, elevators have intercommunication systems in case of mechanical failures. Alarm buttons, emergency lighting, and emergency power are often provided.

Automatic freight handling. Automatic loading and unloading devices have been incorporated into modern freight elevators. A call button activates the automatic pickup; the elevator arrives, the load is pulled into the car, the car moves to the proper floor, and the load is discharged.

Sky lobbies. At the two World Trade Center Tower Buildings in New York City, a new technique has been introduced for minimizing the space required for elevators. Each 110-story building is divided into three layers. The lower layer, the first 41 floors of the tower, has four banks of six elevators each; similarly, the middle and upper layers each have their own four banks of six elevators. At the 44th and 78th floors there is a "sky lobby," connected to the main floor by 11 high-speed shuttle elevators.

Observation cars. Transparent walled elevators rising on the outside of buildings and observation towers have recently grown popular; the original was probably that installed in the Eiffel Tower, Paris (1889). Such observation elevators have glass-enclosed cabs affording passengers a view as they ride.

Elijah ben Solomon

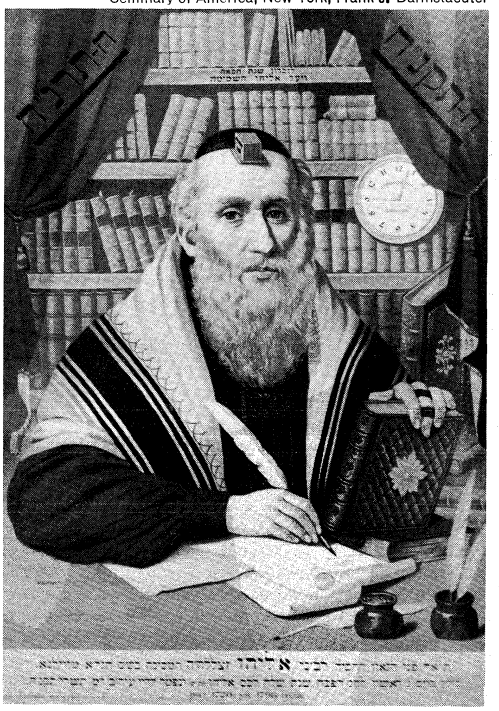
The status of Elijah ben Solomon Zalman, the Vilna *gaon* ("Excellency"), as the outstanding authority in the religious and cultural life of Jewry in Lithuania in the 18th century derived from his personal qualities of character and intellect, not from any institutionally defined leadership role. Indeed, he never held a rabbinic office or title, but his way of life as well as his achievement epitomize the role of the saintly scholar in Jewish traditional culture. His personality—the historical as well as the legendary one—and the religious and social tenets impressed by it shaped the peculiarly "Litvak" (Lithuanian–Jewish) attitude to life and culture of eastern European Jewry and later of their descendants in the West. They also influenced forms of Jewish culture that were opposed in principle to much that Elijah taught, such as Hasidism (18th-century pietistic mysticism) and Haskala (the 18th–19th-century Jewish Enlightenment).

Elijah was born April 23, 1720, at Sielec, Lithuania (now Selets, Belorussian S.S.R.), into a long line of scholars. He became famous in early childhood for

prodigious feats of rapid learning and an unusually retentive memory, intellectual gifts he retained to his last day. Married at approximately 18, he settled in Vilna (Vilnius, Wilno), leaving it only for the penitential *galut* ("exile") journey through Jewish communities in Poland, Lithuania, and Germany and returning in 1748. The rest of his life, Elijah was a central public figure in Vilna—the cultural centre of eastern European Jewry—leading the Jewish community through a combination of a life devoted to study, prayer, vision, and meditation and of teaching a chosen circle of devoted pupils. The Vilna community supported him with a stipend that came largely from funds bestowed by one of Elijah's ancestors for the support of scholars from his family. It added its own funds and also gave Elijah a rent-free apartment. Thus, the community gave him a monthly payment higher than the salary of the communal rabbi, though he had no explicit social function; it did so because of his exemplary life and voluntary leadership.

Leader of the Jewish community in Vilna

Picture from the photographic archive of the Jewish Theological Seminary of America, New York, Frank J. Darmstaedter



Elijah ben Solomon, engraving by an unknown artist.

Elijah's view of man and his struggle for self-realization throughout history was based on the assumption that for every individual there exists a peculiar path, "according to the specific roots of his soul and the particular nature of his body." In the first era of history, prophets revealed to each man his own path. In the following era, when prophecy had ended, one had to turn inward and discover one's way for oneself. Elijah held that, theoretically, this could be still done even in the present era of decline; but temptation and deception are ripe and active. Spiritual safety lies, therefore, in following the uniform Torah—the divine guidance or law.

Individual strength and guiding authority marked Elijah's spiritual life. He steadily and systematically restrained his extraordinarily quick perception and compelled himself to constant analysis and repetition, an intellectual self-discipline that he called "grinding." He rejected his own active dream life, which was full of scholarly insights and visions. Indeed, he resented the knowledge imparted to him in sleep, for he sought to worship through conscious intellectual labour; gifts from on high—even through the intermediary of heavenly angels and heralds—were seen as misleading. His many visions were even more suspect to him, for he feared evil forces that might have lurked within them.

Elijah's vast knowledge in all fields of traditional Jewish learning in Talmud and Midrash (the traditional interpretative and commentative literature) and in biblical exegesis, as well as in mystical literature and lore, was combined with a deep interest in and knowledge of philosophy, grammar, and folk medicine. He studied day and night not only as the best way to worship God but also as the true method of exercising proper leadership, which he believed should be the emanation of a scholar overflowing with learning. Elijah's metaphor for this is that of a large central vessel filling itself up to overflowing into smaller vessels—the pupils—who in their turn overflow into groups around them; thus does the central teacher influence the whole people.

Elijah put this theory in practice and drew a small circle of very able and influential pupils to him, most of whom were already rabbis or preachers. Outstanding among them were Ḥayyim ben Issac, rabbi of Volozhin, the founder of a new type of Lithuanian yeshiva (Talmudic academy) and Elijah's successor as leader of Lithuanian Jewry; and Jacob ben Wolf Kranz, an itinerant preacher of great renown, who created a new school and style of preaching.

Elijah usually avoided public activities and engaged actively in certain causes only as an extraordinary form of his unceasing leadership and teaching from his study. The most conspicuous and sustained of his public activities was his implacable fight against Ḥasidism, which lasted from 1772 until his last day. He feared and despised it as an "idolatrous," superstitious, vulgar, and antischolarly movement and participated in a manifesto excommunicating its adherents. Ḥasidic admiration for miracles and visions, adulation of their group leader (the *tzaddiq*), and striving for collective joy, with the aid of alcoholic liquor and dancing, were to him the propagation of all he rejected for himself. Moreover, Ḥasidic stress on prayer was to him an attack on the supremacy of Torah study, which he held sacred.

Opposition to Ḥasidism

Elijah died at Vilna on Oct. 9, 1797. As a result of his concentrated devotion to incessant, wakeful learning and direct, oral teaching, as well as his concern with minute textual criticism and emendation and the urgent tempo of his intellectual work, all that is extant from him are notes of his teachings kept by his pupils or short manuscript notes of his own written in the margins of basic texts. These have been combined and edited into more than 40 works now in print in all fields of his interest, yet some material still remains in manuscript. Lately, there has been ascribed to him a prophetic work, *Kol ha-tor* ("Voice of the Turtledove") foretelling the success of Zionism, but it is, in its main elements, probably a modern forgery.

Elijah's main contribution to posterity was to provide an example of the intellectual love of God in the traditional mode at the threshold of Jewish modernity.

Elimination

Biologically, elimination may be considered to encompass all of the various mechanisms and processes by which life forms dispose of or throw off waste products, toxic substances, and dead portions of the organism. In a more broad context, elimination may be thought to include all waste-disposal processes in nature, including those of entire animal and plant populations as well as of individuals.

GENERAL FEATURES

Definitions. Four terms are commonly associated with waste-disposal processes and are often used interchangeably, though not always correctly, viz., excretion, secretion, egestion, and elimination.

Waste disposal processes

Excretion. Excretion is a general term referring to the separation and throwing off of waste materials or toxic substances from the cells and tissues of a plant or animal.

Secretion. The separation, elaboration, and elimination of certain products arising from cellular functions in multicellular organisms is called secretion. Though these substances may be a waste product of the cell producing them, they are frequently useful to other cells of the organism. Examples of secretions are the digestive enzymes produced by intestinal and pancreatic tissue cells of vertebrate animals, the hormones synthesized by specialized glandular cells of plants and animals, and sweat secreted by glandular cells in the skins of some mammals. Secretion implies that the chemical compounds being secreted were synthesized by specialized cells and that they are of functional value to the organism. The disposal of common waste products should not, therefore, be considered to be of a secretory nature.

Egestion. Egestion is the act of excreting unusable or undigested material from a cell, as in the case of single-celled organisms, or from the digestive tract of multicellular animals.

Elimination. As defined above, elimination broadly defines the mechanisms of waste disposal by living systems at all levels of complexity. The term may be used interchangeably with excretion.

Biological significance of elimination. Waste disposal by single-celled and multicellular organisms is vital to their well-being and to the continuance of life. Animals must take in (ingest) energy-containing chemical compounds, extract a portion of the energy to power their life processes, and dispose of the unusable material or by-products formed during the energy-extraction process. An analogous series of events occurs in an internal combustion engine. Fuel, containing energy, is taken into the engine, where it is burned, and a portion of the energy released is used to move the pistons. As in living cells, a portion of the energy-containing material (fuel) not utilized in the engine is exhausted in the form of carbon monoxide, carbon dioxide, and other by-products of combustion. Blockage of the exhaust system in an engine results in loss of efficiency and eventual total breakdown. Similarly, the rate of waste disposal in biological systems can and does provide a means of controlling the metabolic rate. Complete blockage of waste-disposal mechanisms in living systems is as effective in destroying vital functions as the cutting off of food, oxygen, or water from the system. In addition, some substances produced as metabolic by-products are toxic in themselves and must be removed from living cells at a rate equal to that at which they are produced by those cells. Thus, the excretion of waste products from living cells must occur continually in order to ensure the normal progression of vital chemical events.

Importance of elimination in living systems

Waste and poisonous substances produced by the metabolic activities of plant and animal communities must, in a similar manner, be removed or detoxified if community well-being is to be preserved. Collective wastes of individual organisms composing a community, if allowed to accumulate to any marked degree, will eventually destroy the lives of all the community members.

The biosphere, composed of all individuals and communities of life forms and their environments on the Earth, is equally sensitive to the effects of waste and poison accumulation. A continual buildup of substances harmful to life forms can only result in the eventual destruction of most or all of the presently existing species of plants and animals.

Types of wastes. Waste products may be categorized as metabolic or nonmetabolic. The difference lies in whether the substances in question are produced by the chemical processes of a living cell or are merely passed through the digestive tract of an organism without actually entering into its life processes.

The nonmetabolic wastes are mainly materials that, by virtue of their chemical makeup, are indigestible or unusable by an organism. In addition, nonmetabolic wastes include any substances that are absorbed, ingested, or otherwise taken into a living system in excess of the needs and storage capabilities of the organism. These substances include digestible (metabolizable) as well as indigestible materials, and they may be excreted almost immediately, even though they are often usable as food.

Metabolic and nonmetabolic wastes

Metabolic wastes may be separated into gases, liquids, solids, and heat. Heat, though usually not classified as a waste product, should be classified as such because it is a by-product of metabolic activity and must be eliminated to avoid harmful elevation of body temperatures in warm-blooded animals.

Gaseous wastes. Oxygen produced during photosynthetic reactions in green plants and certain bacteria may be considered to be a waste, or at least a by-product, requiring removal. Carbon dioxide is produced by all animals and by green plants in darkness. Nitrogen gas is produced by denitrifying sulfur bacteria (*Thiobacillus*), and ammonia is excreted by decay-causing bacteria and by most invertebrate and vertebrate animals.

Liquid wastes. The sole liquid waste produced as a metabolic by-product by all animals and photosynthetic plants in darkness is water.

Solid wastes. Several important kinds of materials may be classified as solid wastes. Among them are nitrogenous wastes, by-products of protein and amino acid metabolism by animals; nitrite and nitrate compounds produced by nitrifying bacteria; and sulfur and sulfates resulting from the metabolic activities of sulfur bacteria. Numerous other substances also enter into solid wastes to be disposed of by organisms. Iron compounds in insoluble form are secreted by iron bacteria that have utilized soluble iron compounds. Various resins, fats, waxes, and complex organic chemicals are exuded from certain plants—as in the latex from rubber trees and milkweeds. Organic pigments from the breakdown of biological pigments, such as hemoglobin in vertebrates, become components of solid waste. Inorganic salts, including molecules and ions such as carbonates, bicarbonates, and phosphates resulting from life sustaining chemical reactions, eventually may become solid waste products.

METHODS OF WASTE DISPOSAL

Disposal of metabolic and nonmetabolic wastes involves both active and passive mechanisms. In general, gaseous wastes are eliminated principally without the direct expenditure of energy on the part of the living system. The solid and liquid waste-disposal mechanisms utilized by higher animals are active (energy consuming) systems that act to separate waste materials from vital substances prior to excretion. Methods of disposal may be classified into specific and nonspecific systems.

Specific elimination mechanisms. Three pathways exist in this context: (1) the alimentary canal, (2) the respiratory system, and (3) the kidney.

Alimentary canal. The alimentary canal is a pathway utilized almost exclusively for the elimination of solid wastes of an indigestible nature, and the act of elimination by this means is termed egestion. Materials disposed of in this manner cannot be said to have entered the tissues of the animal but are the residue of enzymatic and absorptive activities occurring in the digestive tract. True metabolic wastes are excreted by means of the flow of bile from the liver into the intestine. The destruction of cells, in animals, produces bile pigments—residues of hemoglobin and other pigments—which may be considered to be the principal metabolic wastes eliminated via the alimentary canal. Waste disposal in this manner requires little energy expenditure other than that employed in the peristaltic contractions of muscle in the walls of the tract that act to push material along the length of the tube.

Respiratory system. This pathway is concerned principally with the gaseous waste products of metabolism (carbon dioxide and ammonia), which move to the external environment by means of diffusion from the cells of origin. In animals, transport is by means of the circulatory system when present or simply by diffusion through the cell membranes of lower animals. A few multicellular, aquatic animals lose carbon dioxide to the surrounding water by way of diffusion through the thin

vascular membranes of their general body surface. In most higher animals, however, the skin is too hard or thick and nonvascular to function effectively in gas disposal. In these animals, gills and lungs—aggregations of thin, moist, vascular membranes—have evolved. Membranes of the gills of aquatic animals and the lungs of terrestrial forms are provided with large surface areas for the diffusion of waste gases from the circulatory system to the outside environment. Because carbon dioxide is soluble in the body water, it can easily diffuse into the circulatory system, in solution, from the cells of origin.

Carbon dioxide elimination

Transport and excretion of carbon dioxide requires little energy as it diffuses along concentration gradients from cells to the circulation and finally to the outside environment.

Because more carbon dioxide (CO_2) is produced by metabolic activity than can be carried in the circulation system in the form of dissolved CO_2, the major portion is transported to the gills and lungs as bicarbonate (HCO_3^-), via two chemical reactions:

$$CO_2 + H_2O \leftrightharpoons H_2CO_3 \rightleftarrows H^+ + HCO_3^-.$$

Thus, carbon dioxide reacts with water, producing carbonic acid, which in turn dissociates to produce a hydrogen ion and a bicarbonate ion. In the lungs or gills, the reverse of these reactions occurs, and carbon dioxide diffuses out of the body into the outside environment. Certain aquatic animals are capable of eliminating gaseous ammonia—derived from protein breakdown—by way of specialized cells in their gill tissues.

Salt secretion by way of specialized cells in the gills occurs in marine vertebrates whose bodies constantly absorb salt through thin membranes of their oral, respiratory, and body surfaces.

The kidney. Kidneys have evolved in multicellular animals as a highly sophisticated channel for waste disposal, and they function to regulate the levels of water, salts, and organic materials in the bodies of higher animals. Materials eliminated via the kidney include nitrogenous waste products (ammonia, uric acid, urea, creatine, creatinine, and amino acids), excess quantities of salts and water that may be taken into the body, and various other organic materials produced by life-sustaining chemical reactions. Functionally, the kidney is a microfilter that initially removes dissolved as well as some suspended materials from the circulation system, along with large quantities of water. These substances are differentially reabsorbed, before being excreted as urine, to a degree that varies considerably throughout the animal kingdom. For example, animals that absorb large quantities of water into their bodies (such as freshwater fishes) excrete copious quantities of water in their urine. The reverse is true of many desert animals, which must conserve water and therefore produce a thick, semisolid urine. The kidney, in its various stages of evolution, functions at the expense of considerable metabolic energy and cannot be considered to be a passive system.

Nonspecific mechanisms of waste disposal. A multitude of disposal mechanisms exist throughout the plant and animal kingdoms for the disposal of excess plant and animal material. Among plants, the shedding and dropping of bark, leaves, and twigs might, in a broad sense, be said to represent disposal mechanisms. Certain plants, in addition, secrete or exude resins, sap, and other substances that accumulate in excessive quantities within the plant.

Elimination of particulate wastes from blood stream

Specialized, mobile, amoeba-like cells exist in the blood and tissues of animals and engulf particulate wastes resulting from the disintegration of dead cells or the intake of foreign particles into the bodies of animals. Waste matter thus stored inside these small cells is removed from contact with the organism or its metabolism and may be considered to be eliminated whether or not the material is ever actually eliminated from the body of the organism during its normal life cycle.

Toxic substances are produced by normal metabolic activities. Though some of these poisons are eliminated in their original chemical form, others, such as some nitrogenous compounds, are altered biochemically to less toxic compounds. In this manner, more of the original waste may be safely stored, or permitted to accumulate without harmful effects to the organism, until they can be eliminated. In addition, toxic chemicals that are inadvertently ingested or produced by bacterial action (infection) are frequently converted to nontoxic forms by enzymatic and antibody (immune) reactions. Such materials can then safely be eliminated with other wastes along normal pathways of excretion.

Heat is eliminated from the bodies of animals by conduction to the external surface of the organism. In animals possessing a circulatory system, heat travels in the fluid of the circulation system from the deeper portions of the body to the surface. At the body surface, heat is lost by physical processes of convection, radiation, conduction, and evaporation of sweat.

COMPARATIVE OVERVIEW OF ELIMINATION SCHEMES

Protista. No specialized elimination mechanisms are present in algae, fungi, protozoans, and slime molds, the main groups of protists. Metabolic wastes (carbon dioxide, water, oxygen, and nitrogenous compounds) diffuse through the cell membranes of these single-celled organisms into the outside environment. Particulate wastes pass from the bodies of certain protozoans to the exterior by way of small openings in the body surface—anal pores and other cell openings.

Elimination in protists is carried out passively and therefore requires little or no expenditure of metabolic energy on the part of the organism.

Plants. Plants are not generally considered to possess special mechanisms of elimination. Photosynthetic activities of green plants, in the presence of light, produce oxygen, which diffuses out through openings in the leaves (stomata) or through the cell walls of roots and other plant structures. Excess water passes to the exterior via similar routes and is eliminated by processes of guttation (droplet exudation) and transpiration (evaporation of water from plant surfaces).

Green plants in darkness or plants that do not contain chlorophyll produce carbon dioxide and water as respiratory waste products. Carbon dioxide is secreted in the same manner as oxygen via diffusion through stomata and cell walls. Materials that are exuded by some plants —resins, saps, latexes, etc.—are forced from the interior of the plant by hydrostatic pressures inside the plant and by absorptive forces of plant cells. These forces are passive in nature, and exudation requires no energy expenditure on the part of the plant.

Animals. Diverse mechanisms have evolved that enable the various animal species to inhabit a wide range of environments. In animals whose bodies consist of a single layer of cells, waste disposal is accomplished principally by diffusion from the site of waste production to the outside environment. This method is very efficient when the distances over which wastes diffuse are relatively short, when there is a high surface area to volume relationship, and when the rate of waste production is relatively low. In more complex animals, however, waste elimination by diffusion through the body wall to the exterior is less efficient because individual cells are further removed from the exterior surface of the organism. The presence of specialized mechanisms of elimination in higher animals enables wastes to be rapidly transported to the exterior surface of the body (see EXCRETION AND EXCRETORY SYSTEMS).

Efficiency of the diffusion mechanism of waste disposal

Sponges. Phylogenetically, the sponges (phylum Porifera) are the simplest of animals, being multicellular and composed of specialized cells in a single layer for the maintenance of life processes. Elimination in these aquatic animals proceeds by diffusion of gaseous wastes into the surrounding water and by the ejection of solid wastes and indigestible material from the digestive cells into the streams of water that constantly flow through the animal.

Coelenterates. The jellyfishes, coral animals, ctenophores, and comb jellies possess a rudimentary canal-like cavity in their two-layered bodies for the ingestion, digestion, and egestion of food and wastes. Gaseous wastes are

eliminated by diffusion, and solid wastes in dissolved or undissolved form pass out through an opening in the body wall that serves the dual purposes of food intake and waste elimination.

Flatworms. Flatworm bodies consist of three layers of cells, and in this aquatic group elimination is similar to that of the less complex animals. Food and solid wastes enter and leave through a common opening in the well-developed digestive tract, which consists of a mouth, pharynx, and gastrovascular cavity.

Nemertine worms. The digestive and excretory systems of the aquatic proboscis worms is more efficient than that of lower animals in that a well-defined mouth, intestine, and excretory opening (anus) permit the one-way flow of food and waste through the animal. Egested food and nitrogenous wastes, which are secreted into the intestine, are passed along it to the anus by peristaltic waves of the smooth muscle lining the intestinal walls. The efficiency of waste elimination is increased by the presence of a well-defined circulatory system, which enhances the carriage of wastes to the intestine.

Nematodes. An additional excretory structure has evolved in the roundworms. Excretory canals located on both sides of the intestine facilitate waste disposal by carriage of material to an excretory pore in the body wall.

Other invertebrates. Increasing structural complexity is accompanied, in invertebrates, by more efficient waste-disposal mechanisms. In the phylum Mollusca (clams, snails, oysters, mollusks, octopuses, and squids), gills are present, adding another more efficient channel for waste disposal. A heart increases the rate of flow in the circulatory system and speeds the transport of wastes to the gills. An excretory, kidney-like organ acts to remove metabolic wastes from the circulation and body fluid prior to excretion. All basic mechanisms of excretion are thus present in relatively simple animals. As invertebrates become more specialized and complex, as in the arthropods (insects, crabs and other joint-legged animals) and annelids (segmented worms), adaptations exist whereby excretion is modified for purposes of survival in nonaquatic environments.

Vertebrates. Though the wastes produced by vertebrates differ little qualitatively from those of higher invertebrates, increased structural complexity and body size, in combination with environmental adaptations, require more specific waste-disposal mechanisms in order to maintain a constant internal environment. The presence of highly efficient, water-retaining kidneys, for example, permits vertebrates to inhabit arid, hot regions of the Earth. It seems proper, within the vertebrate group, to consider elimination schemes as variations of mechanisms common to all higher animals but which enable animals to inhabit widely diversified environments.

PROBLEMS OF WASTE DISPOSAL IN THE BIOSPHERE

Environmental pollution

Man is unique among living things in that his activities result in the production of waste materials (pollutants) that, by virtue of their chemical structure, are poisonous to all living things, including himself (see BIOSPHERE; CONSERVATION OF NATURAL RESOURCES; and POLLUTION CONTROL). While the metabolic and nonmetabolic wastes produced by most living things are used in the maintenance of various ecological cycles of the biosphere, substances such as insecticides, waste metals, strong acids and alkalies, atmospheric poisons, etc., act to unbalance and interrupt natural cycles. The addition of such materials to the biosphere poses a serious threat to all life on Earth.

Complex chemical cycles in the natural world act to utilize the waste products of all living systems. Biological wastes of one life group become the energy sources of other groups. Disposal of water-borne wastes on a biosphere level involves such processes as the filtering of water through fine soil, the settling out of particulate matter in streams and lakes, and the destruction of wastes by lower life forms (bacteria and fungi). Carbon dioxide, produced by the oxidation of organic molecules, diffuses into the atmosphere, where it may dissolve in the surface waters of the world or be utilized by green plants during photosynthesis. The nitrogenous wastes of animals are utilized directly by bacteria and are eventually recycled by way of plants to become the proteins and amino acids consumed by animals. Thus, all living things, on a broad scale, are dependent on one another and on natural biogeochemical cycles.

Eliot, George

One of the great English novelists of the Victorian Age, George Eliot (the pen name of Mary Anne Evans) developed the method of psychological analysis characteristic of modern fiction. She was born at Chilvers Coton, Warwickshire, November 22, 1819, on an estate, for the owner of which her father was agent. Her command of England's Midland dialects is not strange; she heard little else until she went as a boarder to Mrs. Wallington's School at Nuneaton (1828–32). There she came under the influence of Maria Lewis, the principal governess, who, along with a formal Johnsonian diction, inculcated a strong evangelical piety in the young girl. At her last school (1832–35), conducted by the daughters of the Baptist minister at Coventry, her religious ardour increased. She dressed severely and engaged earnestly in good works. The school gave her a reading knowledge of French and Italian, and after her mother's death had compelled her to return home to keep house for her father, he let her have lessons in Latin and German. In 1841, when her father turned his business over to his son Isaac, she moved with him to Coventry.

Education

George Eliot, chalk drawing by F.W. Burton, 1865. In the National Portrait Gallery, London.

There she became acquainted with a prosperous ribbon manufacturer, Charles Bray (1811–84), a self-taught freethinker who campaigned boldly for secular education, trade unions, extension of the franchise, and other radical causes. Mrs. Bray came of an earnest Unitarian family; her sister, Sara Hennell, was immersed in theological and philosophical speculations, and her brother, Charles Hennell, was the author of *An Inquiry Concerning the Origin of Christianity* (1838), a book that precipitated Miss Evans' break from orthodoxy that had been

long in preparation. Her favourite Scott's novels had early shown her that papists might have noble characters, and she knew many Dissenters who lived better lives than many churchmen. Various books on the relation between the Bible and science had instilled in her keen mind the very doubts they were written to dispel. In 1842 she told her father that she could no longer go to church. The ensuing storm raged for several months before they reached a compromise, leaving her free to think what she pleased so long as she appeared respectably at church, and she lived with him until his death in 1849.

Early literary endeavours

The Brays and the Hennells quickly drew her from extreme provincialism, introducing her to many ideas in violent antithesis with her Tory father's religious and political views. When Charles Hennell married in 1843, she took over from his wife the translating of D.F. Strauss's *Das Leben Jesu kritisch bearbeitet*, which, published anonymously as *The Life of Jesus Critically Examined* (3 vol., 1846), had a profound influence on English rationalism. After the wedding Mrs. Hennell's father, R.H. Brabant, invited Miss Evans to visit at Devizes. A rather silly man, he had worked for years on a book (never completed) that was to dispose forever of the supernatural elements in religion. They read German and Greek together and discussed theology on long walks; soon Mrs. Brabant became jealous of their intimacy, and, before the term of her visit, Mary Anne was forced to leave. Mrs. Hennell felt that her father had acted ungenerously. Out of the humiliation of this episode George Eliot drew the horrible vividness of Mr. Casaubon in *Middlemarch*.

She spent the winter of 1849–50 at Geneva, reading widely, living in the family of François d'Albert Durade, who painted a portrait of her. Like those by Mrs. Bray (1842) and Sir Frederic Burton (1865), all in the National Portrait Gallery, it shows her with light brown hair, gray-blue eyes, and a very fair complexion. Returning to Coventry, she spent the rest of 1850 with the Brays, pondering how to live on the £100 a year left by her father. After John Chapman, the publisher of *The Life of Jesus Critically Examined*, got her a chance to review R.W. Mackay's *The Progress of the Intellect* in *The Westminster Review* (January 1851), she decided to settle in London as a free-lance writer, and in January 1851 she went to board with the Chapmans at 142, Strand.

Soon after her arrival Mrs. Chapman and the children's governess, who was also Chapman's mistress, became jealous of Marian, as she now signed her name, and after ten weeks she returned to Coventry in tears. Doubtless her feelings were strongly attracted to the magnetic Chapman, whose diary supplies these details, but there is no evidence that she was ever his mistress. A few months later he bought *The Westminster Review*, and Marian, contrite at the domestic complications she had unwittingly caused, returned to London. For three years, until 1854, she served as subeditor of *The Westminster*, which under her influence enjoyed its most brilliant run since the days of John Stuart Mill. At the Chapmans' evening parties she met many notable literary figures in an atmosphere of political and religious radicalism. Across the Strand lived the subeditor of *The Economist*, Herbert Spencer, whose *Social Statics* (1851) Chapman had just published. Marian shared many of Spencer's interests and saw so much of him that it was soon rumoured that they were engaged. Though he did not become her husband, he introduced her to the two men who did.

Relationship with George Henry Lewes

George Henry Lewes was the most versatile of Victorian journalists. In 1841 he had married Agnes Jervis, by whom he had four sons. In 1850 Lewes and a friend, the journalist Thornton Leigh Hunt, founded a radical weekly called *The Leader*, for which he wrote the literary and theatrical sections. In April 1850, two weeks after the first number appeared, Agnes Lewes gave birth to a son whose father was Thornton Hunt. Lewes, being a man of liberal views, had the child registered as Edmund Lewes and remained on friendly terms with his wife and Hunt. But after she bore Hunt a second child in October 1851, Lewes ceased to regard her as his wife, though, having condoned the adultery, he was precluded from suing for divorce. At this moment of dejection, his home hopelessly broken, he met Marian Evans. They consulted about articles and went to plays and operas that Lewes reviewed for *The Leader*. Convinced that his break with Agnes was irrevocable, Marian determined to live openly with Lewes as his wife. In July 1854, after the publication of her translation of Feuerbach's *Essence of Christianity*, they went to Germany together. In all but the legal form it was a marriage, and it continued happily until Lewes' death in 1878. "Women who are content with light and easily broken ties," she told Mrs. Bray, "do *not* act as I have done. They obtain what they desire and are still invited to dinner."

At Weimar and Berlin she wrote some of her best essays for *The Westminster* and translated Spinoza's *Ethics* (still unpublished), while Lewes worked on his pioneer life of Goethe. By his pen alone he had to support his three surviving sons at school in Switzerland as well as Agnes, whom he gave £100 a year, which was continued until her death in 1902. She had four children by Hunt, the last born in 1857, all registered under Lewes' name. The few friends who knew the facts agreed that toward Agnes his conduct was more than generous, but there was a good deal of malicious gossip about the "strong-minded woman" who had "run off with" her husband. Marian's deepest regret was that her act isolated her from her family in Warwickshire. She turned to early memories and, encouraged by Lewes, wrote a story about an episode in Chilvers Coton parish during her childhood. Published in *Blackwood's Magazine* (1857) as "The Sad Fortunes of the Reverend Amos Barton," it made an instant success. Two more tales, "Mr. Gilfil's Love-Story" and "Janet's Repentance," also based on local events, appeared serially in the same year, and Blackwood republished all three as *Scenes of Clerical Life* (2 vol., 1858) under the pseudonym George Eliot.

Adam Bede (3 vol., 1859), her first long novel, she described as "a country story—full of the breath of cows and the scent of hay." Its masterly realism—"the faithful representing of commonplace things"—brought to English fiction the same truthful observation of minute detail that Ruskin was commending in the Pre-Raphaelites. The book is rich in humour. The germ of the plot was an anecdote her Methodist aunt told of visiting a girl condemned for child murder. The dialect of the Bedes she had heard her Derbyshire uncles speaking with her father, some of whose early experiences she assigned to Adam. But what was new in English fiction was the combination of deep human sympathy and rigorous moral judgment. *Adam Bede* went through eight printings within a year, and Blackwood doubled the £800 paid for it and returned the copyright.

Adam Bede

In *The Mill on the Floss* (3 vol., 1860) she returned again to the scenes of her early life. The first half of the book, with its remarkable portrayal of childhood, is irresistibly appealing, and throughout there are scenes that reach a new level of psychological subtlety.

At this time historical novels were in vogue, and when Lewes during their visit to Florence in 1860 suggested Savonarola as a good subject, George Eliot grasped it enthusiastically and began to plan *Romola* (1862–63). First, however, she wrote *Silas Marner* (1861), which had thrust itself between her and the Italian material. Its brevity and perfection of form made this story of the weaver whose lost gold is replaced by a strayed child the best known of her books, though it has suffered unfairly from being forced on generations of school children. *Romola* was planned as a serial for *Blackwood's*, until an offer of £10,000 from *The Cornhill Magazine* induced George Eliot to desert her old publisher; but rather than divide the book into the 16 installments the editor wanted, she accepted £3,000 less, an evidence of artistic integrity few writers would have shown. Details of Florentine history, setting, costume, and dialogue were scrupulously studied at the British

Museum and during a second trip to Italy in 1861. It was published in 14 parts between July 1862 and August 1863. Though the book lacks the spontaneity of the English stories, it has been unduly disparaged.

George Eliot's next two novels are laid in England at the time of agitation for passage of the Reform Bill. In *Felix Holt, the Radical* (3 vol., 1866) she drew the election riot from recollection of one she saw at Nuneaton in December 1832. The initial impulse of the book was not the political theme but the tragic character of Mrs. Transome, one of her greatest triumphs. The intricate plot popular taste then demanded now tells against the novel. *Middlemarch* (8 parts, 1871–72) is by general consent George Eliot's masterpiece. Under her hand the novel had developed from a mere entertainment into a highly intellectual form of art. Every class of Middlemarch society is depicted from the landed gentry and clergy to the manufacturers and professional men, the shopkeepers, publicans, farmers, and labourers. Several strands of plot are interwoven to reinforce each other by contrast and parallel. Yet the story depends not on close-knit intrigue but on showing the incalculably diffusive effect of the unhistoric acts of those who "lived faithfully a hidden life and rest in unvisited tombs."

Daniel Deronda (8 parts, 1876), in which George Eliot comes nearest the contemporary scene, is built on the contrast between Mirah Cohen, a poor Jewish girl, and the upper class Gwendolen Harleth, who marries for money and regrets it. The less convincingly realized hero, Daniel, after discovering that he is Jewish, marries Mirah and departs for Palestine to establish a home for his nation. The picture of the Cohen family evoked grateful praise from Jewish readers. But the best part of *Daniel Deronda* is the keen analysis of Gwendolen's character, which seems to many critics the peak of George Eliot's achievement.

In 1863 the Leweses bought the Priory, 21, North Bank, Regent's Park, where their Sunday afternoons became a brilliant feature of Victorian life. There on November 30, 1878, Lewes died. For nearly 25 years he had fostered her genius and managed all the practical details of life, which now fell upon her. Most of all she missed the encouragement that alone made it possible for her to write. For months she saw no one but his son Charles Lee Lewes; she devoted herself to completing the last volume of his *Problems of Life and Mind* (1873–79) and founded the George Henry Lewes Studentship in Physiology at Cambridge. For some years her investments had been in the hands of John Walter Cross (1840–1924), a banker introduced to the Leweses by Herbert Spencer. Cross's mother had died a week after Lewes. Drawn by sympathy and the need for advice, George Eliot soon began to lean on him for affection too. On May 6, 1880, they were married in St. George's, Hanover Square. Cross was 40; she was in her 61st year. After a wedding trip in Italy they returned to her country house at Witley before moving to 4, Cheyne Walk, Chelsea, where on December 22, 1880, George Eliot died. She was buried at Highgate Cemetery.

MAJOR WORKS

NOVELS: *Scenes of Clerical Life*, 2 vol. (1858; "The Sad Fortunes of the Reverend Amos Barton," "Mr. Gilfil's Love-Story," and "Janet's Repentance," all first published in *Blackwood's Magazine* in 1857); *Adam Bede*, 3 vol. (1859); *The Mill on the Floss*, 3 vol. (1860); *Silas Marner: The Weaver of Raveloe* (1861); *Romola*, 3 vol. (1863; first published in *Cornhill Magazine*, 1862–63); *Felix Holt, the Radical*, 3 vol. (1866); *Middlemarch: A Study of Provincial Life*, 4 vol. (1871–72); *Daniel Deronda*, 4 vol. (1876).

OTHER WORKS: *The Spanish Gypsy* (1868), drama in blank verse; *The Legend of Jubal and Other Poems* (1874), which ends with, "Oh, May I Join the Choir Invisible"; *Impressions of Theophrastus Such* (1879), a collection of moral essays; *Essays and Leaves from a Note-Book*, ed. by C.L. Lewes (1884), mostly reprinted from journals.

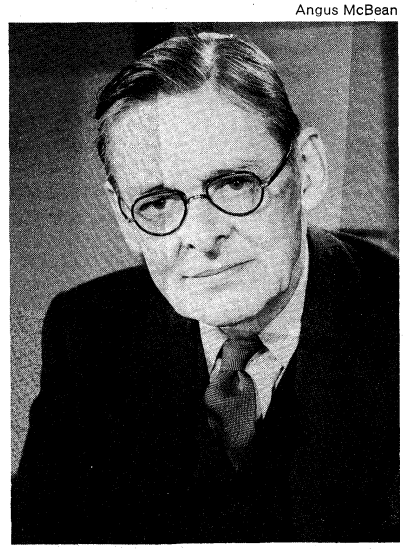
TRANSLATIONS: D.F. Strauss, *The Life of Jesus Critically Examined*, 3 vol. (1846; trans. from the German begun by Mrs. Charles Hennell and completed anonymously by George Eliot); L. Feuerbach, *The Essence of Christianity*, trans. from the German (1854); and B. Spinoza, *Ethics* (unpublished).

BIBLIOGRAPHY. GORDON S. HAIGHT, *George Eliot: A Biography* (1968), the definitive life, includes materials omitted by J.W. CROSS in *George Eliot's Life As Related in Her Letters and Journals*, 3 vol. (1885), rev. ed. with additions, 1 vol. (1887). *The George Eliot Letters*, ed. by GORDON S. HAIGHT, 7 vol. (1954–55), is a basic source of information; Haight's *George Eliot and John Chapman, with Chapman's Diaries* (1940), gives valuable details of her early years in London; and *The Essays of George Eliot*, ed. by THOMAS PINNEY (1963), collects her most important journalistic writings. JOAN BENNETT, *George Eliot: Her Mind and Art* (1948), has sound criticism of the novels. F.R. LEAVIS in *The Great Tradition* (1948; new ed., 1962), ranking George Eliot among the four great English novelists, proclaims vigorous opinions, some of which he later revised. One of the subtlest general studies is BARBARA HARDY, *The Novels of George Eliot: A Study in Form* (1959; reprinted with corrections, 1967). JEROME THALE, *The Novels of George Eliot* (1959); and BERNARD J. PARIS, *Experiments in Life: George Eliot's Quest for Values* (1965), both concentrate on the moral and philosophical ideas in her work. U.C. KNOEPFLMACHER, *George Eliot's Early Novels: The Limits of Realism* (1968), studies her compromise in the search for form between her vision of the real world and the ideal world of her moral beliefs. HENRY AUSTER, *Local Habitations: Regionalism in the Early Novels of George Eliot* (1970), less limited than its title suggests, offers much perceptive comment and includes a well-selected bibliography; MARGHANITA LASKI, *George Eliot and Her World* (1973), is richly illustrated. (G.S.Ha.)

Eliot, T.S.

As poet, dramatist, literary critic, and editor, T.S. Eliot exercised a strong influence on 20th-century culture in the period between World Wars I and II; his experiments in diction, style, and versification revitalized English poetry, and in a series of critical essays he shattered old orthodoxies and erected new. He pronounced on social and cultural questions, and as director of the publishers Faber & Faber Ltd. he was a generous and discriminating patron of young poets. The publication of *Four Quartets*, during World War II, led to his recognition as the greatest living English poet and man of letters with the award in 1948 of the Order of Merit and the Nobel Prize for Literature.

Angus McBean



T.S. Eliot, 1954.

Family background and early years. Thomas Stearns Eliot was born in St. Louis, Missouri, on September 26, 1888. His first American paternal ancestor, Andrew Eliot, a shoemaker of East Coker, Somerset, arrived in Boston in 1670. The poet's grandfather, the Rev. William Greenleaf Eliot, migrated from Boston to St. Louis immediately after his graduation from Harvard in 1834. A fervent Unionist, Unitarian, and anti-slavery man in a slave state, he was a founder of Washington University, which would have been named for him but for his objection; he became its chancellor in 1872. The poet's father, Henry Ware Eliot, broke with family tradition

and went into business; his mother, Charlotte Champe Stearns, was a prolific poet of some reputation, author of a life of her father-in-law and of a poetic drama on the martyrdom of the 15th-century Italian religious reformer Savonarola, to which her son wrote an introduction in 1926. At the time of the poet's birth, the Eliots had been in Missouri 54 years; yet they retained, against Southern and Western influences, the New England political and theological culture. Late in life the poet said that he was glad to have been born in St. Louis instead of Boston or New York or London. He was, nevertheless, a New Englander to the end.

Early influences

Eliot's family background is important for an understanding of his career, for he was allowed the widest education available in his time, with no influence from his father to be "practical" and to go into business. From Smith Academy in St. Louis he went to Milton, in Massachusetts; from Milton he entered Harvard in 1906; he was graduated B.A. in 1909, after three instead of the usual four years. The men who influenced him at Harvard were George Santayana, the philosopher and poet, and the critic Irving Babbitt. From Babbitt he derived an anti-Romantic attitude that, amplified by his later reading of British philosophers F.H. Bradley and T.E. Hulme, lasted through his life. In the academic year 1909–10 he was an assistant in philosophy at Harvard.

The year 1910–11 was crucial for the man who was to become one of two or three great poets of the first half of the 20th century. He spent the year in France, attending Henri Bergson's lectures in philosophy at the Sorbonne and reading poetry with Alain-Fournier, whose "lessons" gave Eliot a mastery not only of the French language but of Symbolist poetry from Charles Baudelaire through Jules Laforgue to Stéphane Mallarmé. In 1914 he first met Ezra Pound. In 1946 he was to publish in *Poetry: A Magazine of Verse* a defense of Pound's literary career (ignoring Pound's politics) in which he described the arid literary milieu of young American poets in the decade before World War I. Both Eliot and Pound turned to poets in other languages—Pound to the troubadours and the early Renaissance poets of Italy, Eliot to Laforgue and Dante, who even more than John Webster and John Donne helped Eliot to find his own style. From 1911 to 1914 he was back at Harvard reading Indian philosophy and studying Sanskrit under the distinguished scholar Charles Lanman. In 1913 he read Bradley's *Appearance and Reality;* by 1916 he had finished, in Europe, a dissertation entitled *Knowledge and Experience in the Philosophy of F.H. Bradley* (not published until 1964); but World War I had intervened, and he never returned to Harvard to take the final oral examination for the Ph.D. degree.

Early publications. Eliot was to pursue four careers: editor, dramatist, literary critic, and philosophical poet. He was probably the most erudite poet of his time in the English language. His undergraduate poems were "literary" and conventional. His first important publication, and the first masterpiece of "modernism" in English, was "The Love Song of J. Alfred Prufrock." Nothing like the first three lines of "Prufrock" had previously appeared in English poetry:

"The Love Song of J. Alfred Prufrock"

> Let us go then, you and I,
> When the evening is spread out against the sky
> Like a patient etherized upon a table. . . .

Eliot had given a copy of the poem to his friend Conrad Aiken, who passed it on to Ezra Pound, who in turn sent it to Harriet Monroe, editor of *Poetry*, where it languished more than a year because Miss Monroe was not sure it was poetry. Although Pound had printed privately a small book, *A lume spento*, as early as 1908, "Prufrock" was the first poem by either of these literary revolutionists to go beyond experiment to achieved perfection. It represented a break with the immediate past as radical as that of Samuel Taylor Coleridge and William Wordsworth in *Lyrical Ballads* (1798). From the appearance of Eliot's first volume, *Prufrock and Other Observations*, in 1917, one may conveniently date the maturity of the 20th-century poetic revolution; for, in addition to the title poem, the book contained "Preludes" and "Portrait of a Lady"—both mature works; and the revolution had come of age. The significance of the revolution is still disputed, but the striking similarity to the Romantic revolution of Coleridge and Wordsworth is obvious: Eliot and Pound, like their 18th-century counterparts, set about reforming poetic diction. Whereas Wordsworth thought he was going back to the "real language of men," Eliot sought a diction that might be spoken by an educated person, "neither pedantic nor vulgar." (He wrote of Swinburne: "For the first time in verse of such eminence, sound exists without sense.")

For a year he taught French and Latin at the Highgate School; in 1917 he began his brief career as a bank clerk in Lloyds Bank Ltd. During this period he was also a prolific reviewer and essayist in both literary criticism and technical philosophy. In 1919 he published *Poems*, which contained the poem "Gerontion," a meditative interior monologue in blank verse: nothing like this poem had appeared in English. It was with the publication in 1922 of *The Waste Land*, however, that Eliot achieved an international reputation.

International recognition with *The Waste Land*

This poem, in five parts, proceeds on a principle of "rhetorical discontinuity" that reflects the fragmented experience of the 20th-century sensibility of the great modern cities of the West. For Eliot is the poet of the secularized city, the decay of *urbs aeterna* (the "eternal city"). This is the ultimate theme of *The Waste Land*, concretized by the constant rhetorical shifts, the juxtapositions of contrasting styles. But it is not, as his early critics supposed, a simple contrast of the heroic past with the degraded present; it is rather a timeless, simultaneous awareness of moral grandeur and moral evil. The original manuscript of about 800 lines was cut down to 433 at the suggestion of Ezra Pound. *The Waste Land* is not Eliot's greatest poem, though it is his most famous.

"Programmatic criticism"

Eliot has said that the poet-critic must inevitably write "programmatic criticism"—that is, criticism that expresses the poet's own interests as a poet, quite different from historical scholarship, which stops at placing the poet in his background. Consciously intended or not, this kind of criticism creates an atmosphere in which the poet-critic's own poetry will be better understood and appreciated than if it had to appear in a literary milieu dominated by the standards of the preceding age. Eliot's essay "Tradition and the Individual Talent," appearing in his first critical volume, *The Sacred Wood* (1920), is historically analogous to and as historically important as Wordsworth's "Preface." Tradition, according to Eliot, must be earned by the poet; it is not a repetition of the work of the immediate past ("novelty is better than repetition," he said); it comprises the whole of European literature from Homer to the present. The poet writing in English may therefore make his own tradition by using materials from any past period, in any language. This point of view is "programmatic" in the sense that it disposes the reader to accept the revolutionary novelty of Eliot's polyglot quotations and serious parodies of other poets' styles in *The Waste Land*. Also in *The Sacred Wood*, "Hamlet and His Problems" sets forth Eliot's theory of the objective correlative:

> The only way of expressing emotion in the form of art is by finding an "objective correlative"; in other words, a set of objects, a situation, a chain of events which shall be the formula for that particular emotion; such that, when the external facts, which must terminate in sensory experience, are given, the emotion is immediately evoked.

Eliot adapted the phrase from either Santayana or from the U.S. painter and author Washington Allston and placed it in the context of his impersonal theory of poetry; it thus had an immense influence toward correcting the vagueness of late Victorian rhetoric by insisting on a correspondence of word and object. Two other essays, first published the year after *The Sacred Wood*, almost complete the Eliot critical canon: "The Metaphysical Poets" and "Andrew Marvell," published in *Selected Essays, 1917–32* (1932). In these essays he effects a new historical perspective on the hierarchy of English poetry, putting at the top the Metaphysical poets

of the 17th century and lowering poets of the 18th and 19th centuries. Eliot's second famous phrase appears here: "dissociation of sensibility," invented to explain the change that came over English poetry after Donne and Marvell. This change seems to him to consist in a loss of the union of thought and feeling. The phrase has been attacked; yet the historical fact that gave rise to it cannot be denied; and with the poetry of Eliot and Pound it had a strong influence in reviving interest in certain 17th-century poets. The first, or programmatic, phase of Eliot's criticism ended with *The Use of Poetry and the Use of Criticism* (1933), his Charles Eliot Norton lectures at Harvard. Shortly before this his interests had broadened into theology and sociology; three short books, or long essays, were the result: *Thoughts After Lambeth* (1931), *The Idea of a Christian Society* (1939), and *Notes Towards the Definition of Culture* (1948). These book-essays, along with his *Dante* (1929), an indubitable masterpiece, broadened the base of literature into theology and philosophy: whether a work is poetry must be decided by literary standards; whether it is great poetry must be decided by standards higher than the literary.

Essays on theology and sociology

The criticism and the poetry are so interwoven, so much the product of a unified mind and sensibility, that it is difficult to discuss them separately. The great essay on Dante appeared two years after Eliot had become an Anglo-Catholic (1927); in that year he also became a British subject. The first long poem after his conversion was "Ash Wednesday" (1930), a religious meditation in a style entirely different from that of any of the earlier poems. Indeed, Eliot never repeated himself, though every poem is unmistakably his. "Ash Wednesday" was not well received in an era that held that poetry, though autonomous, is strictly secular in its outlook; it was misinterpreted, typically by the critic Edmund Wilson, as an expression of personal disillusion.

Later career and influence. Eliot's masterpiece is *Four Quartets*, taken as a single work, though each "quartet" is a complete poem. The four parts, published at intervals between 1935 and 1941, were issued as a book in 1943. This led to the award to Eliot, in 1948, of the Nobel Prize for Literature. Perhaps the high-water mark of poetry in English of the 20th century is the passage in "Little Gidding" in which the poet meets a "compound ghost," a figure composite of two of his masters: William Butler Yeats and Mallarmé. The scene takes place at dawn in London after a night on duty at an air-raid post during an air-attack; the master speaks in conclusion:

> From wrong to wrong the exasperated spirit
> Proceeds, unless restored by that refining fire
> Where you must move in measure, like a dancer.
> The day was breaking. In the disfigured street
> He left me, with a kind of valediction,
> And faded on the blowing of the horn.

The passage is 72 lines, in modified terza rima; the diction is as near to that of Dante as is possible in English; and it is a fine example of Eliot's belief that a poet can be entirely original when he is closest to his models.

Dramatic works

The plays, which begin with *Sweeney Agonistes* (published 1926; first performed in 1934) and end with *The Elder Statesman* (first performed 1958; published 1959), are, with the exception of *Murder in the Cathedral* (published and performed 1935), inferior to the lyric and meditative poetry. Eliot's belief that even secular drama attracts people who unconsciously seek a religion, that in fact all drama has a religious structure of progress toward self-knowledge, reconciliation, or purification, led him to put drama above all other forms of poetry. All his plays are in a blank verse of his own invention, in which the metrical effect is not apprehended apart from the sense; thus he brought "poetic drama" back to the popular stage. *The Family Reunion* (1939) and *Murder in the Cathedral* are Christian tragedies, the former a tragedy of revenge, the latter of the sin of pride. The other plays are comedies in which the plots are derived from Greek drama. The most successful of these plays is *The Cocktail Party* (first performed 1949; published 1950), based upon the *Alcestis* of Euripides.

Eliot's career as editor was ancillary to his main interests, but his quarterly review, *The Criterion* (1922–39), was the most distinguished international critical journal of the period. He was a "director," or working editor, of the publishing firm of Faber & Faber Ltd. from the early 1920s until his death.

Editor of *The Criterion*

Eliot's posthumous volume of criticism, *To Criticize the Critic, and Other Writings* (1965), contains two essays of great value: the title essay is a review and a severe but not falsely modest evaluation of his literary criticism; "American Literature and the American Language" deals with the chauvinist myth of American English as a separate language and with equal conviction treats British and American literature as branches of one literature. The first half of the 20th century will probably be known to historians as the age of Eliot, as the mid-18th century was the age of Johnson. But Samuel Johnson came at the end of the Neo-classical period and summed it up; whereas Eliot, as critic and poet, created his age. He always kept his private life rigorously in the background. In 1915 he married Vivian Haigh-Wood; after 1933 she was mentally ill, and they lived apart; she died in 1947. In January 1957 he married Miss Valerie Fletcher, with whom he lived happily until his death on January 4, 1965, in London.

MAJOR WORKS

POETRY: *Prufrock and Other Observations* (1917); *Poems* (1919); *Ara Vos Prec* (1920), incorporates *Prufrock* and *Poems* with additional verse, including "Gerontion"; *The Waste Land* (1922); *Poems, 1909–25* (1925), incorporates *Ara Vos Prec*, *The Waste Land*, and "The Hollow Men"; *Journey of the Magi* (1927); "Ash Wednesday" (1930); *Collected Poems, 1909–35* (1936), incorporates *Poems, 1909–25*, "Ash Wednesday," chorus from *The Rock*, "Burnt Norton," and others; *Old Possum's Book of Practical Cats* (1939); *Four Quartets* (1943), each of the four issued as a separate pamphlet: "Burnt Noron" (1941); "East Coker" (1940); "The Dry Salvages" (1941); "Little Gidding" (1942); *Collected Poems, 1909–62* (1963).

CRITICISM: *Ezra Pound: His Metric and Poetry* (1917); *The Sacred Wood: Essays on Poetry and Criticism* (1920); *Homage to John Dryden* (1924), contains "John Dryden," "The Metaphysical Poets," and "Andrew Marvel"; *For Lancelot Andrewes: Essays on Style and Order* (1928); *Dante* (1929); *John Dryden: The Poet, the Dramatist, the Critic* (1932); *Selected Essays, 1917–32* (1932, rev. ed. 1951); *The Use of Poetry and the Use of Criticism* (1933); *Elizabethan Essays* (1934); *Essays Ancient and Modern* (1936); *The Music of Poetry* (1942); *The Classics and the Man of Letters* (1942); *What Is a Classic?* (1945); *Milton* (1947); *Poetry and Drama* (1951); *The Three Voices of Poetry* (1954); *On Poetry and Poets* (1957); *To Criticize the Critic and Other Writings* (1965).

OTHER PROSE WORK (sociology and church politics): *Thoughts After Lambeth* (1931); *After Strange Gods—A Primer of Modern Heresy* (1934); *The Idea of a Christian Society* (1939); *Reunion by Destruction* (1943); *Notes Towards the Definition of Culture* (1948).

TRANSLATION: *Anabasis—A Poem by St. J. Perse with a Translation by T. S. Eliot* (1930).

PLAYS: *Sweeney Agonistes: Fragments of an Aristophanic Melodrama* (pub. in *Criterion*, 1926; pub. separately 1932); *The Rock* (1934); *Murder in the Cathedral* (1935; film script, 1951); *The Family Reunion* (1939); *The Cocktail Party* (1950); *The Confidential Clerk* (1954); *The Elder Statesman* (1959).

BIBLIOGRAPHY. Three distinguished works on Eliot are ELIZABETH DREW, *T.S. Eliot: The Design of His Poetry* (1949), a Jungian interpretation of Eliot's symbolism; F.O. MATTHIESSEN, *The Achievement of T.S. Eliot*, 3rd ed. (1958), with a supplementary chapter by C.L. BARBER covering the works written after Matthiessen's death in 1950; and HELEN GARDNER, *The Art of T.S. Eliot* (1949), a brilliantly perceptive study that, however, could not include criticism of the later plays. Other valuable long studies are HUGH KENNER, *The Invisible Poet* (1959); GROVER C. SMITH, *T.S. Eliot's Poetry and Plays* (1956); and LEONARD UNGER, *T.S. Eliot: Moments and Patterns* (1967), an essay on the influence of Joseph Conrad. Studies of the plays are DAVID JONES, *The Plays of T.S. Eliot* (1960); and E. MARTIN BROWNE, *The Making of T.S. Eliot's Plays* (1969), a work indispensable to the understanding of Eliot's methods of dramatic composition, since Browne produced and directed all the plays and was to that extent a collaborator. The first symposium on Eliot, and still valuable,

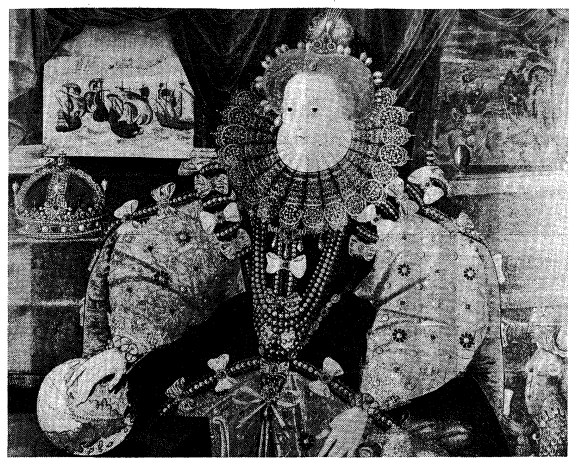
is LEONARD UNGER (ed.), *T.S. Eliot: A Selected Critique* (1948). Others are B. RAJAN (ed.), *T.S. Eliot: A Study of His Writings by Several Hands* (1948); TAMBIMUTTU and RICHARD MARCH (eds.), *T.S. Eliot: A Symposium* (1948); NEVILLE BRAYBROOKE (ed.), *T.S. Eliot: A Symposium for His Seventieth Birthday* (1958); and HUGH KENNER (ed.), *T.S. Eliot: A Collection of Critical Essays* (1962). These symposia represent cumulative insights of permanent value. The latest symposium, ALLEN TATE (ed.), *T.S. Eliot: The Man and His Work* (1966), published a year after Eliot's death, is retrospective in emphasis, including personal reminiscence and criticism by I.A. Richards, Herbert Read, Conrad Aiken, F.V. Morley, Bonamy Dobrée, Helen Gardner, John Crowe Ransom, G. Wilson Knight, E. Martin Browne, Austin Warren, and 16 other critics. CLEANTH BROOKS, *Modern Poetry and the Tradition* (1939), contains the most perceptive analytical commentary on *The Waste Land*. CONRAD AIKEN, *Collected Criticism* (1968), contains a review of *The Waste Land*, written three months after the poem appeared, as valid today as it was in 1923. See also VALERIE ELIOT (ed.), *The Waste Land: A Facsimile and Transcript of the Original Drafts Including the Annotations of Ezra Pound* (1971). Two general surveys of Eliot's career—including his family background, education, public life, philosophy, and social and political ideas—contain as much relevant information as one may reasonably expect to find until Mrs. Eliot authorizes an official biography: HERBERT HOWARTH, *Notes on Some Figures Behind T.S. Eliot* (1964); and RUSSELL KIRK, *Eliot and His Age* (1971).

(A.Ta.)

Elizabeth I of England

One of the greatest of all English sovereigns, regarded with admiration and pride by English people not only in her own time but in later ages, Queen Elizabeth I, who reigned from 1558 to 1603, owed her outstanding success to her own prudence and statecraft and also to her shrewd judgment of character and her unrivalled capacity to inspire loyalty and devoted service. The daughter of King Henry VIII by his second wife, Anne Boleyn, she was the third of Henry's children to ascend the throne, following the brief reigns of her sickly brother, Edward VI, and her elder sister, Mary I. After Mary's attempt to restore Catholicism in England and, even more unpopular, her marriage with Philip II of Spain, the accession of Elizabeth—who had always been connected with the Protestant cause and who, an attractive young woman of 25, contrasted sharply with her sad, middle-aged sister—was inevitably greeted with relief and delight. It was the queen's achievement that she converted this ephemeral goodwill into a constant loyalty and awe, firmly assuming the reins of power and impressing observers as a monarch obeyed as absolutely as her father had been. Even her indecisiveness and other marks on her character, perhaps deriving from the terrifying years of her childhood, were turned to advantage in the service of the state.

Early life. Born at Greenwich Palace on September 7, 1533, and brought up mainly at Hatfield House in Hertfordshire, Elizabeth had an exacting childhood, full of reverses of fortune and of dangers from political and religious intrigue. Only her extreme prudence saved her from being held an accomplice in the alleged treason of Thomas, Lord Seymour, who, in the reign of her young brother, Edward VI, was executed on the accusation of planning to marry her and overthrow the government of his brother, the Lord Protector. Lord Seymour was the husband of Elizabeth's stepmother, Catherine Parr (Henry VIII's last wife, who had survived him), in whose house Elizabeth was then living. In the reign of her sister, Mary, she suffered an even more traumatic and nerve-wracking ordeal when she was imprisoned in the Tower of London during attempts to prove her cognizant of Sir Thomas Wyat the Younger's rebellion of 1554; her position as next in the succession and her connection from birth with the Protestant cause made her a constant threat to her Catholic sister, Mary, and to the ambitious plans of Mary's husband, King Philip of Spain. Only extreme circumspection saved her in these crises, and the habit of giving what she later called "an answer answerless" characterized almost all of her political and personal affairs for the rest of her life.



Elizabeth I, the Armada portrait by Gower (d. 1596). In Woburn Abbey, Bedfordshire.
From the Woburn Abbey Collection, by kind permission of His Grace, the Duke of Bedford

Reign. *The years of consolidation.* Elizabeth came to the throne upon the death, on November 17, 1558, of her sister, Mary. The first 12 years of the reign established Elizabeth's value with the majority of the nation, Protestant and Catholic alike. Her religious settlement of 1559, though enforcing the Protestant religion by law and declaring the celebration of the mass illegal, was for the time exceptionally tolerant. Catholics could opt out of the obligatory monthly attendance at the parish church on payment of a moderate fine, and their private celebration of mass was not interfered with, except when the government suspected treason. But in 1570 the compromise that most of them had found bearable was abruptly shattered by the interdict of Pope Pius V against "Elizabeth, the Pretended Queen of England," releasing all her subjects from their allegiance to her. English Catholics were thus, inevitably, but for the most part with cruel injustice, placed under the suspicion of being actual or potential traitors. The penal laws against them increased in severity in direct proportion to the action of Catholic powers on the Continent, reaching their height when the Jesuit missionaries began to be dispatched to England, from 1580 onward.

The religious settlement of 1559

The "Virgin Queen." In view of her keen enjoyment of men's society and the role some of her never-consummated marriage plans played in England's foreign policy, Elizabeth's celebrated virginity requires a brief consideration. Her friendship with several men was couched in a romantic idiom: they included Sir Christopher Hatton, lord chancellor from 1587 to 1591; Sir Walter Raleigh, courtier, historian, and adventurer; the young and impulsive Earl of Essex; and above all Lord Robert Dudley, whom she created earl of Leicester in 1564. Her famous love affair with Dudley, reaching its spectacular height when he entertained her at Kenilworth Castle in 1575, survived even her discovery of his secret marriage to her cousin, Lettice Knollys, the widowed countess of Essex, in 1579. Her devotion to him lasted until his death in 1588, the news of which caused the queen to shut herself up alone for so long that at last Lord Burghley, the Lord High Treasurer and for 30 years Elizabeth's most trusted servant, had her door broken open. Her obvious susceptibility, combined with her refusal to marry, gave rise to rumours that she was unchaste and had borne bastards or that she had some physical disability that made a sexual union impossible. The latter theory is dismissed by Lord Burghley's memorandum on the Queen's marriage negotiations with the French king's brother, the duc d'Alençon, in 1579: "Her Majesty . . . has no sickness, nor lack of natural functions in those things that properly belong to the procreation of children." But Leicester's words to the French ambassador in August 1566, that he had known the Queen since she was a child of eight and from that time she had always said, "I will never marry," suggest an explanation. When Elizabeth was two years and

eight months old, her father executed her mother, Queen Anne Boleyn; when she was eight years and five months old, he executed her cousin and stepmother, Queen Catherine Howard. These two events in the life of so young a child may have produced a psychological condition never outgrown. It is often said that Elizabeth would have liked to marry Leicester but considered it impolitic because he was unpopular and his first wife, Amy Robsart, had died suddenly in suspicious circumstances in 1560. But by 1566 she could have done so, for the nation had become so anxious to see the queen married and a mother—an heir being their only safeguard against civil war and invasion in case of her death—that Parliament besought her to marry anyone she liked. Negotiations for her hand played a very important part in Elizabeth's foreign policy, from her accession to the final breaking-off in 1583, when she was 49, of the courtship of the duc d'Alençon. These negotiations had been of great use in detaching Alençon from the sphere of his brother, King Henry III of France, and in ensuring that when Alençon entered on a campaign in the Netherlands injurious to Spanish interests, he would be doing so not to increase French influence in that area but as an ally of the English crown.

Affection for Leicester

The controversy over Mary, Queen of Scots. After the religious settlement of 1559, the inextricable confusion of religion and politics in the 16th century was again exemplified in Elizabeth's greatest domestic peril. Mary Stuart, hereditary queen of Scotland, was also, by descent from Henry VIII's sister Margaret, heiress presumptive to the English throne. Those who thought unlawful Henry VIII's second marriage—that to Anne Boleyn after he had his marriage with Catherine of Aragon annulled—regarded her as queen of England already. This was Mary's own view, and after she returned to Scotland in 1561 on the death of her husband, the young French king Francis II, she never ceased to plan her acquisition of the English throne. She believed that if she appeared on English soil, the English Catholics would rise to welcome her and dethrone Elizabeth. Though this proved a delusion, she exploited the possibility of gaining powerful assistance elsewhere.

When Mary's reverses in Scotland finally drove her to take refuge in England in 1568, the Scots refused to have her back on any terms, and it was too dangerous to let her go abroad, where she would obviously collect a French or Spanish army and try to invade England. There was, therefore, no alternative but to keep her in honorable confinement. Mary at once began to plot her escape and always declared that this was all she wanted, but the three major conspiracies in which her complicity was proved—the Ridolfi Plot of 1571, the French duc de Guise's enterprise of 1582, and the Babington Plot of 1586—all included the murder of Elizabeth in their objectives, and all three envisaged an invasion of England by the dreaded Spanish Army that was engaged in repressing the resistance of the Netherlanders. This army's reputation for remorseless cruelty helps to explain the fear and hatred aroused by the Queen of Scots and the fierce pressure put upon Elizabeth by Parliament, after the discovery of each of the major plots, to have her executed.

The announcement of Pope Gregory XIII in 1580 that it would be no sin to send Elizabeth out of the world, and the murder of 1584 of the other great heretic leader, William I the Silent, who had organized Dutch resistance against the Spanish, drove the English into making a Bond of Association in 1584, signed by men in every shire, by which they swore that if Elizabeth were murdered they would prosecute to the death the persons by whom and for whom the act had been done. In the Parliament of 1585 this resolve was incorporated into the Act for the Preservation of the Queen's Safety, in the drawing up of which Elizabeth herself made a statesmanlike alteration to the effect that the interested person should be condemned to death and his or her heirs disqualified from the succession, only if, upon trial, he or she was convicted of guilty foreknowledge. This amendment was not only just but made it possible for Mary's son, James VI of Scotland, to remain in the position of Elizabeth's heir presumptive, provided he did not engage in treason against her; and the tacit understanding thus created shielded England from possible future attempts by France or Spain to gain the vacant throne. The next year, on the discovery of the Babington Plot, Mary was tried under this Act and found guilty, in October 1586, of conniving at Elizabeth's attempted murder. It took the government three months to persuade the Queen to sign the death warrant. Elizabeth undoubtedly meant the sentence to be carried out, but when the Privy Council acted on the warrant without telling her, she had a hysterical collapse, declaring she had never authorized or intended the final step. Nevertheless, popular rejoicing at the news of the Queen of Scots' execution on February 8, 1587, was unequivocal; all over London the church bells were rung for 24 hours.

The Bond of Association

Defeat of Spain and the Armada. Elizabeth had caused Spain as much injury as she could without provoking a full-scale retaliation. Sir Francis Drake, who had returned from his three-year voyage around the world in 1580, had a private arrangement with her that he should pillage Spanish treasure ships returning from America, and that, if he were caught, she was to disavow him. In 1585 she dispatched a small force under Leicester to aid the Netherlands in their resistance; this was withdrawn in 1586. The execution of the Queen of Scots made the prospect of invading England more attractive to King Philip because it meant that if he now won the English crown, it would be for himself. A devastating raid by Drake on Spanish shipping and stores at Cadiz and Lisbon in April 1587 finally determined Philip to attack England before completing the subjection of the Netherlands.

The Spanish Armada, launched in July 1588, was intended to pick up the Spanish Army on the Flemish coast and land it at the Thames estuary. The defeat of the Armada, caused partly by the superiority of English ships and seamanship, partly by the Netherlanders' ships that kept the Spaniards blockaded in the ports, and partly by the gales that worked havoc on the Spanish galleons as they were driven into the North Sea, proved to be one of the decisive naval battles of history. The Queen's obstinate belief until the last moment that war could be avoided caused the English fleet to be short of stores and ammunition; but the superiority and seaworthiness of the fleet itself was the direct result of the program of shipbuilding she had steadily pursued, which was considered by contemporary historians to be one of the achievements of the reign. The news of the Armada's destruction had not come in when the Queen reviewed the land forces drawn up at Tilbury to resist the expected invasion. The speech she made on this occasion showed her total identification with her people and her pride in being their queen. She said she had come to live or die among them and added:

Speech at Tilbury

> I have but the body of a weak and feeble woman, but I have the heart and stomach of a king, and a king of England, too, and think foul scorn that any Prince in Europe should dare to invade the borders of my realm.

She spoke with complete confidence in the loyalty that her 30 years' work had earned her. Sir Francis Walsingham, Elizabeth's principal secretary, was told by one of his agents that "nothing so much displeased the king of Spain as the loyalty of the Catholics to their queen during the late enterprise."

The years of fruition. The last 15 years of Elizabeth's reign saw a great burst of national vigour, nowhere so remarkable as in literature. This era encompassed the work of the playwright Christopher Marlowe, the poet Edmund Spenser, and a host of other lyric poets and writers of prose, as well as the first stages of the amazing careers of Francis Bacon and Shakespeare. But the queen's own great work was done. She enjoyed immense popularity and prestige, but she became an old woman who had outlived her dearest friends; Leicester died in 1588, Walsingham in 1590, Hatton in 1591, Burghley in 1598. She was left with a group of men more anxious to gain advantage for themselves than to serve her; but the

tragic affair of Robert Devereux, earl of Essex, in the last years of her reign, showed that her great powers as a monarch were not in eclipse. This young man had attractive qualities and some abilities, but he was selfish and lacking in judgment. He was the stepson of Leicester, who had brought him forward to oust Walter Raleigh. The great favour and kindness the old Queen showed him made him altogether miscalculate the degree of his influence over her. Essex had distinguished himself for bravery and chivalry in 1596 in an action against Cadiz undertaken by the English because the Spaniards had laid siege to Calais and were, it seemed, planning a second invasion; but at home his envious and domineering temper caused him to make enemies of Burghley's son Robert Cecil, and of Sir Walter Raleigh and the lord admiral, the Earl of Nottingham.

Discontent with English rule had made Ireland dangerous throughout Elizabeth's reign because it offered an invasion base to Spain. In 1598 the Irish earl of Tyrone inflicted a crushing defeat on the English deputy at Armagh, and rebellion broke out all over the country. A disciplinary expedition was necessary; Essex demanded the leadership and was given it, lavishly supplied with money and men; but he disobeyed the Queen's injunctions as to how he was to proceed, with the disastrous result that he failed while refusing to carry out her orders. Rushing back to England (also against the Queen's positive commands) to tell his own story, he was put under arrest by the Privy Council. An enquiry cleared him of treason, but he was not allowed to enter the Queen's presence again. This complete reversal of his previous position was too much for his overbearing nature; he made his house a focus for disaffected people of all kinds; and, hearing that his arrest was ordered, he set out with some 200 followers in an attempt to raise the City of London, meaning to return with crowds at his back to arrest his enemies on the council and overawe the Queen. For this act of high treason he was executed on February 25, 1601.

Rebellion of Essex

The story that Elizabeth had given Essex a ring, promising that if he were ever under her displeasure and sent it to her, it should gain his pardon, and, further, that he had, in fact, attempted to send it to her but that it was held up by Lady Nottingham, the wife of his enemy, would be too absurd to require notice, except for its undying persistence. The notion that Elizabeth, apparently foreseeing trouble with him, would have given to a subject a virtual license to commit treason with impunity hardly deserves comment. A vague reference to such a story is found in John Webster's play, *The Devil's Law Case*, written in 1623; but it is first told at length by an Italian, Gregorio Leti, in his *Historio o vero vita di Elisabetha, regina d'Inghilterra* (History of the True Life of Elizabeth, Queen of England), a romancing pseudo-biography published in 1692. The story is dismissed by such 19th-century historians as the German Leopold von Ranke and the Englishman John Lingard; more important, it is demolished by Elizabeth's own words to the French ambassador in June 1602. He could see that she still mourned Essex' death, but she said to him: "I had put up with but too much disrespect to my person, but I warned him that he should not touch my sceptre." She said further: "When the welfare of my state was concerned, I dared not indulge my own inclinations."

In the last few years of Elizabeth's reign she found her careful financial policy defeated by conditions she could not control. Her reserves had been exhausted, and prosperity brought inflation; she sold crown lands and much of her jewelry. She also salaried some of her beneficiaries by granting them the exclusive right to sell a commodity; since they then possessed the monopoly, they could force up the price. That this practice was causing wide discontent was brought to the queen's notice by her last Parliament, that of 1601. She at once declared that the most offensive items on the list should be removed. When a deputation waited on her the following day to thank her, she made them the greatest speech of her life, in which she said: "Though God hath raised me high, yet I count this the glory of my crown, that I have reigned with your loves," adding, in words that summed up her inspiration of 45 years, "I have cause to wish nothing more than to content the subject, which is a duty that I owe."

James VI of Scotland had long been informally recognized as her heir. The last service she performed for her country was on her deathbed, at the palace of Richmond in London, on March 23, 1603. Almost speechless, she was asked to make a sign if she acknowledged him as her successor. She made the gesture that lent her authority to a peaceful succession and died early the next morning. King James's bishops, in their preface to the King James Version of the Bible, published in 1611, spoke for their own time and for posterity when they described her death as "the setting of that bright, *Occidentall Starre* Queene Elizabeth of most happy memory."

Character and achievements. Elizabeth's famous reign of 45 years was a personal achievement to which every trait she possessed contributed. At her accession, England, if it were to survive as an independent power, was in urgent need of unity. The nation was divided between Catholic and Protestant. The Queen, while committed to the Protestant cause, was devoid of religious fanaticism and wanted a compromise acceptable to as many of her subjects as possible. A marriage alliance with France or Spain would have dragged England into war behind one of these great powers, but in any case the Queen did not want to marry. The resources of the country were at a low ebb; Elizabeth, alone of his descendants, had inherited the financial ability of her grandfather, Henry VII. The charges of government were defrayed by the sovereign's own revenues; where these proved inadequate, Parliament was summoned to vote money. Elizabeth, by her stringent economy and vigilant oversight, made a great contribution to the independence of the crown. Finally, the vigorous but small nation of 4,000,000 needed a figure to inspire them with national consciousness.

Elizabeth was exceptionally gifted for this role. Twenty-five years old at her accession, she was of striking appearance, very erect, her face pale and aquiline, with the red-gold hair of her forebears of the Yorkist dynasty. Highly strung but energetic, she was an accomplished horsewoman, a rapid walker, and fond of dancing. Her interest in dress and her passion for precious stones helped to invest her public appearances with a glamorous quality. She had been highly educated and spoke Latin, French, Spanish, Italian, and Flemish. The Spanish ambassador at the court of her elder sister, Mary Tudor, had said: "The Princess Elizabeth is very dangerous; she has a spirit full of incantation."

Personal appearance

From the day of her coronation procession until her death, the people knew that their queen loved them. With this emotional response, Elizabeth combined an acute capacity to assess talent and character. She was brilliantly served by the men she chose to help her, above all by William Cecil. At her accession she made him chief secretary of state, and in 1571, when he took the office of lord treasurer, relinquishing his previous post to the second greatest of her public servants, Francis Walsingham, Elizabeth created him Lord Burghley.

The Queen was not easy to work with; her high spirit was accompanied by a neurotic caution and a dread of committing her small kingdom at times when her advisers thought safety lay in decisive action. But though she sometimes abused Burghley passionately, their partnership was based on deep mutual trust, Elizabeth saying: "No Prince in Europe had such a counsellor as she had of him."

The nation's enthusiasm for Elizabeth was based on a strong economic foundation. Her fierce reluctance to make war secured for it a prosperity that steadily increased. The scenes that accompanied her opening of the Royal Exchange built by the financier Thomas Gresham (1571), as shown in William Harrison's *An Historicall Description of the Islande of Great Britayne* (1577), indicate the development of national wealth and domestic comfort; and the trade demonstration arranged for the Queen's visit to Norwich in 1578, where a rhyming ad-

dress contained the words: "We bought, before, the things that now we sell,/God's peace and thine we hold and prosper well," point to the nation's consciousness of success with which she was associated.

The external dangers threatening England were, throughout Elizabeth's reign, very great. Spain or France would take any opportunity of acquiring England, the possession of which would tip the scale in the struggle for European supremacy; and the papacy, seeing that the Queen was committed irrevocably to Protestantism, was anxious to see this bastion of heresy destroyed. Elizabeth did what she could to protect herself by giving cautious aid to those who were resisting her enemies—the Huguenots (Protestants) in France and the various provinces of the Netherlands struggling to preserve their liberties against the ferocious tyranny of Philip of Spain. Even the defeat of the Armada did not finally avert the menace of Spain, which was continued through its attack on Henry IV of France in the 1590s and caused Elizabeth to authorize raids upon Spanish bases in 1596 and 1597. But after 1588 her European fame developed a legendary, almost supernatural quality; and the judgment made on her by the French ambassador in 1597, that "she is a very great Princess, who knows everything" reflected a general verdict.

BIBLIOGRAPHY. Some of Queen Elizabeth's formal letters, and her personal additions to letters written on her behalf, may be found in the *Calendar of British State Papers: Domestic Series*, the 2 vol. for the years 1547–80 and 1581–90, ed. by R. LEMON (1856–65) and the 3 vol. for the years 1591–94, 1595–97, and 1598–1601, ed. by M.A.E. GREEN (1867–69). The *Acts of the Privy Council of England*, in 25 vol. covering the years 1558–1601 and ed. by J.R. DASENT (1893–1905), show the Queen at work with her council. Selections from Elizabeth's official addresses are published in *The Public Speaking of Queen Elizabeth*, ed. by G.P. RICE (1951). Her *Letters* were edited by G.B. HARRISON (1968), her *Poems* by L. BRADNER (1964), and *A Book of Devotions: Composed by Her Majesty Queen Elizabeth* with translations by A. FOX was published in 1970.

Contemporary writings about Elizabeth include FRANCIS BACON, *Felicity of Queen Elizabeth*, written in 1608, to be found in full collections of his *Works* or in *Essays Civil and Moral*, ed. by J.S. BLACKIE (1886). JOHN FOXE, "Imprisonment of the Princess Elizabeth" is included in his *Actes and Monuments. The Diary of Dr. John Dee*, the Queen's astrologer, was edited by J.O. HALLIWELL (1842).

The best biography is E. JENKINS, *Elizabeth the Great* (1958). SIR JOHN NEALE, *Queen Elizabeth I* (1959), is authoritative; as is J.B. BLACK, *The Reign of Elizabeth, 1558–1603*, 2nd ed. (1959). Earlier biographies are those of AGNES STRICKLAND (1870) and MANDELL CREIGHTON (1896). Readable biographies include N.J. WILLIAMS, *Elizabeth, Queen of England* (1967); and J.M. LEVINE, *Elizabeth I* (1969). R.C. STRONG, *Portraits of Queen Elizabeth I* (1963), is a valuable study.

Some excellent and authoritative works deal with special aspects of Elizabeth's life. These include the three by CONYERS READ, *Mr. Secretary Walsingham and the Policy of Queen Elizabeth*, 3 vol. (1925); *Mr. Secretary Cecil and Queen Elizabeth* (1955); and *Lord Burghley and Queen Elizabeth* (1960). E. JENKINS explored the Queen's relation with Liecester (1961), LYTTON STRACHEY that with Essex (1928), and W.F. OAKESHOTT that with Raleigh in *The Queen and the Poet* (1960). Elizabeth's earliest years are dealt with by W.H. TAPP, *Anne Boleyn and Elizabeth at the Royal Manor of Hanworth* (1953); and her adolescence with insight and style by EDITH SITWELL, *Fanfare for Elizabeth* (1946). DAME EDITH'S *The Queens and the Hive* (1962), dealt with Elizabeth's relations with her sister Mary Tudor, with Mary Queen of Scots, and with Catherine de Medici. M.A.S. HUME gave an account of *The Courtships of Queen Elizabeth* (1896, reprinted 1964). SIR JOHN NEALE, *Elizabeth I and Her Parliaments*, 2 vol. (1953–57), is a standard work. The Queen's part in the Elizabethan church settlement is dealt with in C.S. MEYER, *Elizabeth I and the Religious Settlement of 1559* (1960); and in W.P. HAUGAARD, *Elizabeth and the English Reformation* (1968). C.H. WILSON in *Queen Elizabeth and the Revolt of the Netherlands* (1970), shows the Queen's attitudes in foreign policy. Court details can be gleaned from F.S. BOAS, *Queen Elizabeth, the Revels Office and Edmund Tilney* (1938); and I. DUNLOP, *Palaces and Progresses of Elizabeth I* (1962). The impact of the Elizabethan legend in France is shown in J.H. GREW, *Elisabeth d'Angleterre: la reine vierge dans la littérature française* (1932).

An antidote is P. COMPTON, *Bad Queen Bess* (1933). Curiosities engendered by the Elizabethan legend include A. DODD, *The Marriage of Elizabeth Tudor* (1940), to Leicester, with Bacon and Essex as issue; and G.E. SWEET, *Shake-Speare: The Mystery* (1963), which maintains that Elizabeth was the author of Shakespeare's works.

(E.Je./Ed.)

Elopiformes

The order Elopiformes contains about 12 species of marine and brackish water fishes, the best known of which are the bonefish, tarpons, and ladyfishes. A few are prized as gamefishes, but only the Pacific tarpon (or oxeye) is of economic importance as a food fish, supporting a major fishery in Southeast Asia. The terms "ladyfish" and "bonefish" have both been used for *Elops saurus* and for *Albula vulpes*. In this article the name ladyfish is applied only to *Elops* and bonefish only to *Albula*. The tarpons and ladyfishes are fast-swimming predators with adult lengths of up to 2.5 metres in tarpons and about 1 metre in ladyfishes. The bonefish and the Japanese gisu are specialized bottom feeders. All except the gisu are coastal fishes of warm oceans, most common in latitudes from 20° N to 20° S.

Primitive position among teleosts

Elopiforms are of interest to the ichthyologist as the most primitive living teleost fishes, standing in much the same relation to the higher bony fishes as do the egg-laying mammals (monotremes) to other mammals. As is usual with primitive groups, the elopiforms have an extensive fossil record, with many more fossil than recent species.

General features. Despite their archaic structure, elopiforms are related by their life history to more specialized groups such as the eels. Like eels, elopiforms have a ribbonlike, translucent, pelagic larva (leptocephalus) that undergoes a striking metamorphosis involving shrinkage to about half the maximum larval size. The bonefish, tarpons, and ladyfish spawn close to shore. The eggs are shed and fertilized in shoal water, sinking to the bottom. Elopiforms are prolific breeders; a large Atlantic tarpon (*Tarpon atlanticus*) was estimated to contain more than 12,000,000 eggs, about seven times as many as in the proverbially fecund cod. The newly hatched leptocephali may be carried out to sea by offshore currents, but metamorphosis only occurs close inshore, and it is probable that larvae carried far out to sea die.

During or immediately after their metamorphosis, the postlarvae migrate inland and accumulate in brackish pools or creeks, often connected with open water only at extreme high tide. Such environments are stagnant and low in oxygen, and air breathing (see below) is an important aid to survival. The juvenile fish feed on small crustaceans, insect larvae, and other small animals, moving back to the sea as young adults. The gisu (*Pterothrissus gissu*), which differs from other elopiforms in inhabiting deeper and colder waters, is apparently an exception to this pattern of development, larval life and metamorphosis taking place in deep water, without the postmetamorphic inland stage that is experienced by other elopiforms.

With the exception of the gisu, elopiforms are coastal fishes, able as adults to enter brackish or fresh water. Adult ladyfishes and tarpons are typical predators of coastal waters, feeding mainly on other fishes. The Atlantic tarpon is renowned for leaping out of the water; the Pacific tarpon (*Megalops cypinoides*) and ladyfishes (several species of *Elops*) behave similarly, "rolling" at the surface. The purpose of this behaviour seems to be the intake of air. Like all of the other primitive teleosts, the elopiforms possess an open duct to the swim bladder, and air that is taken in at the mouth can be passed into the swim bladder.

Behaviour related to air intake

In tarpons the swim bladder is lunglike, partially compartmented and highly vascularized. Tarpon are obligate air breathers, dying from asphyxiation if prevented from reaching the surface, an unusual condition for a species in which adults normally inhabit well oxygenated waters.

Such an adaptation, however, is certainly advantageous in the stagnant pools where postlarval life is spent. The tarpons exhibit a further modification of the swim bladder, a pair of forward outgrowths that contact the auditory region of the braincase and are partially enclosed in bony bullae, a modification that presumably improves the sense of hearing.

The bonefish is a bottom feeder in shallow water, coming in with the tide and grubbing with its snout for worms and shellfish, which it crushes with its rounded palatal teeth. The deep-water gisu feeds mainly on worms, probably by similar methods.

Paleontology and classification. *Fossil history.* The family Elopidae is the only extant teleostean family whose fossil record extends back into the Jurassic (about 140,000,000 years ago). The Upper Jurassic genus *Anaethalion* is included in this family on the basis of some forms that were extremely similar to the modern *Elops*. The genera *Notelops*, from the Lower Cretaceous of Brazil, and *Osmeroides*, widely distributed in Upper Cretaceous seas, were probably true elopids, but the allocation of numerous little-known Cretaceous genera currently placed in the Elopidae, often on the basis of negative evidence, must be considered tentative. The earliest known member of the tarpon family appears to be the fossil *Sedenhorstia*, from the Upper Cretaceous of Europe and Lebanon. Fossils assigned to *Megalops* appear in Eocene deposits. The earliest member of the extinct suborder Pachyrhizodontoidei, *Rhacolepis* (from the Lower Cretaceous of Brazil), was small and resembled the ladyfishes, but later, Upper Cretaceous, members of this group become considerably more specialized. *Pachyrhizodus*, from the Cretaceous chalks of Europe and North America, exceeded three metres in length and superficially resembled a tuna. Pachyrhizodontoids may well have been large fast-swimming predators of the open sea, a niche which is now filled by the tunas.

The genus *Albula* has been recorded in the Upper Cretaceous of North America and in the Paleocene of Europe, but typically albulid tooth plates occur in Lower Cretaceous deposits. Several Cretaceous and Tertiary albulid genera have been described on the basis of otoliths ("ear-stones"). *Istieus*, from the Upper Cretaceous of Germany, had characteristics that were very similar to those of the modern *Pterothrissus*.

Annotated classification.

ORDER ELOPIFORMES

Elopomorph fishes having a long but not eellike body; scales containing bone-cells; teeth on the parasphenoid bone; a transverse sensory canal across the snout; broad infra-orbital bones extending back to the operculum, 55–90 vertebrae, a primitive tail skeleton with 2 free vertebrae supporting 6–7 hypural bones, tail fin large and forked.

Suborder Elopoidei

Mouth terminal and snout unmodified; 2 supramaxillaries; many branchiostegal rays (23–35); teeth small; large gular plate between the lower jaws; 7 hypural bones.

Family Elopidae (ladyfish or tenpounder)

Upper Jurassic to Recent. Very generalized fish, the living forms having 32–35 branchiostegal rays and the swim bladder unmodified. Length to 0.9 metre; weight to about 13 kilograms. One living genus, *Elops*, with 5 or 6 species, circumtropical. Numerous fossil genera.

Family Megalopidae (tarpons)

Swim bladder partially cellular, lunglike, and connected with the ear; scales large; 23–25 branchiostegal rays. Two living genera, *Megalops* and *Tarpon*, each with one species, recently shown to differ in the ear to swim-bladder connection. *Tarpon* confined to the Atlantic; *Megalops* to the Indian and Pacific oceans, ranging from Africa to the Philippines. *Tarpon* length to 2.5 m, weight to 150 kg; *Megalops* to 1.5 m.

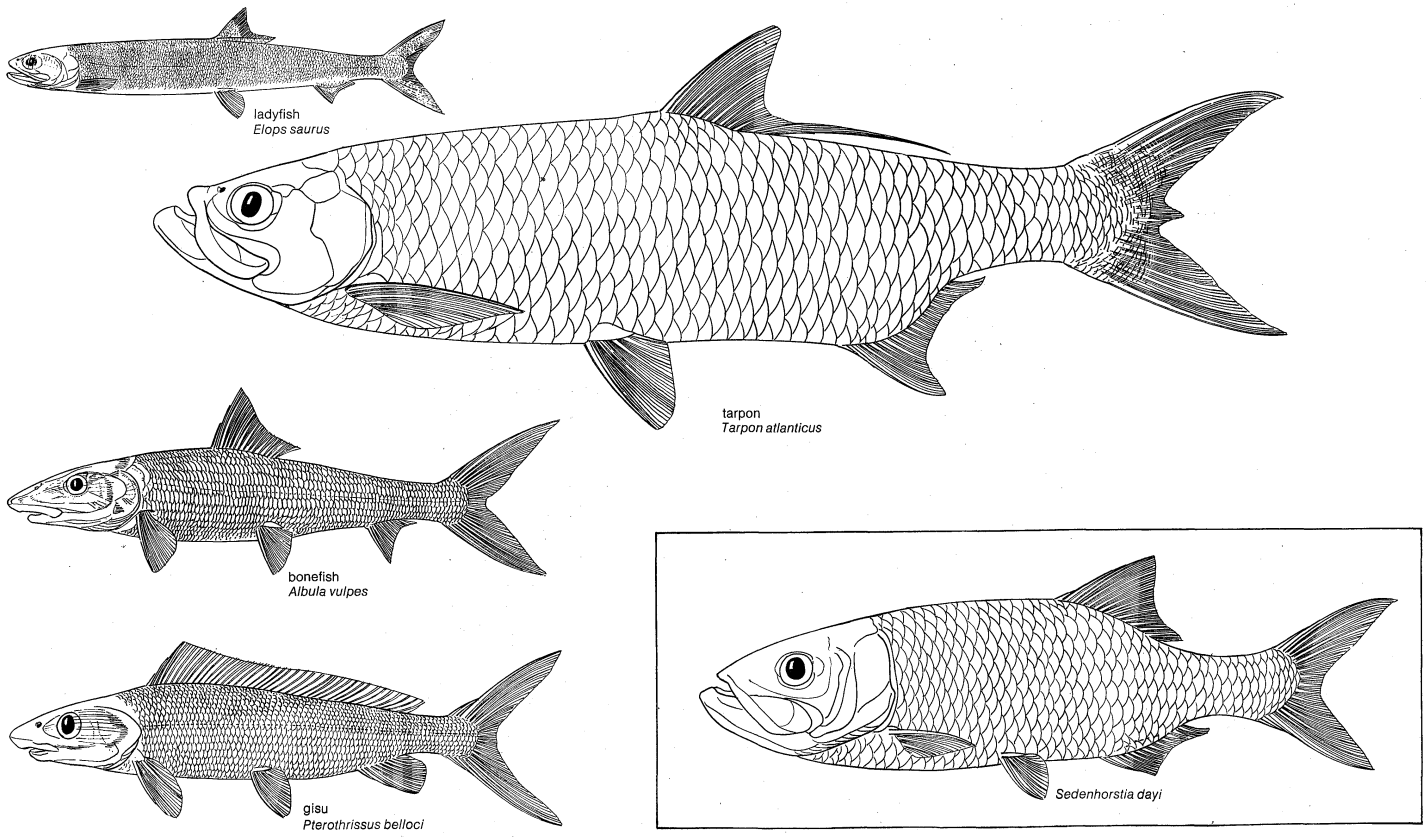
†Suborder Pachyrhizodontoidei

Fossil; Lower to Upper Cretaceous. Parietal bones separated by supra-occipital; gular plate absent; teeth large, pointed, and set in deep sockets. Length to 3 metres.

Suborder Albuloidei

Snout enlarged; mouth small and underslung; crushing teeth on palate; single supramaxillary bone; gular plate small or absent; 6 hypural bones.

From (*Elops saurus, Tarpon atlanticus, Albula vulpes*) *McClane's Standard Fishing Encyclopedia* edited by A.J. McClane, illustrated by Richard E. Younger, Copyright © 1965 by Holt, Rinehart and Winston, Inc., reproduced by permission of Holt, Rinehart and Winston, Inc.; (*Pterothrissus belloci*) from M. Poll, "Resultats scientifiques de l'Expedition oceanographique belge dans les eaux cotieres africaines de l'Atlantique Sud (1948-1949)," III, Teleosteens malacopterygiens, vol. IV, fasc. 2, 1953, p. 14, fig. 5



Body plans of several elopiform fishes.

Family Albulidae (bonefishes and gisu)

Upper Cretaceous to Recent. Characteristics those of suborder. Two living genera: *Albula* (2 species) and *Pterothrissus* (2 species). Length to 70 cm, weight to about 6.5 kg. *Albula* inhabits coastal waters, *Pterothrissus* deeper waters (below 200 m).

†*Family Phyllodontidae*

Fossil. Upper Cretaceous and Early Tertiary. Known only from thick tooth plates, with many superimposed series of replacement teeth. Five genera; from Africa, Europe, and North America.

Critical Appraisal. The chief problem in defining and classifying the elopiforms is the reliance on primitive features, which are merely negative evidence against relationships with other, more advanced groups. Similar problems arise among the most primitive members of all animal groups. The possession of a leptocephalus larva places the elopiforms as the basal order of the cohort Elopomorpha, which also contains the eels, halosaurs, and notacanths. But it is only on negative evidence (absence of specializations) that the elopoids and albuloids are associated, and the absence of any notable specializations in elopoids makes the placing of fossil forms in this group rather doubtful.

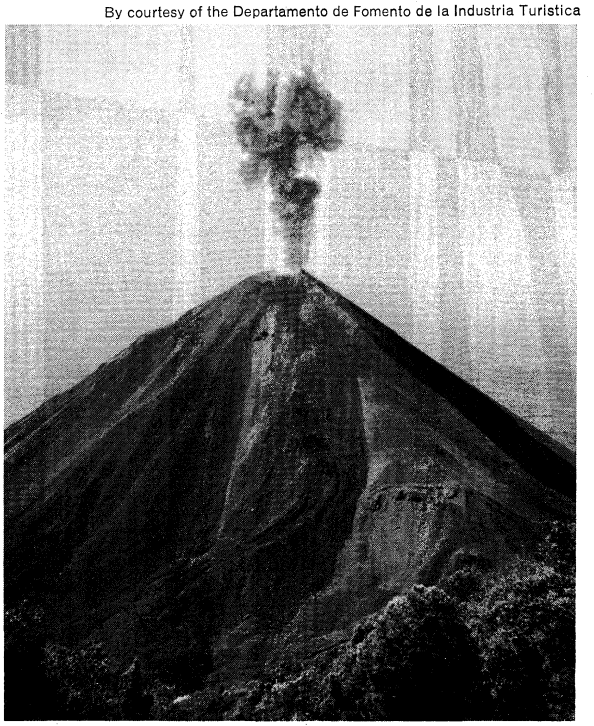
El Salvador

El Salvador, a republic, is the smallest and most densely populated country in Central America. With a population of about 3,541,000 people concentrated in an area of 8,098 square miles (20,975 square kilometres), El Salvador has a population density of about 460 persons per square mile. To the south it has a 199-mile-long coastline on the Pacific Ocean; it is the only Central American country without a Caribbean coastline. To the west it is bounded by the Republic of Guatemala, and to the north and east by the Republic of Honduras. Its capital is San Salvador (population 337,000). The boundary with Honduras, which caused a small war between the two states in 1969, remains in dispute.

The great majority of Salvadorans are mestizo (of mixed Spanish–Indian descent) and Catholic. El Salvador, a land of lakes and volcanoes, is the fourth largest producer of coffee in Latin America and—together with Costa Rica, Guatemala, Honduras, and Nicaragua—a member of the Central American Common Market (CACOM); for coverage of historical aspects, see CENTRAL AMERICAN STATES, HISTORY OF.

The landscape. *Relief features.* The territory of El Salvador includes mountain ranges, volcanoes, plains, lakes, and river valleys. Five regions may be distinguished. These are: (1) the narrow coastal plains, situated between the coastal ranges and the Pacific Ocean, comprising about 10 percent of El Salvador's area; (2) the southern mountain chain, which is volcanic, has an average height of about 4,000 feet and comprises about 30 percent of the territory; (3) the central plain, constituting about 25 percent of the territory, which it crosses from the west to the southeast at heights that vary from about 1,300 to 2,600 feet; (4) the valleys of the Lempa and Grande de San Miguel rivers, which are cut into the central plain and account for about 20 percent of the territory; (5) the northern mountain region, which covers about 15 percent of the country's surface and consists of the Metapán and the Chalatenango mountain chains; the altitudes in this region of El Salvador vary from 4,900 to 6,500 feet.

By courtesy of the Departamento de Fomento de la Industria Turistica



Volcán de Izalco, El Salvador, during an eruption.

Volcanoes

More than 20 volcanoes are situated in the southern mountains, being clustered into five groups which stretch across the country. The westernmost are Izalco (6,004 feet [1,830 metres] high and known as the "Lighthouse of the Pacific"), San Marcelino, Santa Ana (which is 7,812 feet [2,381 metres] high and is the highest mountain in the country), Los Naranjos, Aguila, San Juan de Dios, Apaneca, Tamajaso, and La Laguneta; to the east of these are located San Salvador (6,430 feet) and Las Pavas; next come San Vicente and Ciguatepeque; then Tecapa, Taburete, Buenapa, Usulután, Chinameca, and San Miguel (6,985 feet); finally, farthest to the east, is located Conchagua (4,078 feet), near which are some smaller volcanoes. Several of these volcanoes are still active.

Drainage and soils. El Salvador has more than 300 rivers, of which the most important is the Lempa, which is the only one that is in part navigable. The Lempa, which has many tributaries, rises in Guatemala, crosses a corner of Honduras, cuts across the northern range, flows eastward for more than 80 miles, and then flows south for 65 miles across the southern range to the Pacific. The Grande de San Miguel River System drains eastern El Salvador. The coastal plain is well drained not only by the Lempa and Grande de San Miguel rivers, but also by many other short ones. There are a number of lakes, of which the two largest are Lago de Ilopango (about 25 square miles), and Laguna de Coatepeque (about 15 square miles).

The most productive soils in the country are those of the southern mountain ranges; they are derived from lava and volcanic ash. The soils of the central plains and the valley region are generally shallow and stony. The soils of the coastal plain are alluvial.

Climate. The climate is tropical but is moderated by altitude in the interior; in general it is warm rather than hot, varying between 59° F and 73° F (15° and 23° C). Heavy rains, known as the "temporales," fall in the winter season from May to October. The dry *verano* (summer) season lasts from November to April. There is considerable climatic variation in the different regions. The Pacific lowlands and low areas in the middle Lempa Val-

ley have mean monthly temperatures between 78° and 85° F (25° and 29° C). At San Salvador, the capital, which is 2,156 feet above sea level, the maximum monthly mean temperature is 95° F (35° C) in March and the lowest monthly mean is 58° F (14° C) in January. In the mountains, above 4,800 feet, mean monthly temperatures vary between 63° and 72° F (17° and 22° C). Annual precipitation on the Pacific lowlands averages about 68 inches; on the southern and northern mountain ranges, at heights between 2,000 and 3,500 feet, the average is between 70 and 97 inches; the higher mountains receive a little more. Annual precipitation recorded in the deeper valleys and surrounding plateau-like areas is between 45 and 60 inches.

Vegetation and animal life. The higher mountain regions have temperate grasslands and the remnants of deciduous oak and pine forests. On the central plains and in the valleys small deciduous trees, bushes, and subtropical grasslands are found. The coastal plains and the lower slopes of the southern mountains are covered with either savanna (parklike grassland) or deciduous forests. Among the many species of trees is the balsam, known for its beauty and soft perfume; its trunk yields excellent lumber as well as resin that is used in antiseptics and medicinal gums.

Trees and tree products

Valuable wood also is obtained from the cedar, mahogany, laurel, nispero (a fruit tree which also yields chicle), and madrecacao (a tree with pink flowers) trees, and is used for the manufacture of furniture. Particularly beautiful is the maquilishuat tree, whose flower is the national emblem of El Salvador; the tree has thick foliage and vividly coloured flowers when in bloom; it is found both in the countryside and in the cities. Several species of palm and coconut trees grow in the coastal zone. In addition, there are many varieties of tropical fruit, such as coconut, tamarind, melon, watermelon, and mango.

Because of the amount of land under cultivation, El Salvador is considerably less rich in wild animal life than most Central American countries. Rodents, reptiles, and insects of many kinds, however, are common. There is a wide variety of bird life, which includes wild duck, the white and the royal heron, the urraca (which has a blue breast and a grey head, and is known for its call which resembles a scoffing laugh), the blue jay, and many more, some of which have fine plumage. Although a great

variety of fish, as well as turtles and crocodiles, inhabit streams, lakes, and rivers, most of the fish caught commercially or for sport come from offshore waters and coastal lagoons; they consist chiefly of mullet, grunts (food fish found in tropical and subtropical waters which emit grunting sounds), snappers, jacks, groupers (a species of sea basses found in tropical and subtropical waters), sharks, and anchovies.

Human settlement. Sixty percent of the population live on the hot coastal plains and hills. Rice and cotton are cultivated in this region, but much more land is used either for pasture or forest than for crops. A significant proportion of the nation's beef, forest products, sesame, sugar, corn, and fish is produced here. The southern volcanic ranges, which consist of cone-shaped volcanoes and areas of gently sloping land, have more than 60 percent of the country's population. San Salvador, the capital, is situated in this region, as also are most of the cities with more than 10,000 inhabitants. Some 90 percent of El Salvador's coffee, tobacco, and manufactured goods are produced in this area, as also are two-thirds of its corn, beans, fruits, vegetables, and sugar, as well as half of its cotton, rice, and animal and forest products. The central plains and the valley regions are inhabited by 25 percent of the population, who live in rural areas and small towns. It is the driest region in the country and has more pastureland than cropland. A cattle-raising area, it also produces corn, beans, vegetables, henequen (a fibre used for making ropes and coarse fabrics), and simple manufactures.

The northern mountain region, inhabited by only about 6 percent of the population, has no towns. The people are dispersed in deep valleys and live chiefly by subsistence farming and cattle raising, although they also grow a little coffee and engage in some lumbering.

San Salvador, the capital, founded in 1525, is situated in the Valle (valley) de Las Hamacas and contains about a quarter of the country's urban population. A road and rail centre, it boasts several beautiful parks and gardens and some sturdy administrative buildings. Its residential suburbs are continuing to grow and it has a number of manufacturing industries. It is six miles to the west of Lago de Ilopango which, lying in the crater of an ancient volcano, is the focus of a popular resort area. In the east of the country, San Miguel is located on the slope of the volcano San Miguel; it is a thriving city where the old Spanish colonial and modern life styles merge. The city of Santa Ana is the commercial centre of western El Salvador.

People and population. Before the Spanish arrived in Salvadoran territory in the 16th century, it was occupied by five Indian tribes—the Pokomans, Chortís, Pipils (or Yakis), Lencas, and Úluas. The Pokomans, Chortís, and Lencas were the more ancient, but the Pipils, whose civilization resembled that of the Aztecs in Mexico, were predominant. The Úluas were represented by scattered groups. The Pipil name for their territory as well as for their capital was Cuscatlán, meaning "Land of the Jewel"; the name is still sometimes applied to El Salvador today. Archaeological ruins dating from Indian times are to be seen at Tazumal, Pampe, El Trapito, and San Andrés. Of several large towns founded by the Indians, Sonsonate and Ahuachapán are still in existence.

*According to the FAO the total water area in 1961 was 417 sq mi (1,080 sq km). Because no breakdown of the water area by department was available, only total areas are given in this table. †Figures do not add to total because of rounding. ‡Preliminary. Source: Official government figures.

Few Spanish settlers arrived to colonize the area, but the intermarriage of these few Spaniards with the Pipil Indians resulted in a racially homogenous people. Almost 90 percent of the contemporary population is mestizo; about 10 percent remains Indian (notably the Izalco Indians, and the Panchos from the village of Panchimalco near the capital), and one percent is white. During the pre-Spanish epoch various Indian dialects were spoken, the most important of these being Nahuatl, spoken in the central region of the country, and Poton, spoken in the east. After the initial conquest, Spanish became the official language and the Indian dialects slowly fell into disuse. While Nahuatl still survives, its use is dwindling; the government, in conjunction with the University of El Salvador, has founded a school devoted to its preservation. About 75 percent of the people are of Roman Catholic religion.

Mestizos

Demographically, El Salvador is confronted with the problem of overpopulation. As mentioned, the population density is about 460 persons per square mile, and the rate of growth exceeds four percent a year. About 300,000 immigrants from El Salvador live in neighbouring Honduras. It is estimated that by 1985 the population will approach 6,000,000 people.

The national economy. The economy is predominantly agricultural, although there has been rapid industrial expansion in recent years. The most important agricultural products are coffee, cotton, and sugarcane. Coffee alone accounts for one-third of the value of the total agricultural production and one-half of the value of exports; it is sold to the United States, Europe, and Japan. Cattle raising is also an important activity. While some woods are used for furniture making, as mentioned earlier, the main forest products are dye woods and balsam, a medicinal gum of which El Salvador is the world's main source. Commercial fishing, regulated by the government, increased considerably in the 1960s and has added to the country's export earnings; shrimps as well as fish are caught. There is no mineral exploitation of significance. The main power source, meeting most of the country's needs, is the hydroelectric project on the Río Lempa 35

miles northeast of San Salvador, which is administered by a government agency.

Industrial development

In the 1960s there was a steadily increasing investment in industry, stimulated by the Central American Common Market. Industrial plants rose throughout the country and existing facilities were expanded, helped by government incentives, an advanced banking system, and development credits from abroad. The manufacturing sector of the economy, which has been steadily growing, now represents about 20 percent of the gross national product. Manufactures include beverages, canned foods, organic fertilizers, cement, plastics, cigarettes, shoes, cotton textiles, leather goods, petroleum products, and machinery.

Tourism is an increasing source of income and is encouraged by both the governmental and private sectors. Since 1965 an international fair has been held every two years to encourage the development of commerce and industry. The Salvadoran banking system is well organized; apart from the Central Reserve Bank of El Salvador there are nine commercial banks. Governmental revenue is mostly raised by sales tax (21 percent), nontax revenue (19 percent), customs (19 percent), and export duties on coffee (over 12 percent).

Transportation. El Salvador has adequate transportation facilities except in some of the more remote areas, such as the mountains of the north. Two main routes of the Pan-American Highway system cross El Salvador from Guatemala to Honduras, forming the framework of a road system that reaches almost all parts of the country; one of these routes runs across the central plains, the other across the coastal plains. Traffic has been interrupted, however, by the closing of the frontier by Honduras after a war between the two states in 1969. Out of some 5,500 miles of roads, about 750 are paved, about 1,900 can be used in all weathers, and about 2,700 are for dry-weather use. There are about 430 miles of narrow-gage railroad, operated by two companies, the International Railways of Central America (IRCA) and the FES (Ferrocarril de E Salvador, or El Salvador Railway Company). For sea commerce, El Salvador relies on three ports—Acajutla, La Libertad, and La Unión. El Salvador's outlet to the Atlantic is through the Guatemalan port of Puerto Barrios, with which San Salvador is linked by road and rail, via Guatemala City. Ilopango Field, a modern airport five miles from San Salvador, is linked to the international airways network.

Administration. The constitution, adopted in 1962, provides for a representative form of government with three branches—legislative, executive, and judicial. All Salvadorans, male and female, who have attained the age of 18, are permitted to vote. Executive power is exercised by the president, his cabinet ministers, and undersecretaries of state. The president is elected by direct, popular vote for a term of five years and is ineligible to succeed himself. Legislative power is vested in a unicameral National Legislative Assembly (Asamblea Nacional Legislativa) that meets in regular session on the first of June and the first of December each year. The number of deputies is determined by apportionment. They are elected by popular vote for two-year terms and can be re-elected. The judicial branch is composed of a Supreme Court of Justice, whose members are selected by the National Assembly, and of other tribunals as established by statute. The Supreme Court consists of ten magistrates, one of whom serves as president.

Second- and third-order administrative divisions

El Salvador's territory is divided into 14 departments, each department is divided into *distritos* (districts) and *municipios* (municipalities); each department has a governor and a substitute governor, appointed by executive power; and each municipality has a popularly elected municipal council composed of a mayor, a secretary, and aldermen, the number of whom are in proportion to the population. Independent in their local functions, the municipalities are limited to economic and administrative activities.

Defense. The Army has a strength of 4,500 men. There is a national guard, a national police, and a treasury police. There is also a small air force, and a navy consisting of two patrol boats and some small craft. Military service for at least one year is compulsory for all Salvadoran males from 18 to 30 years of age. The strength of the army is fixed annually by the national assembly; in no case can it be less than 3,000 men.

Social conditions. The standard of living of artisans in El Salvador is high, but that of agricultural labourers remains low. The government is attempting to ensure a more equitable distribution of income by emphasizing worker's education, sponsoring projects for literacy, and training workers for union activity and community life. The Salvadoran Social Security Institute, established in 1949, provides insurance for all workers affiliated to it. The Institute of Urban Housing is attempting to help overcome a serious housing shortage by providing low-cost housing.

Education. All public and private institutions of learning are under the jurisdiction of the Ministry of Education. Since 1968 the school system has been composed of preschool, primary, and secondary educational categories, followed by university level education. Basic education is free and compulsory, but the illiteracy rate is high. Diversified education takes three years and offers high school degrees in subjects such as science and literature, industrial training, hotel management, agriculture, and cattle raising. El Salvador has pioneered in the educational use of television. There are four institutions of higher education: the University of El Salvador, the Higher Normal School, the School of Social Service, and the José Simeón Cañas University (Universidad Centroamerica José Simeón Cañas). There is also an Institute of Fine Arts and a National Agricultural Institute, as well as schools of public administration, social service, and nursing, and various other vocational schools.

Health. By 1969 it was estimated that there was one doctor for every 4,000 people; most of the doctors service urban areas. There are a number of hospitals and health centres.

Prospects for the Future. El Salvador has, especially since the early 1960s, made considerable economic progress, with industry becoming of increasing significance to the economy. Membership in the Central American Common Market has done much to stimulate the pace of development, although the 1969 war with Honduras, which diverted efforts and resources and hampered regional cooperation, proved a setback. Overpopulation poses a basic challenge that has still to be met. The government is also confronted with the problem of helping to raise living standards for the rural population.

BIBLIOGRAPHY.

Topography and general: DAVID BROWNING, *El Salvador: Landscape and Society* (1971), deals with the population as well as the country, while H.F. GODFREY, *Your El Salvador Guide* (1968), is a general account. DE J. OSBORNE, *Four Keys to El Salvador* (1956), is a good travel book, supplemented by R.N. ADAMS, *Cultural Surveys of Panama-Nicaragua-Guatemala-El Salvador-Honduras* (1957), which places El Salvador in the Central American context.

Economics and history: D.R. RAYNOLDS, *Rapid Development in Small Economies: The Example of El Salvador* (1967), scrutinizes the economy, to whose understanding the BANCO CENTRAL DE RESERVA, *Foreign Exchange Control Law and Regulations for the Application of the Foreign Exchange Control Law* (1962); and the PAN AMERICAN UNION, *Foreign Trade of El Salvador, 1945–56* (1958), contribute. On early-20th-century history, W.H. KOEBEL, *Central America: Salvador* (1914); JOAQUIN LEIVA, *The Republic of El Salvador in Central America* (1913); and P.F. MARTIN, *Salvador of the Twentieth Century* (1911), are all illuminating.

(R.S.V.)

Elton, Charles

Biologist and one of the founders of the modern science of animal ecology, Charles Elton has had a profound influence on the development of this subject throughout the world.

Born on March 29, 1900, at Liverpool, the son of Oliver Elton, young Elton was educated first at Liverpool Col-

lege and then at New College, Oxford, from which he graduated with first class honours in zoology in 1922. Like many others, Elton rebelled against the strong emphasis on comparative anatomy in zoology at that time. Although most of his contemporaries turned to the physical and chemical analysis of animal mechanisms in the laboratory, Elton, at heart a naturalist, went in the opposite direction—to use the scientific method to study the lives of animals in their natural habitats and interrelationships with their surroundings. He set out to turn natural history into science—the science of ecology. The naturalists are the pioneer observers preparing the ground for the ecologists, who follow with their more quantitative and experimental studies. When Elton began his work, he described it as "the sociology and economics of animals."

Influences on Elton's thought

The great naturalists of the past had a marked influence on Elton's outlook. He wrote of Alexander von Humboldt as "perhaps the first ecologist" in that he "created a stirring picture of the plant and animal world as a whole, with its majestic settings and its complex interplay of forces." Moreover, Elton recalled that "Humboldt's writings in turn inspired Charles Darwin, who went further than most of his generation in grasping the tremendous intricacy and importance of plant and animal interrelationships." Elton was particularly impressed by the methodology of U.S. ecologist Victor Ernest Shelford in his book *Animal Communities in Temperate America as Illustrated in the Chicago Region* (1913). He had an opportunity to apply Shelford's ideas in 1921, when, still an undergraduate, he acted as assistant to Julian Huxley on the Oxford University expedition to Spitsbergen; at this time he was given a free hand in making an ecological survey of local animal life. He continued this project on three subsequent expeditions to the Arctic, in 1923, 1924, and 1930. Just as Darwin had been much influenced by the *Essay on the Principle of Population*, of Thomas Malthus, so was Elton influenced by *The Population Problem* (1922) of Alexander Carr-Saunders, who was also a member of the Oxford University expedition to Spitsbergen and who provided Elton with a first-hand introduction to his ideas.

Basic principles of ecology

Elton's first book, *Animal Ecology*, published in 1927, was a landmark not only for his brilliant treatment of animal communities but also for the fact that the main features of his discussion have remained as leading principles of the subject ever since: food chains and the food cycle, the size of food, niches, and the "pyramid of numbers." He also developed more comprehensive ideas about the factors that govern animal numbers. As a result of his Arctic experience, Elton had become a biological consultant to the Hudson's Bay Company, a position that allowed him to make his important studies of the fluctuations in the populations of various furbearing mammals revealed in the trappers' records, which date from 1736. This study in turn led to his research on the fluctuations in Britain's mouse and vole populations as they are affected by their changing environmental conditions.

In 1930 appeared his provocative book, *Animal Ecology and Evolution*, in which he says that "The balance of nature does not exist and perhaps never has existed." Moreover, "in periods of stress it is a common thing for animals to change their habitats and usually this change involves migration." And again, "we are face to face with a process which may be called the *selection of the environment by the animal*, as opposed to the *natural selection of the animal* by the environment." Unfortunately, his increasing concern with population numbers and their fluctuations did not allow him to pursue these exciting evolutionary ideas.

In 1932, Elton established his Bureau of Animal Population at Oxford. It became both a world centre for the collection of data on variations in animal numbers and a research institute in terrestrial ecology. It attracted workers from many countries, providing training for younger men who carried the Elton tradition to distant places, such as California and British Columbia in one hemisphere and Australia and New Zealand in the other. In the same year he became editor of the new *Journal of Animal Ecology*, which was launched by the British Ecological Society largely under his influence. In 1936 Oxford appointed Elton reader in animal ecology, and Corpus Christi College elected him a senior research fellow.

Fluctuating population

Elton's extensive work on mice and voles enabled him to assign his bureau at the outbreak of World War II the task of finding practical methods of controlling rodent pests, a study that saved his country much loss of food during those critical years. The methods he and his colleagues developed and the results they achieved are described in *The Control of Rats and Mice* (1954), which has become the model for such work all over the world. In 1942 he published his study on *Voles, Mice and Lemmings*, and in 1958 he discussed in *The Ecology of Invasions of Animals and Plants* the effects produced by the spread of organisms introduced into an area by both natural and human agencies. Since World War II, Elton has been engaged primarily in habitat studies; these studies formed the basis of his important volume *The Pattern of Animal Communities* (1966). This work gives more general principles, particularly the inverse pyramid of habitats, which corresponds to his pyramid of numbers.

Elton was elected a fellow of the Royal Society of London in 1953, foreign member of the American Academy of Arts and Sciences, and was awarded the Gold Medal of the Linnean Society in 1967 and the Royal Society's Darwin Medal in 1970.

Elton perceived and stated more clearly than anyone else had yet done the outstanding principles governing the complex interplay between different animals and plants in any community, as well as their relations with their habitat. Moreover, he promoted these principles by his inspiration of many students at his Bureau of Animal Population at Oxford. He is widely acclaimed as the ecologist par excellence.

BIBLIOGRAPHY. SIR ALISTER HARDY, "Charles Elton's Influence in Ecology." *J. Anim. Ecol.*, 37:1–8 (1968), is a short general review of Elton's contributions to animal ecology.

Embalming, Burial, and Cremation

From prehistoric times the institutionalization and ritualization of various methods of disposing of the dead have been characteristics of man's cultures and civilizations. Embalming, the art of preserving human remains, has been practiced in many societies, ancient and modern. Whether or not embalming is used, some method or methods of disposal of the body also are employed. The principal methods of disposal are burial—including inhumation (interment in the earth or a crypt, tomb, or similar shelter), water burial, exposure, and cannibalism —and cremation, the reduction of the human remains to ash.

This article covers the practices of embalming, burial, and cremation and the role of burial societies in ancient and modern civilizations (see also DEATH RITES AND CUSTOMS).

Attitudes toward death. Socrates' admonition to his grieving friends—"Be of good cheer and say that you are burying my body only"—represents an attitude toward death that has not been widely accepted, although it is basic to most of the world's important philosophies and religions. Death, consequently, has been celebrated with ceremony and often with splendour to a greater degree than any other rite of passage. In some ancient cultures, as widely distant as Egypt and Peru, the preoccupation with mortuary matters was so intense that a major portion of the social resources—capital and labour, as well as artistic, scientific, and technological skill—was devoted to building a civilization of tombs. In many cultures the treatment of the dead body before, during, and after burial mirrors the way of life and thought to such a degree that graves have yielded to archaeologists and anthropologists answers to the mystery of long-vanished peoples.

Rationale for burial practices

Sociologists vary in their explanations of funeral practices. Some hold them to be mechanisms for releasing tensions and re-establishing group morale; others look upon them as mechanisms for creating tensions and affirming group traditions. Generally, however, most investigators of human behaviour agree that burial practices have their origin in ambivalent emotional responses toward death and the dead: hope and terror, grief and guilt, love and loathing. The dominance of one or the other determines how the corpse shall be treated. Thus, it may be handled lovingly and kept close to the living, as was done among early Christians and continues to be among the Dayak of the Malay Archipelago; or it may be regarded as vile and relegated to a forbidden area, an attitude shared by the ancient Persians and modern Navajo Indians.

Attitudes toward the dead are also derived from concepts of the relationship between life and death. Where the two are closely identified, the hereafter is held to be a spirit world that is an extension of the material here and now, a belief common among primitive people from Homeric Greeks to present-day Ashanti tribesmen, and burial rites are most elaborate. Thus, it is thought that if the dead are to enjoy a happy ever after, they must be provided with all that made life enjoyable: food, drink, clothing, jewels, furniture, and (sometimes) wives and attendants.

Burial practices are simplest among people who make clear distinctions between spirit and matter. To Jews, Christians, Buddhists, and members of other religious groups who believe that death is a "translation" to a spiritual realm, the body is of minor importance after the soul has departed, and material trappings, therefore, are considered irrelevant and irreverent. Originally, the burials of followers of those sects were simple and stark. But ancient customs persist, as the lavishness of modern-day funerals the world over indicates.

EMBALMING

History. For practical as well as theological reasons a well-preserved body has long been a chief mortuary concern. The ancient Greeks, who demanded endurance of their heroes in death as in life, expected the bodies of their dead to last without artificial aid during the days of mourning that preceded the final rites. Other societies, less demanding of their greats, developed a wide variety of preservatives and methods to stave off decay or minimize its effects. Corpses have been pickled in vinegar, wine, and stronger spirits: the body of the British admiral Lord Nelson was returned from Trafalgar to England in a cask of brandy. Even the Greeks sometimes made concessions: the body of Alexander the Great, for example, was returned from Babylon to Macedonia in a container of honey. The application of spices and perfumed unguents to minimize putrefaction was so common a practice that the English word embalming had as its original meaning "to put on balm." Generally, however, the word is used to describe a less superficial procedure, the introduction of agents into the body to ensure preservation.

The beginnings of the art and techniques of embalming are associated principally with ancient Egypt, where, as in parts of Asia and South America, a dry soil and climate encouraged its development. The early practice of wrapping the dead in cloth and burying them in charcoal and sand beyond the reach of the Nile waters preserved the corpses, which retained form and features for a long period. Those naturally preserved mummies are believed to have influenced the religious doctrines because they seemed to prove that the individual existed after his death. A belief in immortality and physical resurrection was central to Egyptian religion, both to the sun worship of early periods and to the later cult of Osiris. Central to the latter was the belief that when all of the elements that were present in life—soul, name, shadow, heart, and body—were reunited, the person would be resurrected, as the god Osiris was after his brother killed and dismembered him.

Since the body had to be attractive enough to lure back the soul and other elements, the highly skilled and trained embalmers took exquisite care to preserve it. Although it is held that embalming skill reached a peak during the New Kingdom period between 1738 and 1102 BC, the most detailed description of the various methods was given by the 5th-century-BC Greek historian Herodotus. The most elaborate method, at first reserved for the royal dead, involved surgical procedures. The brain, intestines, and other vital organs were removed, washed in palm wine, and placed in vases, known as canopic jars, filled with herbs. The body cavities were filled with powder of myrrh and other aromatic resins and perfumes. The incisions were stitched, and the body was placed in nitre (potassium nitrate, or saltpetre) for 70 days, after which it was washed, wrapped in cotton bandages, dipped in a gummy substance, and finally coffined and entombed. In a less expensive procedure, oil of cedar was injected into the body, which was then placed in nitre for 70 days. When the body was removed, the oil was withdrawn along with fleshy parts of the body, so that only skin and bones remained. A third method, employed on the bodies of the poor, consisted of purging the intestines and covering the body with nitre for the prescribed period.

Methods of embalming

A number of other early peoples also practiced embalming of a sophisticated nature. Archaeologists have found evidence of a high degree of embalming skill in the burial chambers of the prehistoric Paraca Indians of Peru. The Guanches, aborigines of the Canary Islands, used methods much like those of the Egyptians, removing the viscera and filling the cavity with salt and vegetable powders. The Jívaro tribes of Ecuador and Peru took the additional precaution of ensuring the immortality of their chiefs by roasting their embalmed bodies over very low fires. In Tibet some bodies are still embalmed according to an ancient formula: the corpse is put in a large box and packed in salt for about three months, after which it is in mummified condition.

The ancient Babylonians, Sumerians, and Greeks seldom practiced any but the most superficial kind of embalming, anointing the body with unguents, perfumes, and spices. Nor did the Jews employ embalming procedures, with the notable exception of Joseph, who ordered embalming for himself and his father, and further departed from Jewish custom by having his body placed in a coffin. Among the ancients who profoundly influenced Western culture only the Romans employed cavity embalming, not for religious reasons but for the temporary preservation of bodies exhibited for some time before burial. Although there is evidence that some early Christians were embalmed, generally they rejected embalming as well as cremation, considering them pagan customs that mutilated the corpse. Such scruples were sometimes overcome by the desire to have an outstanding person linger on, a desire that was reinforced by the belief that the bodies of some of the devout were kept intact after death as a mark of divine favour. Consequently, some Christians were embalmed, a notable example being Charlemagne, whose embalmed and richly dressed corpse was placed in a sitting position in his tomb at Aachen after his death in 814. The body of the 11th-century Spanish epic hero el Cid, which remained seated on an ivory chair in the monastery of San Pedro de Cardeña for a decade before burial, is also presumed to have been embalmed.

During the Middle Ages and the Renaissance a modest amount of embalming was done by specialists who employed the elaborate Egyptian method. For its return from France to England, the body of the 12th-century English king Henry I was embalmed and eviscerated and the cavities stuffed with medicinal herbs. But during the Middle Ages, embalming was such an expensive procedure that even most royal personages could not afford it; involving, as it did, the use of costly spices, unguents, wax, and wrappings in addition to the prices charged by skilled embalmers. Moreover, religious opposition was so strong and skill so limited that few would consider it. Instead, cerecloths, strips of fabric impregnated with wax and wrapped snugly around the body to exclude air, were used. This method of preservation was so prevalent that cerement became a synonym for grave clothes. The great

Practices in the Middle Ages and Renaissance

interest in anatomy and surgery during the Renaissance stimulated experiments with other embalming methods. Leonardo da Vinci, who dissected at least 50 cadavers for study, developed a method of venous injection for preserving them that anticipated modern embalming procedures. One 17th-century Florentine physician is reported to have turned a corpse to stone by injecting the tissues with a solution of silicate of potash and then immersing the body in a mild acid solution.

Development of modern embalming. Embalming by arterial injection as a mortuary practice is considered to have begun in England in the 18th century. The technique had actually been developed in the first half of the 17th century by the noted English physiologist William Harvey in experiments leading to his discovery of the circulation of blood, during which he injected coloured solutions into the arteries of cadavers. Later the Dutch and German scientists Frederick R. Ruysch and Gabriel Clauderus are believed to have used similar arterial-injection techniques to prevent cadavers from decomposing. The Scottish anatomist William Hunter (1718–83), however, is credited with being the first to report fully on arterial and cavity embalming as a way to preserve bodies for burial. His discovery attracted wide attention after his younger brother, John Hunter, in 1775 embalmed the body of a Mrs. Martin Van Butchell, whose will specified that her husband had control of her fortune only as long as her body remained above ground. To meet that condition, Van Butchell had her embalmed, placed her fashionably dressed body in a glass-lidded case in a sitting room, and held regular visiting hours.

The demand for embalming grew in England and particularly in the United States, where it was promoted by a newly emerging group of undertaker-businessmen as superior to the customary but awkward and often unsatisfactory method of preserving bodies for transportation or for viewing by packing them in ice or laying them on "cooling boards," with a concave, ice-filled box fitted over the torso and head. Some of the more enterprising entrepreneurs exhibited well-preserved "cases" in the windows of shops, or took them on tour so that persons in rural areas and small towns could see the latest development.

Acceptance of embalming

The U.S. Civil War was the turning point in breaking down public resistance to "mutilating" the body and in establishing arterial embalming as a common practice in the United States. Although the government had established national cemeteries for the war dead, it freely awarded contracts to undertakers and embalmers to prepare the bodies of soldiers for shipment home. The widespread use of this service by soldiers' families and the embalming of such notable dead as Pres. Abraham Lincoln's son Willie and later of Lincoln himself brought about increased acceptance of the practice and even caused it to become associated with patriotic activity. Early practitioners included a number of vigorous salesmen, including Joseph H. Clarke, a road salesman for a coffin company. Impressed by embalming's possibilities and profits, he persuaded a staff member of a medical college in Cincinnati to institute a brief course in embalming in 1882, thus establishing the basis of mortuary education in the United States. Embalming remains the only specific skill required in the undertaking business.

Modern procedures. In the modern procedure of embalming, the blood is drained from the veins and replaced by a fluid, usually based on Formalin (a solution of formaldehyde in water), injected into one of the main arteries. Cavity fluid is removed with a long hollow needle called a trocar and replaced with preservative. Cavity fluid is also based on Formalin mixed with alcohols, emulsifiers, and other substances (like embalming fluid) to keep the body from shriveling and turning brown. Arterial embalming is not permanent; even such carefully prepared corpses as that of Lenin, on view in the Kremlin, must be given periodic renewal treatment. The chief purpose of embalming is rather to give the body a lifelike appearance during the days in which it is being viewed by mourners. To enhance this, cosmetics and masking pastes are often applied.

In the United States, embalming is a standard practice as a result of the government support it has received, and is mandatory when bodies are being transported by common carrier, and, in many states, usually when there is an interval of more than 48 hours between death and burial. In Europe, however, embalming is rarely practiced. In many countries permits are required; in most it is performed only by medical practitioners, and the costs are relatively high.

BURIAL

Geography, religion, and the social system all influence burial practices. Climate and topography determine whether the body is buried under the ground, placed in water, burned, or exposed to the air; religious and social attitudes determine how elaborate the burials should be. Rank may determine whether the body is placed in the shallow trench of a simple burial or in an underground chamber of impressive dimensions and construction; whether the body is thrown into a lake, river, or ocean or launched on a raft or in a ship; whether bonfires or vast pyres are lighted to roast the flesh from the bones and reduce them to ashes; whether the body is left on the ground to be consumed by scavengers or weathered by sun, rain, and wind or placed on scaffolds or high towers. In modern Tibet, for example, where four methods are used, water disposal is considered adequate for the members of the lowest classes; burial in the earth and exposure to the air are for the middle ranks; and cremation is reserved for the most exalted.

Rites for kings

The burials of kings and religious leaders have almost universally been characterized by lavish display. From ancient Sumer to modern England, the rites accorded temporal or spiritual rulers have been sumptuous and their tombs costly—whether provided by admiring followers or designed by the lofty themselves. Often the rites have involved great sacrifice of life in addition to wealth. Until recently, when an Ashanti king died—and members of that African tribe kept secret the fact that he was dead—an attendant would be killed at each stage in the preparations so that in death the ruler would have someone with him to perform the services of bathing, dressing, and feeding. To ensure him of company, a number of handsomely garbed and jewelled wives were also dispatched; and a year after death, when the coffin was finally placed in the royal mausoleum, an entourage of wives, cooks, and other servants was entombed with the king.

Modern heads of state are not guaranteed such postmortem attention, but even in the most democratic countries their burial is usually marked by elaborate and costly ceremonies. A rare exception was the modest burial of Pres. Charles de Gaulle, retired president of France, in 1970. At his request he was buried with utmost simplicity in the small cemetery of Colombey-les-Deux-Églises in a plain wooden coffin made by the village carpenter and with only his family, a few close friends, and his neighbours in attendance. His burial contrasted sharply with the pomp and circumstance he enjoyed in life. When the burden of caring for the dead becomes intolerable or excessive, reaction has often occurred, led by religious or by secular authorities and resulting in sumptuary laws limiting expenditures, enacted by such diverse peoples as the ancient Romans, Renaissance English, and the Puritans in the United States.

Inhumation. Burial in the ground by hollowing out a trench in the earth for the body or covering it with rocks or dirt dates back at least to Middle Paleolithic times. Inhumation is the most universal method of burial, as well as being one of the oldest; indeed, some animals employ it. Inhumation of various kinds may be simple or elaborate. Some Eskimo people cover the corpse with a pile of stones or, if stones are not available, with a small ice igloo; the old Norse people built barrows that sometimes reached enormous heights. Similarly, graves may be mere shallow pits, or they may be intricate and beautifully fashioned subterranean palaces sunk deep into the earth and spacious enough to accommodate vast numbers of persons. Excavations of the royal graves

of Ur (dating back to *c.* 3000 BC) revealed, in an inner chamber of one, the body of a ruler with a few intimate attendants and, in surrounding chambers, servants, ministers, dancing girls, charioteers with vehicles and animals, and other persons who had been slain to provide service in death. Skeletons of Bronze Age heroes who had been buried together were found in the royal graves at Mycenae. Recent discoveries in Peru revealed that the Paraca burial chambers, hewn out of solid rock 18 feet (about five metres) below the surface of the ground, were large enough to accommodate as many as 400 corpses with all of the belongings it was thought they would need in the afterworld. Customarily, however, graves have been planned for the burial of individuals.

Burial in caves

Caves, a natural refuge of man, have also been used for the dead. The ancient Hebrews used natural single-chamber caves and hewed oblong recesses lengthwise into the walls to accommodate the dead, a custom that encouraged the building of mausoleums. At first regarded as sacred places, they came to be considered unclean; by the time of Christ they were coated with lime so that they could be recognized and avoided—the literal origin of the metaphoric "whited sepulchres." Among many people, however, the sepulchral caves continued to be regarded as sacred and eventually became places of worship. Among them are thousands of rock temples in western India and in Sri Lanka (Ceylon), some of which received elaborate architectural and sculptural treatment. In Egypt, rock temples were sometimes fronted with an open-air exterior building; an example is Abu Simbel, which extended 180 feet (55 metres) into the rock formation. Both caves and earth graves encouraged the development of other burial practices: the use of coffins and rich graveclothes and burial goods.

Even the positioning of the body came to acquire significance, generally of a religious nature, though involving other considerations. Customarily the body is placed in an extended position, in or out of a coffin, as if in sleep. Bodies of Muslims are laid so that the right side faces Mecca; those of Buddhists are laid with the head to the north. The bodies of ancient Egyptians were placed to face toward the west, perhaps as an indication of the importance of the land of the dead. The Dagari (Dagaba) people of Africa base distinctions on sex. According to one scholar, in death, men are laid on their right side facing east so that the rising sun will tell them to prepare for hunting or farming, and women are laid facing west so that the setting sun will warn them the time has come to prepare the evening meal. Not all groups prefer the sleeping position. Early cultures buried their dead in a crouching or squatting position. In Babylon and Sumer, the sleeping position was reserved for the more exalted; servants killed and buried with their rulers were placed in a crouching position so that they would be ready to serve at royal command. Indians of the Americas often bury their dead in a fetal position, sometimes in a basket or clay urn, with knees under the chin and the body neatly tied into a death bundle. Upright burial has been favoured by other people, particularly for warriors; in Vienna in 1970, it was reported that a club for the "Vertically Buried Loved Ones" was enjoying popularity; burial was being effected in a plastic tube placed upright in a deep hole.

Water burial. The association between water and immortality is reflected in the myths of many cultures, myths that often centre around a god-hero who sails away from his people in death with the promise to return again. The bodies of chiefs and heroes, therefore, have often been set adrift on rivers and oceans in death ships. Among the Norse, even those who were interred were sometimes given such a bier—a custom that was widespread from Iceland to England during the 7th and 8th centuries AD. Perhaps the most famous of such ship burials that have been excavated was that at Sutton Hoo in Suffolk, England. In one mound, archaeologists found the remains of a wooden boat for 38 rowers, 85 feet (26 metres) long, that had been dragged a half mile (about one kilometre) from the river and lowered into the ground. Even women were so honoured, as revealed by excavations at Oseberg in Norway of an impressive Viking ship that had been used as a grave for two women.

Ship burials

Water burials have been common in other cultures. In the South Pacific it was customary to place the dead in a canoe and launch that on the water. Not all water burial involves a ship or raft, however. In the Solomon Islands, bodies are simply laid on a reef to be eaten by sharks; in other places they are wrapped and weighted with stones. In Tibet the bodies of the poor, as well as those of beggars, lepers, and babies, are sometimes thrown into rivers and streams. No special preparations are made in some places; in others, weights are attached before bodies are thrown in; in still others, they are dismembered before being put in the water. In Western cultures, water burial is still employed on occasion when people die during a sea voyage. Recently, there has been a growth in the practice of scattering the ashes on water after cremation—particularly along the Pacific coast of the United States. That custom obtains also in various parts of Asia. In Laos the ashes of the cremated are often strewn at sea; in India a bone-throwing ceremony concludes the Hindu death observances. Within a year after death the remains are taken to the Ganges and thrown into the sacred water; if it is not possible to do that, they are thrown into another river or stream with the hope that they will eventually make their way to the Ganges.

Exposure. Placing the body where it may be eaten by scavenging birds and animals or weathered to its essential elements has been held by many groups to be the most desirable form of disposal for spiritual as well as material reasons. The Zoroastrians have been perhaps the most widely known practitioners of this type of burial, which developed out of the belief that the corpse is so unclean that to inter or to cremate it would contaminate the "pure elements" of earth, fire, and water. Since the 6th century BC it has been their custom to leave bodies on mountains or hills at a distance from the community. In Bombay the Parsis (as the Indian descendants of the Persian refugees are called) maintain "towers of silence," high circular structures. The dead are carried to them, and funeral servants place them on stone beds surrounding a central pit. After the hovering vultures have stripped the flesh from the bones—usually within a few hours—the bones are gathered and dropped into the central pit. In Tibet, where cremation, water, and ground burial are also employed despite difficulties, exposure is common, partly because of the religious belief that bodies without souls have no significance. The Mongolian nomads, who consider it honourable as well as expedient to die "on the plain," practice several types of exposure. Whenever possible, the sick and the infirm are taken from the tents before the moment of death. Usually, the body is left to be eaten by scavengers. Bodies of infants and children are sometimes placed in a sack and abandoned at a crossroad; the first Mongol thereafter to pass the spot is obliged to open the sack so that the spirit may take flight into the afterlife. A number of people who expose the dead use trees and platforms (tree burial). Among them are the primitive Balinese, the Nāga tribes of India, the tribes of central Australia, and the Sioux and other North American Indian groups. Commonly, the Sioux robed the dead in their best clothing, sewed them into a deerskin or buffalo shroud, and carried them to a platform about eight feet (2.5 metres) high. Various possessions and gifts were placed on the scaffold, and the body was allowed to remain there for a year; at the end of that time it was taken down and given an earth burial.

Tree burial

Cannibalism. Ritualistic cannibalism, or anthropophagy, includes eating the flesh of slain enemies to obtain their strength and virtues; some believe that by ingesting the ghost or soul, which resides in the flesh, they can render it harmless, destroy it utterly, or make it subservient to the will of the eater. That is a reason for exocannibalism's (eating the flesh of persons outside the tribe or group) having been fairly common among Australian and Maori tribesmen, the Eskimos, and some Central African people. Not all corpses are eaten. In some cases,

only fallen warriors, medicine men, and women who die a violent death are consumed.

Endocannibalism, the eating of relatives or members of the social unit, has been widely practiced. In the funeral feasts of coast tribes of north central Australia, relatives eat the dead so that they may no longer be sad. Southern Australian tribes used to carry the corpse around, nibbling a piece of it when grief overcame the survivors. Slavonic people ate their parents; so did the Kallatiai people of India, and, according to Strabo's account, the people of Ireland also considered it desirable to eat dead relatives. The Mayorunas and Acumas along the Orinoco River felt it was better to be eaten by friends than by worms; and the Cocomas, also of South America, considered it a show of honour to the dead.

Second burial. Among many people, particularly in primitive cultures, a period of waiting occurs between the first and second burial that often coincides with the duration of decomposition. The origin of this practice is considered to be the different concept of death held by these peoples. In modern societies, death is regarded as instantaneous; it is not so in primitive societies, where it is held to involve a slow change, a passage from the visible society of the living to the invisible one of the dead. During the period of decomposition the corpse is sometimes treated as if it were alive, provided with food and drink, and surrounded by company. Often the dead were kept at home with the living; among the Dayak people of Borneo, chiefs and social leaders were kept in the longhouse with the entire village—a practice to which Dutch officials objected so strenuously that temporary houses were built for the dead. Some groups, the Indonesians, for example, attached mystical importance to the disintegration of the body, collecting and carefully disposing of the liquids produced by decomposition—sometimes mixing them with rice to ingest them. In some cultures the body is mummified or given earth burial or exposed to air during the interval before final burial, as mentioned above. In Bali, where the soul is believed to have left completely by the 42nd day after death, the body, which has been mummified or given earth burial, is cremated. Among Australian Bushmen the bones are allowed to bleach in the sun for several months, after which they are cleaned, painted, and placed in a hollow pole, which has been elaborately decorated with the totem symbols of the dead warrior. In Romania it was the custom to disinter the dead at fixed intervals—three years after burial for a child, five for a youth, and seven for an older person. Then the bones were washed with wine and water, put into a linen bag, and taken to the church for a second burial. The final burial, which was widely believed to mark the entrance of the soul into the land of the dead, was characterized by ceremony and often involved the whole community. A funeral feast was customarily served, and at the end of the affair, the mourners re-entered society.

Concepts of death

In some rare instances the second burial is a collective one. Every ten or 12 years the Hurons of North America held a "feast of souls," a major festival during which the remains of the dead were gathered up and deposited in the communal burial place. Another type of secondary burial also occurs, but it is one that has to do with cemetery space. In a number of South American and European countries where space is relatively scarce, people often lease a grave. At the end of three or five years the body is exhumed, and the bones are put into a niche in an ossuary or disposed of in a common grave.

Collective second burials

Cemeteries. Where and how the dead are finally sheltered have preoccupied many people, modern and ancient, highly civilized and primitive. As with methods of burial, the answers have been dictated by geography, religious beliefs, and social attitudes and also by aesthetic and sanitary considerations. Cemeteries, consequently, may be simple or elaborate—built with a grandeur that overshines the community of the living, as is the case in many rural areas in Central and South America. Also, the places may be regarded as "holy fields" or taboo areas. In countries such as Japan and Mexico, cemeteries are festival places on certain occasions set aside to honour the dead. In other countries and among other religious groups, they are simple and stark, shunned except at time of need.

In most cultures, providing a place for the dead was originally a family obligation because of the widespread belief that ties of kinship last beyond death. The land bought by the biblical Abraham from the sons of Heth had as a principal feature a cave in which his dead could be buried. Having a family mausoleum or graveyard is a custom that has endured in various parts of the world, East and West. And their locations have often been selected with great care: in China *feng shui* ("augury") experts picked sites calculated to provide "good wind and water"; Koreans traditionally hired geomancers to divine auspicious locations, out of the range of vision of "baleful spirits." The desire to be united with ancestors has been very strong. Dutiful Oriental sons return the bodies of their parents to Japan and China at sometimes enormous cost; in the Western world, there is much traffic, with bodies shipped by air, rail, and boat "back home." Even when the tribe or the community took over the obligation, burial in the communal graveyard was a jealously guarded privilege. Strangers could dwell in towns and cities but could not be buried in their cemeteries. Special cemeteries were set up by the ancient Jews, the Romans, and other people for criminals and foreigners and the poor. The infamous 30 pieces of silver returned by Judas were spent to provide a grave for strangers. In Europe from the medieval period until well into the 19th century, convicted witches and murderers, along with suicides, were excluded from the cemeteries.

Sanitary precautions have influenced the nature and location of cemeteries. Romans and Jews, for example, regarded cemeteries as hazardous and established their graveyards outside the walls of Rome and Jerusalem. The ancient Egyptians and the Chinese also shared the concern for sanitation. Christians, on the other hand, had no such concern: they used catacombs as combined mass graves and places of worship, and when they were allowed to practice their religion freely, they buried the dead in churches and churchyards. Overcrowding became very common after the 6th century, when many secular authorities decided to revert to the Roman custom of permitting burial only outside the walls of the city. Church land was not subject to secular sanitary laws, and during the Middle Ages and Renaissance the problem intensified. The secularization of cemeteries came about in the Western world on a mass scale during the early years of the 19th century, largely because of the growing interest in public health and sanitation. In France and other parts of western Europe, many cemeteries were set up outside the cities, managed as public services by city and state governments. In the United States and England, private individuals and organizations began to establish cemeteries. One of the largest 19th-century projects was England's Brookwood, organized by the London Necropolis Company. It had a private railway station in London and two in the cemetery, its own telegraphic address, and special areas for different religions, nationalities, social organizations, and professions. Perhaps the most famous of the type is California's Forest Lawn. In the United States there continue to be public cemeteries, cooperative cemeteries, church cemeteries, and large, mutually owned cemeteries. In addition to state, county, and municipal cemeteries, the federal government operates a complex of national cemeteries in the United States and abroad for military servicemen and members of their families.

Concern for sanitation

In recent years elaborate monuments and gravestones have in many places been replaced by markers flush with the ground, so that from a distance the cemetery seems to be a grassy field—an appearance that has stimulated the change of name from cemetery to memorial park. In other places the preference for above-ground burial has encouraged the building of high-rise mausoleums. Nationalistic preferences are evident in cemeteries in Paraguay: there, Germans, Jews, and Russians are usually buried in the earth, and those of Spanish and Slavic origin in niches and pantheons; Italians use both.

CREMATION

History. The practice of reducing the body to its essential elements by burning it on open fires was introduced to the Western world by the Greeks as early as 1000 BC. They seem to have adopted cremation from some northern people as an imperative of war, to ensure soldiers slain in alien territory a homeland funeral attended by family and fellow citizens. Corpses were incinerated on the battlefield; then the ashes were gathered up and sent to the homeland for ceremonial entombment. Although ground burial continued (even a symbolic sprinkling of earth over the body fulfilled requirements, as *Antigone* reveals), cremation became so closely associated with valour and manly virtue, patriotism, and military glory that it was regarded as the only fitting conclusion for an epic life.

Cremation of military heroes

The *Iliad* makes plain how elaborate and important cremations were. In that, Zeus himself forced Achilles to surrender Hector's body to his father so that he, King Priam of Troy, could have it cremated royally. The greater the hero, the greater was the conflagration. Achilles set the pattern in providing a pyre 100 feet (30 metres) square for his friend Patroclus. Achilles himself was incinerated even more gloriously after his death—in "raiment of the gods" after 17 days of mourning. After the flames were quenched with wine, his bones were bathed in oil and wine and placed in a golden urn with those of Patroclus. Lavish funeral feasting and funeral games followed, and a great tomb was erected for him on a headland above the Hellespont.

The Romans followed Greek and Trojan fashion in cremating their military heroes. Virgil's *Aeneid* scornfully contrasts the etiquette of the "unhappy" Latins with that of the Roman's Trojan ancestors. During the 12-day truce, declared so that both armies could cremate dead warriors, the Latins burned many without ritual or count and later heaped the bones together, covering them with a mound of earth. The Romans, on the other hand, observed all the proprieties. They covered the pyre with leaves and fronted it with cypresses; after it was set ablaze, troops shouting war cries circled it and cast trophies taken from the slain Latins into the fire. They poured the blood of animals on the flames, and, when the fires were quenched, washed the bones in wine and placed them in urns. Cremation became such a status symbol in Rome that constructing and renting space in columbariums (vaults or similar structures with niches in the walls to receive the ashes of the dead) became a profitable business. By about AD 100, however, cremations were stopped. Among the various explanations cited are the spread of Christianity and the influence of Oriental mystery cults, which abhorred fire. Although cremation was not explicitly taboo among Christians, it was not encouraged by them because of pagan associations and because of the concern that it might interfere with the promised resurrection of the body and its reunion with the soul. The most practical reason is that cremations were dangerously threatening wood shortages, since so much timber was being felled for pyres.

Explanations for cessation of cremation

Scandinavians favoured cremation, believing that it helped free the spirit from the flesh and also that it kept the dead from harming the living. While some communities preferred ship burials for their heroes (see above), the *Beowulf* epic indicates the esteem in which cremation was held and how closely the ritual conducted by the Geats to honour their leader paralleled the Greek and Roman epic cremations. After the Icelandic conversion in AD 1000, cremation was rare in western Europe until the 19th century, except in emergencies. During an outbreak of the Black Death in 1656, bodies of 60,000 victims were burned in Naples during a single week. The unfavourable associations, intensified during World War II, when hundreds of thousands of persons were incinerated in Nazi concentration camps, did much to discourage the use of cremation in the West. In India and some other countries where the custom is ancient, cremation is considered very desirable. It is the wish of all devout Hindus to be incinerated in Benares. The waterfront of that holy city is lined with concrete and marble slabs on which pyres are erected. The remains are then deposited in the Ganges. In some Asiatic countries it is available to only a favoured few: in Tibet it is usually reserved for the high lamas; in Laos it is for those who die "fortunately"; *i.e.*, of natural causes at the end of a peaceful and prosperous life. Cremation ceremonies in Bali are colourful and gay. On a "lucky" day, bodies of a number of worthies, which had been temporarily buried or embalmed, are carried to a high and decorative tower made of wood and bamboo and cremated. Forty-two days later a second tower, with effigies instead of bodies, is burned to assist the soul on its journey toward the highest heaven. The ashes of the towers, like those of the bodies, are scattered on the water.

Modern cremations. Cremation in the modern manner is very different. Open fires are not used; instead, the body is placed in a chamber where intense heat transforms it in an hour or two to a few pounds of white, powdery ash. That is disposed of in accordance with law and sentiment: scattered in a garden or some other preferred spot, placed in an urn and kept at home, or taken to a cemetery for burial in a small plot or in a columbarium.

The revival of interest in cremation in Europe and the United States began in 1874, when Queen Victoria's surgeon, Sir Henry Thompson, published his influential book *Cremation: The Treatment of the Body After Death*. He also organized the Cremation Society of England in association with Anthony Trollope, Sir John Tenniel, the dukes of Bedford and Westminster, and other articulate critics of burial practices. Although it was not until 1884 that a British court first ruled cremation a legal procedure, it won immediate support on both sides of the Atlantic. For more than a century social and religious reformers had protested such practices as the long and sometimes disorderly wakes, or watches, held over the bodies of dead persons prior to burial. Physicians and sanitary engineers were alarmed over cemeteries, holding the saturated burial grounds to be poisonous to men and animals. The British movement prompted action in the United States, where the first crematorium was built in Washington, Pennsylvania, in 1876. Five years later the New York Cremation Society was organized; in 1913 the Cremation Association of America was organized. Growth of the practice has been slow in the United States, however, where by the 1970s only about 8 percent of the dead were cremated. It has been more readily accepted in some European and Asiatic countries: the figure in England, West Germany, and Denmark, for example, is more than 50 percent; it has been climbing steadily. In Japan, where cremation was illegal in 1875, the practice has become almost universal.

Revival of interest in cremation

As the shortage of cemetery space in urban areas becomes more acute and as objections are answered, cremation may become the principal form of burial. Many Protestant churches have actively supported it; the Roman Catholic Church has announced that it is not prohibited. The Orthodox Jewish religion, however, continues to declare it forbidden. Legal objections—that it would allow crimes to go undetected—are being countered by improvements in techniques and standards in coroners' offices. Cemetery owners and undertakers have also minimized their opposition, since cremation has proved to be no less profitable than more traditional methods of burial.

BURIAL SOCIETIES

In small, cohesive groups, where each member has social significance, it is the community's obligation, understood and accepted, to assure him a burial according to established custom. As communities grow in size, complexity, and wealth, however, so do the fears of its members that they will be denied a "proper" funeral. In the urban environment the ordinary individual—socially insignificant—worries that his departure will be unmourned and that what he understands to be a decent funeral may be beyond his means.

History. Religious organizations have guaranteed that some final attention will be paid; and membership in some sects also eliminates financial concerns, since the faithful

Religious and secular societies

are provided with a funeral and burial without charge. Early Christians conducted funerals as acts of charity: members of the community, under clerical supervision, prepared the body, assisted at the religious ceremony, and carried it in joyful procession to a resting place held as common property. Those early practices have persisted into the 20th century in many places, even in the United States, where funerals are highly commercialized. Funerals and burials of members of "Old Order" Amish communities are carried out in that manner. Burial committees connected with Friends Meetings in Ohio and some other states handle the routines without pay, including making the coffin and arranging a memorial service.

In many urban societies, whatever the dominant religion, people have organized mutual-aid burial societies. In China, as in other parts of the Orient, mutual-aid groups used to be very common, although the present government guarantees burial. In Western cultures, secular burial societies date back to ancient Rome, where they were established by workingmen to prevent their bodies' being consigned to the common burial pit with the corpses of slaves and aliens. The societies used members' contributions to build columbariums for the cremated remains and to pay for other funeral services.

Secular burial societies were revived during the Middle Ages, after simple Christian rites had given way to more elaborate and costly ceremonies. For small initial sums and nominal additional contributions when a member died, the societies paid for prayers and masses for the souls of the departed and provided the necessary paraphernalia for the ceremony—hearse, pall cloth, bier, and candles. The craft guilds, which played such an important role in medieval life, levied special assessments to pay funeral expenses of members and to provide them with postburial prayers. In time, funeral activities became so extensive that the guilds and burial clubs had to hire men to perform some of the services: bidders, who summoned others to a wake; bell ringers, who took to the streets on the day of the funeral and its first anniversary, urging hearers to pray for the dead soul. The Reformation did little to minimize funerary extravagance; although the amount spent for prayers and masses diminished, that spent for goods and services increased—particularly after coffins came into vogue. During the 16th and 17th centuries, mutual-aid societies for burial continued to flourish in large cities. The need for them increased as industrialization and urbanization accelerated, shattering the communal pattern of funerals and encouraging lavish expenditure. By the late 19th century it had reached incredible heights all across Europe, even among the poorest, as the novels of Dickens and Dostoyevsky indicate. Burial societies offered survivors the only hope against ruinous expenses. European and Oriental groups carried the idea to the United States, where the need had been intensified by the secularization of cemeteries and the rise of the undertaking business.

Increasing expenditures for funerals

Some societies offered limited and occasional benefits, like the Basque Society in Florida, which bought coffins and held them for use by members at the time of death. Membership in some fraternal organizations offered a place in the member-owned cemetery and a funeral with all the group in attendance. Some of the mutual-aid societies transplanted Old World burial practices to teeming cities in the New World. Some had a permanent impact on art and culture, including Negro societies in Southern cities: the membership fee included a marching band to the cemetery. Organizations with wider interests found themselves in the business of funeral relief. Some trade unions bought cemeteries so that members could be buried at low cost; consumer cooperatives in the Middle West, like those in England and Scandinavia, offered the full range of goods and services at a modest fee. Responsible insurance companies tried to minimize display. A study of funeral costs in 1928, financed by the Metropolitan Life Insurance Company, focussed national attention on the ways in which policyholders' survivors were being penalized by funeral extravagance.

Modern societies. Religious and consumer groups began to explore methods of obtaining simple and dignified funerals at reasonable cost. The modern funeral and memorial societies movement in the United States was launched in 1939 at two ends of the country. Acting independently, members of the Community Church in Brooklyn and the People's Church in Seattle worked out agreements with local undertakers enabling members to select in advance the kinds of funerals they preferred. (No payment was made until the service was rendered.) Since then more than 100 nonprofit societies have been organized in the United States and Canada, affiliated with the Continental Association of Funeral and Memorial Societies. Although originally many of them were sponsored by churches and ministerial associations, all are nondenominational and controlled by members, in accordance with the requirements of the Cooperative League of the USA, to which the Continental Association belongs. By 1971 so many societies had been established north of the border that the Memorial Society Association of Canada was organized. In addition to offering economic benefits to members—prices available for some services have been a small fraction of the national average—all of the societies conduct educational activities to inform people in their communities about the religious and financial values of simple funerals. Their rejection of extravagant display has won the movement the endorsement of religious leaders of all denominations and of persons involved in consumer education. The societies have encouraged members to donate bodies for medical research—a growing tendency in the United States.

Embryology, Human

The human body, like that of most animals, develops from a single cell produced by the union of a male sex cell and a female sex cell. Human development follows closely the basic vertebrate pattern, and it departs only in certain details from the type specifically characteristic of mammals. A prenatal period, in which most of the developmental advances occur, is followed by a long postnatal period. Only at about the age of 25 are the last progressive changes completed. Each new individual starts as a fertilized, activated egg. Further progress depends upon cell proliferation, the growth of daughter cells, the differentiation of organs and their tissues, and the integration of the body and its parts into a coordinated, func-

tioning mechanism. The present article is concerned with the development that occurs before birth, and it is in this sense that the term embryology is used. Postnatal development is discussed in the article DEVELOPMENT, HUMAN.

Normal development

GAMETOGENESIS

Preparatory to development in the usual sense is the production of mature sex cells, male and female. The main steps in their development are similar, even though the two end products differ in size, form, and function. Primordial sex cells become recognizable as large, pale elements in embryos about three weeks old and 2.5 millimetres (0.1 inch) long. From a location near the hind end of the embryo, they migrate forward and colonize the region of the future sex gland. Here they multiply and become the source of all definitive sex cells. The general process of advance by which the primordial cells and their progeny become mature, functional elements, or gametes, is called gametogenesis. In the female the production of large, mature eggs is specifically named oogenesis. The comparable stages in producing motile spermatozoa in the male constitute spermatogenesis.

Origin of sex cells

In both sexes there is a period of proliferation that increases cell numbers. More important still is the fact that all sex cells that progress toward maturity undergo two successive cell divisions of a special nature. These reduce the chromosome number by half. Each human cell has two sets of chromosomes, each set numbering 23. One group was provided by the male parent of an individual and the other group by the female parent. The process by which the double set of chromosomes in a sex cell is reduced to a single set is called maturation.

Reduction is accomplished by means of a sequence of two modified cell divisions in which the chromosomes divide but once. This process, named meiosis, accomplishes several important results: (1) One benefit is to prevent a further increase in chromosome number (beyond the normal 46) when a male and a female gamete unite and produce a new individual. (2) Another result is to prepare for the transmission of hereditary characteristics received from both parents, since any random combination of chromosomes from the original parental sets may regroup in the daughter cells. (3) Still another objective, attained in spermatogenesis, is to segregate the male and the female type of sex-determining chromosome and pass only one of these into a single male gamete, thus preparing for later sex determination. (For additional details on meiosis, see CELL AND CELL DIVISION.)

Prenatal formation of ovarian follicles; cyclic activities after puberty

Oogenesis. In the later months of female fetal life, a capsule consisting of a single layer of ordinary cells surrounds each primordial sex cell, called an oogonium. The encased oogonium and its cellular capsule are designated as a primary ovarian follicle. At birth such follicles number several hundred thousand, and proliferation ends. There are no further advances until cyclic activities begin at puberty. Henceforth, early in each menstrual cycle, a number of primary follicles enter into a period of growth. The encapsulating follicle cells become multilayered, and the enlarging oogonium, enclosed in a gelatinous secretion called the zona pellucida, gains the name of primary oocyte. Meanwhile, the solid follicle acquires a fluid-filled cavity and the oocyte is crowded toward the periphery. By the middle of the menstrual month, all but one of the growing follicles have discontinued their advances and have begun to degenerate. At this time the single surviving follicle is a prominent sac ten millimetres (about 0.4 inch) or more in diameter. Shortly before it ruptures, the contained primary oocyte completes the first of its meiotic divisions.

An outstanding feature of oogenesis, or the production of an ovum, is that while the nuclei of the daughter cells are essentially identical, the allotments of cytoplasm, the cell substance outside the nucleus, are very unequal. In the first division one daughter cell retains almost all of the cytoplasm and is then called a secondary oocyte. The other daughter cell is a tiny, nonfunctional element known as the first polar body. Each daughter cell, however, contains the reduced number of 23 chromosomes, since in this division each mated chromosome pair separates and only one of its components passes into a daughter cell. The final maturation division takes place subsequent to ovulation, and then only in the event of fertilization. During penetration of the spermatozoon into the cytoplasm of the secondary oocyte, the second polar body is pinched off in a meiotic division that is much like ordinary cell division, called mitosis. The first polar body may or may not subdivide, but theoretically the maturative process ends with the production of a ripe ovum (technically called an ootid) and three tiny, abortive polar bodies. If fertilization fails to occur, the secondary oocyte dies as such. Compared to ordinary cells of the body, the ripe egg is truly large (0.12 millimetre, or about 0.005 inch), being just visible to the naked eye. The production of a single egg instead of millions, as by some lower vertebrates, is correlated with greater surety of fertilization and with protected development within the mother's body.

Formation of sperm cell

Spermatogenesis. The primary sex cells, or spermatogonia, of the fetal testis remain dormant within the testis tubules until the time of puberty. They then enter into proliferative activity that continues indefinitely into adult life. Some daughter spermatogonia continue as mitotic stem cells (unspecialized cells from which more specialized cells develop). Others grow into primary spermatocytes and proceed through the two meiotic divisions that first produce secondary spermatocytes and then spermatids, the immediate precursors of spermatozoa. All of these final cells possess the reduced set of 23 chromosomes. The chromosomal behaviour parallels that occurring in the oocytes.

Spermatogenesis differs from oogenesis in several important respects. The spermatids are all equal in size and are potential spermatozoa but must first undergo a radical alteration in shape and organization. This process of transformation into atypical, motile cells is called spermiogenesis. Moreover, spermatids are of two kinds, half carrying the X-chromosome and half the Y-chromosome as the result of the reductional segregation of the unmatched X–Y pair of sex chromosomes. (By contrast, all ootids carry the X-chromosome.)

Each spermatid remodels drastically into a tadpole-shaped element with a relatively large head, a slender neck, and an extremely long, vibratile tail. The transforming spermatids bury their heads in the cytoplasm of certain tall, radially arranged supporting cells and possibly receive nourishment from them. When complete, the young spermatozoa become detached and are transported passively through the smaller ducts of the testis to the convoluted, or tortuous, epididymis. Here they are stored until finally discharged from the body. A spermatozoon is 0.06 millimetre (0.002 inch) long, which is one-half the diameter of the ovum. Yet in volume the ovum is 85,000 times as great. Both gametes differ only in matters of detail from those of other vertebrates, and most invertebrates.

OVULATION AND SEMINATION

Release of egg and discharge of sperm

Ovulation. Soon after the first polar body is shed, the follicle ruptures. Its growth is rapid in the final hours, but bursting involves a poorly understood weakening of the superficial follicular wall. The collapse tears the secondary oocyte away from the already loosened bed of follicle cells in which it has lain and also expels the oocyte on a wave of escaping follicular fluid. Both oocyte and its associated first polar body remain encased within the gelatinous zona pellucida, to which follicle cells will still adhere for a time. These several events make up the process of ovulation. The liberated oocyte is promptly taken up into the open end of the uterine tube and then is transported downward. The fertilizable life of the free oocyte is probably less than 24 hours.

Semination. Discharged seminal fluid contains some 250,000,000 spermatozoa, now motile by lashings of the tail. Forward progress is about two millimetres per minute (a little less than five inches per hour). When deposited in the vagina the sperms ascend through the uterus

and into the uterine tubes, mainly as the result of muscular movements in those organs rather than through swimming ability of the sperms. Apparently in about one hour some sperms reach the upper ends of the tubes. The total number attaining this level never increases greatly and remains small in comparison to the enormous number initially discharged.

FERTILIZATION

Penetration of the ovum by the sperm and their union

The development and liberation of the male and female gametes are steps preparatory to their union through the process of fertilization. Random movements first bring some spermatozoa into contact with follicle cells adhering to the secondary oocyte, which still lies high in the uterine tube. The sperms then propel themselves past the follicle cells and attach to the surface of the gelatinous zona pellucida. Some sperm heads successfully penetrate this capsule by means of an enzyme, hyaluronidase, which they secrete, but only one makes contact with the cell membrane and cytoplasm of the oocyte and proceeds farther. This is because the invading sperm head releases a substance that initiates surface changes in the oocyte cytoplasm that other competitors cannot master.

The sole successful sperm is engulfed by a conical protrusion of the oocyte cytoplasm and is drawn inward, tail and all. Once within the periphery of the oocyte, the sperm advances toward the centre of the cytoplasm. During this journey the head swells and converts into a typical nucleus, now called the male pronucleus, and the tail detaches. It is during the progress of these events that the oocyte initiates its final maturation division. Following the separation of the second polar body, the oocyte nucleus reconstitutes typically and is then called the female pronucleus of the ripe egg. It is now ready to unite with its male counterpart and thereby consummate the total events of fertilization.

The two pronuclei next approach, meet midway in the egg cytoplasm, and lose their nuclear membranes. Each resolves its diffuse chromatin material into a complete, single set of 23 chromosomes. Centrioles (complex particles involved in cell division), apparently supplied by the sperm, appear, and a mitotic spindle organizes with the two sets of chromosomes arranged midway on it—ready to proceed with a typical mitosis. This climax in the events of fertilization creates a joint product named the zygote. It contains all the essential factors for the development of a new individual.

The fundamental results of fertilization are the following: (1) reassociation of a male and female set of chromosomes (thus restoring the full number and providing the basis for biparental inheritance and for variation); (2) establishment of the mechanism of sex determination for the new individual (this depending on whether the male set of chromosomes included the X- or the Y-chromosome); (3) activation of the zygote, initiating a beginning toward the production of a new individual.

CLEAVAGE AND BLASTULATION

Cleavage. The onset of mitosis (ordinary cell proliferation by division) in the activated zygote is a first step toward development in the ordinary sense of that term, and the cells so produced are the first external sign of future body building. To this end, the relatively enormous zygote straightway subdivides into many smaller cells of conventional size, suitable as early building units for the future organism. This process is called cleavage and the resulting cells are blastomeres (Figures 1A–D).

Formation of blastomeres

The tendency for the progressive increase in cell numbers to follow a doubling sequence is soon disturbed and then lost. Each blastomere receives the full complement of paternal and maternal chromosomes.

Subdivision of the zygote into blastomeres begins while it is still high in the uterine tube. The cohering blastomeres are transported downward chiefly, at least, by muscular contractions of the tubal wall. Such transport is relatively rapid until the lower end of the tube is reached, and here cleavage continues for about two days before the multicellular cluster is expelled into the uterus. The full reason for this delay is not clear, but it serves to retain the cleaving blastomeres until the uterine lining is suitably prepared to receive its prospective guest.

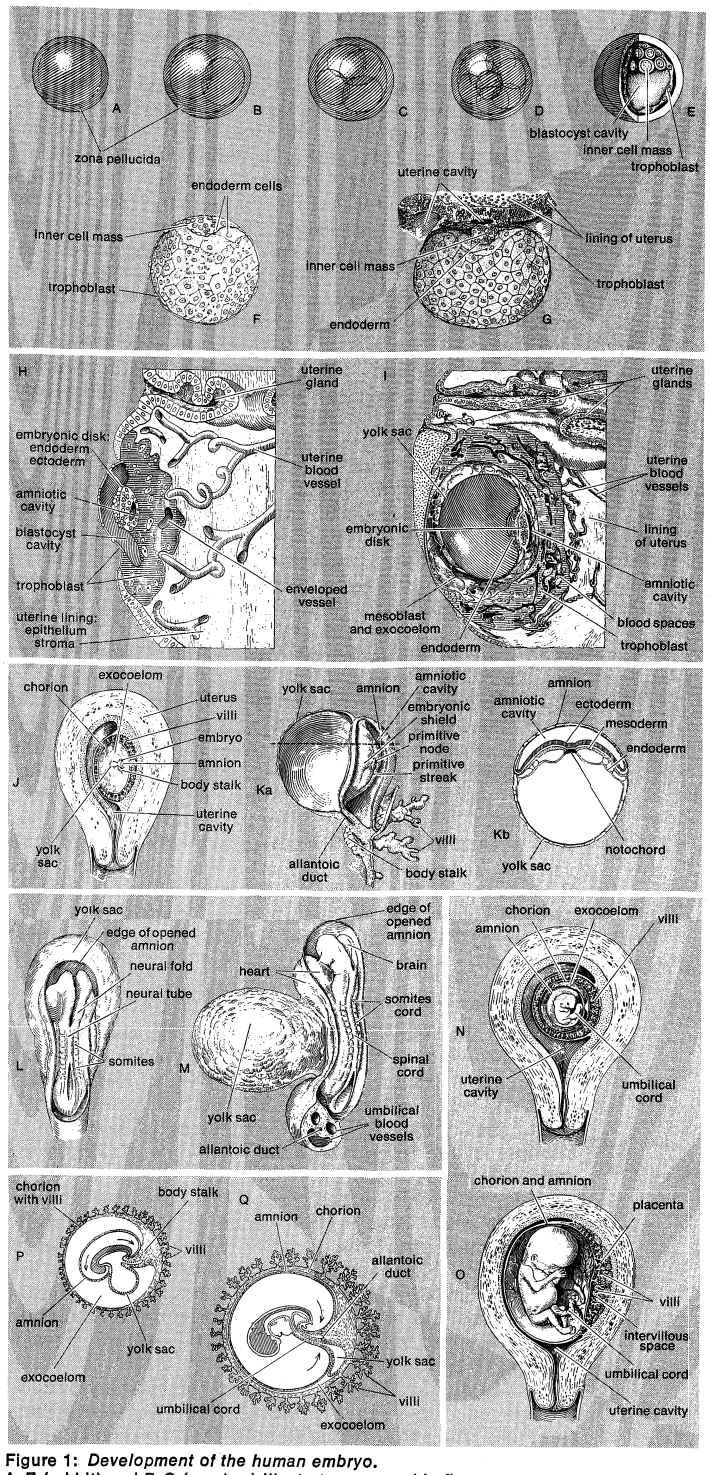

Figure 1: *Development of the human embryo.*
A–E (rabbit) and F–G (monkey) illustrate comparable first stages of human development. (A–D) Cleavage of ovum (magnified 80 ×). (E) Early free blastocyst, partially opened (magnified 80 ×). (F) Older free blastocyst, halved (magnified 60 ×). (G) Late attached blastocyst, halved (magnified 70 ×). (H–J) Half sections of embryos implanted in uterine lining: (H) at 7½ days (magnified 80 ×); (I) at 13 days (magnified 37 ×); (J) at 23 days (magnified ¼ ×). (Ka) Embryo of 18 days at disk (or shield) stage, three-quarter view (magnified 9 ×). (Kb) Cross section through same embryo at level of broken line in Ka. (L) Embryo of 21 days with amnion opened, back view (magnified 8 ×). (M) Embryo of 23 days with yolk sac and opened amnion (magnified 9 ×). (N,O) Embryo of six weeks and fetus of three months, respectively, within halved amnion, chorion, and uterus (magnified ¼ ×). (P,Q) Diagrams showing especially amnion growth and formation of umbilical cord; stages correspond to J and N.
Drawing by James F. Didusch

Since the human egg contains little inert yolk material, and since this is distributed rather evenly throughout the cytoplasm, the daughter cells of each mitosis are practically equal in size and composition. This type of cleavage is known as total, equal cleavage. The sticky blastomeres adhere and the cluster is still retained for a time within the gelatinous capsule—the zona pellucida—that had enclosed the growing and ovulated oocyte. There is no growth in the rapidly dividing blastomeres, so that the total mass of living substance does not increase during the cleavage period. Cleavage is not a mechanism designed primarily to distribute particular developmental qualities, either nuclear or cytoplasmic, to specific blastomeres, which then carry out assignments that give rise to particular parts of the embryo. In a sense, therefore, cleavage is essentially a nonspecific fractionating preliminary rather than a process of truly constructive development.

Passage of blastomeres into uterus; formation of morula and blastocyst

Morula and blastocyst. By the fourth day after ovulation, a cluster of about 12 blastomeres passes from the uterine tube into the uterus. When the cluster numbers 12 to 16 blastomeres it is called a morula (Figure 1D). By the time some 30 blastomeres have been produced, pools of clear fluid accumulate between some of the internal cells, and these spaces soon coalesce into a common subcentral cavity. The resulting hollow cellular ball is a blastula of a particular type that occurs in mammals and is called a blastocyst; its cavity is the blastocoel (Figure 1E, F).

An internal cellular cluster, eccentric in position and now named the inner cell mass, will develop into the embryo. The external capsule of smaller cells, enveloping the segregated internal cluster, constitutes the trophoblast. It will contribute importantly to the formation of a placenta. During its stay within the uterine cavity, the blastocyst loses its gelatinous capsule, imbibes fluid, and expands to a diameter of 0.2 millimetre (0.008 inch); this is nearly twice the diameter of the zygote at the start of cleavage. Probably several hundred blastomeres have formed before the blastocyst attaches to the uterine lining.

IMPLANTATION AND PLACENTATION

Late in the sixth day after ovulation the naked, sticky blastocyst comes into contact with the uterine lining and adheres to it (Figure 1G). The site of attachment is variable and not predetermined. The uterine lining has already been preparing, under the influence of ovarian hormones, for the reception of the blastocyst. Among these preparations has been the elaboration and expulsion, by the uterine glands, of a secretion that serves as nourishment for the blastocyst, both when it is free and during its implantation. Directly after blastocyst attachment come its establishment within the thickened uterine lining and the participation of its trophoblastic capsule in the differentiation of a placenta, a structure that enables the developing embryo to enter into a prompt, physiological dependence on the mother.

Implantation. The trophoblast of the blastocyst exerts an enzymic, destructive influence on the swollen uterine lining, leading to erosion of both the superficial epithelium of the uterine lining and also its deeper, cellular connective tissue (Figure 1H). This early stage of invasion ends in a few days; the blastocyst is then completely buried within a more superficial and compact layer of the total uterine lining (Figure 1H, I). While the blastocyst is completing this phase of implantation, its original shell of cellular trophoblast steadily proliferates a multitude of cells that lose their outermost membranes and merge. The result is a thick peripheral layer consisting of a common mass of cytoplasm in which many nuclei are embedded. This external investment is called syncytial trophoblast.

The implanted blastocyst next proceeds to establish itself as a parasite within the uterus. The syncytial trophoblast becomes a spongy shell containing irregular cavities (Figure 1I). This expanding mass destroys cellular connective tissue and glands encountered in its path. Both the cellular and derivative syncytial trophoblast have the capacity of ingesting such tissue. The erosive process also taps capillaries and small blood vessels, and blood liberated in this way is likewise taken up into the trophoblast. Such engulfed blood cells and fragments of tissue are presumably utilized for nourishment in the early period of establishment of the expanding blastocystic sac. Yet these erosive activities decline in intensity by the end of the third week of development, and at this time the sac is completing the first phase of its specialization.

Syncytial trophoblast; its formation and effects
