**Kinds of marketing research.** Advertising research attempts to evaluate the effectiveness of advertising expenditures and to guide future advertising efforts. Market analysis and forecasting try to identify and measure the markets for specific products and to estimate sales possibilities. Performance analysis helps a company evaluate how well it is meeting its objectives in such areas as sales, its share of the market, sales-force performance, costs, and profits. Research in physical distribution aims to increase a manufacturer's efficiency in moving products along the channels of distribution. Product research runs a gamut from identifying the needs and characteristics of product users to testing package designs.

Although the basic practices of marketing research originated in the U.S., the methods have been adopted in most parts of the world in varying degree. Western European and Japanese marketing research expanded during the 1950s and 1960s. The Soviet Union and other eastern European countries have established agencies to furnish marketing research to their nationalized industries.

Marketing research is not an exact science; it has not eliminated important areas of uncertainty in managerial decision-making and probably never will. It indicates only the conditions that exist, not what to do about them. It may also be expensive, and its value must be measured against its cost. Finally, the information provided soon becomes out of date.

**Basic procedures.** There are certain general procedures in marketing research, although they are not applicable to all cases. A six-step scheme for conducting research on a marketing problem is: (1) preliminary analysis, in which potentially influential factors and variables are examined, often based upon an extensive search for relevant data; (2) definition of the problem; (3) planning of the research study, which consists essentially of determining how the data will be obtained and how they will be organized in order to permit sound conclusions and recommendations; (4) collection and tabulation of data, which may be primary data gathered by observation, experimentation, or survey, or secondary data obtained from governmental or private sources; (5) interpretation of the results; and (6) presentation of the results to management, including assistance to management in following up the study's conclusions and recommendations.

Each of the six steps listed above involves serious problems of methodology and technique for the marketing researcher. In step four, for example, if the researcher wishes to gather his data by survey he must usually decide among mail, telephone, and personal interviews. He is also faced with the questions of the survey's validity

(whether it measures what it is intended to measure) and of its reliability as a sample of the entire market. The researcher must further decide how much stress to put on quantitative "facts" in his survey as against the qualitative issues of motivation—that is, why respondents answer in various ways.

#### MERCHANDISING AND PRODUCT DEVELOPMENT

In traditional economies, the goods produced and consumed often remain the same from generation to generation—including food, clothing, and housing. As economies develop, the range of products available tends to expand, and changes occur in the products themselves. In contemporary industrialized societies, products, like people, go through life cycles: birth, growth, maturity, and decline. This constant replacement of existing products with new or altered products is of great concern to professional marketers. The development of new products involves all the departments of a business—production, finance, research and development, even personnel administration and public relations.

**Product design.** When a customer purchases a product he receives not only the item itself but, along with it, labelling, branding, packaging, sometimes a warranty, and perhaps the assurance of the availability of such services as repairs. In designing the product, these other things must be considered with it. Participants in the designing of a product may include consumers, middlemen, and industrial buyers, as well as the manufacturer. In a buyer's market—that is, one in which sellers must compete actively for the consumer's patronage—the greatest influence on product design is likely to be the consumer's reaction, actual or anticipated. Because of the closeness of middlemen (particularly retailers) to the consumer, they are often in an excellent position to anticipate consumer reaction to a planned product. Some giant retailers (e.g., Marks and Spencer, Ltd. in Great Britain, or Sears, Roebuck and Company in the U.S.) play major roles in designing the products they sell. Industrial users may also take an active hand in designing the items they buy because the items often fit into an existing or planned production system. The degree of patent protection offered by the government is another factor affecting product design. Manufacturers of pharmaceuticals in Italy, for instance, lacking adequate patent protection, engage in very little original product research; they tend to copy innovations in other countries. France, on the other hand, grants an unusual degree of protection to designers of fashion products, such as women's clothing, despite the fact that manufacturers in most other countries are more or less free to copy those designs.

Product design takes basically three forms: innovation, alteration of an existing product, and the development of new applications for a product that remains the same. Examples of innovation include many antibiotic drugs, a wide variety of plastics, and innumerable electrical appliances, ranging from television to electric toothbrushes. Most invention today is done by the product research and development departments of manufacturing firms, rather than by independent inventors. Examples of alteration of an existing product range from the change made in an automobile motor to reduce air pollution to such minor changes as the addition of a butter drawer to a refrigerator. Other changes merely vary the style of a product—an office typewriter, a woman's coat—to make it more attractive to the consumer. An example of a new application for an existing product may be seen in the electric blender, which was originally used to reduce soft fruits and vegetables into pulp or juices; eventually its kitchen uses were expanded so that today it is promoted as a device for chopping and mixing a wide variety of foods.

**Product line and product mix.** A product (or service) may be thought of merely as giving the owner basic utilitarian satisfactions, as an automobile, for example, provides transportation. On the other hand, many goods go beyond merely practical requirements: the automobile may offer aesthetic satisfaction because of its design, or enhance its owners' status, or appeal to unconscious desires for virility, power, youthfulness, or dignity. The way

Adapting products to markets

Three main types of product design

a product is defined may also depend on the orientation of the manufacturer. Thus, a maker of electrical refrigerators may limit his market interests to the selling of his product as narrowly defined or, on the other hand, may think of his business more broadly as the arresting of food deterioration. In defining his product, however, the manufacturer must consider the marketing, technological, financial, and even legal problems that may arise when he tries to enlarge his scope.

Marketers are continually altering their "product lines" by adding new products, changing existing ones, and dropping others. A product line is an assortment of items that have some affinity to one another, whether from the way in which the customer makes use of them or the way in which he mentally relates the products to each other. Within each product there are additional classifications by style, colour, size, or other characteristics.

In setting up a product line, the marketer must consider the whole process of selling and distribution, including the prices at which the goods are to be sold, the approach to middlemen within the channels of distribution, the personal selling efforts required, and so forth. These elements must, in turn, be integrated with production, finance, research and development, and other nonmarketing functions within the firm.

**Packaging and branding.** Customers in France still carry their long loaves of bread unwrapped; small produce dealers in Italy wrap their vegetables in newspapers or place them in customers' string bags; and industrial wholesalers in many countries still sell nuts, bolts, nails, and other materials in bulk. But in most industrial countries the packaging of merchandise has become a part of the selling effort; marketers now specify exactly the types of packaging that will be most appealing to prospective customers. The importance of packaging in distributing the product has increased with the spread of self-service—in wholesaling as well as in retailing. Packaging is sometimes designed to facilitate the use of the product, as with aerosol containers for room deodorants; in Europe, such condiments as mustard, mayonnaise, and catsup are often packaged in tubes. Some packages are reusable, making them attractive to customers in some of the poorer countries where metal containers, for instance, are often highly prized.

Branding is used to identify the product of a specific seller. Like packaging, a brand may become part of the product in the mind of the customer. Manufacturers' brands are found in most parts of the world, including the Soviet Union. Wholesalers' or retailers' brands (also called dealers' brands, private brands, or private labels) are employed by large department stores, large wholesale establishments, chain stores, and retail cooperatives.

Part of the marketer's product policy is his product guarantee or warranty, in which the manufacturer or middleman promises the purchaser certain services and performance standards. By explicitly stating his guarantees, the manufacturer may limit his liability, while also acquiring an additional promotion message. In most countries, large manufacturers and retailers are more likely to have specific policies on guarantees than are their smaller competitors, probably because they have more to gain or lose by the way in which their guarantees are interpreted.

**Advertising.** As it is handled in large organizations, advertising is one of four components of marketing promotion, the other three being personal selling, sales promotion, and public relations. If marketing is integrated into a single organizational unit, advertising usually comes under the purview of the marketing chief, along with personal selling and sales promotion. Public relations in the larger firms is usually separated from marketing in the organizational structure.

Advertising may be defined as any paid form of marketing promotion directed toward masses of potential customers (for a fuller discussion, see ADVERTISING). Manufacturers usually favour national or regional media in the effort to gain acceptance for their products and brands. Retailers, on the other hand, attempt to stimulate a more local buying response. Much advertising is not

intended for the general public but for industrial buyers, and it appears in various trade publications.

Advertising is most pervasive in highly industrialized countries, where it is used to move products along the distributive channels. The Soviet Union and other east European countries have in recent years adapted advertising techniques to their socialized economies. The methods and media used in different countries vary considerably. In the U.S., for example, radio and television draw most of their revenue from advertising. France, on the other hand, does not permit advertising on its nationally operated television systems. In Japan, with its unusually high literacy rate, advertisers have access to a variety of newspapers, magazines, and other printed media; in Spain, where illiteracy is high among older women, advertisers emphasize the radio and the cinema.

#### WORLDWIDE TRENDS

As marketing has become more influential and pervasive in industrialized countries, its development has taken two different routes. On the one hand, channels of distribution have been compressed—that is, the number of intermediaries between the original producer and the final consumer has decreased. This has come about through a process of vertical integration up and down the marketing structure: mergers, expansion, cooperation, voluntary ties, and long-term contractual relationships among distributors have all worked to this effect. On the other hand, new marketing institutions and new ways of operating have developed. Industrialization has encouraged diversity in marketing. Developments in mass communications, for example, have increased the number of ways in which advertising and promotion may be carried on. While in some respects products have become more uniform, producers make greater efforts to cater to the individualized tastes of consumers and to tailor their products for specific segments of a market.

Marketing has not been without its critics. In the more industrialized countries, objections have been raised to the practice of inducing "forced obsolescence" of products through changes in their design; to the economic waste involved in heavy expenditures on marketing and advertising; and to the use of hard-sell techniques to make consumers buy. Along with this has gone a more general type of criticism directed at the ends of economic activity, questioning the social desirability of promoting the use of tobacco, conventional automobiles, supersonic aircraft, and even industrial growth in general.

Important changes have taken place in the marketing methods used in the Soviet Union and other Communist countries. Institutions corresponding to advertising and marketing research agencies have come into being in those countries. Branding of products is used to an increasing extent. Consumer credit is increasingly available for the purchase of major appliances. Packaging has become more attractive and more functional. Self-service techniques have been adapted to Soviet methods of retailing, although on a small scale. In the 1960s, however, Soviet citizens and knowledgeable Western visitors still complained of shoddy merchandise, the difficulty of obtaining repairs, the cumbersome nature of the three-stage cashier system used in many retail stores, and the nonprofessionalism of retail personnel.

**BIBLIOGRAPHY.** Among the most widely used textbooks are: THEODORE N. BECKMAN and WILLIAM R. DAVIDSON, *Marketing*, 8th ed. (1967); EDWARD W. CUNDIFF and RICHARD R. STILL, *Basic Marketing: Concepts, Decisions, and Strategies*, 2nd ed. (1971); E. JEROME MCCARTHY, *Basic Marketing: A Managerial Approach*, 4th ed. (1971); CHARLES F. PHILLIPS and DELBERT J. DUNCAN, *Marketing: Principles and Methods*, 6th ed. (1968); FREDERICK D. STURDIVANT *et al.*, *Managerial Analysis in Marketing* (1970); and MARTIN ZOBER, *Principles of Marketing* (1971).

Several works of a more conceptual and theoretical nature are: WROB ALDERSON, *Dynamic Marketing Behavior: A Functional Theory of Marketing* (1965); HELMY H. BALIGH and LEON E. RICHARTZ, *Vertical Market Structures* (1967); REAVIS COX *et al.* (eds.), *Theory in Marketing: Second Series* (1964); JOHN A. HOWARD, *Marketing: Executive and Buyer Behavior* (1963); and DAVID B. MONTGOMERY and GLEN L. URBAN, *Management Science in Marketing* (1969).

## Markets

What economists mean by the term market

Markets in the most literal and immediate sense are places in which things are bought and sold. In the modern industrial system, however, the market is not a place; it has expanded to include the whole geographical area in which sellers compete with each other for customers. Alfred Marshall, whose *Principles of Economics* (first published in 1890) was for long an authority for English-speaking economists, based his definition of the market on that of the French economist A. Cournot:

Economists understand by the term Market, not only particular market place in which things are bought and sold, but the whole of any region in which buyers and sellers are in such free intercourse with one another that the prices of the same goods tend to equality easily and quickly.

To this Marshall added:

The more nearly perfect a market is, the stronger is the tendency for the same price to be paid for the same thing at the same time in all parts of the market.

The concept of the market as defined above has to do primarily with more or less standardized commodities such as wool or wheat or shoes or automobiles. The word is also used to deal with, for example, the market for real estate or for old masters; and there is the "labour market," although a contract to work for a certain wage is not quite the same thing as the sale of a packet of goods. There is a connecting idea in all of these various usages—namely, the interplay of supply and demand.

### TYPES OF MARKETS

Most markets consist of groups of intermediaries between the first seller of a commodity and the final buyer. There are all kinds of intermediaries, from the brokers in the great produce exchanges down to the village grocer. They may be mere dealers with no equipment but a telephone, or they may provide storage and perform important services of grading, packaging, and so on. In general, the function of a market is to collect products from scattered sources and channel them to scattered outlets. From the point of view of the seller, dealers channel the demand for his product; from the point of view of the buyer, they bring supplies within his reach.

There are two main types of markets, in which the forces of supply and demand operate quite differently, with some overlapping and borderline cases. In the first, the producer offers his goods and takes whatever price they will command; in the second, the producer sets his price and sells as much as the market will take.

**Markets for primary products.** The first type is common among primary products—that is, those that depend upon animal, vegetable, and mineral resources. The general run of agricultural commodities is produced under competitive conditions by relatively small scale cultivators scattered over a large area. The final purchasers are also scattered, and centres of consumption are distant from regions of production. The dealer, therefore, since he is indispensable, is in a stronger economic position than the seller. This situation is markedly true when the producer is a peasant who lacks both commercial knowledge and finance so that he is obliged to sell as soon as his harvest comes in; it is true also, though to a lesser extent, of the capitalist plantation for which the only source of earnings is a particular specialized product. In this kind of business, both demand and supply are said to be inelastic in the short run—that is, a fall in price does not have much effect in increasing purchases and a rise in price cannot quickly increase supplies. Supplies are subject to natural variations, weather conditions, pests, and so forth; and demand varies with the level of activity in the centres of industry and with changes in tastes and techni-

The behaviour of primary commodity markets

cal requirements. Under a regime of unregulated competition such markets are, therefore, tormented with continual fluctuations in prices and volume of business. Though dealers may mitigate this to some extent by building up stocks when prices are low and releasing them when demand is high, such buying and selling often turns into speculation, which tends to exacerbate the fluctuations.

The behaviour of primary commodity markets is a serious matter when whole communities depend upon a single commodity for income or for employment and wages. The agricultural communities that form part of an industrial economy are therefore generally sheltered from the operation of supply and demand by government regulations of various types, price supports, or tariff protection. Though some attempts have been made to control world commodity markets, these are generally more talk than performance. Some nations, Australia for example, have been able to make enough profit from primary commodity exports to attract capital into the development of industry; but most of the so-called developing countries find their export earnings insecure and insufficient. Their spokesmen complain that the world market system operates in favour of the industrialized nations.

**Markets for manufactures.** The other type of market prevails in the sphere of manufactured goods. The market for manufactures is what economists call "imperfect," because each company has its own style, its own reputation, and its own locations; and all of the arts of advertisement and salesmanship are devoted to making it even more imperfect by attracting buyers to particular brand names. Even small businesses that depend upon outside channels of retail distribution may have the final say in what prices they will charge, and great corporations can differentiate their goods in order to create demand for them.

In this type of market, supply normally is very elastic—that is, responsive to demand—in the short run. Stocks or inventories are held at some point in the chain of distribution; while stocks are running down or building up, there is time to change the level of production, and once a price has been set, it is rarely altered in response to moderate changes in demand. Even in a deep slump, defensive rings may often be formed to prevent price cutting.

In the long run, as well as in the short, supply is responsive to demand in the market for manufactures. It is easier to change the composition of a firm's output than it is to change the production of a mine or a plantation. And when changes in demand are not too rapid, gross profits from one plant can be siphoned off and invested in something quite different. When business is good, moreover, there is continual new investment so that productive capacity is adapted to meeting changing requirements. Workers themselves may not even be aware of changes in the final commodities to which their work contributes, and the level of wages for any grade of factory labour is very little affected by the fortunes of a particular market.

**Markets under Socialism.** Markets are essential to the free enterprise system; they grew and spread along with it. The propensity "to truck, barter, and exchange one thing for another" (in Adam Smith's words) was exalted into a principle of civilization by the doctrine of *laissez-faire*, which taught that the pursuit of his self-interests by the individual would be to the benefit of society as a whole. In the Soviet Union and other Socialist countries, a different kind of economy exists and a different ideology is dominant. There are two interlocking systems in the economy of the Soviet Union: one for industry and one for agriculture; and the same pattern is followed, with variations, in the other Socialist countries. Industrially, all equipment and materials are owned by the state, and production is directed according to a central plan. In theory, payments to workers are thought of as their share of the total production of the economy; in practice, however, the system of wages is very much like that in capitalist industry except that rates as a rule are set by decree and the managers of enterprises have little scope for bargaining. Workers may move around looking for jobs, but there is no "labour market" in the capi-

The behaviour of markets for manufactured goods

Markets in Communist-governed countries

talist sense. Materials and equipment are distributed among enterprises by the state planning offices. (Faulty planning has given rise to intermediaries who operate between enterprises, but this is not at all the same thing as the highly developed markets in materials, components, and equipment that exist under capitalism.)

Consumption goods, on the other hand, are distributed to Soviet households through a retail market. Though some Socialist idealists, regarding buying and selling as the essence of capitalism, have advocated that money should be abolished altogether, in a large community it has proved to be most convenient to provide incomes in the form of generalized purchasing power and to allow each to choose what he pleases from whatever goods are available. Classical economists usually assert that the advantage of the retail market system is that it runs itself without excessive regulation; the housewife who goes shopping is in charge of her own money and need account to no one for what she does with it. Retail markets in Soviet-type economies are said to differ from those in capitalist economies in that while in both systems the buyer is in this sense a principal, the seller in the Soviet system is an agent. Retailers and manufacturers all serve as agents of the same authority—the central plan. Rather than making it their business to woo and cajole the customer, sellers throw supplies into the shops in a somewhat arbitrary way and the customer searches for what he wants.

Soviet agriculture is organized on principles quite different from those operative for manufacturing. Collective farms, though managed in an authoritarian way, are like cooperatives in which members share in the income of their farm in respect to the “work points” each can earn. The value of a work point is affected by the prices set for the products of the farm, and these are politically, rather than only economically, determined. In the Western industrial economies, there is also a political element involved in the setting of agricultural prices; generally the problem here is to prevent excess production from driving prices too low. For the Soviets, the problem was the opposite. There, agricultural output failed to expand rapidly enough to keep pace with the requirements of the growing industrial labour force, and prices were therefore kept down so that they would not be unfavourable to the industrial sector. At the same time, individual members of the collective farms were permitted to sell the produce of their household plots on a free market. In this specific market, the peasant was as much a principal as the buyer.

In China, cooperative farms established after 1949 were much more genuinely cooperatives than were those in the Soviet Union, and trade with the cities in China is organized through a kind of Socialist wholesaling. City authorities place contracts with neighbouring farms, specifying prices, varieties, quantities, and delivery dates, and then direct the supplies to retail outlets, which are part of the Socialist economy. A similar system controls trade in manufactured consumer goods. Through the retail shops, the authorities keep a finger on the pulse of demand and guide supply as far as possible to meet it by the contracts that they place with the Socialist manufacturers. By adapting to its own requirements a particular element in the market system—wholesale trade—the Chinese economy seems to have avoided some of the difficulties that the Soviets have encountered.

An example of socialism without a formal market was seen in the early days of the cooperative settlements known as kibbutzim in Israel, where cultivators shared the proceeds of their work without any distinction of individual incomes. (Because a kibbutz could trade with the surrounding market economy, its members were not confined to consuming only the produce of their own soil.) At the outset some of the kibbutzim carried the objection to private property so far that a man who gave a shirt to the laundry received back just some other shirt. But to dispense altogether with market relationships is apparently possible only in a small community in which all share a common ideal, and the austere standards of the original kibbutzim have softened somewhat with growing prosperity; but they still maintain a small-scale example of economic efficiency without commercial incentives.

#### THE MARKET IN ECONOMIC DOCTRINE

**The abstract nature of traditional market theory.** The key to the modern concept of the market may be found in the famous observation of the 18th-century British economist Adam Smith that “The division of labour depends upon the extent of the market.” He foresaw that modern industry depended for its development upon an extensive market for its products. The factory system developed out of trade in cotton textiles, when merchants, discovering an apparently insatiable worldwide market, became interested in increasing production in order to have more to sell. The factory system led to the use of power to supplement human muscle, followed in turn by the application of science to technology, which in an ever-accelerating spiral has produced the scope and complexity of modern industry.

The economic theory of the late 19th century, which is still influential in academic teaching, was, however, concerned with the allocation of existing resources between different uses rather than with technical progress. This theory was highly abstract. The concept of the market was most systematically worked out in a general equilibrium system developed by the French economist Léon Walras, who was strongly influenced by the theoretical physics of his time. His system of mathematical equations was ingenious, but there are two serious limitations to the mechanical analogy upon which they were based: it omitted the factor of time—the effect upon peoples’ present behaviour of their expectations about the future; and it ignored the consequences for the human beings concerned of the distribution of purchasing power among them. Though economists have always admitted the abstract nature of the theory, they generally have accepted the doctrine that the free play of market forces tended to bring about full employment and an optimum allocation of resources. On this view, unemployment could only be caused by wages being too high. This doctrine was still influential in the Great Depression of the 1930s.

**Modifications of the theory.** The change in view that was to become known as the Keynesian Revolution was largely an escape to common sense, as opposed to abstract theory. In a private-enterprise economy, investment in industrial installations and housing construction is aimed at profitability in the future. Because investment therefore depends upon expectations, unfavourable expectations tend to fulfill themselves—when investment outlay falls off, workers become unemployed; incomes fall, purchases fall, unemployment spreads to the consumer goods industries, and receipts are reduced all the more. The operation of the market thus generates instability. The market may also generate instability in an upward direction. A high level of effective demand leads to a scarcity of labour; rising wages raise both costs of production and incomes so that there is a general tendency to inflation.

While the English economist John Maynard Keynes was attacking the concept of equilibrium in the market as a whole, the notion of equilibrium in the market for particular commodities was also being undermined. Traditional theory had conceived of a group of producers as operating in a perfect market for a single commodity; each produced only a small part of the whole supply; for each, the price was determined by the market; and each maximized its profits by selling only as much as would make marginal cost equal to price—that is to say, only so much that to produce a little more would add more to costs than it would to proceeds. Each firm worked its plant up to capacity; *i.e.*, to the point where profitability was limited by rising costs. This state of affairs, known as “perfect competition,” is quite contrary to the general run of business experience, particularly in bad times when under-capacity working is prevalent. A theory of imperfect competition was invented to reconcile the traditional theory with under-capacity working. This in its turn was attacked as unrealistic. The upshot was a general recognition that strict profit maximizing is impossible in conditions of uncertainty; that prices of manufactures are generally formed by adding a margin to direct costs, large enough to yield a profit at less than capacity sales; and that an increase in capacity generally has to be accompanied by

19th-century views

The turn toward realism

The kibbutzim in Israel

some kind of selling campaign to ensure that it will be used at a remunerative level.

Once it is recognized that competition is never perfect in reality, it becomes obvious that there is great scope for individual variations in the price policy of firms. No precise generalization is possible. The field is open for study of what actually happens, and exploration is going on. Meanwhile, however, textbook teaching often continues to seek refuge in the illusory simplicity of the traditional theory of market behaviour.

#### THE HISTORICAL DEVELOPMENT OF MARKETS

Economies  
without  
markets

History and anthropology provide many examples of economies based neither on markets nor on commerce. An exchange of gifts between communities with different resources, for example, may resemble trade, particularly in diversifying consumption and encouraging specialization in production, but subjectively it has a different meaning. Honour lies in giving; receiving imposes a burden. There is competition to see who can show the most generosity, not who can make the biggest gain.

Another kind of noncommercial exchange was the payment of tribute, or dues, to a political authority, which then distributed what it had collected. On this basis, great, complex, and wealthy civilizations have arisen in which commerce was almost entirely unknown: the whole network of supply and distribution was operated through the administrative system. Herodotus remarked that the Persians had no marketplaces.

The distinguishing characteristic of commerce is that goods are offered not as a duty or for prestige or out of neighbourly kindness but in order to acquire purchasing power. It is clearly a convenience to all parties to have a single generally established currency-commodity. Once a commodity is acceptable as money, its use to store purchasing power overshadows its use for its original purpose; it ceases to be a commodity like any other and becomes the very embodiment of value.

**The origin of markets.** Markets as centres of commerce seem to have had three separate points of origin. The first was in rural fairs. A typical cultivator fed his family and paid the landlord and the moneylender from his chief crop. He had sidelines that provided salable products, and he had needs that he could not satisfy at home. It was then convenient for him to go to a market where many could meet to sell and buy.

The second point was in service to the landlords. Rent, essentially, was paid in grain; even when it was translated into money, sales of grain were necessary to supply the cultivator with funds to meet his dues. Payment of rent was a one-way transaction, imposed by the landlord. In turn, the landlord used the rents to maintain his warriors, clients, and artisans, and this led to the growth of towns as centres of trade and production. An urban class developed with a standard of life enabling its members to cater to each other as well as to the landlords and officials.

International  
markets

The third, and most influential, origin of markets was in international trade. From early times merchant adventurers (the Phoenicians, the Arabs) risked their lives and their capital in carrying the products of one region to another. The importance of international trade for the development of the market system was precisely that it was carried on by third parties. Within a settled country, commercial dealings were restrained by considerations of rights, obligations, and proper behaviour. In medieval Europe, for example, dealings were regulated in the main by the concept of the "just price," that is, a system of valuations that assured the producers and merchants an income sufficient to maintain life at a level suited to their respective positions in society. But in trade in which the dealer is not subject to any obligation at either end, no holds are barred; purely commercial principles have free play. It was in trade (for instance, the export of English wool to the weavers of Italy) that the commercial principle undermined feudal conceptions of rights and duties. As Adam Smith observed, a great leap occurred when trade released the forces of industrial production.

Throughout history the relations between the trader and

the producer have changed with the development of technique and with changes in the economic power of the parties. The 19th century was the heyday of the import-export merchant. Traders from a metropolitan country could establish themselves in a foreign centre, become experts on its needs and possibilities, and deal with a great variety of producers and customers, on a relatively small scale with each. With the growth of giant corporations, the scope of the merchant narrowed; his functions were largely taken over by the sales departments of the industrial concerns. Nowadays it is common to hold international fairs at which industrial products are displayed for inspection by customers, a grand and glorified version of the village market; the business, however, consists in placing orders rather than buying on the spot and carrying merchandise home. The function of the independent wholesaler, like that of the merchant, has declined as great retail businesses have grown to a scale whereby they can deal directly with manufacturers; but specialized exchanges for primary commodities are still important.

**Financial markets.** Along with a growth of trade in goods, there has been a proliferation of financial markets. A stock exchange is an organized market for dealing in the securities of businesses and governments. Currently, dealings in securities that came into being in the past predominate over dealings in new issues, and the greater part of industrial investment is financed by retention of profits. Instead of serving mainly as a channel for lending to industry, the chief functions of a stock exchange are to provide a convenient way for owners of property, inherited or newly saved, to place their wealth in income-yielding form, and to provide liquidity and security for them by making a market in which financial assets can readily be realized or redeployed. Dealings in a commodity market, as noted earlier, necessarily contain a speculative element; but in the market for securities, speculation overshadows all else. The art of speculation, as Keynes said, is "to anticipate what average opinion expects average opinion to be." The notorious instability of stock exchanges, with their disturbing effects upon the availability of finance for business and upon the nominal wealth of shareholders, may have repercussions in the market for real goods and services.

Another kind of financial market is the so-called money market. The money market is not an organized exchange; nor is it confined to money in the ordinary sense. The phrase refers to what might be called wholesale transactions in money and short-term credit carried on mainly by large commercial banks. Through the banking system, government authorities (say, the Bank of England or the United States Federal Reserve Board) have some power to control the market for money. But the more the authorities attempt to exercise their powers, the faster the money market develops new organs for bringing lenders and borrowers together and new types of transferrable obligations that are "almost money," in order to escape from control. (An example of this is the huge Eurocurrency and Eurobond markets in which money and financial instruments are bought and sold independently of national monetary authorities.)

#### THE MARKETS AND SOCIAL WELFARE

The branch of academic teaching called the "economics of welfare" is nowadays generally expounded by starting with a presumption in favour of laissez-faire and free competition and then following it by a list of reservations and exceptions that destroy its validity. One is first asked to imagine a particular group of individuals, each with his tastes for a predetermined list of specific commodities, with a predetermined endowment of labour power, with specified equipment and stocks, and with a given body of technical knowledge. These individuals can produce various alternative combinations of commodities. If resources were fully utilized, it would be impossible to produce more of any one commodity without producing less of others. One could then speak of an "opportunity cost" of each commodity—that is, the cost of producing a little more of it in terms of the amounts of other commodities that would have to be sacrificed.

Stock  
markets  
and money  
markets

Conflicts of  
interest

On the other side of the market, the same individuals appear as consumers. If their tastes are all alike, it can be argued that there is one set of outputs and prices at which the relative subjective valuations are proportional to relative opportunity costs. This situation is the optimum in the sense that any move away from it would reduce the total satisfaction. The argument is not so simple when different consumers have different tastes. At any one pattern of prices established in the market (with full utilization of resources), each consumer can adjust his purchases so as to maximize his satisfaction at those prices. Then, starting from that set of prices, it can be shown that no one consumer could be made better off, by changing the composition of output, without making some other worse off. This is a powerful argument for the status quo, wherever it may happen to be. At every other point, there would be a different status quo, with a pattern of prices suiting some consumers better and some worse than the one that was chosen at the beginning of the argument.

The first general objection that is now admitted to this scheme (over and above some technical points within its own terms) is that it is purely static. Actual life is lived in the stream of time. In any economy, tastes, commodities, resources, and technology are continuously changing and modifying each other.

Second, there is a deep-seated inconsistency in the assumptions: when every individual pursues his own advantage, atomistic competition cannot persist, for any group of sellers or of buyers can gain by acting together and sharing the benefits among individual members of the group. Perfect competition, like free trade among nations, can persist only when there is some rule of behaviour that overrides pure self-interest.

Third, it is necessary to consider the distribution of consumption between individuals who make up the market. The purchasing power of each is limited by the receipts that he draws from his sales. His receipts depend on the amount of his original endowment and the price of the product he offers to sell. It is obvious that the distribution of the benefits of the market between individuals is quite arbitrary, and the market optimum is therefore not the same as their welfare optimum. When this objection to the laissez-faire principle is admitted, it is often suggested that inequalities might be corrected by a system of bounties and taxes; but this has never been taken seriously as a practical scheme.

A fourth set of objections comes under the heading of differences between private and social costs. The classic example is the smoke nuisance, which imposes costs upon the public that the factory concerned cannot be charged for. Examples of this phenomenon on a devastating scale are now daily coming to notice. At the same time there are many socially beneficial activities for which it is impossible to collect adequate payment from individuals in a society of unequal wealth and income—not only performances of grand opera but the whole of education and the health service.

Thus the doctrine that the free play of individual interests in a competitive market maximizes welfare for society as a whole has been demolished by its own exponents. Yet these notions still have an important influence on the formation of ideology. The rationalization grew out of the 19th-century utilitarian philosophers' hedonistic calculus, which regarded all human life as governed by the pursuit of pleasure and avoidance of pain. This train of thought identifies pleasure with consumption, leaving out of account the whole sphere of conditions in which work is carried on, and finally it sees consumption in terms of spending money. The whole economic basis of life is thus reduced to terms of commercial transactions. As the American critic Thorstein Veblen pointed out,

so great and pervading a force has this habit of pecuniary accountancy become that it extends, often as a matter of course, to many facts which properly have no pecuniary bearing and no pecuniary magnitude, as, for example, works of art, science, scholarship, and religion.

**The politics of the market.** The doctrines of laissez-faire are attractive in many ways. If the economy is a self-regulating mechanism and if economics is a system

of scientific laws, then moral and political problems are excluded. Questions of social justice do not arise. The function of government is to be strictly neutral between interested parties. But when people come to recognize that the market, by its very nature, is necessarily a scene of conflicting interests, every element in it becomes a moral and political problem. This is distressing because one can no longer rely upon "principles of economics" to provide safe and simple rules for finding the correct solutions.

The intrusion of politics into economic affairs increased dramatically in all the Western industrial nations after 1945. Capitalism took on a new shape, with certain characteristics that distinguish it from all former systems. The reasons for this mutation in the free market economy are numerous. Perhaps the most important was the experience of the great slump of the 1930s. After the war, public opinion, business interests, politicians, and administrators were united in resolving that massive unemployment must not be allowed to recur. Indeed, those who earlier had been the strongest adherents of laissez-faire became the strongest supporters of policies to maintain full employment, arguing that this is the best way to preserve the free enterprise system. Some observers of modern capitalism have maintained that the real purpose of the full-employment policy is to maintain profitability for the great corporations, but it cannot be denied that the results are important for all classes.

The traditional doctrines of the economists are still influential. Even John Maynard Keynes, whose critique of the traditional economics had so much to do with creating the new, gave his blessing to the old conception of the free market. He argued that if our central controls succeed in establishing full employment, there is no objection to be raised against the orthodox theory of the manner in which private self-interest will determine what in particular is produced, or how the value of the final product will be distributed.

Evidently this view owes more to sentiment than to logic. It is impossible to have a policy designed to maintain effective demand in the abstract. Every policy must have some concrete content. The instruments in the hands of government—monetary policy, the exchange rate, taxation, government expenditure—impinge in specific ways upon specific interests. Taxation may be designed to foster either investment or consumption; if the latter, it may be done either by adhering to the principle of "to him that hath shall be given" (that is, by a proportional reduction in direct tax rates) or by favouring lower income groups. Government investment cannot be neutral either; there is no criterion for allocating funds in a neutral manner between, say, armaments and hospitals.

While economic affairs grow ever more overtly political, at the same time commercial influences spread into new spheres. Old notions of loyalty, service, and proper behaviour are undermined by commercial principles. Continuous inflation and rapid technical change make it necessary for every group to defend itself against the erosion of its relative income and status. It would appear that the new capitalism, for all its benefits, may have been developing internal contradictions of its own that threaten its future stability.

**Market Socialism.** The approach to the market has changed in the Soviet sphere also. The Soviet style of administration and ideology was formed in the struggle for rapid and massive industrialization under Stalin's five-year plans. By the 1960s the Soviet economy had become too large and complex to be administered in the highly centralized fashion of earlier years. Some economists in Russia and eastern Europe, seeing that capitalism was providing its working class with a rising level of real earnings and an enticing variety of goods and services, came to the conclusion that the secret of its success lay in the price mechanism and the interplay of supply and demand. The notion of "market Socialism" thus came into vogue. The rigid, overcentralized administration of industry by a system of directives had, admittedly, led to considerable waste and inefficiency, and there was great scope for improvement in management. But the notion

Laissez-faire as an ideal

Communist economic reforms

that a general solution could be found by introducing the criterion of profitability into Soviet enterprises turned out to be illusory. The secret of private enterprise (both for good and for ill) is that it is private; the manager of a capitalist concern acts as a principal and is able to use initiative and judgment. A Socialist manager that is told to make profits is still an agent acting under instructions, necessarily anxious to appear correct and to avoid responsibility. The profit goal may be somewhat less confusing and contradictory than the old multitude of targets handed down from above, but it is still arbitrary because it depends upon a system of prices fixed by decree. When the enterprise is granted the freedom to set its own prices (as in Yugoslavia), it is back to the anomalies of imperfect competition and of instability of markets. There is a school of thought that holds that the way ahead for the Soviet type of economy lies not in less planning but in more—in improving efficiency by intelligent application of devices such as linear programming with the assistance of modern computers. But mathematical methods can apply only in the strictly limited sphere of using pre-existing resources for predetermined ends. It is obvious that the mathematicians cannot instruct the planners on what new products to produce. There remains the problem of finding some means of bringing the needs and tastes of would-be consumers to bear upon both the design and the composition of the flow of production intended for their benefit.

Meanwhile, many of the new and developing nations find that the opening up of their resources and their markets turns out to be more advantageous for established businesses based on successful capitalist industry than for struggling newcomers in their own countries. The economic performance of the so-called developing countries does not give much support to the doctrine that the free play of market forces can be relied upon to maximize human welfare.

**BIBLIOGRAPHY.** ADAM SMITH's famous discussion of the division of labour is found in the first chapter of *An Inquiry into the Causes of the Wealth of Nations* (1776). For ALFRED MARSHALL's approach to the market, see his *Principles of Economics*, 9th ed., 2 vol. (1961). The instability of markets for primary commodities is the theme of the Argentinian economist RAUL PREBISCH, *Towards a New Trade Policy for Development* (1964). The development of the general equilibrium approach to markets by LEON WALRAS *et al.* is well recounted by JOSEPH SCHUMPETER in *A History of Economic Analysis* (1954). A critical account of the theory of imperfect competition is presented in JOAN ROBINSON, *Economics of Imperfect Competition*, preface to the 2nd ed. (1969). A slightly different approach is that of EDWARD H. CHAMBERLIN, *Theory of Monopolistic Competition*, 7th ed. (1956). Economies without markets are described in KARL POLANYI, *Primitive, Archaic, and Modern Economies* (1968), a collection of essays of great interest and originality. The classic appraisal of the market from the standpoint of social welfare is ARTHUR CECIL PIGOU, *The Economics of Welfare*, 4th ed. (1962). Recent appraisals of welfare economics include: I.M.D. LITTLE, *A Critique of Welfare Economics*, 2nd ed. (1957); J. de V. GRAAFF, *Theoretical Welfare Economics* (1957); and MAURICE DOBB, *On Economic Theory and Socialism: Collected Papers* (1955). THORSTEIN VEBLEN's critique of the market ideology is most directly expressed in *The Place of Science in Modern Civilization, and Other Essays* (1919, reprinted 1966). The best short introduction to the Keynesian Revolution is by MICHAL KALECKI, *Studies in the Theory of Business Cycles, 1933-1939* (1966). These essays, published unnoticed in Polish, preceded the great work of JOHN MAYNARD KEYNES, *The General Theory of Employment, Income and Money* (1936). ANDREW SHONFIELD, *Modern Capitalism* (1966), is a study of the ways in which various countries have adapted their economic administration to modern requirements. A more critical view of modern capitalism is that of JOHN KENNETH GALBRAITH, *The New Industrial State* (1967). A Marxist view is set forth by PAUL BARAN and PAUL SWEEZY in *Monopoly Capital* (1968). There is no satisfactory single source on the attempts at economic reform in the Soviet Union and other countries with socialist economies. A recent summary is MICHAEL ELLMAN, *Economic Reform in the Soviet Union* (1969). The economic problems of the poor countries are examined by GUNNAR MYRDAL in *The Challenge of World Poverty* (1969), a summary of his monumental work *Asian Drama* (1968).

(J. Ro)

## Marlborough, Duke of

One of England's greatest generals, John Churchill, 1st duke of Marlborough, commanded British and allied armies against the hitherto seemingly invincible forces of Louis XIV of France and secured four great victories at the battles of Blenheim (1704), Ramillies (1706), Oudenarde (1708), and Malplaquet (1709).

Marlborough, painting attributed to J. Closterman (1656-1713). In the National Portrait Gallery, London.

John Churchill was born on May 26, 1650, at Ashe, Devonshire. His father, Sir Winston Churchill, MP, possessed only a moderate property but was sufficiently influential at the court of Charles II to be able to provide for his sons there and in the armed forces. John, the eldest, advanced rapidly both at court and in the army but, marrying for love (as well as for beauty), remained throughout his life dependent upon his career in the public service for financial support. In the 17th century it was normal and honourable for a successful general to exploit his position in the manner of a modern property speculator, and war, which involved the feeding and equipping of tens of thousands of men and horses, offered an opportunity to make large profits. England, however, had withdrawn from involvement in the early wars of those European powers that feared the aggrandizement of Louis XIV, so that Churchill, although made a lieutenant general and effective commander in chief, as well as a peer of the realm, under James II, was in no sense as yet a rich man. He demonstrated his political acumen by surviving the expulsion of the Roman Catholic James II in 1688, transferring his allegiance to the Dutch prince of Orange, who was to become William III, three weeks after his landing in England, having already given William assurances that he would in all circumstances stand by the Protestant religion. He was rewarded by William with the earldom of Marlborough, membership of the Privy Council, confirmation of his military rank, and a succession of commands in Flanders and in Ireland between 1689 and 1691, in which he was uniformly successful.

Marlborough, in the prime of life by contemporary standards, appeared to be on the threshold of great achievements when, suddenly, at the end of 1691, he was removed from all his appointments. In the following May he was imprisoned in the Tower of London on suspicion of being implicated in the intrigues aiming at the restoration of James II, with the support of a French invasion to be launched from Cherbourg in the summer of that year. Released soon afterward, he yet remained wholly out of favour at court for three years and out of employment for the remainder of the war. Responsible contemporaries, however, never suspected him of treason. Although Marlborough certainly acted like all leading politicians of his age by making comforting assurances to the contender for the throne, as an insurance lest the regime be overthrown once more, as it had been twice already in

Military career

Marlborough's own lifetime, his quarrel with William did not originate in any suspicion of treason. He was dismissed, rather, because he put himself at the head of a substantial English faction opposed to the favours William bestowed on his Dutch associates.

In 1701 Louis XIV made it clear that he was again intent on advancing, through war, his claims upon the now vacant throne of Spain and the Spanish Empire. William III, now a sick man and in what turned out to be the last year of his life, appointed Marlborough to be, in effect, his successor in the struggle against the ambitions of Louis XIV, to which, in England as in Holland, William had devoted his life. On her accession, Queen Anne confirmed the appointment, and Marlborough crossed to the Continent to undertake the first of ten successive campaigns in command of the English and Dutch forces and their auxiliaries. In this first campaign he displayed all the military skill that was to bring him a reputation unrivalled until Napoleon, and a grateful sovereign made him a duke at the end of it. He was equally successful as a diplomat in first creating and then maintaining the Grand Alliance of great and small powers that combined to oppose the ambitions of Louis XIV, the ruler of the most powerful country in Europe.

Political  
rise and  
fall

At home Marlborough was an important political figure whose support was indispensable to any ministry. The key to this influence lay with his wife, the beautiful Sarah Jennings, who had been Anne's firm companion and guide through all the political upheavals of the past two decades. Anne, though a woman with decided views and prejudices of her own, was, for the time being, content to leave her affairs in the hands of Sarah's husband and his friend and political ally Sidney, earl of Godolphin, whom Anne made lord treasurer and, in effect, prime minister.

Both Marlborough and Godolphin were Tories of a traditional kind and so were staunch supporters of the crown and the court as well as of the church. They allied themselves at first with Robert Harley, later the 1st earl of Oxford, leader of a new breed of Tory hostile to the financial interests nurtured by the war. This alliance provided backing for the war against Louis XIV that produced the great victories of Blenheim (1704) and Ramillies (1706), but increasingly, as the old Tories left the government one by one, Marlborough and Godolphin could find effective and consistent support for the war only from the Whigs. Sarah strongly advocated a Whig alliance, with the result that her influence over Anne, among whose prejudices was a strong dislike of the Whig leaders, rapidly declined. A political crisis in January 1708 resulted in Harley's dismissal, and Marlborough and Godolphin were now entirely dependent upon the Whigs. Although Marlborough continued to win his battles, the Whigs proved unable to secure peace, and, by now weary of war, the people endorsed Anne's dismissal of Godolphin and his Whig colleagues in the general election of 1710. Marlborough, who had already found himself increasingly isolated and without influence during the Whig predominance, was left in command of the army for another year, but when he endeavoured to take a political stand over the terms of peace being negotiated by the new government, he was dismissed in December 1711 from all his appointments after charges of misuse of public money had been made in the House of Commons. He took no further part in public life under Anne, retiring abroad when condemned by the Commons for misappropriation of public money. Although restored to favour under George I, Marlborough was already a sick man and lived in retirement up to his death on June 16, 1722, at Windsor, near London.

Assessment

Marlborough's career therefore ended in disappointment, but that does not suffice to explain the reluctance of subsequent writers to accord due recognition of his greatness. Jonathan Swift, Alexander Pope, William Thackeray, and Thomas Macaulay are among the distinguished writers who have subjected him to savage criticism. Support for such a view seems to come from the checkered nature of Marlborough's career: he deserted one monarch, James II, and was dismissed in disgrace by two others, William III and Anne. Moreover, in the public's

eye, he was suspected of treason under William and accused by Parliament of embezzlement under Anne. Many historians have made much of these episodes and of the fact that Marlborough's sister was James II's mistress and therefore perhaps the person really responsible for his rapid advance at court; and until the appearance of Sir Winston Churchill's biography of his famous ancestor in 1933, Marlborough's personal and political reputation remained largely as Macaulay had left it. Churchill, however, easily exposed Marlborough's detractors by pointing out the contrast between their assertions of treachery and dishonesty and the long-lasting friendships and political connections that Marlborough had enjoyed with the men of his day.

Most of Marlborough's contemporaries offer little assistance toward a reliable assessment of his character. For them, the magnitude of his military achievement or the fierceness of the political controversies in which he became enmeshed after 1708 overshadow everything else about him. Moreover, Sarah's quarrels, at first with Anne and subsequently with almost every one of her contemporaries, reflected adversely upon her husband's reputation. Only Marlborough's contemporary, Bishop Gilbert Burnet (1643-1715), in his *History of His Own Time*, seems to provide a convincing, if colourless, character of the duke. He points to his attractive appearance and, despite a lack of formal education, to his qualities of mind, his memory and his quick understanding of a matter. He had, therefore, all the attributes of a successful courtier, and he used them, in default of any fortune of his own, to advance his career by every means open to him. Unfortunately for Marlborough's reputation, he never discarded these policies even when he had acquired an established position in public life. "But," concludes Burnet "when allowances are made for that, it must be acknowledged that he is one of the greatest men the age has produced." That verdict would appear to remain essentially just.

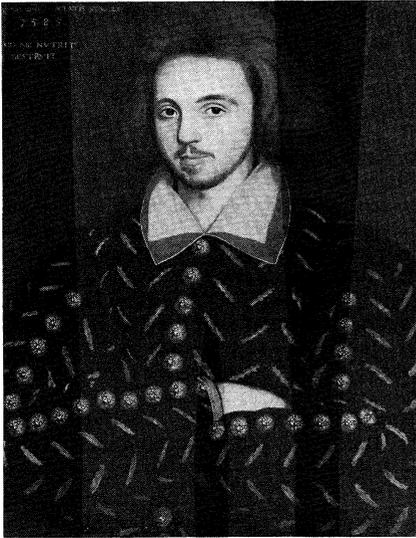

**BIBLIOGRAPHY.** The principal biography remains that of SIR WINSTON CHURCHILL, *Marlborough: His Life and Times*, 6 vol. (1933-38), but the earlier work of WILLIAM COXE, *Memoirs of John, Duke of Marlborough*, 3 vol. (1818-19), remains valuable; and Churchill should be supplemented by the later works of IVOR F. BURTON, *The Captain-General: The Career of John Churchill, Duke of Marlborough from 1702-1711* (1968); A.L. ROWSE, *The Early Churchills, an English Family* (1956); and MICHAEL FOOT, *The Pen and the Sword* (1957).

(I.F.B.)

## Marlowe, Christopher

A major poet and dramatist in his own right, Christopher Marlowe is historically important for his achievement in stimulating the astonishingly rapid growth of drama in Elizabethan England. Before him, dramatic blank verse had been wooden: he made it triumphantly flexible. His *Tamburlaine* and his *Doctor Faustus* were the first truly tragic plays in English. *Edward II* established the dramatic psychological probing that was to become a major concern of Shakespeare and the Jacobean playwrights. *The Jew of Malta* blended the violent and the grimly comic, anticipating the dramatic satires of Ben Jonson and the tragedies of Cyril Tourneur and John Webster.

The second child and eldest son of John Marlowe, a Canterbury shoemaker, Christopher was baptized on February 26, 1564. Nothing is known of his first schooling, but on January 14, 1579, he entered the King's School, Canterbury, as a scholar. A year later he went to Corpus Christi College, Cambridge. Obtaining his bachelor of arts degree in 1584, he continued in residence at Cambridge—which may imply that he was intending to take Anglican orders. In 1587, however, the university hesitated about granting him the master's degree; their doubts (arising from his frequent absences from the university) were apparently set at rest when the Privy Council sent a letter declaring that he had been employed "on matters touching the benefit of his country"—apparently in Elizabeth I's secret service—and denying that he was intending to enter the English college at Reims, in France, which was preparing Roman Catholic missionary priests to be sent to England.

Marlowe, alleged portrait by an unknown artist, 1585. In the collection of Corpus Christi College, Cambridge.

Early works

**Literary career.** In a playwriting career that spanned little more than six years, Marlowe's achievements were diverse and splendid. Perhaps before leaving Cambridge he had already written *Tamburlaine the Great* (in two parts, both acted by the end of 1587). Almost certainly during his later Cambridge years, he had translated Ovid's *Elegies* and the first book of Lucan's *Pharsalia* from the Latin. About this time he also wrote the play *Dido, Queen of Carthage* (published in 1594 as the joint work of Marlowe and Thomas Nashe), in which he turned a humorous eye on the *Aeneid*. But it was *Tamburlaine* that made him famous, and playwriting was his major concern in the few years that lay ahead. Both parts of *Tamburlaine* were published anonymously in 1590, and the publisher omitted certain passages that he found incongruous with the play's serious concern with history: even so, the extant *Tamburlaine* text can be regarded as substantially Marlowe's. No other of his plays or poems or translations was published during his life. His unfinished but splendid poem *Hero and Leander*—almost certainly the finest nondramatic Elizabethan poem apart from Edmund Spenser's—appeared first in 1598; later in the same year it was published along with a continuation by George Chapman, different in tone but also splendid.

There is argument among scholars concerning the order in which the plays subsequent to *Tamburlaine* were written. It is not uncommonly held that *Faustus* quickly followed *Tamburlaine* and that then Marlowe turned to a more neutral, more "social" kind of writing in *Edward II* and *The Massacre at Paris*. His last play may have been *The Jew of Malta*, in which he signally broke new ground. (It is very likely that the poem *Hero and Leander* was written when the theatres had to be closed because of plague in 1592.) It is known that *Tamburlaine*, *Faustus*, and *The Jew of Malta* were acted by the Lord Admiral's Men, a company whose outstanding actor was Edward Alleyn, who certainly played *Tamburlaine*, *Faustus*, and *Barabas*, the Jew.

Themes of the plays

Marlowe was astonishingly learned for a man who died at the age of 29, and this learning, together with a dazzling range of imagination, is manifest in his work. In *Tamburlaine* he went outside Europe, narrated the fortunes of a Scythian shepherd who won the Persian crown, defeated the great Turk Bajazeth, conquered Damascus, defeated the Soldan of Egypt (and made the Soldan's daughter love him), sent his generals into Africa, and conquered Babylon. The scope of this play is the more astonishing as Islām was strange territory for most Elizabethans; yet he could understand that a Muslim could honour Christ, as he has one do in the second part of *Tamburlaine*. In *Faustus* he presented a man who took

the whole universe into his compass, and if he was ultimately damned still went out with more than a whimper. His understanding of theology in this play is masterly. In *Edward II* and *The Massacre at Paris* he dramatized events from English and French history. In *The Jew of Malta* he looked to a melting pot in which Christians and Turks and Jews came together and resisted union. His comic commentary in *Dido, Queen of Carthage* and in *Hero and Leander* makes the first an elegant squib and the second a masterpiece of narrative poetry.

Yet ultimately Marlowe never commits himself in his work. He was once regarded as an essentially subjective dramatist who projected himself and his dreams through his great characters *Tamburlaine* and *Faustus* so that their triumphs were his dreams for himself and their overthrow had to be by nonhuman powers, the only defeat he could recognize for himself as valid. More recently there has been an attempt to see him as an orthodox Elizabethan Christian, presenting pictures of sinners as object lessons on what should be avoided. Both views do the poet an injustice. At the end of the prologue to Part I of *Tamburlaine*, the audience is urged to

View but his picture in this tragic glass,  
And then applaud his fortunes as you please.

So, too, the prologue speaker to *Faustus* declares:

Only this, gentles—we must now perform  
The form of *Faustus'* fortunes, good or bad:  
And now to patient judgements we appeal. . . .

In this second instance there is merely a hint of neutrality, for the matter was dangerous; but the emphasis on the need for "patience" suggests a repudiation of the easy response an audience of the time might be likely to make. He makes the prologue speaker to *The Jew of Malta* Machiavelli himself, who comes, he says, to "frolic with my friends" in England and who urges that the Jew should not be thought less of "Because he favours me." The line must have brought a laugh but also a shock in the theatre of Marlowe's time. *Edward II* has no prologue or epilogue, no long self-revealing speech from a major character, but of all the plays it most obviously takes its stand on "neutrality." The beholder is made to feel the shortcomings of every character, the corruption that power brings, and the strange distinction that extreme suffering can confer on even the weakest of men. This play includes a death scene that surpasses in cruelty anything else that the Elizabethans and Jacobean could offer. The biographical documents make it plain that Marlowe was himself a violent man: he was also a man who could imagine what violence was like for its victim.

Moving to London from Cambridge in approximately 1587 and wanting to make his mark in the theatre with a serious play, he could be imagined doing as his friend Thomas Kyd did in *The Spanish Tragedie* (c. 1590)—adapting the Senecan mode of dramatic writing (the rhetorical display of intense emotion) to the English stage. But *Tamburlaine* is Senecan only in its frequent use of the long speech: in all other respects it is superficially closer to popular native plays in its concentration on a tyrant's career, its ending in that tyrant's death through natural causes (or possibly through the operation of divine anger). *Doctor Faustus* goes to the native tradition of the "morality play" (including the good and bad angels, the seven deadly sins, and the various devils that Marlowe's countrymen were used to seeing on the stage), telling a story of temptation, fall, and damnation, driving home—though with a deep and characteristically Marlovian irony—the moral lesson. In *Edward II* and *The Massacre at Paris* Marlowe's pattern was again native, influenced by Shakespeare's *Henry VI* plays. *The Jew of Malta* also drew upon the "moralities" to some extent, for *Barabas* is something of a "Vice"—that figure, exulting in mischief for its own sake, so commonly found in earlier 16th-century drama. But he is also a caricature of Machiavelli, as the Elizabethans saw him, as well as a caricature of the *Tamburlaine* or *Faustus* figure who dreamed of power and found absurdity.

Marlowe quickly had both imitators and detractors. Robert Greene, in 1588, in a prefatory epistle to his own

Marlowe's  
imitators  
and  
detractors

*Perimedes the Black-Smith* referred to the stage as "daring God out of heaven with that Atheist *Tamburlan*" and to "such mad and scoffing poets, that have propheticall spirits, as bred of *Merlins* race" ("Merlin" is a variant of "Marlowe"). In 1592 in his death-bed tract, *Greene's groats-worth of witte, bought with a million of Repentance*, he included a warning to three dramatists against the way the theatre would treat them. One of these (there can be no doubt that it was meant to be Marlowe) he reproved for saying "There is no God" and urged him to repent. These were dangerous words to bring forward against one in 1592. Sometime after the tract was published the publisher apologized for the attack that Greene had made on Shakespeare but made it clear that he was indifferent to any resentment felt by Marlowe.

**Final years.** Even so, Marlowe had friends; and he was possibly still involved in "matters touching the benefit of his country" right up to his death. He may have been the "Marlin" (like "Merlin," a variant of his name) who is on record as carrying letters from France to Sir Robert Cecil (principal secretary to the Queen) in 1592. In that year, too, he was involved in a street affray in Canterbury (a similar affair in 1589 had resulted in a man's being killed, though not by Marlowe). From 1591 he was sharing a room with his friend Thomas Kyd, who was arrested on May 12, 1593, and then tortured, on suspicion of treasonable activity. His room being searched, papers were found "denying the deity of Jesus Christ." Six days later a warrant from the Privy Council was issued for Marlowe's arrest. He was found at Sir Thomas Walsingham's house at Chislehurst, Kent, but was only required to give daily attendance on their lordships "until he shall be licensed to the contrary." This was indeed an apparently lenient course to take, especially in view of what Kyd was later to declare against him—and probably had already declared under torture.

On May 30, 1593, during a long day spent in a tavern at Deptford, a suburb to the southeast of London, with Ingram Frizer, Nicholas Skeres, and Robert Poley, Marlowe was killed. He had been in dubious company indeed: Poley was a double spy; Skeres had probably been concerned with Poley in the so-called Babington Plot (against the Queen's life) in 1586; both Poley and Frizer, like Marlowe, had relations with Sir Thomas Walsingham, who was occupied with detecting and frustrating plots against the Queen's life and who had implicated Mary Stuart in the Babington Plot. The story told at the inquest on Marlowe's death was that Marlowe and Frizer quarrelled about the tavern bill, that Marlowe drew his dagger, that Frizer seized the dagger and killed Marlowe in self-defense. Marlowe was buried on June 1; Frizer was pardoned on June 28.

Kyd, as has been seen, was arrested and tortured earlier in May. Probably after Marlowe's death, Kyd wrote two letters to Sir John Puckering, the lord keeper, declaring that the blasphemous and treasonable papers found in his room were Marlowe's property. He accused Marlowe of blasphemy and violence. Soon afterward, Richard Baines, an informer, gave further evidence against the now dead poet: he was blasphemous, seditious, treasonable, a defender of homosexuality and tobacco, a man who had read an "atheist lecture." Who was really responsible for Marlowe's killing can only be wondered at: their lordships of the Privy Council may have known that Marlowe knew too much about them; his friends may have feared what he might be able to say of them under torture. The official story about a quarrel over the reckoning could, of course, be true, but the company was more than dubious and the strange leniency of the Privy Council in not keeping Marlowe as a prisoner suggests something not quite in order.

His death was seen by some people as evidence of God's vengeance on atheists—by Gabriel Harvey (who believed Marlowe died of the plague), by Thomas Beard in *The Theatre of Gods Judgments* (1597), by William Vaughan in *The Golden Grove* (1600). In Francis Meres's *Paladis Tamia* (1598) there was added the fictitious detail that Marlowe was stabbed "by a bawdy serving-man, a rival of his in his lewde love."

Marlowe's  
murder

Yet there were posthumous tributes, too—from the dramatists George Peele, Michael Drayton, John Marston, and others. Most notable of all was Shakespeare's remembrance of him in *As You Like It*, in which the circumstances of his death are recalled ("a small reckoning in a little room"), and where he is quoted (a line from *Hero and Leander*) and addressed as "Dead shepherd." Shakespeare also had him in mind in the Pyrrhus speech of *Hamlet*, in an echo of "the face that launched a thousand ships" in *Troilus and Cressida*, and perhaps in the references to "Widow Dido" in *The Tempest*. Shakespeare may have had one of Marlowe's Ovid translations in his memory when he wrote "The Phoenix and Turtle." In his own time Marlowe dominated the stage and maintained his primacy until Shakespeare came to full growth. The Victorians thought of him as a lyrical and rhetorical poet not properly at home in the theatre. But the 19th-century view of the theatre's range was less than that in the 20th century when an increasing awareness of Marlowe as a dramatist developed.

#### MAJOR WORKS

PLAYS (in probable order of composition, with dates of publication): *Tamburlaine the Great* (1590); *The Tragical History of D. Faustus* (1604); *The Troublesome Raigne and Lamentable Death of Edward the Second, King of England* (1594); *The Famous Tragedy of the Rich Jew of Malta* (1633).

POEMS AND TRANSLATIONS: *Hero and Leander* (1598), long narrative poem, only the first third by Marlowe, who died before it was finished; "The Passionate Shepherd to His Love" ("Come Live with Me, and Be My Love"), Marlowe's only surviving lyrical poem, first published in the miscellany *Englands Helicon* (1600).

**BIBLIOGRAPHY.** S.A. TANNENBAUM, *Christopher Marlowe: A Concise Bibliography* (1937, suppl. 1947), is useful in listing early editions, biographies, and critical studies.

**Editions:** The standard edition is still that published in 6 volumes under the general editorship of R.H. CASE (1930–33): this includes a biography by C.F. TUCKER BROOKE (1930), along with an edition of *Dido* in the same volume, and editions of *Tamburlaine* (ed. by U.M. ELLIS-FERMOR, 1930; rev. ed., 1951), *The Jew of Malta* and *The Massacre at Paris* (ed. by H.S. BENNETT, 1931), *Poems* (ed. by L.C. MARTIN, 1931), *Doctor Faustus* (ed. by F.S. BOAS, 1932; rev. ed., 1949), and *Edward II* (ed. by H.B. CHARLTON and R.D. WALLER, 1933; rev. ed. by F.N. LEES, 1955). C.F. TUCKER BROOKE's edition of the *Works* (1910) is the standard one-volume text. SIR WALTER GREG's companion volumes, *Doctor Faustus 1604–1616: Parallel Texts* and *The Tragical History of the Life and Death of Doctor Faustus: A Conjectural Reconstruction* (both 1950), are of the first importance for the textual history of the play, although Greg's views on the dating of *Faustus* and on the question of collaboration have been challenged. The Case edition is being replaced by the Revels edition of the *Works of Christopher Marlowe*, in which *Doctor Faustus*, ed. by J.D. JUMP (1962), *Dido, Queen of Carthage* and *The Massacre at Paris*, ed. by H.J. OLIVER (1968), and *The Poems*, ed. by M. MACLURE (1968), have appeared. A complete Marlowe edition by FREDSON BOWERS is forthcoming.

**Biography and criticism:** The best biography is F.S. BOAS, *Christopher Marlowe: A Biographical and Critical Study* (1940). Valuable contributions have been made by J.L. HOTSON, *The Death of Christopher Marlowe* (1925); and P.H. KOCHER, *Christopher Marlowe: A Study of His Thought, Learning, and Character* (1946). Two outstanding works of criticism are HARRY LEVIN, *The Overreacher: A Study of Christopher Marlowe* (1954); and J.B. STEANE, *Marlowe: A Critical Study* (1964). Levin is at his best in considering the complexities of Marlowe's mind, Steane in his sensitive response to the poetic quality. The earlier view of Marlowe's outlook and of the character of his plays is well represented in U.M. ELLIS-FERMOR, *Christopher Marlowe* (1927). F.P. WILSON, *Marlowe and the Early Shakespeare* (1953), illuminatingly brings together the two major English dramatists of the 1590s. Three recent anthologies of critical essays are: *Marlowe: A Collection of Critical Essays*, ed. by C. LEECH (1964); *Critics on Marlowe*, ed. by JUDITH O'NEILL (1969); and *Twentieth Century Interpretations of Doctor Faustus*, ed. by W. FARNHAM (1969).

(C.L.)

#### Mars

Mars, the red planet, is named for the Roman god of war. The first known association of the planet with destruction

was made in Babylonia about 3,000 years ago, where astronomers named the planet Nergal after their god of death and pestilence. The early Greeks named the planet Ares, for their god of battle. Mars is accompanied in its journey around the Sun by two satellites, Phobos (fear) and Deimos (terror), named after the mythical chariot horses of Mars. The astronomical symbol for Mars ( $\delta$ ) represents a shield with a spear.

Of the nine known planets, Mars is fourth in order of distance from the Sun and seventh in order of diminishing size and mass. It completes its orbit about the Sun once in 687 days and spins on its axis with a period only slightly longer (37 minutes) than a terrestrial day. Orbital data for Mars are listed in Table 1; physical parameters in Table 2.

**Table 1: Orbital Elements of Mars\***

Mean distance from Sun (semimajor orbital axis)	227,800,000 km
Eccentricity	0.093374
Inclination	1.84989°
Mean longitude of node	49.29686°
Mean longitude of perihelion	335.43689°
Sidereal period	686.9804 mean solar days
Mean synodic period	779.94 mean solar days
Mean orbital velocity	24.1 km/sec

The telescopic view of Mars reveals dark markings on a bright red-ochre surface. Occasionally, there is clear visual evidence of a tenuous atmosphere. Meteorological phenomena in the form of local clouds and, sometimes, planet-wide obscurations of the dark surface markings are seen. The planet has white caps at both poles. These features are observed to undergo seasonal and occasionally unexpected changes.

Mars was an enigma to ancient astronomers, who were bewildered by its apparently capricious motion, sometimes direct, sometimes retrograde, across the sky. Johannes Kepler solved this problem in 1609. Using Tycho Brahe's superior observations of the planet, he was able to deduce empirically its laws of motion and so pave the way for the modern gravitational theory of the solar system. Kepler found that the orbit of Mars was an ellipse along which the planet moved with non-uniform but predictable motion. He was able to demonstrate why the planet's motion had confounded earlier astronomers who had based their theories on the older Ptolemaic idea of hierarchies of circular orbits. In the words of Kepler: ". . . Mars alone enables us to penetrate the secrets of astronomy which otherwise would remain hidden from us."

The planet has played a major role in the development of planetary astronomy. It is at the centre of considerable debate concerning the existence of extraterrestrial life and is presently one of the primary targets of the United States' planetary exploration program. High-resolution pictures and other measurements of the Martian surface and atmosphere obtained by the Mariner 4, 6, and 7 spacecraft in 1965 and 1969 have provided us with the most detailed information that exists on conditions on another planet.

Hyron Spinrad, a well-known U.S. planetary spectroscopist, has called 1963 the "year one" for modern investigations of the planet. Since then a greater effort may have been made to understand Mars than was made in all previous years, and, in any case, our knowledge of the planet, and especially of its atmosphere, has changed radically. The main stimulus has been the Mariner Planetary Fly-by Program and, in the following sections, we shall often refer to the remarkable photographs of Mars returned by Mariner 6 and 7.

**MARTIAN PHENOMENA**

**Observing conditions: basic data.** Mars moves around the Sun at a mean distance approximately 1.52 times that of the Earth from the Sun, but the large eccentricity (0.093) of its orbital ellipse brings Mars at its closest

**Table 2: Physical Parameters for Mars**

Equatorial radius	3,393 ± 4 km
Polar radius (from equatorial radius and optical flattening)	3,352 km
Optical flattening	0.012
Dynamical flattening	0.00525

approach to 206.5 million kilometres from the Sun and at its furthest to 249.1 million kilometres. Mars completes an orbit in roughly the time Earth completes two, and, therefore, Mars spends most of its year far from the Earth in directions that are near the Sun. At closest approach, Mars is less than 56 million kilometres from the Earth but recedes to almost 400 million kilometres; thus, it is not generally available for detailed observation.

Astronomical observations of Mars are best made when the planet is at opposition—that is, when the planet is in the opposite direction in the sky to the Sun. At this time the planet culminates near local midnight and is close to the Earth. Successive oppositions occur at intervals of approximately two years and seven weeks; because this interval, called the synodic period, is not commensurate with the orbital period of Mars, an opposition may occur at any point in the orbit. Oppositions near perihelion are called favourable, or perihelic, because then the planet is closest to both the Earth and the Sun and is, therefore, brighter and appears larger than usual. The largest angular size that the planet can attain is 25 seconds of arc. Oppositions that occur near aphelion are the least favourable, for then the planet is farther from the Earth (101,000,000 kilometres) and at its greatest distance from the Sun. Such oppositions are called aphelic, the planet being less bright and smaller than at the average opposition, and it may attain an angular diameter of only 14 seconds of arc.

One further factor that critically influences the observability of Mars at opposition is that the orbital plane of Mars is inclined at an angle of 1.85° to the Earth's orbital plane. At Martian perihelion, Mars is well south of the Earth's orbital plane. Consequently, at favourable oppositions Mars is badly placed in the sky for observations in the Northern Hemisphere and is best observed from sites south of the Equator. The situation is reversed for aphelic oppositions.

The north pole of rotation of the planet is pointed in the direction of the sixth magnitude star best known by its *Bonner Durchmusterung* catalog number, BD 52°2880, which is located near the bright star Deneb in the constellation of Cygnus. BD 52°2880 is therefore the Martian "pole star" about which the apparent daily motion of the heavens takes place. As is the case with the Earth, the direction of the pole in the sky changes slowly, owing to gravitational torques exerted by the Sun on the planet's equatorial bulge. This precession causes the Martian pole to move along a small circle in the sky with a period of 97,000 Martian years.

The axis of rotation is not perpendicular to the orbital plane of the planet but is inclined at an angle of 24.936°, and, as for the Earth, the tilt gives rise to the phenomenon of seasons on Mars. The Martian year consists of 668.6 Martian (solar) days. For 371 Martian days, or a little over one-half of the Martian year, the Sun appears overhead at some northern latitude and it is spring and sum-

Conditions at Martian opposition

Martian "pole star"

mer in the Northern Hemisphere. The orientation and eccentricity of the orbit, however, leads to an important characteristic of the seasons on Mars: they are quite uneven in length. The summer solstice, which separates spring from summer, occurs considerably later than the midtime between the times of passage through the spring and fall equinoxes. The southern summer is short and hot while the northern summer is long and cool (see Table 3). These are important factors in understanding the seasonal behaviour of the polar caps (described below).

**Table 3: Length of Seasons on Mars**

Northern Hemisphere	Southern Hemisphere	mean Martian days
Spring	Fall	194.2
Summer	Winter	176.8
Fall	Spring	141.8
Winter	Summer	155.8

Mars is a small planet. Its equatorial radius is about half that of the Earth, and its mass only one-tenth the terrestrial value. It follows that Mars possesses four times less surface area than the Earth and its gravity is reduced by a factor of nearly 3. To escape the gravitational pull of Mars, a velocity of only 5.024 kilometres per second is required. Thus, a rocket need only supply to an object one-fifth of the energy that would be needed on Earth to free it from the gravitational attraction of the planet.

Mars is observed to be spheroidal in shape. Optical observations indicate that the polar radius of the planet is about 40 kilometres less than its equatorial radius. This surprisingly large figure exceeds, by a factor of 2, the maximum value predicted from theory. A rotating planet the surface of which is free of stress should take on the shape of an oblate spheroid. The degree of flattening should lie between two limits: an upper limit, corresponding to a homogeneous planet, and a lower limit, corresponding to a planet with the mass heavily concentrated at the centre. The upper limit for Mars, which can be computed from its known mass, radius and rotation rate is 0.00571. The observed optical value is 0.012. It would therefore appear that the surface of Mars may be under considerable stress.

**Data from visual observations.** The earliest telescopic observations of Mars in which the disk of the planet was seen were those of Galileo Galilei, who, in 1610, noted that the planet did not appear to be perfectly round. In 1636 the Italian astronomer Francesco Fontana produced the earliest drawings that show markings on the disk of the planet. Some of these drawings show Mars in the gibbous phase, that is, with more than half the visible disk illuminated. Unfortunately, the markings drawn by Fontana bear no resemblance to the planetary details now known, and the Dutch scientist Christiaan Huygens is credited with the first accurate drawings of surface markings. In 1659 Huygens made a drawing of the planet that shows a major dark marking on the planet now known as Syrtis Major. Polar caps on the planet were first noted by Giovanni Domenico Cassini around 1666.

The accomplishments of visual observers are many. Mars' tenuous atmosphere was first noted by the German-born British astronomer William Herschel, who also measured the tilt to the rotation axis and first discussed the seasons of Mars. The rotation of the planet was discovered by Huygens (1659) and measured by Cassini in 1666. He found the rotation period to be 24 hours and 40 minutes, which is in error by a mere three minutes, a remarkable accomplishment for that time. The moons of Mars, so important in determining the mass of Mars, were also discovered visually, by the 19th-century U.S. astronomer Asaph Hall.

Visual observations have accumulated a rich compendium of meteorological and seasonal phenomena that occur on the planet, such as numerous cloud phenomena (there are yellow, blue, white, and gray clouds), the waxing and waning of the polar caps, seasonal

changes in the colour and extent of the dark areas, a "wave of darkening" in the markings that sweeps across the planet in phase with the melting of the polar caps, a green haze and bright transient spots.

**Martian maps.** The first map of Mars was produced in 1830 by the German astronomers Wilhelm Beer and Johann H. von Mädler. The earliest system of longitude and latitude, not too different from that in use today, was defined by these pioneers. Better maps with the first systematic attempts to name the markings were subsequently produced by three astronomers—Richard A. Proctor (1867) and Nathaniel E. Green (1877) of England and Camille Flammarion (1877) of France. The nomenclature for the markings was based on the names of prominent scientists and observers of the planet such as William Herschel, William R. Dawes, Pierre-Simon Laplace, Wilhelm Beer, Dominique Arago, and Johann Schröter.

The Italian astronomer Giovanni Schiaparelli produced the first modern map of Mars (1877), and it contained the basis of the system of nomenclature in use today. The names are in Latin and are formulated predominantly in terms of the ancient geography of the Mediterranean area in mythical and biblical times. This map also showed, for the first time, indications of a system of canals, or channels, on the bright areas, and Schiaparelli is usually credited with their first description. According to the U.S. astronomer Samuel Glasstone, however, the idea of canals originated ten years earlier in the work of the Italian astronomer Angelo Secchi.

Since Schiaparelli's time, the map of Mars has been constantly improved, and hundreds of new details have been added to it. Moreover, photography has played an increasingly important role in this process. In 1958 the International Astronomical Union adopted a formal list of place-names on Mars related to a map of Mars drawn by G. de Mottoni and based on a large number of photographs of the planet taken by the French astronomer Henri Camichel at the Pic du Midi Observatory (see Figure 1). The remarkable quality of this map is borne out by comparison with the far-encounter picture of Mars returned to Earth in 1969 from the Mariner 6 and 7 spacecraft. In a review of his own researches, the U.S. astronomer Clyde W. Tombaugh gives some interesting background information on observing Mars and the detail that appears on visual maps of Mars (he is referring in particular to one of his own):

Unless an observer has good eyes and is willing to spend hundreds of hours looking with effective telescopes, he has little chance of seeing such detail to this extent. It is never all visible simultaneously. Not only must the terrestrial atmosphere be very steady but also colors and many details are visible only at certain Martian seasons. While a number of canals, oases, and small white spots are frequently visible, others are so rarely seen that their visibility may depend on secular causes, such as volcanic degassing in some local area, perhaps. Several details on this map have been visible to the writer for less than a total of five minutes over a span of forty years!

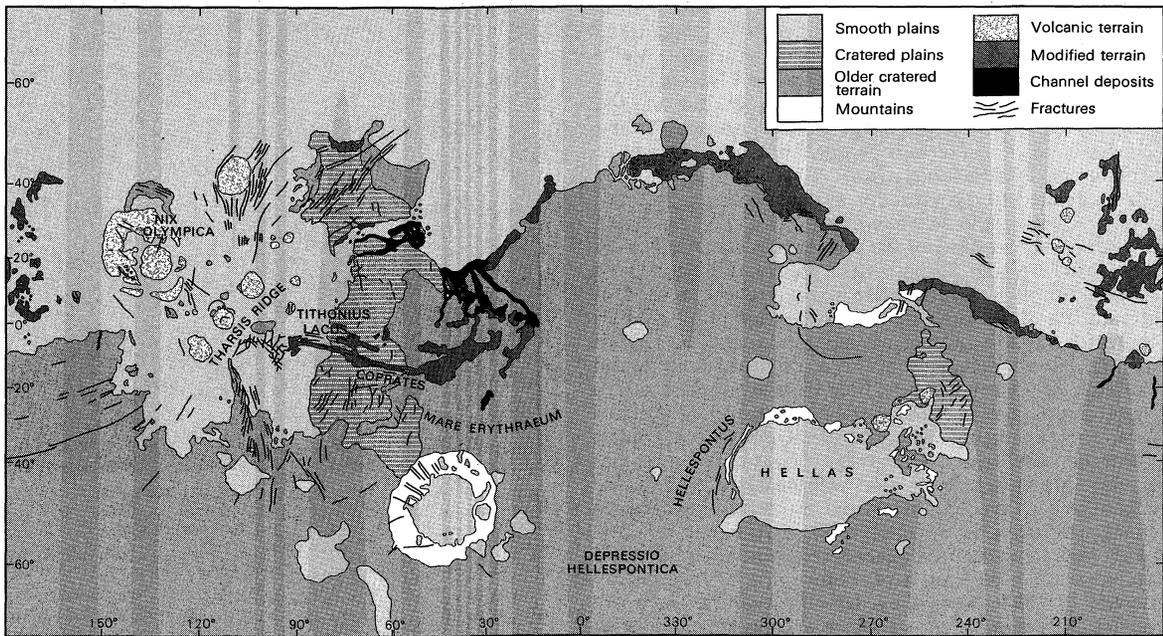

The above remarks are particularly cogent in relation to the long controversy over the existence of the canals, which continued from the early years of this century until finally settled by the Mariner photographs.

One of the most assiduous observers and students of Mars was the U.S. astronomer Percival Lowell, who founded the Lowell Observatory in Flagstaff, Arizona. He believed that he had identified some 500 canals and insisted that they were the work of intelligent beings on the planet rather than natural features. Lowell recorded the canals as remarkably straight, or very regularly curved, narrow filaments (sometimes double), stretching across vast areas of desert and intersecting in a seemingly organized manner at small dark spots. These spots, called oases, were discovered and named by his contemporary, the U.S. astronomer William H. Pickering of the Harvard Observatory.

The vast wealth of detail included in Lowell's maps was disputed by many of his colleagues, who were unable to locate the features or saw them with quite different characteristics. A few extremely competent observers were

never able to see the canals at all: among them the U.S. astronomers Milton L. Humason and Walter Baade, who used the Mt. Wilson 100-inch reflector under almost perfect conditions. Others found that under good conditions the canals were not continuous features but broke up into a discontinuous series of lines and dots. The controversy may be considered closed, however, for the pictures of the planet returned by Mariner 6 and 7 show no obvious signs of features that could correspond to the canals seen by Lowell. It would appear that the canals are, at best, chance alignments of large craters that become visible in moments of exceptional atmospheric clarity.

**Data from photographic observations.** Visual observation of planets has suffered a decline in modern times following the introduction of new techniques. Photographic monitoring of Mars has largely supplanted visual observation. Surprisingly, this is not because ground-based photography can produce high-quality images but rather because the technique is far less subjective. Many Martian phenomena are in fact too delicate and subtle to

be registered on the photographic plate and are only available to the eye of the visual observer.

The chief photographic problems are blurring and rapid tremor of the image due to the time-dependent inhomogeneities in the atmospheric path through which the light must travel. The state of the atmosphere produces the phenomenon referred to as seeing. Unless exposures are short enough and made to coincide with moments of good seeing, the resulting picture will be blurred. Nevertheless, remarkable photographs of Mars, some in colour, have been made that illustrate most of the phenomena reported by visual observers. The reader is particularly referred to the monograph "A Photographic History of Mars" by the U.S. astronomer Earl C. Slipher of the Lowell Observatory, who devoted a lifetime's work to a photographic study of the planet.

A controversial phenomenon reported by many Martian observers from photographs has been called the blue haze, or violet layer. A comparison of photographs taken through blue and red filters shows that the contrast of

The blue haze and blue clearings

surface features is less in blue light. Slipher found that if the wavelength of the light was less than 4600 angstroms, then dark features on the surface were generally totally obscured. Occasionally exceptions, called blue clearings, occur when the obscuration lifts for a short time and the visibility of the dark markings is re-established. Many theories, none entirely satisfactory, have been devised to explain this phenomenon. Most presume that the blue haze is related to the presence of some scattering or absorbing agent in the Martian atmosphere. To investigate this phenomenon some of the television pictures taken by the Mariner 6 and 7 spacecraft, described below, were exposed through a blue filter similar to those used in groundbased telescopic studies of the blue haze. No evidence for any loss of contrast was found, and the experimenters have concluded that this result clearly refutes the existence of an atmospheric, blue haze layer and that the cause of the phenomenon must be a property of the surface. This conclusion has not been universally accepted.

**Diurnal and seasonal activity.** The major seasonal changes are closely associated with changes in the polar caps. The caps wax and wane, and corresponding periodic changes occur in the appearance of surface features. One of the more enigmatic sequences that take place is called the wave of darkening, a phenomenon first reported by Lowell in 1894. Near the edge of either polar cap, a general darkening of the surface markings appears in early spring as the cap begins to recede; then the darkening moves away from the receding polar cap, sweeps toward, and finally crosses the Equator in an indistinct band of heightened contrast to dissipate in the opposite hemisphere. The waves, one in each hemisphere, travel at an apparent speed of about 35 kilometres per day. Studies of the phenomenon were carried out by the French-U.S. astronomer Gérard de Vaucouleurs in 1939 and by the U.S. astronomer John H. Focas in 1962, using photometric techniques rather than subjective visual reports. The waves are well documented quantitatively, but no satisfactory explanation has yet been devised.

The markings are observed to undergo changes in colour and sometimes in extent. Charles F. Capen of the Jet Propulsion Laboratory, California Institute of Technology, an expert visual observer, reports the following behaviour in the Trivium Charontis region: in the spring the area is medium-dark gray with brown tints, olive drab with darkening wave, and taking on intense black later. In summer the area stays black. In fall the colour is dark gray and brown, turning to medium-dark gray and brown tints in the winter.

The reported colours of the dark features have been subject to considerable discussion, particularly because colour recognition is largely subjective. It has been questioned if the colours reported are accurate or are merely a reflection of physiological processes in the eye and mind of the observer. A straightforward answer is not entirely possible, but photoelectric spectrophotometry (a purely objective technique) of the dark areas has shown that they are actually red, although less so than the bright areas on the planet.

Diurnal changes are observed on the planet. The most striking examples are in the far-encounter pictures returned from the Mariner 6 and 7 spacecraft. These show mottled areas on the afternoon side with relatively bright, often diffuse patches, which change on a day-to-day basis. Some of the patches are striking in their geometric regularity and are presumably associated with surface features. The best example is a bright ring, 500 kilometres in diameter, associated with the region called Nix Olympica (see Figure 2). None of these patches appear to be clouds, for they show no apparent motion with respect to the surface nor any of the characteristics of clouds on the Earth (waves, cloud streets, etc.). They seem to be intimately connected with the ground, and it has been suggested that they may be fogs or ground frosts. Unfortunately, neither of these possibilities makes sense when examined carefully. Frosts of carbon dioxide are ruled out because the surface is too warm, and water-ice frosts are unlikely because of the extremely low partial pressure of water in the atmosphere.

#### THE SURFACE

**Appearance from the ground.** To the ground-based telescopic observer, the Martian surface is characterized by red-ochre-coloured bright areas with superimposed, dark markings. It has been usual to refer to the bright areas as deserts and the majority of large dark areas as *maria* (sing. *mare*); i.e., oceans or seas. It is now absolutely certain that these dark areas are not, and in all probability never were, covered by expanses of water. Nor do they appear to be closely similar to the well-known dark *maria* on the Moon. It therefore seems more reasonable to refer below simply to the dark and bright areas on the planet than to use the older terms.

The most prominent dark areas occupy a band around the planet between 10° and 40° S. Their distribution is irregular, and the Northern Hemisphere has only a single major feature, Mare Acidalium.

Dark markings cover about one-third of the total area of the planet's surface, and the best ground-based maps, such as those by G. de Mottoni and by J.H. Focas, show them to be made up of a myriad of well-developed structures, patches, and groups of spots. High resolution photographs have confirmed this description: dark regions such as Meridianii Sinus are made up of such patches pockmarked with craters. The Mariner pictures also show that the transition from dark areas to bright areas is often quite abrupt and irregular, taking place in distances of less than 10 kilometres.

The most remarkable fact about the dark areas is their ability to change. They are observed to undergo both seasonal and long-term variations in both size and colour. In the words of E.C. Slipher: "The markings are in a state of perpetual and bewildering fluctuation, the slower and more gradual ones partly through change in the illumination of the Martian air and partly through inherent change in the markings themselves." Bright areas, which represent about 70 percent of the planet's surface, are also well endowed with subtle shadings and intricate features—the so-called canals and oases.

**The character of the surface.** The character of the surface on linear scales below 100 kilometres was a matter of conjecture until the pictures of Mariners 4, 6, and 7 (Figures 3-6) were returned to Earth in 1965 and 1969. On scales smaller than one kilometre, speculation is still a factor, but some statements can be made. Finally, on the microscale of the individual particles that make up the surface, little can be said with certainty, but a broad picture, based on the interpretation of spectrophotometric, polarimetric, and thermal-infrared temperature measurements, can be drawn.

Mariner pictures show the surface to be composed of at least three distinct types: chaotic, cratered, and featureless terrain. The high-resolution pictures cover only a fraction

The wave of darkening

Nix Olympica region

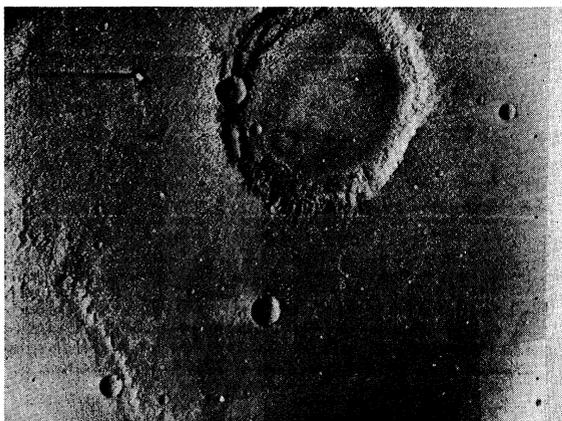

Figure 3: *Martian surface showing features similar to the Moon.* The large flat-bottomed crater is believed to be a typical older crater; smaller cup-shaped craters are younger. Mariner 6 photograph, frame 18.

of the surface of the planet, and the possibility remains that types of terrain with still other characteristics may be present on the planet.

Cratered  
terrain

The cratered terrain appears to be extremely old. The number of very large craters found on the Mariner photographs implies an age of at least several billion years; these regions of the surface could even be primordial, in spite of the probability that the meteoric-bombardment flux on Mars could be 25 times greater than that on the Moon because of the greater proximity of Mars to the asteroid belt (see Figure 5).

The craters are of two types: large and flat bottomed, small and bowl shaped. The latter are similar to impact craters on the Moon. A particularly striking difference between the cratered terrain on Mars and the Moon is the absence on Mars of the swarms of secondary craters and ray structures often associated with large lunar craters. This is consistent with the greater role of erosion processes on Mars as compared with that on the Moon. Ernst J. Öpik, for example, has estimated that erosion processes on Mars, even though only 0.03 percent as effective as those on Earth, would cause substantial obliteration of craters with sizes of up to 10–20 kilometres.

Chaotic  
terrain

Chaotic terrain appears to be much more recent in formation, and the Mariner experimenters suggest that it is probably the result of ongoing modification processes. This type of region is characterized by irregular areas of chaotically jumbled short ridges and depressions (see Figure 4). The scale of the features is typically one to three kilometres across by two to ten kilometres long. These regions seem to be relatively young because they are practically uncratered. Only three possible craters have been recognized in the million-square-kilometre region that has been examined.

By courtesy of National Aeronautics and Space Administration

Figure 4: *Chaotic terrain full of jumbled ridges unlike anything found on the Moon or on the Earth.* Detail from Mariner 6 photograph, frame 14.

A big surprise in the Mariner pictures was the discovery of featureless terrain in the bright region called Hellas (see Figure 5). The surface appears structureless down to the limit of resolution and is devoid of craters. Hellas is a large, bright, roughly circular region, some 1,900 kilometres in diameter, due south of the prominent dark area Syrtis Major. The resolution limit of the high-resolution cameras was 300 metres, and no craters, ridges, etc., are seen on the floor of the region. An explanation of this phenomenon has not yet been forthcoming.

Feature-  
less terrain

A further important observation provided by the Mariner pictures is the absence of any indications of tectonic activity. There is no evidence for mountain ranges, folding, or volcanic activity at all in the pictures. This would seem to imply that the interior of Mars is considerably less active than that of the Earth.

The relationship between the classical canals and oases and features observed in the pictures is rather sketchy, but some oases, such as Juventae Fons and Oxia Palus, have been identified with single, large, dark-floored craters. Two canals, Gehon and Cantabras, appear to coincide with "quasi-linear" alignments of several dark-floored craters. Nix Olympica, discovered by Schiaparelli in 1879 and observed from the Earth to be associated with a brightening, suggestive of isolated peaks on which frost might condense or clouds might form, has been found to be a very large crater with a bright rim, or skirt.

By courtesy of National Aeronautics and Space Administration

Figure 5: *Featureless terrain in the region of Hellas.* The absence of details even at the highest resolution remains unexplained; lack of any disturbance of the region over millions of years is highly improbable. Mariner 7 photograph, frame 28.

**The composition of the surface.** The German-born U.S. astronomer Rupert Wildt seems to have been the first to have suggested the now popular idea that the surface of Mars might be made up largely of iron oxides. It is argued that the surface should be rich in iron, partly because the body of the planet is probably inactive and therefore undifferentiated, and partly because of the possibility of large meteoric influxes of iron-bearing material from the asteroid belt. A possible source of oxygen could be the photodissociation of water by ultraviolet light in the atmosphere (see below). Mars is therefore often visualized as a "rusty planet." This hypothesis has been tested by comparing the polarization properties of various iron oxides—limonite, goethite, hematite—with the observed dependence of polarization on the phase of the planet. The French astronomer Audouin Dollfus found that the observed dependence of the polarization of reflected light from the planet with phase is in good agreement with laboratory observations of pulverized limonite. Unfortunately, such comparisons are not unique, and it is difficult to draw specific conclusions. The variation of the reflectivity of the surface with colour contains information on the chemical nature and the microscopic state of the soil. The U.S. astronomers Thomas McCord and John B. Adams find from observational data that the mean reflective properties of the Martian surface are duplicated by pulverized, oxidized basalts. Probably the best that can be said is that the

photometric and polarimetric observations are not in conflict with the hypothesis of a surface consisting of an oxidized form of common terrestrial igneous rocks.

The mechanical state of the surface is similarly difficult to assess. It seems clear from polarization data and information on the rate of change of the temperature of the surface with time that the surface is covered, both dark and bright areas, with a layer of fine dust. In this respect the surface of Mars is probably much like that of the Moon. A number of features of the environment on Mars may imply significant differences in the micro-state of the surface from that of the Moon. The presence of an atmosphere should lead to effective aeolian erosion, that is, scouring by wind-borne particles; the rapid rotation of the planet compared to the Moon will make the process of thermal creep more effective on Mars than on the Moon; and finally, the presence of even minute amounts of water vapour in the atmosphere gives rise to the possibility that extensive regions of permafrost may exist on the planet. F.A. Wade and Jane de Wys have noted that in the presence of permafrost, freeze-thaw processes in the top layer may significantly modify the structure of the ground. The modification processes on Mars would presumably be similar to those that take place in cold regions on the Earth.

Possibility  
of  
permafrost

The presence of available water supplies on Mars is a matter of prime interest, and the suggestion that the Martian surface could support large areas of permafrost has been the subject of several investigations. The U.S. astronomers Robert B. Leighton and Bruce C. Murray, in a study of the thermal properties of the Martian surface, have included a discussion of the depth below the surface at which permafrost would be stable. They could not deduce the thickness of the frozen layer because factors such as the heat flow from the interior and the temperature gradient that supports it, the permeability of the surface soil, and, finally, the supply of water are unknown. Nevertheless, as water vapour is observed in the atmosphere, there must be a considerable supply. Leighton and Murray's numerical experiment showed that permafrost is likely to be present 40 centimetres below the surface above latitude 60° in the Southern Hemisphere and 20 centimetres below the surface at latitude 60° N. The ground near the North Pole would be entirely and permanently frozen.

It has been shown that liquid water is not necessary for the formation of permafrost. In a laboratory experiment simulating the Martian environment, the U.S. astronomer Richard S. Young and his collaborators have demonstrated the formation of permafrost in porous soil overlain with an atmosphere containing small amounts of water vapour. If the Martian soil is sufficiently porous, water vapour carried poleward by the atmosphere will tend to be trapped in the soil.

Thermal creep operates on slopes and is the motion of surface material that may be induced by alternate expansion and contraction caused by rise and fall of the temperature. This process may be expected to erode crater rims and other sharp surface features. It has been estimated that the rate of movement of granular surface material down a 17° slope on Mars could be as high as 1.5 centimetres per year.

**Surface relief: topographic features.** Early visual observers of the planet concluded that high mountain ranges of the terrestrial variety were not present on Mars. In 1906 Percival Lowell calculated that mountains with heights greater than 0.8 kilometres would have been detected as irregularities at the terminator, a probable overstatement; C.W. Tombaugh has revised the value to 8.4 kilometres. The evidence against mountain building from the Mariner pictures also seems clear, even though the coverage of the planet is far from complete. There are no signs of orogenic activity in the pictures.

There is, however, plenty of evidence for topographic relief on the surface of the planet on the continental scale. Elevation differences of as much as 10 kilometres are now known to exist over scales of thousands of kilometres. Thus, the differences in elevation, while large, only imply gentle slopes on the surface.

The history of the search for large-scale topographic relief is fascinating and has an ironic twist. In a sense, the search for large elevation differences grew out of the controversy over the nature of the dark areas. The proponents of the "vegetation" theory of the dark areas considered them to be low lying and hence warmer, moist, and therefore more conducive to life. The temperatures of dark areas are indeed a few degrees warmer than surrounding bright areas. The opponents of the above hypothesis preferred to attribute the temperature of dark areas and their curious ability to change their appearance on a seasonal basis to inorganic causes. The fact that they are warmer is simply a result of their being darker, which is just another way of saying that they absorb more energy from the Sun. Their apparent ability to change their appearance is presumed to be the result of the transport and deposition of small dust particles by the prevailing winds. The opponents of the vegetation hypothesis supposed the dark areas to be elevated with respect to the bright areas.

In 1965 the U.S. astronomer Ronald A. Wells noticed that white clouds that tended to form and remain stationary over certain bright areas were aligned with the boundaries of adjacent dark areas. Wells thought of these clouds as lee clouds formed in the prevailing wind as it crossed the dark areas. He concluded that the latter must therefore be high ridges. Further circumstantial evidence was provided by the U.S. astronomers Carl Sagan, James B. Pollack, and Richard M. Goldstein in 1966. They found that surface regions with high radar reflectivity were correlated with dark areas. The regions of high reflectivity were not actually coincident with the dark areas but were always somewhat displaced in longitude. The conclusion that the above authors reached was that the dark areas were elevated regions with very low slopes. The slopes had to extend over extremely large distances, which implied that elevation differences of about 10 kilometres existed.

The 1967 and 1969 oppositions provide the final surprising chapter to this story. In 1967 precise radar-ranging methods were used by Gordon H. Pettengill and his collaborators to scan a narrow swath of the planet along latitude 22° N. The timing of the radar echoes led to the first direct and conclusive evidence that large elevation differences in fact did exist on the surface, but, ironically, there was little correlation between the dark areas and elevation. In 1969 the radar was extended to more southerly latitudes, and good data from this source is now available between the Equator and 22° N. Another investigation using an entirely different technique has confirmed and extended these measurements. The U.S. astronomers Michael J.S. Belton and Donald M. Hunten have made extensive measurements of the amount of carbon dioxide gas in the atmosphere at hundreds of points on the disk from latitudes 25° S to 40° N. If small meteorological effects are neglected, the amount of carbon dioxide is closely related to the relative elevation of the surface. These observations have therefore also provided a map of surface topography.

Radar  
reflections

Elevation  
correlated  
with  
amount of  
carbon  
dioxide  
above  
surface

The major topographic features that have been found on the planet are as follows. The dark area Syrtis Major is part of a high ridge rising 10 kilometres above the surrounding areas and stretches for at least 4,000 kilometres north-south across the Equator. The Arabian Desert is an extensive basin running parallel to the Equator and encompassing 90° in longitude. The highest area of the planet is the bright desert Tharsis, which appears to be a vast dome 4,000 kilometres in diameter. Mare Acidaliu, the only major dark area in the Northern Hemisphere, coincides with a shallow depression leading southward.

**Temperatures.** The temperature environment on Mars is considerably more rigorous than on the Earth for two reasons: first, the greater distance of Mars from the Sun means that less heat is received from it; and, second, the extreme thinness and composition of the atmosphere are important factors in allowing much greater diurnal fluctuations in temperature. On Earth, the atmosphere has sufficient opacity in the thermal infrared to block and

slow down the rate of energy loss from the surface at night, limiting the lower extreme in temperature. On Mars, the tenuous carbon dioxide atmosphere is unimportant in this respect, and greater differences between night and day temperatures occur at the surface.

The mean temperature, averaged over the entire planet, can be estimated from the solar input and well-known radiation laws. It is found to be about 210° K, and this value has been confirmed by measurements of microwave radiation. The microwave measurement gives an average temperature that is not the instantaneous temperature of the surface but applies to some level a short distance below the surface where the diurnal variations of temperature have been damped out. The measurement is important as it indicates that there are no large sources of heat inside the planet.

Temperature changes

The actual temperature of the surface on the daylight side and just across the terminator have been measured most recently in 1954 using the 200-inch Palomar telescope and in 1969 using an infrared radiometer aboard the Mariner 6 and 7 spacecraft. In the equatorial regions the diurnal variation of temperature is found to be about 100° K. Rising rapidly at first during the early morning to a maximum of roughly 290° K at about 1300 hours and then dropping off rapidly again in the afternoon, the temperature is above freezing (273° K) for about three to four hours during the day. Temperatures fall off at higher latitudes, dropping suddenly on the polar caps to about 150° K. The dark areas are about 10° K warmer than the brighter areas. No observational data is available about nighttime temperatures, but theoretical thermal models that correctly predict the postnoon, daytime maximum indicate that the equatorial nighttime temperature will have fallen to about 175° K by dawn. The above equatorial temperatures refer to the conditions at the 1954 opposition, and because of the ellipticity of the Martian orbit the maximum daytime temperature can be expected to vary by about 30° K from perihelic conditions to those at aphelion. The 1954 opposition was approximately midway between perihelion and aphelion.

#### THE POLAR CAPS

The general seasonal behaviour of the polar caps is one of the more elaborately documented phenomena on Mars. Consider first the southern polar cap. In early spring the cap has its greatest dimensions and stretches from the pole to a latitude of about 50° S. As spring proceeds, the cap sublimates and begins to recede at a rate of about 1° of latitude every five days. During this time the edge of the cap takes on a ragged appearance. Eventually, gaps appear that break the cap into well-defined fragments. This process is repeated each year, and the location of the fragments is always the same. As the polar snow recedes, a dark-blue band, first noted by Wilhelm Beer and Johann von Mädler in 1830, is seen at the edge of the cap. This dark collar follows the recession of the cap. One-third of the Martian year later the cap has disappeared. A brief interlude of atmospheric clarity then follows, which terminates in early fall with the rapid formation of the polar hood. This is an atmospheric phenomenon and consists of haze and clouds that vary from day to day. Occasionally, the hood is sufficiently transparent in the red region of the spectrum to allow photographs of the new polar cap forming beneath it to be taken. The hood is far more extensive than the cap itself and has been reported to extend to within 35° of the Equator.

The polar hood

The behaviour of the northern polar cap is similar, although not exactly the same in detail. The differences are mainly due to a combination of the effects of the lengths of the seasons and the variation in distance from the Sun. Although the northern summer is longer than the southern, the northern cap never entirely disappears because the planet is at a greater distance from the Sun during the northern summer, and, correspondingly, less heat is received from the Sun. Further minor differences between the phenomena in the Northern and Southern Hemispheres, such as in the characteristics of the dark collar and the behaviour of the polar hood, have been described by Clyde W. Tombaugh.

The nature of the polar caps is a controversial subject that may soon be reconciled. An early hypothesis was that they were simply water ice. This view can be traced back to William Herschel, who imagined the polar caps of Mars to be just like those on Earth. In 1898 the Irish scientist George Johnstone Stoney pointed out that this was not necessarily so and suggested that the caps might consist of frozen carbon dioxide, though this idea remained speculation until 1947, when the U.S. astronomer Gerard P. Kuiper discovered CO<sub>2</sub> in the planet's atmosphere. The idea was particularly attractive because no water vapour had then been detected in the atmosphere. Nevertheless, Kuiper in 1948 was persuaded that the caps had reflection spectra that were characteristic of water ice rather than CO<sub>2</sub>. Similar spectra, published by the Soviet astronomer V.I. Moroz in 1966, indicated the same result, and the idea that the polar caps were predominantly water ice became widely accepted. But in 1966 R.B. Leighton and B.C. Murray published an important numerical study of the thermal environment on Mars, which throws considerable doubt on the water ice hypothesis. The calculations, although based on gross simplification of the actual conditions on Mars, indicated that carbon dioxide gas would freeze out of the atmosphere. Moreover, the computations showed that polar caps so formed would behave in a way similar to that which was observed.

Data from the Mariner 6 and 7 spacecraft now appear to have resolved the problem (see Figure 6). On board the spacecraft were an infrared radiometer that could measure the temperature of the surface and an infrared spectrometer that could look with high spatial resolution for characteristic features in the spectrum of the reflected light from the polar cap without the interference of absorption in the Earth's atmosphere. The radiometer experimenters reported that, as the field of view of their instrument swept over the polar cap, the temperature dropped to within 2° K of the predicted temperature for frozen carbon dioxide. The discrepancy may be easily accounted for, thereby demonstrating that a polar cap composed of CO<sub>2</sub> would be stable at the time it was observed. If the measured temperature had been, say, 10° higher, the CO<sub>2</sub>-ice hypothesis would have been untenable. The infrared spectrometer provided conclusive evidence that frozen CO<sub>2</sub> does exist on the surface. The spectrum contained features at 3.0 and 3.3 microns, which are characteristic absorptions of solid CO<sub>2</sub>.

The above evidence, plus the calculations of R.B. Leighton and B.C. Murray, has led astronomers to conclude with considerable confidence that the polar caps are predominantly solidly frozen CO<sub>2</sub>. The presence of frozen water is not entirely excluded, for small amounts of water vapour have been observed in the atmosphere, and the polar regions will progressively collect such water. It is most likely, therefore, that the polar caps also contain some water ice. An additional possibility is that the northern polar cap, which never completely disappears, may have a solid core of water ice. Samuel Glasstone has made an estimate of the depth of the snowfall at the South Pole on Mars based on R.B. Leighton and B.C. Murray's calculations and finds that the average depth might be some three to five feet.

It has been observed and mentioned above that the caps fragment as they recede so that certain regions in which the covering remains are left isolated. Presumably, these regions are colder than the average, and the Martian snow is able to endure on them. The Mountains of Mitchel, named after their discoverer, Ormsby MacKnight Mitchel, form one such fragment in the Southern Hemisphere. The naming of this and other such features as mountains is based on a direct analogy with the Earth, where the tops of high mountains are cold regions and can support snow throughout the year. In 1967 it was pointed out that this reasoning may be quite fallacious in the case of Mars and that the area known as the Mountains of Mitchel may actually be a low-lying depression. The argument that leads to this peculiar state of affairs centres on the extreme thinness of the Martian atmosphere. It has, unlike the terrestrial atmosphere, so

Nature of the Mountains of Mitchel

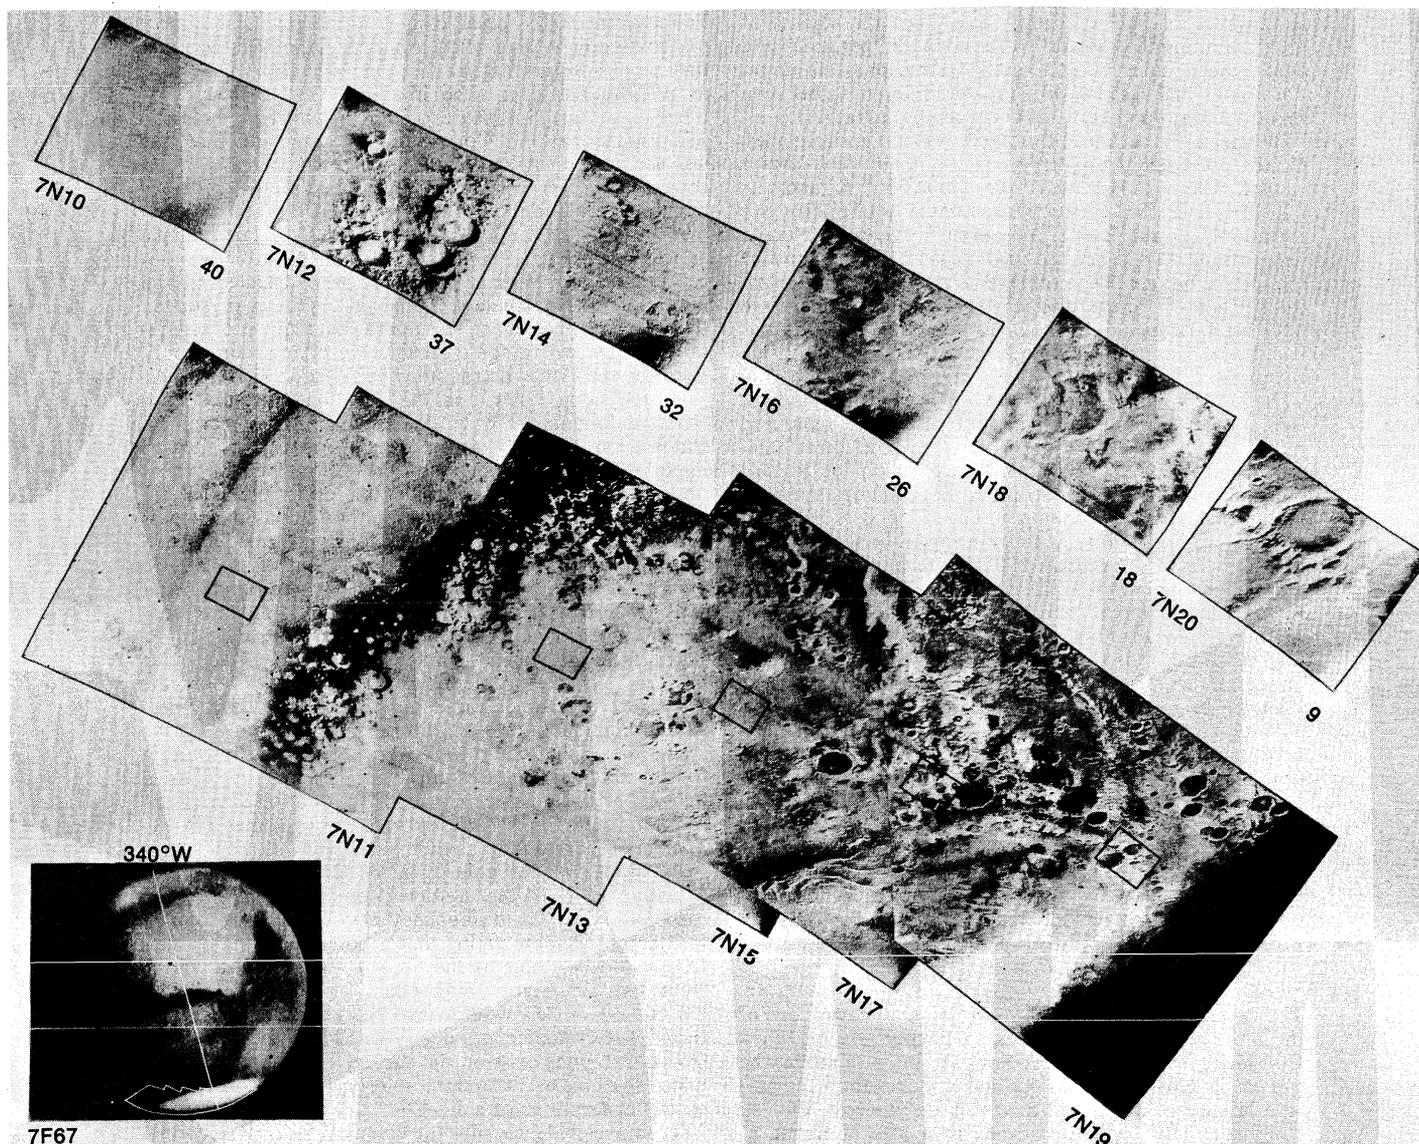

Figure 6: Mars.  
(Centre) Mosaic from Mariner 7 frames of a region close to the edge of the south polar cap showing "snow," probably frozen carbon dioxide, lying in shadowed areas and on high ground. Outlined areas are enlarged above, and coverage relative to the planet and the central meridian (white line) are indicated bottom left.

By courtesy of National Aeronautics and Space Administration

little heat capacity and ability to block outgoing thermal radiation that temperature probably plays little role in the determining of the equilibrium of carbon dioxide snow; the equilibrium will be determined by the overlying pressure of carbon dioxide in the atmosphere. Therefore, regions on which snow lingers will be those of high atmospheric pressure—*i.e.*, low-lying areas and valleys. At present there is little observational evidence for or against this idea, but the theoretical argument seems quite sound.

#### THE ATMOSPHERE

**Basic atmospheric data.** The lower atmosphere is thought to consist mainly of carbon dioxide gas that has been released slowly from the crust and interior over times comparable with the lifetime of the planet. Water vapour and carbon monoxide have been positively identified by spectroscopic means, but only in very minute quantities. Small admixtures of spectroscopically inert gases, such as argon, also may be present in the atmosphere.

The characteristic temperature of the atmosphere, averaged over the illuminated (daytime) side, is roughly 200° K. This is colder than the mean temperature of the underlying surface, about 250° K. The difference is due to the

presence of temperature gradients in the lower atmosphere that have an average value of about 4° per vertical kilometre.

The atmosphere is very thin by terrestrial standards, the surface pressure being less than one-hundredth that on the Earth. In spite of its thinness, the Martian atmosphere is observed to support clouds. One variety, the so-called yellow clouds, are most reasonably explained in terms of small dust particles. These clouds can be widespread and have been observed to move at high speeds (up to 100 kilometres per hour), indicating that the atmosphere is capable of violent large-scale motions. The study of the dynamics of planetary atmospheres is relatively new, but some highly sophisticated numerical simulations of the Martian atmosphere have been performed and are briefly reviewed below.

The atmospheric data returned by the successful Mariner 4 flyby of Mars in 1965 led to radical changes in the understanding of the Martian atmosphere. More insight is to be expected from the successful Mariner 6 and 7 experiments when the final data is released. Mariner 4 also returned the first sounding of a planetary ionosphere (other than that of the Earth) and thereby launched the special subject of Martian aeronomy, the study of the Martian upper atmosphere.

**Composition and surface pressure.** Before 1947 there had been no chemical identification of any of the gases in the Martian atmosphere. Its composition was postulated by a variety of arguments, including analogies with the Earth, spectroscopic upper limits on various gases, and the kinetic theory applied to escape of gases from a planetary atmosphere. The atmosphere was presumed to be composed largely of nitrogen. Between 1925 and 1963 the surface pressure was estimated by photometric measurements and arguments based on the scattering power of the atmosphere and the amount of polarization that it could induce in the reflected solar light. In 1954 Gérard de Vaucouleurs discussed all of the available data and concluded that the surface pressure was  $85 \pm 4$  millibars, about one-tenth of the atmospheric pressure on Earth. The quoted error illustrates the confidence that was generally attributed to this determination. It is now known that the result was incorrect, being too high by a factor of about 10. The above methods led to an incorrect result for reasons that are now fairly well understood, and it was simply a misfortune that apparent agreement between results from several independent methods produced overconfidence in the value quoted above.

First  
detection  
of CO<sub>2</sub>

The first gas to be identified, carbon dioxide (CO<sub>2</sub>), was detected in 1947, as noted above, by Gerard P. Kuiper, who used a lead sulphide detector, developed during World War II, and what were then new techniques in infrared, astronomical spectroscopy. It was generally believed at this time that the surface pressure was about 100 millibars, and Kuiper's spectra appeared to imply that carbon dioxide was only a minor constituent. Estimates put the CO<sub>2</sub> content at no more than 1 or 2 percent of the total atmosphere. It was subsequently pointed out that Kuiper's spectra were consistent with an essentially pure CO<sub>2</sub> atmosphere with a surface pressure of 13 millibars.

The 1963 opposition brought new understanding of the Martian atmosphere. A group of three extremely faint lines near 0.87 micron was discovered in the Martian spectrum. They were immediately identified as being due to carbon dioxide, a gas already known to exist in the atmosphere. What was surprising about the three features was that, according to what was then believed to be the atmospheric composition, they should not have been visible at all. Their discovery showed that something was wrong about the established ideas.

The main result of this investigation was to reduce the estimate of the atmospheric surface pressure by a factor of nearly 4, to 25 millibars, and to show that CO<sub>2</sub> could be a major constituent of the atmosphere. The study also had the effect of exposing the uncertainties in the photometric and polarimetric methods that had been used previously. Considerable uncertainties, however, still remain in this work, and the succeeding oppositions in 1965, 1967, and 1969 found many groups of observers supplying new techniques to the problem of obtaining spectra of Mars. These efforts were supplemented in 1965 and again in 1969 with flyby data from Mariner 6 and 7, which proved the Martian atmosphere with radio waves. Additional unique data was obtained from the infrared and ultraviolet spectrometers on board the spacecraft.

Mean  
pressure of  
atmos-  
phere

The net result of ground-based spectroscopic investigations into the amount of CO<sub>2</sub> in the planet's atmosphere is that the mean surface partial pressure of the gas is now, in the early 1970s, set at  $5.5 \pm 0.6$  millibars. This figure is based on many diverse experiments on three separate bands of CO<sub>2</sub>. A considerable part of the estimated uncertainty is due to the imprecision of laboratory data on the CO<sub>2</sub> bands, a condition that can in due course be corrected. Such diverse techniques as photographic spectroscopy, photoelectric spectrophotometry, Michelson interferometry and Fabry-Perot interferometry have been used in CO<sub>2</sub> studies and produce comparable results.

The amount of CO<sub>2</sub> is comparatively large: it is nine times the amount currently present in the Earth's atmosphere, but considering the tremendous amount of CO<sub>2</sub> that has been cycled through the Earth's atmosphere and is now chemically locked in terrestrial, sedimentary rocks, the

Martian CO<sub>2</sub> content represents slightly less than 1/1000 of that on the Earth. These figures represent a rather ill-defined mean of the surface partial pressure. The amount of CO<sub>2</sub> above any specific point on the surface may differ considerably from it because of the large variations in altitude in the surface topography. Michael J.S. Belton and Donald M. Hunten, for example, found that they were unable to detect any CO<sub>2</sub> at all over the midpart of Syrtis Major, while the adjacent bright area Libya showed more than the average amount. Further, the amount of CO<sub>2</sub> in the atmosphere may vary considerably over the Martian year because of the alternate deposition and release of CO<sub>2</sub> from the polar caps. The numerical study conducted by Robert B. Leighton and Bruce C. Murray predicts that the total amplitude of the variation should be about 38 percent of the mean pressure, a very large change. Attempts have been made to detect this observationally, but the available data are too crude to make any meaningful deductions.

Spectroscopy has not been able to provide a measure of the total atmospheric pressure with any great accuracy because of technical difficulties in dealing with a spectrum integrated across the entire illuminated disk of Mars. The radio occultation experiments performed on the Mariner spacecraft are much more reliable for this purpose. Data from six occultations are now available, two from each Mariner flyby mission. As the spacecraft disappears behind the limb of the planet as seen from the Earth, the radio link between the spacecraft and the Earth cuts through the atmosphere. Corresponding changes in intensity and phase occur in the radio signal, which can be interpreted in terms of atmospheric and ionospheric properties.

A reversed but otherwise similar situation occurs when the spacecraft reappears from behind the planet at the end of the occultation. The interpretation is somewhat dependent on the assumed composition of the atmosphere, but it appears that the mean atmospheric pressure is five to seven millibars. A full analysis of all the available data pertaining to the mean atmospheric pressure on Mars is not yet available, but a value of six millibars is not likely to be changed much.

In summary, it is clear that carbon dioxide is a major constituent of the Martian atmosphere (see Table 4). At

**Table 4: The Composition of the Martian Atmosphere**  
(fraction by volume)

Carbon dioxide	80-100 %
Inert gases (argon, neon, etc.)	0-20 %
Nitrogen	<1 %
Oxygen	<0.3 %
Carbon monoxide	0.08 %
Water vapour*	0.04 %

\*Variable and unevenly distributed in the atmosphere.

one extreme the atmosphere may be essentially pure CO<sub>2</sub>, while at the other the fraction of CO<sub>2</sub> by weight could be no less than about 80 percent. In the latter case the balance of the atmosphere could be argon or perhaps neon. Nitrogen is also a possibility, but the ultraviolet-spectrometer experiment of Charles A. Barth and his associates on Mariner 6 and 7 showed no indications of any of the characteristic emissions of the nitrogen molecule. Barth has indicated that the amount of this gas in the atmosphere must be very small, less than 1 percent of the total atmosphere. Two other constituents that have been detected in the lower atmosphere are water and carbon monoxide. Only trace amounts are present, and the water content is highly variable. The U.S. astronomer Lewis D. Kaplan finds that the amount of carbon monoxide is about 0.08 percent of the atmosphere. The CO molecule was discovered in the infrared spectrum of Mars generated by the Michelson interferometer of Pierre and Janine Connes. The detection of oxygen has been the subject of many spectroscopic studies, but oxygen has not been positively identified. In 1968 Michael T.J.S. Belton and Donald M. Hunten reported the tentative

The  
"water  
problem"

identification of oxygen at the 0.3 percent level, but this observation has not yet been confirmed or denied.

The "water problem" is intimately connected with the possibility of life on the planet. Water in the Martian atmosphere was first identified in 1963 by Lewis D. Kaplan, Guido Münch, and Hyron Spinrad from the same photographic plate that yielded their important discoveries about CO<sub>2</sub>. The investigation of water content is made exceedingly difficult because of the masking of weak planetary lines by strong absorptions due to water vapour in the Earth's atmosphere. The researches since 1963 by Ronald Schorn and others indicate that the atmospheric water content on Mars is always small. It is also variable and may show a seasonal dependence, though this latter behaviour has not been firmly established. The distribution of water vapour with respect to the Equator, however, has definitely been shown to be asymmetric, more water vapour being present in the summer hemisphere. Water vapour characteristically appears in amounts corresponding to about 20 or 30 microns of precipitable water. These unfortunately chosen units (which are traditional) correspond to a mean atmospheric-fractional content of about 0.04 percent. At the mean temperature of the Martian atmosphere, this corresponds to a relative humidity of about 50 percent, which is not particularly dry. Because the near surface air temperatures are considerably higher than the mean, the daytime humidity near the surface will be far lower and the lower air extremely dry.

Atmospheric water vapour molecules can be destroyed quite rapidly on Mars through the action of ultraviolet light as a result of inefficient shielding by CO<sub>2</sub> and the lack of ozone in the atmosphere. The light hydrogen atoms formed in the process then diffuse up through the atmosphere and ultimately escape to space. This produces a net gain of molecular oxygen in the atmosphere. Donald M. Hunten and Michael B. McElroy from the United States find that this process may explain the observed hydrogen emission in the upper Martian atmosphere, measured by Charles A. Barth with the Mariner 6 and 7 ultraviolet spectrometer. Other conclusions in Hunten and McElroy's analysis are that dissociation and the accompanying reactions could remove the entire observed amount of water vapour in the atmosphere in the relatively short time of 100,000 years, implying a continuous source of replacement water. The destruction of water will leave behind a considerable amount of oxygen which presumably oxidizes the surface material. This latter process would be facilitated by the action of ultraviolet light producing ozone and atomic oxygen near the surface.

**Temperature.** The vertical structure of the Martian atmosphere—that is, the relation of temperature to altitude—is determined by a complicated balance of radiative, convective, and advective energy transport. In the upper atmosphere thermal conduction also is important. A considerable amount of effort has been invested in predicting the typical structure that would occur on Mars and its dependence on the time of day.

A primary factor is the composition of the atmosphere, which is almost pure CO<sub>2</sub>. This can quickly radiate away its heat so that the atmosphere can respond rapidly to changes of insolation and changes in ground temperature, unlike the Earth's atmosphere, in which 70 percent of the gas is radiatively inert and does not respond rapidly to thermal imbalances. Thus, on Mars, large diurnal fluctuations are predicted for the lower atmosphere. At nighttime the lower atmosphere cools off quickly, producing strong inversions in the temperature profile and strong diurnal components to the local winds. On Earth this type of inversion is limited to the first tens of metres near the ground and drives only minor local winds, such as sea-shore and land breezes.

In 1968 the U.S. astronomers Richard Goody and Peter Gierasch described the probable conditions in the equatorial lower atmosphere as follows: near the ground, in the first few metres, there is a turbulent boundary layer marked by very large temperature gradients. Temperature drops of as much as 70° K can take place in this

layer. The noontime air temperature a few metres from the ground is always much lower than the ground temperature. (This phenomenon also occurs on the Earth.) Above the boundary layer, up to an altitude of about five kilometres, the atmospheric temperature undergoes large diurnal variations in an attempt to follow the diurnal changes in the ground temperature. At night the air is stable, but in daytime the region is characterized by strong turbulence. Above five kilometres the temperature varies much less and up to a height of about 15 kilometres falls off only at about 5° per kilometre. This region is turbulent in the daytime and stable at night. The maximum height reached by the daytime turbulence is about 15 kilometres, and this height is identified as the Martian tropopause. Michael B. McElroy has shown that from 15 to about 90 kilometres the atmosphere is nearly isothermal at a temperature of about 160° K. Above 90 kilometres, the mesopause, the temperature begins to rise again at a rate of about 4° per kilometre owing to the deposition of solar energy in the tenuous higher atmosphere.

The mean temperature of the daytime atmosphere has been measured at 200° K from the distribution of the absorption in the rotational structure of CO<sub>2</sub> bands. The same bands also show an indication of the temperature gradient in the lower atmosphere.

More complete data on the vertical structure at six locations on Mars are available in preliminary form from the radio occultation experiments on the Mariner spacecraft. These data appear to be in reasonable agreement with the theoretical description given above.

**Atmospheric dynamics.** Forecasting the weather by means of numerical models of the atmosphere is one of the largest branches of meteorology. In recent years, some of the techniques for predicting and following the dynamical state of the Earth's atmosphere have been applied to Mars. As the terrestrial techniques are generally quite reliable and bring out quite accurately the overall dynamical properties of the Earth's atmosphere, reasonable results can be expected when the same techniques are applied to the Martian atmosphere. Atmospheric motions on Mars seem to be far more violent than on the Earth for reasons connected with the thinness of the atmosphere, its ability to adjust rapidly by radiative exchange of energy to local conditions of insolation, the lack of oceans with their large storage capacity for heat, and the fact that a large fraction of the atmosphere is deposited and released from the polar caps in spring and fall.

In the winter hemisphere the zonal wind speeds in the free atmosphere reach 250 kilometres (about 160 miles) per hour in a westerly direction. The winds in the summer hemisphere are in direct contrast, being in the opposite direction with a speed of, at most, 100 kilometres (about 63 miles) per hour in equatorial and low latitudes, falling off to light speeds of perhaps 18 kilometres (about 11 miles) per hour at midlatitudes and higher. Because of the deposition of CO<sub>2</sub> on the winter polar cap, there is a net transport of material across the Equator, and meridional wind speeds may reach 33 kilometres (about 22 miles) per hour across the Equator. At the time of the equinoxes the wind pattern begins to resemble that seen in the Earth's atmosphere. The zonal winds in midlatitudes are westerlies in both hemispheres, with average speeds of 70 to 110 kilometres (about 45 to 70 miles) per hour. The equatorial region is marked by gentle easterly winds. The meridional wind component is very small.

This picture of motions in the Martian atmosphere is tentative; it outlines the overall characteristics in a very rough way. In particular, the calculation omits any consideration of the large-scale topography of the surface that has recently been mapped by radar and spectroscopic techniques.

#### THE INTERIOR OF MARS

Little is known about the interior of Mars. Models of the interior of Mars have been constructed, as they have for the other terrestrial planets, on the basis of the mass and dimensions of the planet (or, alternatively, its mean densi-

Wind  
speeds

ty), and the dynamical ellipticity of the planet. This latter quantity is a measure of the difference in the moments of inertia of the planet along and perpendicular to its axis of rotation. It is therefore a measure of the internal density distribution in the planet. The dynamical ellipticity generally differs from the optical ellipticity, which can be measured directly (although with great difficulty) from the image of the planet. The latter is of little use in discussion of the internal structure because its value may be strongly influenced by unrelieved strains and distortions in the upper crust of the planet. Physical data on the equation of state of materials (*i.e.*, their response to changes of pressure and temperature) are also required. In the discussion of the terrestrial planets these kinds of data are based on what is known of the behaviour of terrestrial material.

There are two types of simple models. In one, the internal composition can be different from that of the Earth: the planet is visualized as being made up of certain proportions of silicate and metallic (iron) phases, and the proportions are presumed to vary from one planet to the next. The second type of model constrains the composition to be the same in all cases. The observed differences in the mean density and dynamical ellipticity are then presumed to be governed by strong phase changes in the material at certain pressures and temperatures in that material. The general conclusion from the many studies that have been carried out is that Mars possesses at most a very small core and is far more homogeneous than the Earth. The work of the U.S. astronomers Robert L. Kovach and Don L. Anderson would indicate that the Martian interior could also be similar to an undifferentiated Earth—*i.e.*, a planet with the same mean density as Earth but with no core—and satisfy the observational constraints.

It is effectively impossible to make estimates of the temperatures in the interior of the planet or of its thermal history because of the absence of factual information. Nevertheless, the consensus appears to be that the planet does not have a liquid, metallic core. This is borne out by the observed absence of a magnetic field. Mariner 4 carried a magnetometer, which implied that the dipole magnetic field on Mars was less than that of the Earth by a factor of 0.0003.

The interior of Mars appears, therefore, to be dormant. This is supported by circumstantial evidence from the Mariner pictures on which no obvious signs of tectonic activity on the planet have been found.

#### THE SATELLITES

The two satellites of Mars were discovered during the 1877 opposition by Asaph Hall of the U.S. Naval Observatory. Phobos, the inner and larger of the two, was discovered six days after the discovery of the fainter outer moon, Deimos. The orbit of Phobos is unique in that it is extremely close to the planet. At a mean distance of 2.8 planetary radii from the centre it approaches the so-called Roche limit of 2.4 planetary radii. This limiting distance corresponds to the range at which gravitationally bound bodies of the same mean density as the planet could be broken apart by the gravitational force of the planet. The orbital period of Phobos about Mars is 7 hours and 39 minutes. This short period means that the moon travels around Mars twice in a Martian day. Thus, an observer at a suitable point on the planet would see Phobos rise and set twice in a day.

Not all observers on the surface of Mars could see the moons, however, because of their proximity to the planet and their near Equatorial orbits. At latitudes greater than approximately 70° north or south, for example, Phobos would never be seen.

The dimensions of the satellites are difficult to judge from Earth-based telescopes because they are too small for their disks to be discerned. The area of the object is commonly estimated from the amount of light that it reflects. This procedure is uncertain to the extent that it requires an assumption about the moon's albedo; *i.e.*, its ability to reflect light. Nevertheless, the rough diameters of Phobos and Deimos have been estimated in this way at

16 and 10 kilometres, respectively. The size and shape of Phobos can now be put on a more satisfactory basis because the satellite was photographed passing between Mars and the Mariner 7 spacecraft. The shape of the satellite was resolved and found to be noticeably elongated in the plane of its orbit. The ratio of maximum to minimum diameter is at least 1.3, the apparent dimension being about 18 × 22 kilometres. The albedo of the satellite, 0.065, is therefore lower than was expected and turns out to be the lowest known in the solar system. To an observer close up, the surface of the satellite would appear to be black.

The discovery of the satellites was of considerable importance because the period of their motion about the planet provides basic information on the mass of the parent planet. The most accurate estimates of the mass are now derived from the orbit of the Mariner flybys. Additional information on the distribution of mass in the interior of Mars can be obtained from the rate of recession of the nodes of the satellite's orbit. This information leads to the specification of the dynamical ellipticity discussed in the previous section.

#### THE QUESTION OF LIFE ON MARS

Is life present on Mars? This question can be answered only in the most speculative terms in the light of present knowledge of the planet. Nevertheless, the possibility of life establishing itself on Mars and propagating can be discussed in a qualitative way. The arguments can be conveniently arranged as answers to the following series of simple questions: (1) Is there any evidence for life in the available observations of Mars? (2) Could terrestrial life forms propagate under present conditions on Mars or under probable conditions in the past? (3) Are there any simple physical modifications of terrestrial life processes that would allow terrestrial life forms to function on Mars? Positive responses to all these questions, even excluding any direct evidence for specific life forms, would amount to high probability for life being present on the planet but would not certify its presence. A direct demonstration that life exists on Mars will probably not be possible without a landing on the planet and direct sampling of any existing life forms.

Life has been defined in a general, concise way by the U.S. biologist Norman H. Horowitz: "... living organisms are systems that reproduce, mutate, and then reproduce their mutations." The latter property, a necessary condition for the evolution of organic life forms, does not concern us here, but a search for evidence of reproduction and the ability to grow among the observations of Mars can be made. The pertinent factors are: (1) the wave of darkening, (2) the ability of dark areas to recover after apparent obliteration by Martian dust storms, (3) seasonal changes in colour of certain regions, (4) long-term changes in the markings, (5) a very weak spectral feature at 3.45 microns recorded as having been observed in the spectra of dark areas, and (6) the amount of water present on Mars. The question whether or not oceans were ever present on the planet is also important. The famous but now discredited Martian canal system historically played a central role in the concept of the possibility of intelligent life on Mars. The wave of darkening and colour changes that propagate in the dark areas across the planet as the southern polar cap disappears might be caused by the growth of Martian flora stimulated by the northern transport of water vapour released from the southern polar cap, but many of the phenomena can also be explained in terms of purely mechanical and meteorological processes.

The reported observations by the U.S. astronomer William M. Sinton of the spectral feature at 3.45 microns, which appears to be present only in the spectrum of dark areas and is listed above, is sometimes quoted as evidence for life on Mars. Absorption near this wavelength is a characteristic of all organic molecules and is connected with the fundamental vibrations of the carbon-hydrogen bond in such molecules. No alternative identification for this absorption has been offered, but a review of Sinton's evidence gives little comfort to those

Martian phenomena pertinent to the determination of possible life

who would accept this observation as a demonstration that organic material is abundant in the dark areas. Absorption features actually appear on Sinton's spectra at 3.69, 3.58, and 3.45 microns. The two strongest of these (which also occurred only in the spectrum of a dark marking) have since been identified as absorption by HDO (deuterated water) in the terrestrial atmosphere. The remaining "feature" at 3.45 microns has not been similarly explained, but, as the weakest of the three, it is unlikely that it would ever have been recognized as an independent feature in the spectrum on its own.

The identification of water on Mars and the possibility that oceans might once have existed on the planet is linked to the question of whether terrestrial life forms could propagate on Mars under present conditions or under probable conditions in the past. Liquid water is generally considered to have been essential in the development of life on Earth and is the primary solvent in the metabolism of terrestrial organisms.

Water has been observed on Mars, but only in the vapour form and then only sporadically and in extremely small quantities. It was pointed out above that the atmosphere near the surface should be extremely dry in the daytime. Liquid water is not likely to exist on the planet except under special conditions. Such conditions may exist below the surface. It has been conjectured that vast amounts of water may exist beneath the surface of the planet at high latitudes in the form of a layer of permafrost, and liquid water may have a transitory existence at the surface of this layer. Other regions may be moist if heat is supplied by near surface volcanic sources. Water vapour was discovered with the help of large telescopes and spectrographs with great difficulty. No other definitive evidence for water exists, although some observers of the planet have interpreted the observations of the dark-blue collar around the polar caps as they dissipate and the occasional dark spot left on the surface after the passage of a white cloud as evidence for the transitory presence of liquid water. This interpretation is not necessarily unique, however.

The photographs of the surface of Mars returned by the Mariner spacecraft have led to rather definite limitations on the amount of water that could ever have existed on the Martian surface. The prevalence of many large craters indicates that the surface is extremely old, perhaps primordial. There are indications of many products of powerful erosion processes that would be expected if large areas of the planet had been covered with water at any time, but in all probability no oceans have existed on the planet for the last 4,000,000,000 years. It is not possible to exclude the former presence of large quantities of water entirely. Conditions at the time of the formation of the planet are unknown (see below).

A further consideration in assessing the possibility of the establishment of organisms on Mars is the radiation environment at the surface. On the Earth we are protected from harmful radiation primarily by the presence of traces of ozone gas in the stratosphere. Ozone blocks out strong ultraviolet radiation that is capable of breaking up large organic molecules, the basis of living organisms. The Martian atmosphere does not contain detectable amounts of ozone gas, and the surface of Mars, therefore, is exposed to ultraviolet radiation. Some researchers discount this as an argument against the propagation of life, pointing out that pigmentation and the availability of sub-surface habitats could provide adequate protection.

The weight of the evidence appears to be against the development of terrestrial types of life on Mars. Nevertheless, life is extremely widespread on the Earth and can thrive under the most unlikely conditions. Plants (lichens) can live under conditions in which they are alternately frozen and thawed out. Other organisms thrive in hot springs, in strong acid solutions, and in powerful organic solvents. When such conditions are considered the Martian environment seems far less rigorous, and the evidence against the propagation of at least a sturdy and perhaps primitive form of life much less conclusive.

The possibility of the presence of intelligent life on the planet has been debated for a century, but an unequivocal

answer is not possible. It was pointed out that the remote detection of life on the Earth by photographic or visual means is extremely difficult. Pictures of populated regions of the Earth taken by satellite from distances as close as 300 miles show few obvious signs of life. On the other hand, it is now at last possible to dismiss the arguments that the canals are evidence of great intelligence on the part of the Martians.

Views regarding Mars have been considerably changed as a result of an almost continuous stream of scientific data from November 1971 through late 1972. Developments include the discovery of massive tectonic activity in the Tharsis-Phoenicis Lacus area. At least four large volcanoes have been found, each of which has very large caldera-like complexes at the summit. The feature on Nix Olympica is, for example, about 150 kilometres wide, much larger than any similar feature on Earth. Other major discoveries are an extremely long (greater than 2,000 kilometres), wide (200 kilometres), and deep (24 kilometres) rift valley, possibly indicating that internal convection is taking place within Mars. Also seen were many long, sinuous features which appear to be old river systems. Both polar caps have been found to have permanent cores that are likely to be frozen water. On arrival of the spacecraft Mariner 9, a major, planet-wide, dust storm was observed that obliterated the surface from view for about six weeks. The dust extended to altitudes of at least ten kilometres. Atmospheric dust has also been found to be responsible for the apparently "featureless" terrain in Hellas. Mariner 9 pictures have recorded craters in that region.

**BIBLIOGRAPHY.** H. STRUGHOLD, "Synopsis of Martian Life Theories," *Advances in Space Science and Technology*, 9:105-122 (1967); and F.B. SALISBURY, "Martian Biology," *Science*, 136:17-26 (1962), are two semi-technical discussions of the possibility that life forms can exist and propagate on Mars. SAMUEL GLASSTONE, *The Book of Mars*, NASA SP-179 (1969), provides a comprehensive semi-technical account of Mars data up to the flights of Mariners 6 and 7 in 1969; also has several enlightening chapters on possibilities for extraterrestrial life. N.W. CUNNINGHAM and H.M. SCHURMEIER, *Mariner-Mars 1969: Preliminary Report*, NASA SP-225 (1969); and R.B. LEIGHTON, "The Surface of Mars," *Scient. Am.*, 222:10, 26-41 (1970), describe the remarkable technical and scientific accomplishments of Mariners 6 and 7. G. DE VAUCOULEURS, *Physics of the Planet Mars* (1954), is a technical exposé of ground-based investigations of Mars up to about 1953, now very much out-of-date. Many of the conclusions have subsequently been shown to be fallacious; nevertheless, the book is valuable from a historical point of view. R.B. LEIGHTON and B.C. MURRAY, "Behavior of Carbon Dioxide and Other Volatiles on Mars," *Science*, 153:136-144 (1966), is a remarkable contribution to the understanding of the seasonal behaviour of the Martian atmosphere and its interaction with surface. E.C. SLIPHER, *The Photographic Story of Mars* (1962), is a complete photographic Earth-based study of Martian phenomena. ARTHUR KOESTLER, *The Sleepwalkers: A History of Man's Changing Vision of the Universe* (1959), gives a magnificent account of the role of Mars in the work of Brahe and Kepler.

(M.J.S.B.)

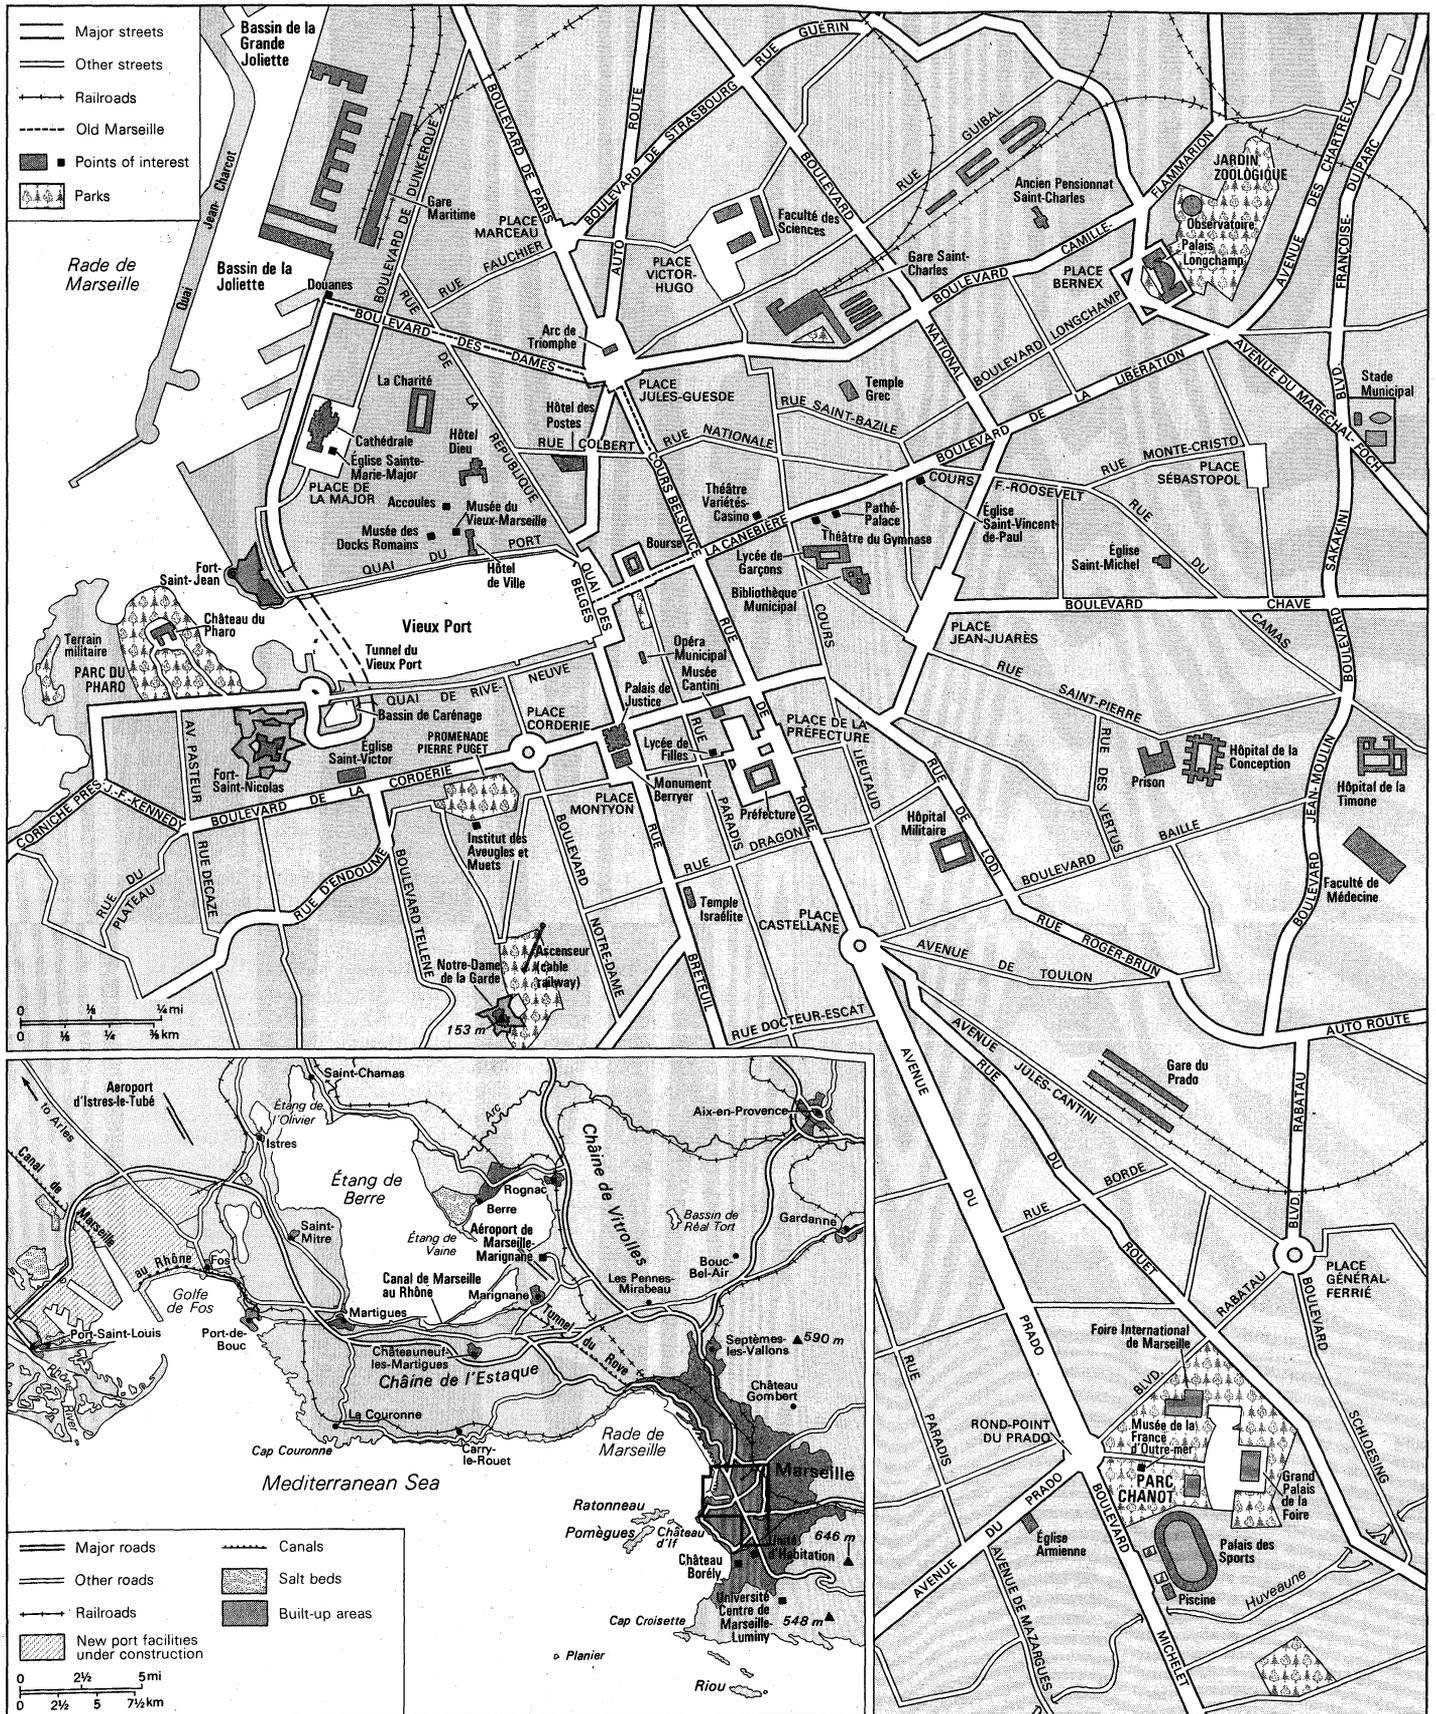

## Marseille

Founded more than 2,500 years ago, the port city of Marseille can look back over a history of vigorous independence asserted against central authority in a variety of forms: Julius Caesar, Louis XIV, the Revolutionary Convention, Napoleon Bonaparte, and Napoleon III. Frenchmen elsewhere, convinced that the Mediterranean climes of Provence could never be fully integrated into either the French realm or the Gallic spirit, long looked upon Marseille as a sort of folkloric institution: a place of comic anecdote and dialect, with a seasoning of picturesque criminality; a place where the citizens played a peculiar form of outdoor bowling known as *pétanque* and concocted the glorious garlic- and saffron-flavoured fish stew known as *bouillabaise*.

However much the proportions of fact and myth are blended in this image, the Marseille of the early 1970s is a major element in the economic and social structure of France. It is the second largest city and the largest commercial seaport of the republic, as well as the capital of

General character of the city

Marginal conditions for life

Central Marseille and (inset) its metropolitan area.

the *département* of Bouches-du-Rhône and of the Provence-Côte d'Azur region. Situated on the Mediterranean's Gulf of Lion within a semicircle of limestone hills, it lies 534 miles (859 kilometres) south-southeast of Paris by rail and 219 miles southeast of Lyon. In the

late 1960s, the city and its metropolitan area had respective populations of 889,000 and 964,000. **The history of Marseille.** The oldest of the large French cities, Marseille was founded as Massalia (Massilia) by Greek mariners from Phocaea in Asia Minor

about 600 bc. Archaeological finds exhibited in the Museum of Antiquities in the 18th-century Château Borély suggest that Phoenicians had settled there even earlier.

*Antiquity and the Middle Ages.* The Massalians spread trading posts inland as well as along the coasts, westward to Spain, and eastward to Monaco, founding the present cities of Arles, Nice, Antibes, Agde, and La Ciotat. Their coins have been found across France and through the Alps as far as the Tirol. In the 4th century bc a Massalian, Pytheas, visited the coasts of Gaul, Britain, and Germany, and a Euthymenes is said to have navigated the west coast of Africa as far south as Senegal.

When their great trade rivals, the Carthaginians, fought the Romans in the Punic Wars, Marseille (Marseilles historically) supported the Romans and received help in subduing the native tribes of Liguria. When war brought Pompey and Caesar into opposition, Marseille opted for the loser and fell to Caesar's lieutenant Trebonius in 49 bc. Although stripped of dependencies, it was permitted to retain its status as a free city in recognition of past services. For some time the university remained the last centre of Greek learning in the West, but, eventually, the city declined almost to extinction. After centuries of invasion and epidemic, it became little more than a huddle of nearly abandoned ruins.

In the 10th century, under protection of its viscounts, the area was repopulated, and it found new prosperity as a shipping and staging point for the Crusades. Gradually, the town bought up the rights of the viscounts, and, at the beginning of the 13th century, it formed a republic around the Vieux Port ("old harbour"), though the upper part of the city and its southern suburb remained under ecclesiastical jurisdiction. The counts of Provence allowed the city great independence, and only in 1245 and 1256 did Charles of Anjou force acknowledgement of his sovereignty. After Marseille was sacked by Alfonso V of Aragon in 1423, King René of Provence, whose winter residence was there, restored prosperity to the city. At this time the manufacture began of the famous laundry soap known as *savon de Marseille*, which is still produced.

*Uneasy union with France.* When Provence, including Marseille, became part of the Kingdom of France in 1481, the city preserved a separate administration directed by royal officials. During the wars of religion, Marseille was fanatically Catholic and long refused to recognize Henry IV as king because, until his conversion to Catholicism and accession to the French throne, he had been leader of the Protestants. During the Fronde, a movement in 1648–53 that opposed royal absolutism, the city sought to conserve its ancient liberties and rose against Louis XIV, who in 1660 came in person, breached the walls, and subdued the revolt. To discourage further manifestations of independence, the King planted Fort-Saint-Nicolas at the southern extremity of the Vieux Port. In the same year, the city pushed inland to the west beyond its walls. A few buildings constructed in this expansion still survive in the area around the Cours Belsunce and the Préfecture.

Marseille joined enthusiastically in the French Revolution. Some 500 volunteers marching to Paris in 1792 sang "The War Song of the Rhine Army," recently composed in Strasbourg. The song, which thrilled the crowds along the route of march, was renamed "La Marseillaise" and became the national anthem of France. As the early federalist concepts were washed out in the blood of the Reign of Terror, however, the city revolted against the ruling Convention. Quickly mastered by force of arms, it was officially designated as "the city without a name." When its commerce was almost destroyed by the maritime blockade of the Continent directed against Napoleon, Marseille became bitterly anti-Bonapartist and hailed the Bourbon restoration. Under Napoleon III, it remained stubbornly republican.

*Building and razing.* The second half of the 19th century saw the expansion of Marseille as the "port of empire," after the elimination of the Barbary pirates in 1815–35, through the conquest of Algeria in 1830, and the inauguration of the Suez Canal in 1869. The great

avenues and many of the monuments of the city were constructed in this period. A serious water problem was solved by a project (1837–48) that brought water from the Durance River. The distribution reservoir above the city was disguised as the Palais Longchamp, containing the Museum of Natural History and the Musée des Beaux-Arts. The Château du Pharo, one of the city's principal landmarks, was built as a villa for Napoleon III and Eugenie at the edge of the bay beyond the Vieux Port, but it was never occupied by the imperial couple. The Bourse (Exchange), completed in 1860 on the main street, now serves as a naval museum, overseas museum, and cultural centre.

Until 1846, the small, picturesque Vieux Port, site of the original Greek installations, was the city's only harbour. Construction of the basin of La Joliette to the north doubled the port surface, and further expansion northward along the coast continued as the need for shipping space grew. The German Army occupied the city from November 1942, but Marseille continued to be an active centre of the French Resistance movement. The Vieux Port quarter, a hillside honeycomb of ancient slums, was ideally suited to clandestine activity, which the Germans tried to arrest by dynamiting the whole district in November 1943, after ordering the evacuation of its 40,000 inhabitants. All the port installations and shipping were destroyed in August 1944 by 2,500 German mines.

*Postwar expansion.* After World War II, the port areas were rebuilt and extended farther north and west to the Étang de Berre, a large lagoon 17½ miles (28 kilometres) from the city. Marignane Airport, on the south bank, was extended into the lagoon in 1970 to accommodate the largest aircraft. The lagoon is connected to Marseille by canal, while another canal on the opposite shore links the Étang to Arles on the Rhône River, which has been rendered navigable in recent years.

Midway between the two cities, one of the world's most ambitious building plans has been undertaken at the village of Fos, located at the entrance to the Roman canal, the Fossae Marianae, that connects with Arles. The deep-water port of Fos, which will equal the capacity of Marseille, 35 miles away, is being developed by the Port Authority of Marseille. The Sud-Européen oil pipeline to Switzerland and Germany originates at Fos. The surrounding swampland has been filled in to receive one of the largest industrial implantations on the Continent and the greatest industrial centre on the Mediterranean. A giant steelworks, to reach a 7,500,000-ton (6,800,000,000-kilogram) capacity by 1980, is being built with Soviet participation and partial funding by the French government; a British chemical giant has built a plastics plant, and French companies are installing a variety of industries. Industrial zones are to be developed in Arles, Aix, and 11 other communities in the region.

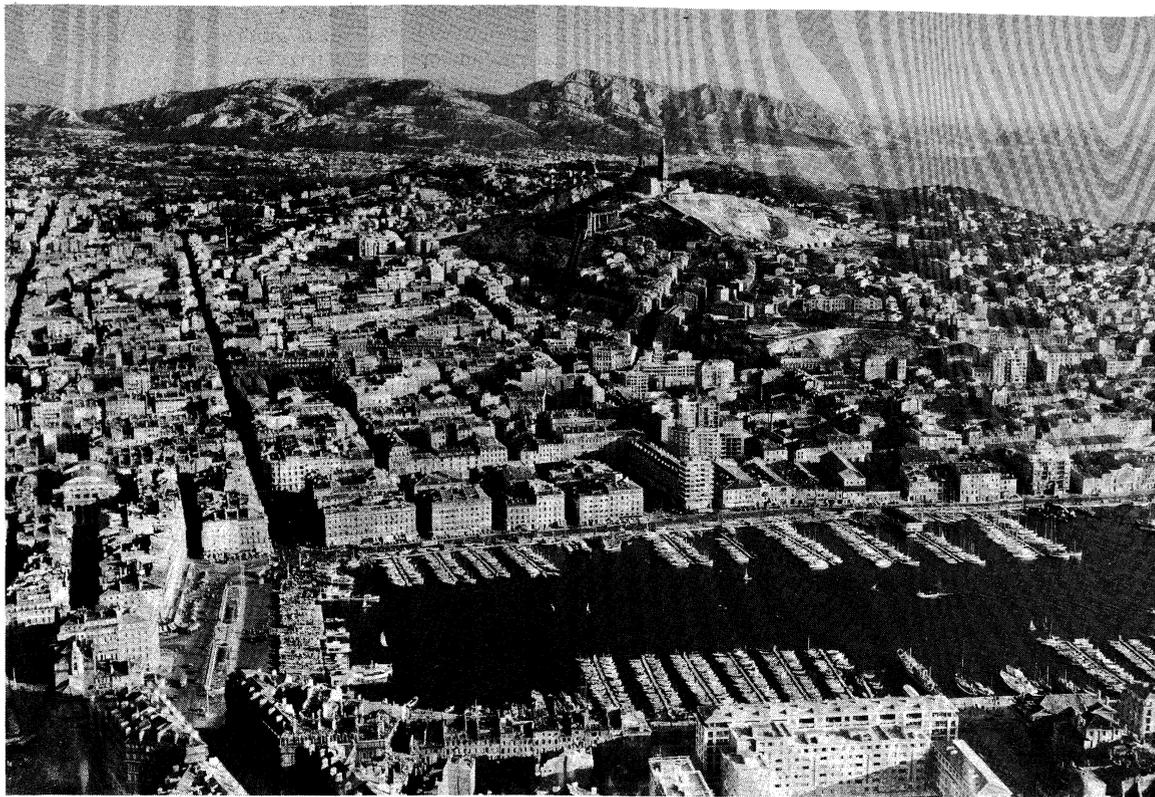

This vast investment and alteration of the Provençal landscape has altered Marseille's conception of itself; the city now aims to be the centre of a large geographic-economic region, the Rhône-Alps-Côte d'Azur. City planning is conducted on a regional rather than a municipal scale, and economic planning embraces the whole region, with substantial financial and technical contributions from the national government. The metropolitan area, officially created in 1966, 1,100 square miles in extent, covers two-thirds of the *département* of Bouches-du-Rhône, and its population was expected to reach some 3,200,000 by the end of the 20th century.

*The contemporary city.* Marseille is becoming increasingly a modern city of elevated highways, vehicular tunnels (including one under the Vieux Port), and tall housing developments, but the most striking change in the 1970s is more psychological than physical: the city is becoming increasingly French. Until the enormous state investments of expertise and money in the region—as exemplified by improvements in flood control, navigation, irrigation, electricity, roads, schools, and hospitals and by promotion of and participation in industrial development—Marseille had felt as neglected by the central authorities as it was laughingly patronized by Frenchmen in other regions.

Marseille  
and the  
Revolution

The Vieux Port and the sanctuary of Notre-Dame de la Garde (centre), Marseille.  
By courtesy of the French Government Tourist Office

The mythical Marseille did indeed have some small basis in fact: it was a sunny, noisy, gay place with a voluble population. Although the general standard of living ranged from modest to poor, the cynicism and tension of Paris was unknown. The port attracted a cosmopolitan population largely concentrated in the seething waterfront district noted for its gangsters and prostitutes. Until the intensified police action of 1971–72, it was a world centre for the illegal manufacture and shipping of drugs, especially heroin. The residential districts beyond the business centre consisted of spacious villas spread along broad avenues shaded by dusty plane trees. The countryside, flecked with tawny villages, began just outside the city.

*The changing face of the city.* The reconstruction of war-damaged neighbourhoods gave an impetus to the building trades, which continued to expand both in the private and public sectors. Le Corbusier's *Unité d'Habitation*, an apartment house that expressed the celebrated architect's ideal of urban family lodging, stood alone amid fields and family houses when it was built at the southern end of town in 1952. It is now surrounded by luxury apartment buildings that extend their masses through the whole district.

From 1955 the city increased the number of primary school classes from 2,500 to 6,500 and constructed 20 new secondary schools. At the southeastern extremity of the city, on the edge of the wild *calanque* ("fjord") region, stands the University Centre of Marseille-Luminy, with residences for 1,500 students. Adjoining are the National School of Architecture, the Regional School of Fine Arts, and the Marseille School of Commerce and Business Administration. The municipality's own computer is housed at this site, as is the computer centre that links the region's hospitals. The Municipal Sports Centre, with a 50,000-seat stadium and an outdoor theatre under construction in 1974, is located there as well; the Regional Institute of Physical Education is to be installed in new buildings nearby. Other university groups in Marseille are the new Saint-Joseph campus in the northeast and the older Saint-Charles in the city centre. Both are concentrated in the sciences, with numbers of specialized laboratories and study institutes. The medical and phar-

maceutical schools are served by two teaching hospital complexes, the *Hôpital Nord* and the *Hôpital de la Timone*. At the conclusion of modernization and construction programs (planned for 1980), Marseille's 12 hospitals will have about 9,000 beds.

For the 100 years preceding 1953, no important thoroughfare had been constructed in Marseille, where the average width of the streets was 19½ feet. To cope with the engulfing tide of automobiles, the city government inaugurated a program of street widening and freeway and tunnel construction that, together with the building program, has altered (and, some feel, banalized) the appearance of Marseille. In spite of such innovations designed to keep vehicular traffic flowing, municipal authorities decided in 1968 that the only solution to the problem was to go ahead with the new mass-transit *Méto* system, for which plans already had been drawn. Two lines, traced to make a loop around the city centre and to serve suburban areas in the north and south as well, would have 28 stations along the underground railway, a project that would take five years to complete. Work on the system had not begun in 1972 because of disagreements between local and national governments on construction costs.

*The historic centre: Vieux Port and environs.* Although some of the old street markets have disappeared, along the edge of the Vieux Port, fishermen and their wives still cry the virtues of their catch, which includes such local delicacies as squid and eel. From this spot, one of the most famous streets in the maritime world, *La Canebière*, climbs eastward up the hill. The name is a corruption of *chênevière*, a place where hemp (*chanvre*) was spun into rope during the Middle Ages. The street, which is thronged by people from around the world and unusually gay for a main business boulevard, is crowded with hotels, cinemas, shops, offices, and many broad-terraced cafes. The upper half is still lined with trees. Behind the Bourse, building operations in 1967 uncovered a section of the Hellenistic ramparts of *Massalia*. Excavated by archaeologists, the site, dating from the 3rd and 2nd centuries BC, was found to consist of walls and towers and three sections of Roman road. The ancient port was also excavated. Nearby, close to City Hall

Innovations in transportation facilities

on the edge of the port, is the Museum of Roman Warehouses (Musée des Docks Romains), which contains storage jars and other remains of commerce under Roman domination.

Ruins and reconstructions

The port entrance is guarded by the Fort-Saint-Jean, a 13th-century command post of the Knights Hospitalers of St. John of Jerusalem; some ruins remain, along with a tower built in the mid-15th century by King René. The extant fortress, dating from the 17th century, was part of a nationwide system of defenses. Restored since the 1944 explosions, the fort now houses the National Centre for Underwater Archaeological Research. The other side of the harbour entrance is occupied by the Fort-Saint-Nicolas. In the harbour itself lie the Frioul Islands, on which the city has developed a large centre for water sports. Between these islands and the mainland is the Château d'If, where Alexandre Dumas's fictional count of Monte Cristo and great numbers of all-too-real state prisoners were incarcerated.

Other historic buildings are dotted around the Vieux Port. In the Place de la Major, the church of Sainte-Marie-Major, built on the ruins of a temple of Diana, dates mainly from the 12th century; it was partially dismantled to make way for the structure that in 1852 replaced it as the city's cathedral. The dome and supporting arches of the old cathedral are sterling examples of Provençal Romanesque stonemasonry.

Nearby, restored in 1971, is the Hospice de la Vieille Charité ("the old charity hostel"), built between 1660 and 1750. The interior courtyard, a series of three superimposed arcades, surrounds a chapel by Pierre Puget, regarded as the most powerful of French Baroque sculptors. Close by is the Hôtel Dieu, the oldest hospital in the city, created at the end of the 16th century. The principal building, by Jacques Hardouin-Mansart, was erected 200 years later and still serves its original function. Almost next door, the belltower of the vanished church of Acoules, a 14th-century spire mounted on a 12th-century tower, marks the centre of Old Marseille.

On the opposite side of the port stands the crenellated, square-towered church of Saint-Victor, built in the 13th century and once attached to an abbey founded about 413. The church rests on crypts dating mainly from the 11th century but also embodying architecture of the Carolingian period (c. 9th century) and of earlier centuries of the Christian Era. When Saint-Victor was built, the abbey was a temporal power of considerable extent, ruling properties in Spain, Sardinia, and the hinterlands of France.

High on the hill over the south side of the Vieux Port stands the celebrated Notre-Dame de la Garde, a sanctuary honoured from the 8th century. Its present structure was built in 1853; its steeple, crowned by a 30-foot gilded statue of the Virgin, rises 150 feet over the hillside. As la Bonne Mère ("the good mother"), the church and the illuminated figure are dear to the citizens, who, by the thousands, make the arduous climb bearing candles to implore celestial intervention on behalf of their city—as when Marseille is to play an international soccer match.

*The people of Marseille.* There are fewer and fewer "typical" Marseillais, as there are fewer and fewer "typical" Cockneys or Brooklynites. These are Mediterraneans of richly mixed antique strains, provincials whose province includes the sea. Of celebrated craftiness but small worldly ambition, they have meticulous interest in local food and drink and flavour their sonorous conversation with pungently phrased folk philosophy. As Marseille-the-big-village is supplanted by Marseille-the-big-city, as educational norms rise, as new industry demands new skill, as the standard of living and the level of ambition fatten, the "typical" type disappears and even the accent becomes diluted. The economically small, independent fisherman, boatman, and craftsman have become picturesque.

Prominent among recent additions to the population are young technicians drawn from other parts of France to run new industries and staff the expanding technical centres. Former colonials, spearheaded by Frenchmen pushed out of Algeria, have had a strong impact on the

community and the economy, notably because of their impatience with traditional mother-country ways of organizing and operating enterprises.

Marseille has always attracted Corsicans—including the Bonaparte family during the Revolution. It is a widespread stereotype that they gravitate to the civil service or to crime. Marseille, as all large ports, is a crime centre: smuggling, pilferage, commercial vice, and assorted illegal means of separating seamen from their money are old practices. There has always been a floating international population of men who follow the sea and women who follow sailors. Import-export trade has always provided the basis for a stable foreign colony, now growing as a consequence of increased foreign investment in the area. Manual labour is increasingly performed by North Africans and Africans who arrive from former colonies of France, mostly under group work contracts.

The city government—the usual popularly elected municipal council—keeps very much alive the historical tradition of local independence in spite of the intimate involvement of many national ministries in financing and planning of projects throughout the area.

*Cultural life.* Marseilles has a total of 11 museums, including a very active Children's Museum. The Museum of Old Marseille was installed in 1960 next to the City Hall in La Maison Diamantée (Diamond House), so called because of its 16th-century facade of projecting diamond-shaped stone lozenges. The Museum of Provençal Art is located at the northeastern limits of the city, in the village of Château Gombert.

The municipality contributes to the Marseille Opera, which maintains a resident company of singers and ballet dancers. The interior of its 18th-century theatre was rebuilt after a fire in 1919. The Théâtre du Gymnase was taken over in 1969 by a group known as Cultural Action of the Southwest; it presents a full season of modern theatre, dance, and music.

As building has increased within Marseille, increased attention has been paid to the conservation and development of the municipality's parks and playgrounds. There are more than 50 sports fields in Marseille, two city swimming pools, and a number of public beaches. The parks of the Château du Pharo, Château Borléy, and Palais Longchamp are extensive.

### Marshall, George C.

Called by Winston Churchill "the organizer of victory," General of the Army George Catlett Marshall, as chief of staff of the U.S. Army (which also included the army air forces) during World War II, raised and equipped the largest ground and air force in the history of the United States.

After his retirement, he was recalled three times by Pres. Harry S. Truman to posts normally held by civilians: head of the mission to China, secretary of state, and secretary of defense. Although a soldier in the best tradition, he successfully maintained the principle of civilian control in military matters, carefully following the political lead of presidents Franklin D. Roosevelt and Truman. So completely did he embody the ideal of the citizen soldier that he was the first professional soldier to receive the Nobel Prize for Peace.

Arts and recreation

George C. Marshall.

Cabinet  
officer

**Early years** Descended on both sides of his family from settlers who had been in Virginia since the 17th century, George C. Marshall, Jr., was born in Uniontown, Pennsylvania, December 31, 1880. His father, a prosperous coke and coal merchant during his younger son's boyhood, was in financial difficulties when George entered the Virginia Military Institute, Lexington, Virginia, in 1897.

After a poor beginning at the institute, Marshall's record steadily improved, and he soon showed proficiency in military subjects. Once he had decided on a military career, he concentrated on leadership, ending his last year at the institute as first captain of the corps of cadets.

Marshall finished college in 1901. Immediately after receiving his commission as second lieutenant of infantry in February 1902, he married Elizabeth Carter Coles of Lexington and embarked for 18 months' service in the Philippines. Marshall early developed the rigid self-discipline, the habits of study, and the attributes of command that eventually brought him to the top of his profession. Men who served under him spoke of his quiet self-confidence, his lack of flamboyance, his talent for presenting his case to both soldiers and civilians, and his ability to make his subordinates want to do their best.

Somewhat aloof in manner, he seemed to some acquaintances icy cold by nature, but he had a blazing temper held under careful control and a great affection and warmth for those close to him. Happily married for 25 years to his first wife until her death in 1927, he remarried three years later, taking as his second wife a widow, Katherine Tupper Brown, whose three children gave him the family he had hitherto lacked.

After his first service in the Philippines (1902-03), he advanced steadily through the ranks, ultimately becoming general of the army in December 1944. In World War I he served as chief of operations of the 1st Division, first to go to France in 1917, and then as the chief of operations of the 1st Army during the Meuse-Argonne offensive in 1918. After the war he served for five years as aide to Gen. John J. Pershing (1919-24) and for five years as assistant commandant in charge of instruction at the infantry school, Ft. Benning, Georgia (1927-33), where he strongly influenced army doctrine as well as many officers who were to become outstanding commanders in World War II.

He was sworn in as chief of staff of the army on September 1, 1939, the day World War II began with Germany's invasion of Poland. When he entered office, the United States forces consisted of fewer than 200,000 officers and men. Under his direction it expanded in less than four years to a well-trained and well-equipped force of 8,300,000. As the chief representative of the U.S. chiefs of staff at the international conferences at Casablanca, Washington, Quebec, Cairo, and Teheran, he led the fight for an Allied drive on German forces across the English Channel, in opposition to the so-called Mediterranean strategy of the British.

A few days after Marshall resigned as chief of staff on November 21, 1945, President Harry Truman persuaded him to attempt, as his special representative, to mediate the Chinese Civil War. Though his efforts were unsuccessful, in January 1947 he was appointed secretary of state. In June of that year he proposed a European Recovery Program, which, known as the Marshall Plan, played a decisive role in the reconstruction of war-torn Europe. Also significant during his secretaryship were the provision of aid to Greece and Turkey, the recognition of Israel, and the initial discussions that led to the establishment of the North Atlantic Treaty Organization (NATO). Marshall left his position because of ill health two years later. Then, in 1950, when he was nearly 70, President Truman called him to the post of secretary of defense, in which he helped prepare the armed forces for the Korean conflict by increasing troop strength and matériel production and by raising morale. For all his services he had received unstinted praise, but, a few months before he left office, he was bitterly assailed by Sen. Joseph McCarthy and his associates, who charged him with conspiracy with President Roosevelt to keep the commanders at Pearl Harbor ignorant of Japanese plans to attack that base in December 1941; with consistently following a pro-Soviet line in strategy; and with the betrayal of Chiang Kai-shek, the leader of Nationalist China. Although the charges were disavowed by many and were refuted or softened by later careful studies, they still darkened the General's last years.

After 1951, General Marshall remained on the active-duty list as the highest ranking general of the army, available for consultation by the government. In 1953 he was awarded the Nobel Prize for Peace in recognition of his contributions to the economic rehabilitation of Europe after World War II and his efforts to promote world peace and understanding. He died at Walter Reed General Hospital, Washington, D.C., on October 16, 1959.

**BIBLIOGRAPHY.** The authorized biography of General Marshall is a projected four or five volume work by FORREST C. POGUE of which three volumes, *Education of a General, 1880-1939* (1963), *Ordeal and Hope, 1939-42* (1966), and *Organizer of Victory, 1943-45* (1973), have appeared. ROBERT H. FERRELL, *George C. Marshall* (1966), a volume in the "American Secretaries of State Series," written without access to unpublished State Department files, is a valuable summary of the period. JOHN ROBINSON BEAL, *Marshall in China* (1970) contains excerpts of the diary of an American news adviser to Chiang Kai-shek during the Marshall mission. H.L. STIMSON and MCGEORGE BUNDY, *On Active Service in Peace and War* (1947), draws heavily on Stimson's manuscript diary for the period 1941-45 in relation to Marshall. His papers are held in the George C. Marshall Library, Lexington, Virginia.

(F.C.P.)

## Marshall, John

As fourth chief justice of the United States from 1801 to 1835, John Marshall was the principal founder of the American system of constitutional law, including the doctrine of judicial review. During his tenure Marshall participated in more than 1,000 decisions, writing 519 of them himself.

**Youth.** Marshall was born on September 24, 1755, near a settlement then called Germantown (now Midland), Virginia, the eldest of 15 children of Thomas Marshall and Mary Keith Marshall. His childhood and youth were spent in the near-frontier region that in 1759 became Fauquier County, later on in the more extensive properties his father acquired in the Blue Ridge mountain area. His education appears to have been largely the product of his parents' efforts, supplemented only by the instruction afforded by a visiting clergyman who lived with the family for about a year, and by a few months of slightly more formal training at an academy in Westmoreland County. His parents, however, had more learning and wider experience to transmit to their children than was common among the farmers and hunters of the backcountry of northern Virginia. Mary Keith Marshall was the daughter of a college-trained Scottish clergyman. Thomas Marshall had been an assistant surveyor to

John Marshall, crayon portrait by F vret de Saint-M min (1770–1852). In the Duke University Law School, Durham, North Carolina.

By courtesy of Duke University, Durham, North Carolina

George Washington, a representative in Virginia's House of Burgesses, and had held a number of other offices. This was the period when the differences between the upland counties and the tidewater aristocracy grew sharp and were paralleled by an increasing sentiment for colonial autonomy and finally for independence among the backcountry residents, whom Thomas Marshall represented.

**Early career.** When political debate with England was followed by armed clashes in 1775, John Marshall, as lieutenant, joined his father in a Virginia regiment of minutemen and participated in the first fighting in that colony. Joining the Continental Army in 1776, he served under Washington for three years in New Jersey, New York, and Pennsylvania, including in this service the harsh winter of 1777–78 at Valley Forge. When the term of service of his Virginia troops expired in 1779, Marshall returned to Virginia and thereafter saw little active service prior to his discharge in 1781.

Marshall's career in law dates from 1780. His only formal training was a brief course of lectures given by George Wythe that he attended at William and Mary College early in that year. Licensed to practice in August 1780, he returned to Fauquier County and was elected to the Virginia House of Delegates in 1782 and 1784. Attending the sessions of the legislature in the capitol at Richmond, he established there both a law practice and a home, after marriage to Mary Ambler in January 1783.

For the next 15 years Marshall's career was marked by increasing stature at the brilliant bar of Virginia. He had not, in 1787, achieved a public position that would have sent him as a delegate to the Constitutional Convention in Philadelphia, but he was an active, if junior, proponent of the Constitution in the closely contested fight for ratification. Virginia was then the largest and most populous of the states. Its ratification was not only essential to the success of the proposed Constitution but was also among the most doubtful. Marshall was elected to the legislature that took the first step toward ratification by issuing a call for a convention to consider ratifying; he was also elected a delegate to the convention. On the floor of that convention the contest on behalf of the Constitution was led by men senior to Marshall—James Madison, Edmund Randolph, Edmund Pendleton, and Wilson Cary Nicholas; Patrick Henry and George Mason led the opposition. Marshall made one address in reply to a general attack by Henry. His principal effort on the floor was, perhaps prophetically, a defense of the judiciary article. It can only be assumed that his acknowledged popularity was employed with at least equal effectiveness off the floor to gain or hold the narrow margin by which Virginia's ratification was won.

With the new government under the Constitution installed, Pres. George Washington offered Marshall ap-

pointment as United States attorney for Virginia. Marshall declined. In 1789, however, he sought and obtained a further term in Virginia's House of Delegates as a supporter of the national government. As party lines emerged and became defined in the 1790s, Marshall became recognized as one of the leaders of the Federalist Party in Virginia. In 1795 Washington tendered him an appointment as attorney general. This, too, was declined, but Marshall returned to the state legislature as a Federalist leader. His first federal service came when Pres. John Adams appointed him member of a commission, with Elbridge Gerry and Charles C. Pinckney, to seek improved relations with the government of the French Republic. The mission was unsuccessful. But reports then were published disclosing that certain intermediaries, some shadowy figures known as X, Y and Z, had approached the commissioners and informed them that they would not be received by the French government unless they first paid large bribes; the reports further revealed that these advances had been rebuffed in a memorial prepared by Marshall. Marshall thereupon became a popular figure, and the conduct of his mission was applauded by one of the earliest American patriotic slogans, "Millions for defense, but not one cent for tribute."

Returned from France, Marshall declined appointment to the Supreme Court to succeed Justice James Wilson but was persuaded by Washington to run for Congress. He was elected in 1799 as a Federalist from the Richmond district, though his service in the House of Representatives was brief. His chief accomplishment there appears to have been the effective defense of the President against a Republican attack for having honoured a British request under the extradition treaty for the surrender of a seaman charged with murder on a British warship on the high seas. In May 1800 President Adams requested the resignation of his secretary of war and offered the post to Marshall. Marshall declined. The President next dismissed his secretary of state and tendered the vacant place in his Cabinet to Marshall. In an administration harassed by dissension and with uncertain prospects in the forthcoming election, the appeal of the invitation must have been addressed principally to Marshall's loyalty. After some hesitation he accepted and almost immediately became the effective head of government when the President retired to his home in Massachusetts for a stay of a few months. In the autumn of 1800, Chief Justice Oliver Ellsworth resigned because of ill health. Adams, defeated in the election of November, tendered reappointment to John Jay, the first chief justice. Jay declined. The President then turned to his secretary of state, and in January 1801 sent to the Senate the nomination of John Marshall to be chief justice. The last Federalist Senate confirmed the nomination on January 27, 1801. On February 4, Marshall accepted the appointment but, at the President's request, continued to act as secretary of state for the last month of the Adams administration.

**Chief justice of the United States.** It fell to Marshall, and to the Supreme Court under and beginning with Marshall, to set forth the main structural lines of the government. Whether the Constitution had created a federation or a nation was not a matter on which agreement could have been won at the beginning of the 19th century. Though judicial decisions could not alone dispel differences of opinion, they could create a body of coherent, authoritative, and disinterested doctrine around which opinion could mass and become effective. To the task of creating such a core of agreement Marshall brought qualities that were admirably adapted for its accomplishment. His own mind had apparently a clear and well-organized concept of the effective government that he believed was needed and was provided by the Constitution. He wrote with a lucidity, a persuasiveness, and a vigour that gave to his judicial opinions a quality of reasoned inevitability that more than offset an occasional lack in precision of analysis. The 35 years of his magistracy gave opportunity for the development of a unified body of constitutional doctrine. It was the first aspect of Marshall's accomplishment that he and the court he headed did not permit this opportunity to pass unrecognized.

The XYZ  
Affair

Beginnings  
of his  
law  
career

Appoint-  
ment to  
the  
Supreme  
Court

Prior to Marshall's appointment, it had been the custom of the Supreme Court, as it was in England, for each justice to deliver an opinion in each significant case. This method may be effective where a court is dealing with an organized and existing body of law, but with a new court and a largely unexplored body of law, it created an impression of tentativeness, if not of contradiction, which lent authority neither to the court nor to the law it expounded. With Marshall's appointment, and presumably at Marshall's instance, this practice changed. Thereafter, for some years, it became the general rule that there was only a single opinion from the Supreme Court. This change of practice alone would have contributed to making the court a more effective institution. And when the opinions were cast in the mold of Marshall's clear and compelling statement, the growth of the court's authority was assured.

*Marbury v. Madison* (1803) was the first of Marshall's great cases and the case that established for the court its power to state and expound constitutional law in disregard of federal statutes that it found in conflict with the Constitution. President Adams had appointed a number of justices of the peace for the District of Columbia shortly before his term expired. Their commissions had been signed and the seal of the United States affixed in the office of the secretary of state, but some of them, including that of William Marbury, remained undelivered. Pres. Thomas Jefferson is believed to have ordered that some of them not be delivered. After unsuccessful application at the Department of State, Marbury instituted suit in the Supreme Court against James Madison, the new secretary. Though the matter was not beyond question, the Court found that Congress had by statute authorized that such suits be started in the Supreme Court rather than in a lower court. But the Supreme Court, speaking through Marshall, held that Article III of the Constitution did not permit this and that the court could not follow a statute that was in conflict with the Constitution. It thereby confirmed for itself its most controversial power, the function of judicial review, of finding and expounding the law of the Constitution.

Once the power of judicial review had been established, Marshall and the court followed with decisions that assured that it would be exercised, and the whole body of federal law determined, in a unified judicial system with the Supreme Court at its head. *Martin v. Hunter's Lessee* (1816) and *Cohens v. Virginia* (1821) affirmed the Supreme Court's right to review and overrule a state court on a federal question. *McCulloch v. Maryland* (1819) asserted the doctrine of "implied powers" granted Congress by the Constitution (in this instance, that Congress could create a bank of the United States, even though such a power was not expressly given by the Constitution). *McCulloch v. Maryland* well illustrated that judicial review could have an affirmative aspect as well as a negative; it may accord an authoritative legitimacy to contested government action no less significant than its restraint of prohibited or unauthorized action. *Fletcher v. Peck* (1810) and *Dartmouth College v. Woodward* (1819) established the inviolability of a state's contracts. *Gibbons v. Ogden* (1824) established the federal government's right to regulate interstate commerce and to override state law in doing so. It must be clearly noted, however, that many of Marshall's decisions dealing with specific restraints upon government have turned out to be his less enduring ones, particularly in later eras of increasing governmental activity and control. It is in this area, indeed, that judicial review has evoked its most vigorous critics.

There was only one term of the Supreme Court each year, generally lasting about seven or eight weeks (a little longer after 1827). Each justice, however, also conducted a circuit court—Marshall in Richmond, Virginia, and Raleigh, North Carolina. It was in Richmond in 1807 that he presided at the treason trial of former Vice Pres. Aaron Burr, during which he successfully frustrated President Jefferson's efforts toward a runaway conviction; Burr was freed. With hardly more than three months annually engaged in judicial duties, Marshall had

much time to devote to private life. He early completed a five-volume *Life of George Washington* (1804–07). He cared for an invalid wife, who bore him ten children, four of whom died in early life. He enjoyed companionship, drinking, and debating with fellow lights in Richmond. In general, for the first 30 years of his service as chief justice, his life was largely one of contentment.

In the autumn of 1831, at the age of 76, he underwent the rigours of surgery for the removal of kidney stones and appeared to make a rapid and complete recovery. But the death of his wife on Christmas of that year was a blow from which his spirits did not so readily recover. In 1835 his health declined rapidly, and on July 6 of that year he died in Philadelphia. He was buried in Richmond.

**BIBLIOGRAPHY.** ALBERT J. BEVERIDGE, *The Life of John Marshall*, 4 vol. (1916–19), is the standard biography of Marshall and the most detailed and comprehensive account of his life and career; it is, however, pervasively laudatory and almost completely uncritical. JAMES BRADLEY THAYER, *John Marshall* (1901, reprinted 1967), is a biographical essay, keenly perceptive in its appraisal of Marshall's career and work as chief justice. CHARLES WARREN, *The Supreme Court in United States History*, rev. ed., 2 vol. (1937), which is a study of the Supreme Court as an institution of government, appropriately gives great emphasis to the court and the chief justiceship of John Marshall.

## Marsupialia

The Marsupialia is a superorder (or order, depending on the authority) of mammals characterized by premature birth and continued development of the newborn while attached to the nipples on the lower belly of the mother. The pouch, or marsupium, from which the group takes its name, is a flap of skin covering the nipples. Although prominent in many species, it is not a universal feature among marsupials; in some species, for example, the nipples are in a well-defined area but are fully exposed or are bounded by mere remnants of a pouch. The young remain firmly attached to the milk-giving teats for a period corresponding roughly to the latter part of development of the fetus in the womb of a eutherian, or placental, mammal.

The largest and most varied assortment of marsupials—more than 100 species—is found in Australia alone: kangaroos, wallabies, wombats, the koala, and a bewildering assemblage of smaller rodent-like forms. About 70 more species are distributed more widely, in Australia (including Tasmania), New Guinea, and a cluster of nearby islands. The wide array of Australian marsupials is reflected in the extensive popular vocabulary of names, many of which are derived from descriptive Aboriginal words. Only two families of marsupials—totalling more than 70 species—are found in the Americas, vestiges of a larger group that originated there as long ago as the Cretaceous Period (from 136,000,000 to 65,000,000 years ago). The family Didelphidae comprises about 65 species of South and Central American opossums, one of which ranges as far north as southern Canada. The family Caenolestidae consists of seven species of ratlike marsupials confined to South America.

### GENERAL FEATURES

**Scientific and economic importance.** Marsupials are of interest to zoologists for several reasons: their current geographical distribution, their remarkable evolutionary expansion in Australasia, their similarity in many respects to placental mammals, and, most obviously, their reproductive adaptations and often bizarre structure.

Fossil evidence indicates clearly that the marsupials originated in the New World, and although the oldest fossils referable to marsupials are found in North America, it is believed that South America is equally likely as the origin of these animals. The current concentration of diverse types of marsupials in Australia and its nearby islands is thought to have occurred as a result of passage over presumed land connections with South America during a mild early geological period before the rise of the placental mammals. Later, toward the beginning of the

The question of origin and spread

Work on the circuit court and his private life

Tertiary Period (starting 65,000,000 years ago), Australia was isolated from all other continental masses, and the marsupials were free to evolve unrestricted by competition from other groups of mammals. Elsewhere, however, the marsupials did badly; they faced strong competition from and were supplanted by the more advanced placental mammals.

Australian marsupials provided products—meat and hides particularly—for the Aboriginal people, whose primitive hunting methods posed no threat to the continued success of the animals as a group. With the appearance of modern methods of hunting and trapping, however, several species of the kangaroo family (Macropodidae) were soon rendered extinct, and many others were brought close to that fate. For a time during the first half of the 20th century, many of the larger marsupials were slaughtered in great numbers for their pelts, which were an item of export in the fur trade; for their hides, which were made into shoes; and for their flesh, which was processed into dog and cat food. The gray kangaroo (*Macropus giganteus*), for example, is a casualty of such wholesale killing. Fortunately, in Australia most marsupials have since that time been accorded protection under law, and efforts are proceeding to conserve many species that were brought to the brink of extermination. The Tasmanian wolf, tiger, or thylacine (*Thylacinus cynocephalus*), thought to have become extinct in the 1930s, may still survive. In 1961 an expedition claimed to have found thylacine tracks in a rain forest on the west coast of Tasmania. The Tasmanian devil (*Sarcophilus harrisi*), once dangerously close to extinction, is now thriving in Tasmania. In the Americas marsupials are also hunted locally for food and other products, but, since numerous and equally desirable placental mammals abound, hunting pressure and the resulting threat of species death are not so strongly felt.

Not only man but also his introduced animals have played a part in the extinction of certain marsupials. Foxes, dogs, and cats continue to prey upon many species of marsupials, as also do the dingoes, canines introduced by the Aboriginals long ago and since gone wild. Brush and forest fires as well as climatic change and the encroachment of civilization are also factors tending to reduce the numbers of marsupial species.

**Size range and diversity.** No extant marsupial even approaches the tremendous size of certain extinct forms, which apparently rivalled the mastodons in bulk. Among the largest living marsupial is *Macropus giganteus*, some individuals of which reach about two metres (six feet) in height, three metres (nine feet) from muzzle to tail tip, and weigh up to 90 kilograms (about 200 pounds); red kangaroos (*Megaleia rufa*) grow to about the same size. The smallest is the planigale (*Planigale ingrami*), a species of marsupial mice that is barely 12 centimetres (4¾ inches) in total length. The vast majority of marsupials lie in the range from the size of a squirrel to that of a medium-sized dog (Figures 1-3).

Structural and behavioral parallels with placental mammals are in some cases quite striking. Such resemblances are examples of convergent evolution, a tendency for organisms to adapt in similar ways to similar habitats. Thus, there are marsupials that look remarkably like moles, shrews, squirrels, and mice. Others, less in structure than in habits, are the ecological counterparts of cats, small bears, and rabbits. Even the larger grazing marsupials, which resemble no placental mammal at all, can be thought of as filling the same ecological role as deer and antelope found elsewhere.

**Distribution and abundance.** There are about 175 species of marsupials native to the Australasian area, primarily in Australia (including Tasmania), New Guinea, Timor, and Celebes. Through man's agency, however, marsupials have been introduced to nearby islands of Australia and especially to New Zealand. The more than 70 native American species occur in South and Central America, with the range extended into North America by the common, or Virginian, opossum (*Didelphis marsupialis*). A number of other species extend into the southern portion of North America.

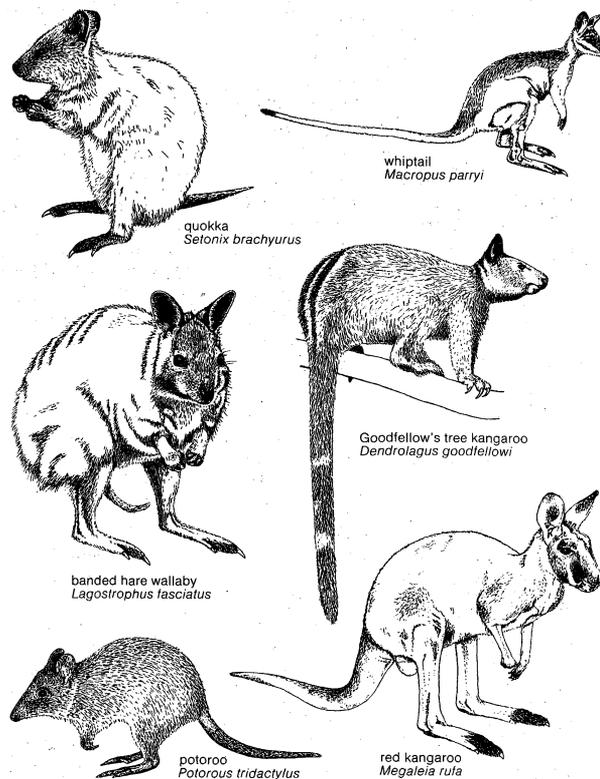

Figure 1: Representative species of the family Macropodidae. Drawing by A.G. Lyne

In terms of numbers of species the didelphids, or New World opossums, rank highest with 65. In sheer abundance, there are more vegetarian than carnivorous marsupials and perhaps more pouched mice than any other kind of marsupial.

The brush-tailed possums (*Trichosurus vulpecula*) exemplify marsupials that have readily adapted to changing conditions brought about by man. As recently as 1932, more than 1,000,000 pelts were sold under such names as Adelaide chinchilla. Protected for part of the year, the brush tails have now become plentiful over the vast interior of Australia and even pestiferous in urban centres. Their adaptability to different locales is attributed to their tolerance for a variety of food, including household refuse.

Koalas (*Phascolarctos cinereus*), reduced to a few thousand in the 1930s as a result of disease and logging and trapping for fur, have recovered their numbers sufficiently to be reintroduced into forested regions.

Although the red kangaroos (*Megaleia rufa*) are being killed in large numbers for commercial products and by farmers and ranchers whose grazing lands they sometimes visit during periods of drought, they are numerous in many parts of inland Australia. The total range of this species is about 2,000,000 square miles. Changes in vegetation resulting from domestic stock have improved the habitat for it in many parts of its range, and the species has increased in abundance.

#### NATURAL HISTORY

**Life cycle.** The life cycle of marsupials exhibits the peculiarities of a mammalian group advanced over the egg-laying monotremes but primitive to the placental mammals. The gestation period of the marsupial ranges from about eight days in the native cat *Dasyurus viverrinus* to 40 days in the red-necked wallaby (*Wallabia rufogrisea*). The young, born in a vulnerable embryonic condition, make their own way to the shelter, warmth, and nourishment of the pouch; in pouchless marsupials the young simply cling to the teats. Those fortunate enough to survive this arduous journey may succeed in attaching themselves to the mother's nipples, which then swell and become firmly fastened—almost physically

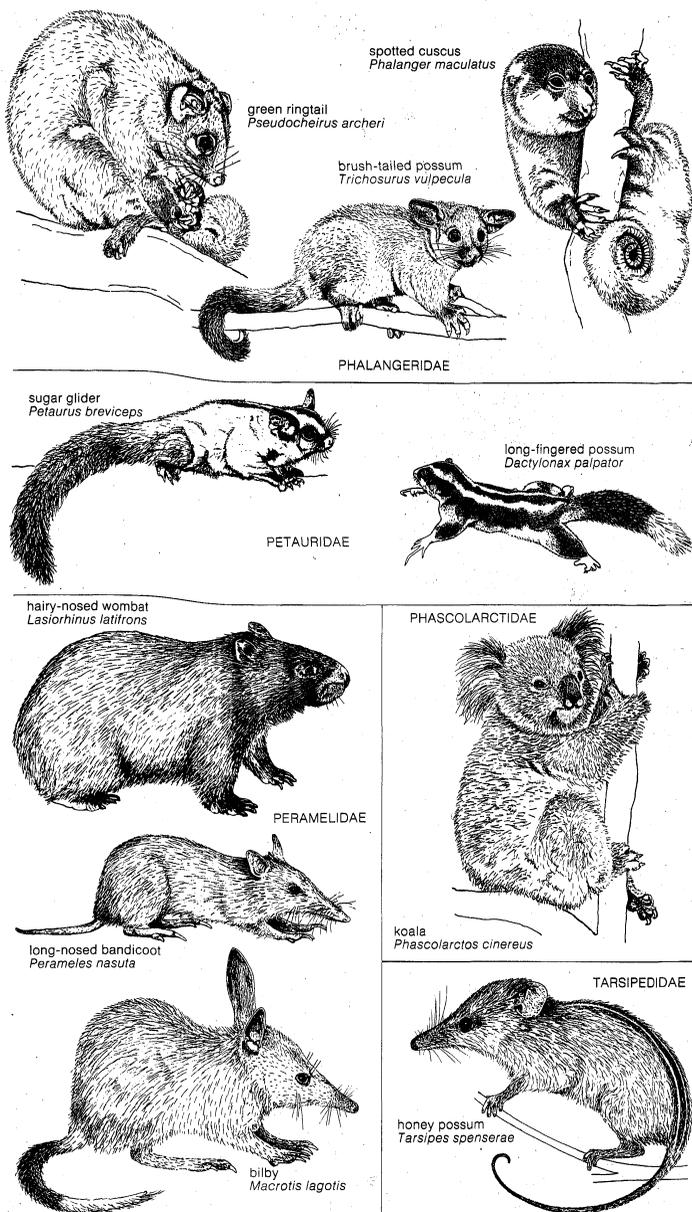

Figure 2: Representative species of the families Phalangeridae, Petauridae, Peramelidae, Phascolarctidae, and Tarsipediae. Drawing by A.G. Lyne

fused—to the mouth tissues of the young. In this condition the young continue their development for weeks or months, after which they are weaned and begin to look after themselves.

The primitive reproductive cycle of *Didelphis marsupialis*

*Didelphis marsupialis* exemplifies one of the more primitive cycles and serves to illustrate the sequence of events in greater detail. It may have two litters yearly throughout most of its range (possibly only one in the northern reaches). The female experiences estrus (heat) and becomes receptive to the male about every 28 days during the breeding season. Heat lasts one or two days, during which an average of 22 ova are shed. Usually only ten young are born in a litter, but as many as 25 young have been reported.

During the first five or six days the embryos form very slowly, but thereafter the rate of development speeds up. The gestation period is short—about 13 days. Just before birth, the mother thoroughly cleans the pouch and her belly fur, licking a smooth path from the birth canal to the pouch. When expelled from the birth canal, the newborn are no larger than honeybees. Blind and grublike, except for their well-developed, clawed forelimbs, they emerge and immediately begin grasping and swimming-like movements along the mother's dampened fur. The

strong ones reach the pouch in less than a minute, an extraordinary feat for so small and incomplete a creature. Only about 60 percent of the newborn reach the pouch; these attach themselves immediately to the teats, at which they remain for four or five weeks (Figure 4). They then begin to leave the pouch for short intervals, scampering back to it whenever danger threatens. The young stay with the mother for 90 to 100 days—toward the last not in the pouch but clinging to her fur. Shortly afterward they are weaned and begin their independent lives.

**Behaviour.** The marsupials are notably less intelligent than placental mammals, a fact that is attributable in part to a simpler brain (see below *Form and function*). It is not surprising, therefore, to find a repertory of behaviour that differs somewhat from that of the more advanced placentals. One peculiarity that may stem from this underdevelopment is restricted vocal ability. Although marsupials are not entirely silent, few of them emit loud sounds of excitement or distress; apparently, none utters grunts of contentment or even cries of hunger when young. What vocalizing they do is more limited and less variable than that of placentals.

There seems to be little detectable social organization among marsupials beyond the short-lived pair bonds during mating. The reproductive cycle in many marsupials is seasonally controlled, and estrus occurs in a predictable rhythm. In the quokka (*Setonix brachyurus*) and many other kangaroos and wallabies, however, the females may bear young at any time of the year. Only one young, called a joey, can be carried by the mother at a time. After suckling for about six months in the pouch, the joey begins to venture out but remains very close to the mother, plunging headfirst into the pouch when alarmed.

Drawing by A.G. Lyne

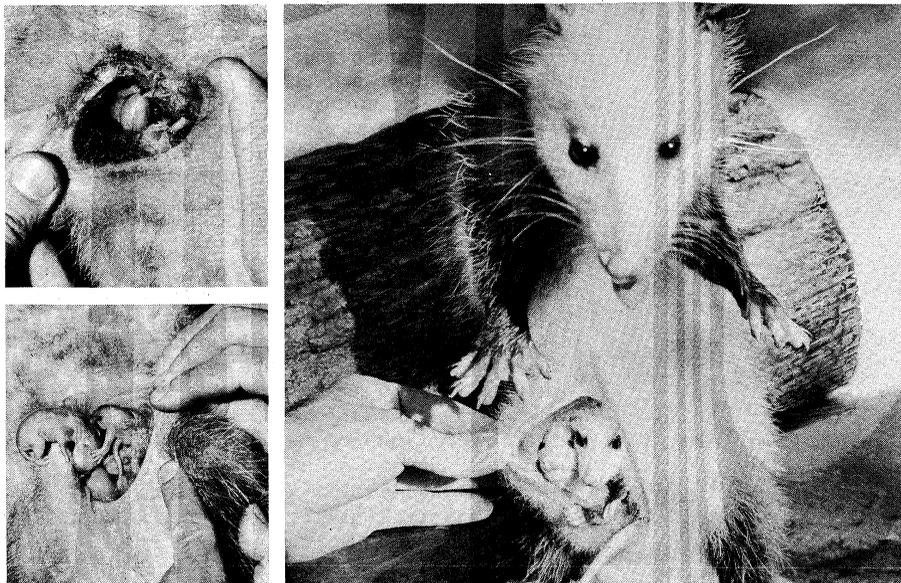

Figure 4: Development of the common opossum. (Top left) In the pouch at three weeks; (bottom left) at seven weeks; (right) mother carrying 10-week-old young.  
Charles Phillip Fox

The males have no interest in the young and will protect neither them nor the females against danger.

Many of the grazing marsupials, such as the kangaroos and wallabies, move in feeding groups called mobs, but these associations do not merit distinction as true herds since the individual members appear to move at liberty, without attention to any leaders or elders. One member can send the mob into a wild rout—individuals bounding off in all directions—by thumping its tail on the ground in a signal of alarm.

The larger marsupials, especially, embody nervous alertness and dull-witted consternation at the same time. A typical response of a red kangaroo when startled is to bound off in full flight—up to 65 kilometres per hour (about 30 miles per hour)—for a relatively short distance, stop short to reconnoitre the disturbance, and, in what appears to be sheer panic, double back toward its adversary and jump over it, sometimes clearing more than three metres (ten feet) in height and a distance of more than eight metres (25 feet) in a single leap.

Although well equipped for escape, a boomer, or large male kangaroo, can stand fast against many of its foes. With agile arms it can spar vigorously, behaviour learned in playful bouts as a joey. But, much more effectively, it can use the forepaws to grip its enemy, while it rocks back on its tail and then swiftly drops its huge clawed hindfeet, an action that has been known to disembowel dogs and men. Despite such fearsome ability, the kangaroos are usually gentle, as are most of the vegetarian marsupials. Whatever violence they commit is usually in response to a distinct threat to themselves.

Such marsupials as the possums (families Burramyidae, Petauridae, and Phalangeridae), wombats (Vombatidae), and koala (Phascolarctidae) usually sleep by day and move about toward dusk in search of food. Except for the agile possums—notably the gliders (*e.g.*, *Acrobates*, *Schoinobates*)—most of these animals are slow-moving and, consequently, easy prey for carnivorous animals. The bush-tailed possum, however, is not easy prey for carnivorous animals.

The most mild-mannered pouched mammal is perhaps the numbat, or banded anteater (*Myrmecobius fasciatus*), a small, slow forest prowler who searches out termites, its favourite food. When disturbed, the numbat hisses; if caught it neither struggles nor bites but simply vents a few grunts in protest. Equally inoffensive and similarly vulnerable to predation is the teddy-bear-like koala, which rummages about at night among eucalyptus branches munching endlessly on the only food it eats—eucalyptus leaves. Its name, an Aboriginal dialect word

meaning “no drink,” refers to the koala’s curious and apparently lifelong abstinence from water. Koalas provide a eucalyptus “soup” for their young at the time of weaning; it is lapped up directly from the parent’s anus. The densely furred cuscuses (*Phalanger*) move among the trees with the same deliberation of the koalas, eating leaves as they go.

Bandicoots—whose apt name means “pig rat”—are especially fond of earthworms and insects and are only occasionally herbivorous. Although generally shy and retiring, bandicoots can at times display a surprising belligerence: with their sharp-clawed feet they can literally scratch their victims to death. Certain marsupial mice (*e.g.*, *Sminthopsis* species) are so hyperactive—like shrews—that to supply their high energy needs they must devour their own weight in food, chiefly insects, each day.

A curious and effective defensive behaviour has been developed to a high degree in *Didelphis marsupialis* of North America: when harassed it hisses and departs, but when attacked and not able to flee, it feigns death (plays possum) so well that the aggressor may lose interest and leave.

The carnivorous marsupials are equipped with other behavioral traits. They are the fierce hunters of flesh. Although as a rule not as fast as comparable placental carnivores, they are persistent in the hunt and swift to kill. The Tasmanian devil is a stout fighter, likened in its bloodlust to the American wolverine. Yellow-footed marsupial mice (*Antechinus flavipes*) cling so tenaciously to their prey that they can be caught like fish on bait. The thylacine, which has been known to rise up on its hindlegs kangaroo fashion when pressed, makes up in perseverance what it lacks in speed and cunning. In sharp, foxlike snaps, thylacines have been known to dispatch an antagonist as formidable as a hunting dog.

**Ecology.** The niches, or ecological roles, that marsupials fill are closely associated with structure. The burrowing species, such as the marsupial mole and the wombats, have powerful foreclaws with which they can tunnel into the ground for food and for shelter. Terrestrial forms, such as the kangaroos and wallabies, possess well-developed hindlimbs that serve both as formidable weapons and catapults by which they can bound over the plains. The greater glider (*Schoinobates volans*) and other Australian “flying” possums have a membrane along either flank, attached to the forelegs and hindlegs, that enables these arboreal animals to glide down from a high perch. A few marsupials spend most of their lives in trees; koalas, for example, are so thoroughly arboreal that they

Defensive  
behaviour  
of kanga-  
roos

Life-  
styles

seem comfortable only when they are among the branches of trees. One marsupial is semi-aquatic, the water opossum—yapok or yapó (*Chironectes minimus*)—of Central and South America. Its thick, oily fur, partially webbed feet, and constrictable pouch opening suit it admirably for swimming and diving in search of food.

The diet of marsupials is as varied as the niches. Many live chiefly on insects and other small animals. Such are the marsupial mice and many of the smaller native cats (family Dasyuridae). The tiger cat and the Tasmanian devil feed largely on birds and small mammals. The numbat uses its remarkable wormlike tongue to lap up termites and ants. Many Australian possums, bandicoots, and American opossums have a mixed diet of plant matter and insects. Certain other marsupials are strictly vegetarian. The wombats feed on grasses, roots, and fungi, which they dig up with their clawed forepaws. The small honey possum (*Tarsipes spenserae*) is specialized to feed on the nectar of flowers.

The entire family of macropodids—the “big-footed” ones—are primarily grass eaters. They include the kangaroos and wallaroo, the wallabies and pademelons, and the rat kangaroos and musk kangaroo. The wallaroo, or euro (*Macropus robustus*), in particular, has a diet almost as restrictive as that of the koala: it can subsist in large part on spiky spinifex grass. Macropodids digest their vegetable food in the same manner as do sheep, cattle, and other ruminants, by relying on intestinal bacteria and protozoans to break down plant matter.

In their turn, marsupials are food for other animals. Foremost among the predators of didelphids and small dasyurids are owls and other birds of prey, snakes, and many carnivorous mammals, including dogs and cats. Some of the larger species of American opossums are eaten locally by man. The enemies of the larger marsupials, the macropodids, include the dingo, fox, eagle, pythons, goannas, and especially man.

#### FORM AND FUNCTION

Marsupials share with other mammals the presence of hair and the suckling of young by mammary glands. With minor differences the various systems of the body, such as the muscular and skeletal systems, are those of the placentals generally. The skull and the brain, however, differ considerably from those of placentals. Differences also exist in the dentition and in the arrangement of digits of the feet.

**Bodily adaptations.** In gross structure, many marsupials have hindlimbs that are larger and more powerful than the forelimbs; such an arrangement is most obvious in the large terrestrial grazing marsupials but is of wide occurrence in some degree throughout the Marsupialia. Arboreal and burrowing marsupials have forelimbs almost as well developed as the hindlimbs, understandable adaptations to their modes of living. Claws, often of considerable size, are invariably present in all marsupials and assist in climbing or digging. The tail, of tremendous size in kangaroos and wallabies, serves as an organ of stability and balance; in smaller and arboreal species it may also be prehensile (adapted for grasping), allowing the animal to hang by it.

Compared with placentals, marsupials differ markedly in both the structure and bulk of the brain. Most notably they lack a corpus callosum, that part of the placental brain that connects the two cerebral halves. In addition, the marsupial brain is smaller relative to skull size: a marsupial cat has about half as much brain tissue as a placental cat of similar skull size. Such insufficiency may account in part for the relative backwardness of marsupials when contrasted with placental mammals.

A feature peculiar to marsupials is the presence of a pair of bones associated with the pelvic girdle. Called the epipubic, or marsupial, bones, they were earlier thought to be a supportive element for the pouch.

The teeth in marsupials are numerous—usually 40 to 50, but as few as 22 in the honey possum and as many as 52 in the numbat. The relationship of milk teeth to adult teeth is not clear; some authorities claim that a single set of teeth lasts throughout life. Typically, there are seven

cheek teeth on each side of the jaw, top and bottom, which are divided into three premolars and four molars; this contrasts with the typical placental condition in which there are four premolars and three molars. Also unlike the placental condition, the number of front, or incisor, teeth differs in upper and lower jaws.

In earlier studies of marsupials much was made of the number and type of incisors (Figure 5). Marsupials with more than three incisors in the upper jaw were said to be

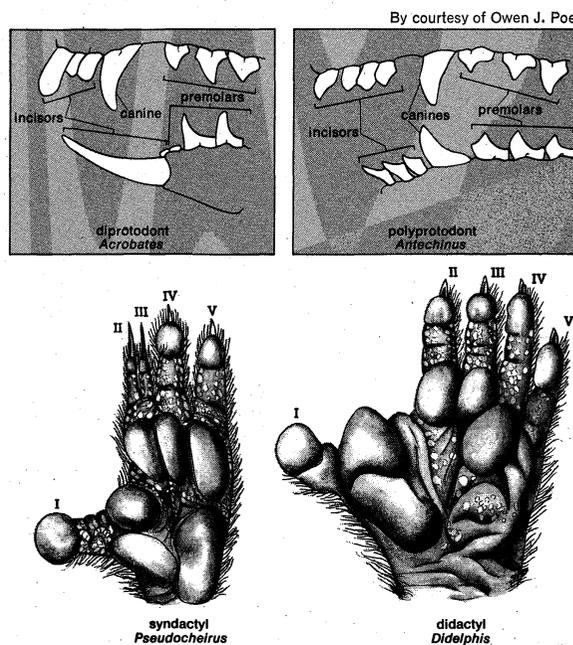

Figure 5: Dentition and fusion of the digits of the hindfoot of marsupials. (Top left) Diprotodont in the pygmy gliders and (top right) polyprotodont in the broad-footed pouched mice. (Bottom left) Digits II and III syndactyl, digit I opposable, in the ring-tailed opossums and (bottom right) digits II and III didactyl, digit I opposable, in the common opossum.

polyprotodont and of a presumed more primitive type since the teeth were more or less unspecialized. Marsupials with three or fewer upper incisors and a corresponding set of modifications of the primitive condition were said to be diprotodont. Subsequent investigations disclosed a gamut of intermediate dentitions, thereby discrediting the distinction.

Another equally unsatisfactory distinction was based on the curious but minor condition in which the second and third toes of the hindfeet are covered in a common sheath of skin. Species showing that condition were syndactylous, and the remainder were didactylous. Classifications were founded on such matters, and the groups were named appropriately Polyprotodontia and Diprotodontia in one scheme, and Syndactyla and Didactyla in another (see below *Classification*).

**Reproductive adaptations.** The most extraordinary anatomical features of the marsupials are the specializations associated with the reproductive system. The most striking of these is the protective pouch around the nipples of the female in many species. The pouch is well developed in kangaroos, wallabies, and wombats; in the tuan (*Phascogale tapoatafa*) and some dasyurids it is poorly developed, represented by lateral abdominal folds. In several South American didelphids, in the rat opossums (family Caenolestidae), and in the numbat, the pouch is lacking entirely. Even among species that have pouches, the degree of development depends upon the breeding condition of the animal, being most obvious when the female is lactating. The pouch in most forms opens forward, especially in upright and arboreal species; in the water opossum and many quadrupedal species the pouch is directed backward. There may be as few as two nipples (as in the koala and wombats) or as many as 27 (as in *Monodelphis*, the short-tailed opossum). The number of teats does not indicate the number of young that are nursed, however; in some cases more young are born than can be

Brain  
peculiarities

in  
pouches

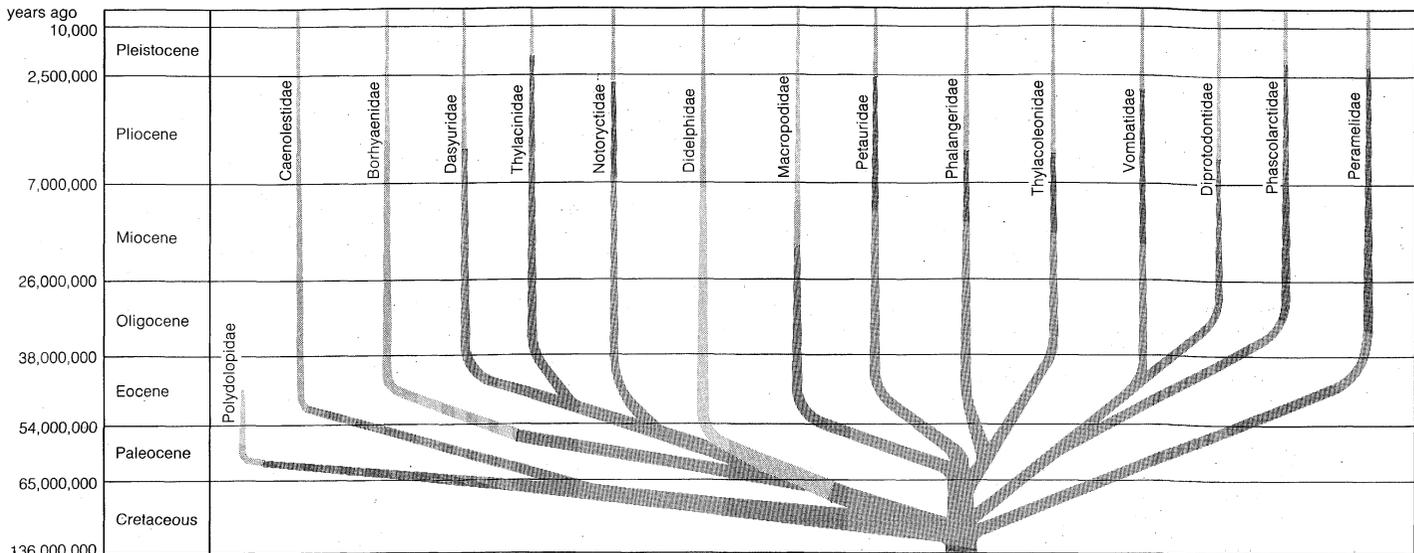

Figure 6: Dendrogram of the marsupials.

suckled at one time, but in most cases fewer young than the number of nipples are brought to full term.

The female reproductive tract is double for most of its length, becoming joined at the posterior ends of the two lateral vaginae. A birth canal, or median vagina, forms at the time of birth; copulation is accomplished by the insertion of the male's penis into the urogenital sinus of the female. The end of the penis is forked in some species. In addition to the peculiar penis, the male also has a scrotum in which the testes hang in front of the penis rather than behind; the testes are abdominal in the pouched male (*Notoryctes*). Most marsupials specialize in brief gestation, as indicated earlier. The developing embryo obtains its food chiefly from its own yolk sac, an embryonic organ provided by the mother. Typically, there is no intimate mother-fetus connection by means of a true (chorioallantoic) placenta, as in placental mammals. The bandicoots develop a rudimentary placenta, but it lacks the extensive ramifying projections (villi) that provide the close connection of mother and fetus tissue in the placentals.

#### EVOLUTION AND PALEONTOLOGY

Geologically, no marsupials have been discovered in Asia, and they are definitely not known from Africa. On the whole they are considered as primitive mammals, but for some 100,000,000 years they have shown a remarkable parallel and convergent evolution with placental mammals in habits, physiological processes, and structures.

Among the oldest marsupials are those represented by undisputed fossils from the Late Cretaceous strata of North America. These specimens are represented mostly by tiny isolated teeth, but parts of jaws have also been found. Until recently, all of the fragments were classified in the American opossum family, Didelphidae, but it has been observed that these early marsupials were already specialized in different directions. *Alphadon*, a genus of primarily tiny animals, is most likely a didelphid. On the other hand the group of small to medium-sized creatures, represented by the genus *Pediomys*, seem rather clearly not didelphids and are now placed in their own family, the *Pediomyidae*. The widely known genus *Eodelphis* is almost certainly not didelphid. Among its more conspicuous differences from the Didelphidae are the single- (not double-) rooted, much reduced first lower premolar and the presence of three, not four, lower incisors, of which the middle incisor is greatly enlarged. It is likely that this marsupial is not ancestral to any of the known later genera. Another specimen, known as *Thlaeodon*, is the largest known Cretaceous mammal. Its bulbous premolars and large canines are indicative of an adaptation to a mixed (omnivorous) diet. It appar-

ently is referable to another family. *Alphadon*, earlier thought to be nearer than any of the other Cretaceous genera to an ideal ancestral position for the marsupials as a whole, has been superseded by later finds. Fossil fragments of even earlier date (the Middle Cretaceous of Texas, about 100,000,000 years ago) have been tentatively referred to as *Holoclemensia*, a new genus in the family Didelphidae.

Evidence suggests that marsupials became widespread in the Tertiary Period, beginning 65,000,000 years ago, but they never succeeded as well on other continents as they did in South America and Australasia.

**American marsupials.** *Didelphoids.* Primitive marsupial characteristics in the superfamily Didelphoidea have long been recognized by mammalogists. Some of the features in the dentition, skull, and body skeleton may be reasonably expected to be remarkably like those in the Mesozoic ancestors of all later marsupials. Characters in the molars indicate that didelphoids and the South American borhyaenoids of the Paleocene Epoch (beginning 65,000,000 years ago) and Eocene Epoch (beginning 54,000,000 years ago) are closely related, but the lack of enough fossils makes it impossible to trace the lineage of all marsupial superfamilies back to the known North American Cretaceous fossils (possibly the more direct ancestors of some of the other superfamilies existed at that time). Better knowledge of the skeletons and dentitions of fossil marsupials from the Cretaceous Period and even the Early Cenozoic Era (beginning 65,000,000 years ago) may eventually alter considerably the present interpretation of their superfamily relationships.

*Borhyaenoids.* The oldest known South American marsupials are of the later Paleocene Epoch (about 55,000,000 years old). At that time three superfamilies, Didelphoidea, Borhyaenoidea, and Caenolestoidea, were already in existence. Patterns of the known cheek teeth of the Paleocene and early Eocene borhyaenoids and didelphoids indicate that these marsupials may have descended from a common ancestor no earlier than the Late Cretaceous.

The fossil record of the family Borhyaenidae starts in the late Paleocene and continues into the Pliocene (ending 2,500,000 years ago). No genera are known to have occurred outside South America. Borhyaenids were the flesh-eating mammals of the southern continent during nearly all the Tertiary Period. (True carnivores presumably did not reach that region until late in the Pliocene and Pleistocene.) The family name is derived from the genus *Borhyaena*, hyena-like specimens found in the early Miocene strata (about 26,000,000 years ago) of Argentina. These carnivorous marsupials had massive skulls with thick crushing teeth. Some genera—e.g., *Proborhyaena*—were shorter faced and more robust.

Primitive marsupial characteristics

All borhyaenids were not hyenoid, however. There were the wolflike *Prothalcynus* and *Lycopsis* and the fox- to marten-sized *Cladosictis* and *Amphiproviverra*. One of the most specialized of all was the Pliocene sabre-toothed borhyaenid *Thylacosmilus*; it was about the size of a puma and even more specialized as a stabbing mammal than most sabre-toothed cats. In all, more than 20 borhyaenid genera have been described, revealing a long evolutionary history in South America from a Cretaceous didelphid-like mammal.

**Necrolestoids.** One fossil with a molelike adaptation, called *Necrolestes*, is known from the Miocene of Patagonia. It is the only known genus referable to the family Necrolestidae (superfamily Necrolestoidea), probably basically related to the Borhyaenoidea or Didelphoidea.

**Caenolestoids.** The South American rat opossums (superfamily Caenolestoidea) are also undoubtedly descendants of a Cretaceous group, but the oldest known caenolestoids are already too specialized to reveal affinities with any of the known Mesozoic fossils. Any resemblances they have to Australian groups apparently result from convergent evolutionary trends in certain structures.

The family Caenolestidae has been recorded from early Eocene deposits, but the genera were more numerous later in the Oligocene and Miocene periods. These little marsupials were long known from fragmentary fossils, but in 1895 this supposedly extinct family was discovered as represented in the living Andean mammalian fauna of Ecuador and Bolivia by an animal resembling a small rat in size and appearance and named *Caenolestes*. The diprotodont incisor teeth are suggestive of those in some of the Australian phalangeroids, but the hindfeet show no trace of the phalangeroid syndactylism of the second and third toes. Other genera with living species are *Orolestes* in Peru and *Rhyncholestes* in Chile.

The Polydolopidae is an Early Cenozoic family of small specialized marsupials related to the Caenolestidae. Their fossil remains are abundant in the South American strata of that time. They had transversely compressed and laterally ridged premolars, with serrated crests, and rodent-like incisors. The polydolopids, probably in a large measure, occupied the ecological niches that were later occupied by rodents.

**Australasian marsupials.** Although pre-Pleistocene fossils of Australian marsupials are relatively rare, representatives of the families Dasyuridae, Peramelidae, Phalangeridae, Thylacoleonidae, Macropodidae, and Diprotodontidae appear as fossils in strata as early as the late Oligocene Epoch (26,000,000 years ago). During the Miocene and Pliocene epochs that followed, fossils of the family Vombatidae were laid down. These findings suggest that the Australian families of marsupials originated in the Early Cenozoic.

**Dasyuroids.** The oldest dasyuroid lived during the Middle Tertiary of South Australia; about the size of the present-day *Dasyurus quoll*, it was probably near the stem from which the thylacine evolved. *Glaucodon ballaratensis*, one of the most important fossil dasyuroids, is possibly of Pliocene age; it bore a resemblance to both *Dasyurus* and a Pleistocene member of *Sarcophilus*. The thylacine (*Thylacinus cynocephalus*), which constitutes the family Thylacinidae, is the largest and most widely known of the dasyuroid marsupials. Although its distribution is usually recorded as being restricted to Tasmania, it was represented on the mainland of Australia less than 10,000 years ago and also lived on New Guinea. The last certainly known thylacine was captured in Tasmania in 1930; however, sightings have been recorded of thylacines and their tracks as late as 1961 along a wild stretch of the west coast of Tasmania.

The family relationships of the thylacine are still not fully understood. (Its classification with the extinct Borhyaenidae of South America has almost conclusively been disproved.) Its characters, however, display a remarkable convergent evolution with the American borhyaenids. It seems reasonable to assume that the thylacine and the dasyures arose from a common ancestry. Many authorities place *Thylacinus* in the family Dasyuri-

dae, but until its ancestry is adequately known it seems best to treat it as forming a separate family.

Without a fossil record it is not possible to conclude how closely *Notoryctes*, constituting the family Notoryctidae, is related to the basal stocks of the dasyuroids and to that of the bandicoots, but the absence of syndactylism in the hindfeet suggests they are closer to the dasyuroids. *Myrmecobius*, also lacking a fossil record, is grouped with the family Dasyuridae because of similarities.

**Perameloids.** Members of the superfamily Perameloidea display one of the most primitive characters seen in any Australian marsupials: the retention of an incisor formula of  $\frac{5}{3}$  (polyprotodont) in most of the genera. They have syndactylism in the hindfoot: the proximal and median phalanges (bones) of the second and third digits are enclosed in the same sheath of skin.

Among the perameloids, both *Macrotis* and *Perameles* are represented in the late Pleistocene faunas of Australia. An extinct genus, *Ischnodon*, has been found in the Pliocene strata of South Australia. The most peculiar of all peramelids is the probably extinct (it has not been seen since about 1926) pig-footed bandicoot (*Cheropus ecaudatus*). The common name is derived from the construction of the front foot, in which the second and third digits are of equal length and closely united. The nails, of equal size and length, give the appearance of cloven hooves.

**Phalangeroids.** Only a very hypothetical phylogeny, indicating possible ancestral relationships of the superfamily Phalangoidea to the other superfamilies, can be outlined until an adequate fossil record from the Late Mesozoic and Early Cenozoic has been compiled. The Phalangoidea were probably derived from an ancestral stock that also gave rise to the Perameloidea. Evidently, in this early stock (in contrast to the Dasyuroidea) natural selection was toward syndactylism. Subsequently, one syndactyl stock led to the ancestors of the rat kangaroos, kangaroos, diprotodontids, wombats, koalas, marsupial lions, and phalangers; the other stock gave rise to the bandicoots.

Of the phalangers, *Eudromicia* is the most primitive of all the living genera. It comprises in part the dormouse possums. The retention of the fourth molars and the double-rooted first and second upper premolars distinguish *Eudromicia* from the other dormouse possums, *Cercartetus*, which they notably resemble.

The remains of a tiny marsupial called *Burrarnys* has been found in New South Wales, Australia. The shape of the skull and the pattern of the molars resemble those in *Cercartetus* (including *Eudromicia*), but the premolars are high and serrated. This genus is the basis for the family Burrarnyidae. Once thought to be extinct, several specimens of *Burrarnys* have been found since 1966 in northeastern Victoria.

One of the oldest fossil marsupials of Australasia is part of the skeleton of a brushtail-like possum, *Wynyardia bassiana*, found in late Eocene or Oligocene deposits near Wynyard, Tasmania. It constitutes the family Wynyardiidae. Fossils more closely related to later species occur in the Pleistocene of Australia; others much older occur in the Middle Tertiary of South Australia.

Among the most bizarre of all marsupials are the woolly possums, or cuscuses (*Phalanger*), from which the family and superfamily names are derived. *Wyulda*, the scaly-tailed possum, which is terrestrial and lives among rocks in northwestern Australia, is somewhat intermediate between the brush-tailed possums and the cuscuses. There has been much discussion about the relationships of the so-called marsupial lion (*Thylacoleo*). Most authorities agree that it belongs in a separate family, the Thylacoleonidae. Specimens of the cranium and lower jaws are well-known, and parts of the limb bones and body skeleton have been found. *Thylacoleo* was about the size of an African lion. Its teeth were even more specialized for meat shearing than those in the true cats; for example, the large posterior premolars were as long as 5.7 centimetres (2¼ inches). All the remaining teeth were greatly reduced, except the upper and lower median incisors,

Austral-  
asian fossil

which apparently were utilized in capturing other animals. These great carnivorous marsupials became extinct in Australia less than 26,000 years ago.

Although the genera referred to as the rat kangaroo family (Potoroidae) are closely related to the kangaroo family (Macropodidae) and are classified by some as a subfamily of that group, they apparently have represented a distinct lineage since Eocene time. They may be distinguished from kangaroos by, among other features, several peculiarities of dentition and skull features. The female urogenital system is more specialized than in the Macropodidae. A Pleistocene genus, *Propleopus*, is known, and a species of *Bettongia* and an undescribed genus occur in the Middle Tertiary of South Australia.

The most widely known marsupials are the kangaroos and their relatives (family Macropodidae). The gigantic forms during the Pleistocene were *Procoptodon*, *Sthenurus*, *Protemnodon*, and two species of *Macropus*. *Prionotemnus* is from the Pliocene, but the oldest kangaroos come from rocks probably as old as Miocene.

The macropodids are adapted for jumping. The principal digit in the hindfoot is the fourth, the fifth being somewhat reduced; the syndactyl second and third are reduced to splinters but still bear tiny claws. *Procoptodon* and *Sthenurus* differ from the other kangaroos in having lost all but the fourth digit.

*Vombatoids*. The superfamily Vombatoidea includes the diprotodonts, the koala, and the wombats.

The extinct family Diprotodontidae included the largest of all marsupials, *Diprotodon optatum*. It was built something like a huge ground sloth and attained the size of a large rhinoceros. Special dentition included the large, chisel-shaped median incisors and molar teeth, somewhat like those in certain kangaroos or tapirs, composed of two cross crests. *Diprotodon* was probably abundant in Australia in the late Pleistocene and subrecent time. Its remains have been found in levels contemporaneous with man. At least two other genera, *Nototherium* and *Euowenia*, representing much smaller diprotodontids, also occur in Australian Pleistocene faunas. *Palorchestes*, also of the Pleistocene, previously considered as the largest of all kangaroos, is now known to be a diprotodontid.

This family, like the Macropodidae, had a long Cenozoic history in Australia. *Meniscophus* is known from the Pliocene, and remains of a rather primitive undescribed genus and species are thought to be as old as the Oligocene Epoch. It appears that all known diprotodontids were herbivorous. The family may have been an early offshoot of the phalangeroid stock and perhaps was distantly related to kangaroos and wombats.

One of the most famous of all Australian marsupials is the koala, family Phascolarctidae. Only one species is known, although a rather distantly related genus, *Perikoala*, from the Tertiary of South Australia, has been described. The koala, with its short tail and rather stocky body, so resembles the wombat that the two are considered by some authorities to have arisen from a common ancestor, perhaps not very far back in Cenozoic time. Others believe, however, that the koala is much closer to the ringtails and greater gliders. The wombats (family Vombatidae), which resemble koalas in having no tails, are represented by two Pleistocene fossil genera: the giant wombat, *Phascolonus*, which was as large as a black bear, and *Ramsayia*. (Ed.)

#### CLASSIFICATION

**Distinguishing taxonomic features.** Two earlier classifications of marsupials were based on the number and arrangement of the front teeth and on the appression or separateness of certain toes. Marsupials having at least four upper incisors were named Polyprotodontia; those having three or (usually) fewer upper incisors and no lower canines, Diprotodontia. Marsupials having entirely separate toes on the hindfeet were called Didactyla; those having the second and third toes of the hindfeet enclosed in a common envelopment of skin, Syndactyla. These terms no longer have taxonomic validity, but their adjectival forms are still used to describe the dentition and the character of the hindfeet.

Additional aspects, such as the pattern of hair tracts, blood chemistry, details of reproductive anatomy and physiology, chromosomal morphology, sperm morphology, and behaviour, are currently being employed to structure a new taxonomic system representing more natural units that reflect what are presumed to be fundamental phylogenetic relationships.

**Annotated classification.** The time-honoured position of the Marsupialia as an order of mammals, generally unacceptable for a variety of reasons (see below *Critical appraisal*), is gradually giving way to a system first presented in 1964. As further modified, that arrangement raised the Marsupialia to the rank of a superorder and encompassed four orders, ten superfamilies, and 23 families, as given below. Wholly extinct groups are preceded by a dagger (†).

#### SUPERORDER MARSUPIALIA

(Metatherian, or pouched mammals)

Origin during the Cretaceous, expansion at beginning of the Tertiary, and decline with the rise of placentals thereafter. Currently established in Australia and nearby islands (introduced on New Zealand) and in the Americas. Young born after brief gestation in an embryonic condition; development completed while young are attached to teats, usually in a pouch, or marsupium. Skull elements differ from placentals; braincase small; brain relatively small and simple compared with placentals. Epipubic bones associated with the pelvic girdle. Fewer incisor teeth in lower than in upper jaws. Female reproductive tract doubled in large part (paired vaginae and uteri); testes usually in a scrotal sac and anterior to the forked penis (abdominal testes in *Notoryctes*). Comprises about 80 genera and about 240 species in 4 orders.

##### Order Marsupicarnivora

Comprises 3 extinct superfamilies and 2 extant superfamilies of primarily carnivorous marsupials.

##### †Superfamily Argyrolagoidea

Comprises a single family, Argyrolagidae, represented by *Argyrolagus* from the upper Pliocene to the lower Pleistocene in South America.

##### †Superfamily Borhyaenoidea

Comprises a single extinct family, Borhyaenidae, flesh-eating marsupials of South America during the late Paleocene and into the Pliocene Epoch (about 5,000,000 years ago). Many species had massive skulls and heavy crushing teeth. Named after hyaena-like specimens from Argentinian fossils. Examples: *Prothalcynus*, *Borhyaena*, *Lycopsis*, and the sabretoothed marsupial *Thylacosmilus*.

##### Superfamily Dasyuroidea

Primarily terrestrial carnivores that resemble the didelphids in certain anatomical features. Incisors small and unspecialized (polyprotodont). Digits in hindfeet never joined (didactylous). Marsupium not present in all species; when present it is poorly developed and opens backward. Three families ranging from Australia to nearby islands.

*Family Dasyuridae.* A group widespread over Australasia and represented by marsupial mice and rats (e.g., *Sminthopsis*, *Antechinus*, *Antechinomys*, *Planigale*, *Murexia*, and *Phascogale*), native cats (*Dasyurus*, *Dasyurops*), Tasmanian devil (*Sarcophilus*), numbat (*Myrmecobius*). Includes the smallest known extant marsupial, *Planigale ingrami* (about 12 centimetres in total length). About 18 genera and 48 species.

*Family Notoryctidae* (marsupial moles). Mole-sized marsupials, of the deserts of central and western Australia, remarkably convergent with placental moles of other continents. Pouch opens backward, and there are epipubic bones. One genus, *Notoryctes*, and 2 species.

*Family Thylacimidae* (thylacines). German-shepherd-sized wolflike marsupials. Represented on the mainland of Australia less than 10,000 years ago and in New Guinea, the thylacine was last captured in Tasmania in 1930. A single species, *Thylacinus cynocephalus*, constitutes the family.

##### Superfamily Didelphoidea

Primarily terrestrial American marsupials. Earliest fossils from Cretaceous strata. One extant family, Didelphidae, and 2 fossil families.

*Family Didelphidae* (American opossums). Central and South America boasts many species of unusual adaptations, notably *Chironectes* (water opossum), *Philander* (4-eyed opossums), *Metachirus*, and *Lutreolina*. *Didelphis* ranges as far north as southern Canada. Includes 12 genera and about 65 species.

The massive diprotodonts

†*Family Pedomyidae*. One genus, *Pedimys*, from the Upper Cretaceous in North America.

†*Family Stagodontidae*.

†*Superfamily Necrolestoidea*

Comprises 1 family, Necrolestidae. Based upon molelike fossils from the Miocene (starting 26,000,000 years ago) of Patagonia. One genus, *Necrolestes*.

**Order Paucituberculata**

Comprises a single superfamily of marsupials.

*Superfamily Caenolestoidea*

South American terrestrial marsupials. Earliest fossils from the early Eocene Epoch (about 50,000,000 years ago). One extant family, Caenolestidae, and 2 extinct families.

*Family Caenolestidae*. Ratlike in size and appearance. Diprotodont incisors suggest relationships to Australian phalangeroids, but other evidence disputes such affinities. Includes *Caenolestes* (Ecuador and Bolivia), *Orolestes* (Peru) and *Rhyncholestes* (Chile). Comprises 3 genera and 7 species.

†*Family Groeberiidae*. One genus, *Groeberia*, from the late Oligocene.

†*Family Polydolopidae*. Known from several genera including *Polydolops* and *Amphidolops* from upper Paleocene to late Eocene in South America.

**Order Peramelina**

Comprises 1 extant superfamily with 1 family of primarily carnivorous marsupials. Specimens of modern species are common in Pleistocene cave deposits in various parts of Australia.

*Superfamily Perameloidea* (bandicoots)

Comprises 1 family, Peramelidae. Terrestrial Australian marsupials that resemble rodents, rat-sized to hare-sized. Most genera have primitive polyprotodont dentition: 5 incisors above and 3 below. Syndactylism in hindfeet. Pouch is directed backward. Eight genera and 22 species, including: *Peroryctes*, *Microperoryctes*, and *Rhynchomeles*, primitive genera restricted to New Guinea and adjacent islands; *Perameles* and *Isoodon*, of wide distribution; *Macrotis* (bilbies) and *Chaeropus* (pig-footed bandicoot), restricted to Australia. Largest of the family (weight to 7 kg, or 15 lb.) is *Peroryctes broadbenti*.

**Order Diprotodontia**

Comprises 3 extant superfamilies of primarily herbivorous marsupials.

*Superfamily Phalangeroidea*

Australasian marsupials ranging from squirrel-sized arboreal species to large terrestrial bounders. Syndactylism of the second and third digits in the hindfeet. Four extant families; 2 extinct families.

*Family Burramyidae*. Primarily arboreal mouse- to squirrel-sized marsupials. Includes *Acrobates* (feathertail gliders), *Burramys*, and *Cercartetus* (pigmy possums). Comprises 3 genera and 6 species.

*Family Macropodidae*. Primarily terrestrial medium- to large-sized Australian marsupials. Adapted for jumping, with long hindlegs and long tail for balance. Forelimbs have sharp claws, and thumbs are not opposable. Main digit in hindfoot is the fourth. Extinct giant forms occurred during the Pleistocene, but oldest forms can be traced to the Miocene. Extant macropodids include *Macropus* (gray kangaroos and wallaroos), *Megaleia* (red kangaroos), *Wallabia* (wallabies), *Thylogale* (pademelons), *Dendrolagus* (tree kangaroos), and *Setonix* (quokkas). There are about 19 genera and 47 species.

*Family Petauridae*. Terrestrial and arboreal marsupials. First and second digits of the forelimbs are opposable to the other digits. Molars are adapted for chewing leaves. Includes *Pseudocheirus* (ring-tailed possums), *Petaurus* (sugar gliders), *Schoinobates* (greater gliders), *Gymnobelideus* (Leadbeater's possum), and *Dactylopsila* (striped possums). About 5 genera and 25 species.

*Family Phalangeridae*. Squirrel-sized to cat-sized arboreal species. Includes *Trichosurus* (brush-tailed possum), *Phalanger* (cuscuses), and *Wyulda* (scaly-tailed possum). About 6 genera and 15 species.

†*Family Thylacoleonidae*. So-called Australian marsupial lions, which became extinct less than 26,000 years ago. Teeth remarkably specialized for meat shearing. One genus, *Thylacoleon*.

†*Family Wynyardiidae*. Brushtail-like possums, the oldest fossil marsupials of Australasia, from presumed late Eocene rocks of Tasmania. One species, *Wynyardia bassiana*.

*Superfamily Tarsipedeoidea* (honey possums)

Comprises a single family, Tarsipedidae. Adapted for feeding on nectar of flowers. One species, *Tarsipes spenserae*, of southwestern Western Australia.

*Superfamily Vombatoidea*

Terrestrial and arboreal Australian marsupials, syndactylism of the second and third digits of the hindfeet. Two extant families; 1 extinct family.

†*Family Diprotodontidae*. Large herbivorous marsupial represented in the Australian fossil record as far back as the Miocene.

*Family Phascolarctidae* (koalas). Small bearlike Australian marsupials. Adapted to arboreal living and restricted to a diet of the leaves of a few species of eucalyptus. First and second digits of the forelimbs are opposable to the other digits. There is no tail. Pouch opens backward. One species along the eastern Australian coast: *Phascolarctos cinereus*.

*Family Vombatidae* (wombats). Woodchuck-like marsupials distinct from all others in having a single pair of ever-growing upper and lower incisors and in having rootless, high-crowned cheek teeth. The tail is very short. Includes *Phascolonus*, the giant wombat of the Pleistocene; *Vombatus* (common, or naked-nosed, wombat); *Lasiorhinus* (hairy-nosed wombat). Comprises 2 genera and 4 species.

**Critical appraisal.** An earlier classification, which is still encountered (see MAMMALIA), attributes ordinal rank to the marsupials. Under that system are listed 6 superfamilies and from 13 to 18 families, according to the authority followed. Various attempts to subdivide the order into suborders to accommodate necessary changes required by accumulated taxonomic findings have not been widely accepted. Along with a resurgence of interest in marsupial relationships has developed a growing body of opinion that the order rests too heavily on the presence of a pouch or its vestige. Such a foundation is as unwarranted as the reduction of all recognized orders of placental mammals into a single order because they all possess a placenta. In fact, as many variations and as great a degree of variations are found within the marsupials as are found in the placental mammals. Current opinion, therefore, favours the recognition of the Marsupialia as a superorder comprising four orders as given above.

## Martial

It is to Marcus Valerius Martialis, known in the English-speaking world as Martial, that most of the current knowledge of Roman society in the second half of the 1st century AD can be attributed. His poetic epigrams, numbering over 1,500, review the whole spectrum of his society. In addition, Martial recorded invaluable information on everyday life.

*Early years.* Martial was born on March 1 in one of the years AD 38 to 41 at Bilbilis, a Roman colony in Spain perched on a rock above the Salo River, the waters of which were used in the hardening of steel. The wild scenery of his birthplace probably affected him deeply and fostered in him that capacity for descriptive writing, which is not the least of his many talents. Proudly claiming descent from Celts and Iberians, he was, nevertheless, a freeborn Roman citizen, the son of parents who, though not wealthy, possessed sufficient means to ensure that he received the traditional literary education from a grammarian and rhetorician. In his late 50s he wrote, "My parents were stupid enough to have me taught literature, a paltry subject; but what good were teachers of grammar and rhetoric to me?" Yet this complaint should be taken with reservation, as it occurs in one of those epigrams that stress the inverse ratio of educational intensity to size of subsequent earnings.

In his early 20s, possibly not before AD 64, since he makes no reference to the burning of Rome that occurred in that year, he made his way to the capital of the empire and attached himself as client (a traditional relationship between powerful patron and humbler man with his way to make) to the powerful and talented family of the Senecas, who were Spaniards like himself. To their circle belonged Lucan, the epic poet, and Calpurnius Piso, chief conspirator in the unsuccessful plot against the emperor Nero in AD 65. After the latter incident and its consequences, Martial had to look around for other patrons. Presumably the Senecas had introduced him to other influential families, whose patronage would enable him to make a living as a poet. Yet precisely how Martial lived between AD 65 and 80, the year in which he published a small volume of poems to celebrate the consecration of the Flavian Amphitheatre, or Colosseum, is not known. It is possible that he turned his hand to law, although it is unlikely that he practiced in the courts either successfully or for long.

*Recognition.* By a law passed in AD 9, certain privileges were granted to fathers of three children in Rome, four children in Italy, and five children in the provinces. These privileges included exemption from various charges, such as that of guardianship, and a prior claim to magistracies. They were therefore financially profitable and accelerated a political career. As a mark of special imperial favour, they were occasionally conferred on men such as Martial and the younger Pliny who did not qualify by fatherhood. Martial was almost certainly unmarried, yet he received, probably from the emperors Titus and Domitian, this marital distinction. Moreover, as an additional mark of imperial favour, he was awarded a military tribuneship, which he was permitted to resign after six months service but which entitled him to the privileges of an *eques* (knight) throughout his life. Though he lacked the required property qualification of an *eques*, he could proudly boast that he sat in the first 14 rows of the theatre, behind the orchestra, which were reserved for the senators. As early as AD 84 the poet also owned a small country estate near Nomentum (about 12 miles [19 kilometres] northeast of Rome), which may have been given to him by Polla, the widow of Lucan. This undoubtedly was a welcome change from the city garret, three floors up, on the Quirinal Hill (one of the seven hills on which Rome stands), which he occupied until he acquired a small house of his own, also situated on the Quirinal.

From each of the patrons whom Martial, as client, attended at the morning levee (a reception held when arising from bed), he would regularly receive the "dole" of "100 wretched farthings." Wealthy Romans, who either hoped to gain favourable mention or feared to receive unfavourable, albeit oblique, mention in his epigrams, would supplement the minimum dole by dinner invitations or by gifts. The poverty so often pleaded by the poet is undoubtedly exaggerated; apparently his genius for spending kept pace with his capacity for earning.

Martial's first book, *On the Spectacles* (AD 80), contained more than 30 undistinguished poems, scarcely improved by gross adulation of the emperor Titus. In the year 84 or 85 appeared two undistinguished books (confusingly numbered XIII and XIV in the collection) with Greek titles *Xenia* and *Apophoreta*; these consist almost entirely of couplets describing presents given to guests at the December festival of the Saturnalia. In the next 15 or 16 years, however, appeared the 12 books of epigrams on which his renown deservedly rests. After 34 years in Rome he returned to Spain, where his last book (numbered XII) was published, probably in AD 102. He died not much more than a year later in his early 60s.

The chief friends Martial made in Rome—Seneca, Piso, and Lucan—have already been mentioned. As his fame grew, he became acquainted with the literary circles of his day, meeting great men whose works are still studied today: Quintilian, the learned and humane professor of rhetoric and educational theorist; Pliny the Younger, a brilliant writer of letters; the incomparable satirist Juvenal; and Silius Italicus, who spread the history of the Second Punic War over 17 books of epic verse, closely modelled on Virgil. Whether he knew the historian Tacitus and the poet Valerius Flaccus is not certain. That Martial never mentions Statius, a popular author of epics on the "Seven against Thebes" (mythological warriors who led an army against Thebes, a town of central Greece), and Achilles, a hero of the Trojan War, as well as talented composer of "occasional verse," is indeed surprising, though the omission may be accounted for by Martial's expressed detestation of turgid and involved poetry dealing with the backwaters of mythology.

*Assessment.* Martial has been charged with two gross faults: adulation and obscenity. He certainly indulged in much nauseating flattery of the emperor Domitian, involving, besides farfetched conceits dragging his epigrams well below their usual level, use of the official title "my Lord and my God." Furthermore, he cringed before men of wealth and influence, unashamedly whining for gifts and favours. Yet, however much one despises servility, it is hard to see how a man of letters could have survived long in Rome without considerable compromise. As for the latter charge, Martial introduced few themes not touched on by Catullus and Horace (two poets of the last century BC) before him. His references to homosexuality, "oral stimulation," and masturbation are couched, at least, in a rich setting of wit, charm, linguistic subtlety, superb literary craftsmanship, evocative description, and deep human sympathy. Martial is virtually the creator of the modern epigram, and his myriad admirers throughout the centuries, including many of the world's great poets, have paid him the homage of quotation, translation, and imitation.

Born into an age when greatness was reserved almost exclusively for the epic poet, the Spaniard from Bilbilis had the sense and the self-awareness to shun laurels manifestly beyond his grasp. He was still a true Roman poet, honouring the past and keeping to the mainstream of Greek and Roman tradition. He was, for instance, thoroughly acquainted with the great poets of Rome's Golden Age; Catullus, Tibullus, Sextus Propertius, Lucretius, Virgil, and Ovid. But in Martial's stress on the simple joys of life—eating, drinking, and conversing with friends—and in his famous recipes for contentment and the happy life, one is reminded continually of the dominant themes of Horace's *Satires*, *Epistles*, and *Second Epode*.

### MAJOR WORKS

*On the Spectacles* (*Liber spectaculorum*) (AD 80), recording the opening by Titus of the Flavian Amphitheatre (Colos-

Distinction  
and

favour

Creator  
of the  
epigram

seum); *Xenia*, numbered as Book XIII (AD 84–85), mottoes as presents for guests; *Apophoreta*, numbered as Book XIV, mottoes as gifts to take away; Books, I, II, III, IV, V, VI, VII, VIII, IX, X, XI, XII.

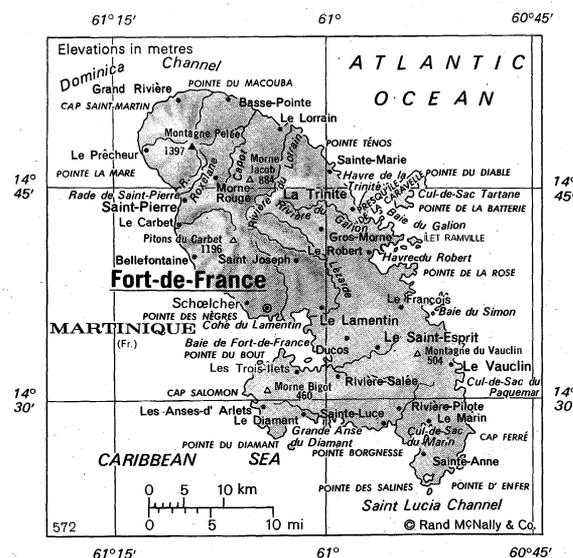

The most convenient complete translation with the Latin on the facing page is in the "Loeb Classical Library," *Martial*, by W.C.A. Ker, 2 vol. (1919–20). A good selection may be found in *Martial's Epigrams: Translations and Imitations*, by A.L. Francis and H.F. Tatum (1924); and *Epigrams, with an English Translation*, by W.C.A. Ker, 2 vol. (1961).

**BIBLIOGRAPHY.** The basic work for an understanding and interpretation of Martial's epigrams is the volume entitled *M. Valerii Martialis Epigrammaton Libri mit erklärenden Anmerkungen*, by LUDWIG FRIEDLAENDER (1886, reprinted 1967). Most other serious work is scattered in numerous classical periodicals and rare dissertations; of this only a very small portion is in English. For the general reader the following books are recommended: the English annotated selections from the poet's work by EDWIN POST (1908, reprinted 1967), H.M. STEPHENSON (1887), and R.T. BRIDGE and E.D.C. LAKE (1906–08, reprinted 1924); A.G. CARRINGTON, *Aspects of Martial's Epigrams* (1960), a useful general study; PAUL NIXON, *Martial and the Modern Epigram* (1927), which discusses Martial's literary influence; and J. WIGHT DUFF, "Martial and Minor Flavian Poetry," in *A Literary History of Rome in the Silver Age from Tiberius to Hadrian*, pp. 498–529 (1927). See also Duff's essays "Varied Strains in Martial," in *Classical and Mediaeval Studies in Honor of Edward Kennard Rand*, pp. 87–99 (1938); and "Martial—the Epigram As Satire," in *Roman Satire*, pp. 126–146 (1936).

(H.H.Hu.)

## Martinique

The island of Martinique is an overseas *département*, or administrative district, of France situated in the eastern Caribbean, about 4,400 miles (7,000 kilometres) from France and about 270 miles north of the coast of Venezuela. It forms part of the Windward Islands and is included in the Lesser Antilles island chain. Its nearest island neighbours are the British dependencies of Dominica 22 miles to the northwest and St. Lucia 16 miles to the south. The main islands of Guadeloupe, the other French overseas *département* in the Windward Islands, lie about 74 miles to the north.

MARTINIQUE

Martinique has an area of 431 square miles (1,116 square kilometres) and, in the early 1970s, a population of about 340,000 inhabitants. The island measures about 50 miles in length and about 22 miles at its widest extent. The smallest of all the French overseas *départements*, its population density of more than 300 inhabitants per square kilometre is one of the highest in the Antilles. The administrative capital and chief town is Fort-de-France (population about 100,000).

The name Martinique is probably a corruption of the Indian name Madiana (Island of Flowers) or Madinina (fertile island with luxuriant vegetation), as reputedly told to Christopher Columbus by the Caribs in 1502. Empress Joséphine, consort of Napoleon I, was born on the island in 1763; she was the daughter of a Martinique planter named Joseph Tascher de La Pagerie (see also GUADELOUPE; for an associated physical feature, see CARIBBEAN SEA).

**The landscape.** *Relief and drainage.* The mountainous relief of Martinique represents the outermost edge of what remained of the original geological formation after the subsidence of the trench that became the Caribbean Sea. The relief of the island takes the form of three principal massifs (mountainous masses). These are Montagne Pelée (4,583 feet, or 1,397 metres) to the north; the Pitons (peaks) du Carbet (of which Lacroix Peak reaches 3,923 feet, or 1,196 metres) in the centre; and Montagne du Vauclain (1,654 feet, or 504 metres high) in the south.

The tortuous relief of the island has led to a complex drainage pattern, characterized by short watercourses. In the south, the Rivière Salée and the Rivière Pilote flow down from the scarps of Montagne du Vauclain. In the centre, the rivers flow outward from the Pitons du Carbet in a starlike pattern; they include the Lorrain, Galion, Capot, and Lézarde rivers. In the north, the Grande Rivière, the Céron, the Rivière Roxelane, the Rivière des Pères, and the Rivière Sèche are little more than irregular torrents.

The northern coastline of Martinique is characterized by steep cliffs; farther south, however, the cliffs become lower with two large bays—Fort-de-France and Le Marin—being located on the western coast. Coral reefs, headlands, and coves occur on the east coast.

*Climate.* The climate is remarkably constant, with the average temperature amounting to 79° F (26° C), with average minimums of about 68° to 72° F (20° to 22° C), average maximums of about 86° to 90° F (30° to 32° C), and temperature extremes of 59° F (15° C) and 93° F (34° C).

The northeast trade winds, which blow almost 300 days a year, temper the heat, but winds from the south are hot and humid and sometimes bring hurricanes.

Rainfall is abundant, especially in July and September, but is very irregularly distributed; it varies from 39 inches to more than 157 inches a year, depending upon the orientation of the relief.

The year consists of two distinct seasons—the relatively dry Lent season, which lasts from December to June, and the rainy winter season from July to December.

*Vegetation and animal life.* The climate, together with the volcanic soil, produces a luxuriant vegetation, which is divided, according to altitude, into four zones: the maritime zone, the lowlands, the former forest zone, and the upper mountain slopes. The maritime zone includes 7,400 acres of mangrove swamp, half of which is located in the bay of Fort-de-France. The beaches are invaded by morning glory, tropical twining herb, and sea grape. The lowland vegetation zone extends from the coast to a height of about 1,500 feet and corresponds to the chalky lands of the Sainte-Anne and Caravelle districts. Here are found ferns and orchids, as well as various trees, including mahogany, white gum, and other species. Above 1,500 feet is the former virgin forest zone, where large trees and bracken are still to be found. As the altitude increases the trees grow smaller. A transitional zone is characterized by peat moss. Above 3,000 feet the upper slopes are almost bare, except for some stunted forest.

There are relatively few kinds of animals on the island. The mongoose was introduced in the 19th century in the hope of eliminating the deadly, rat-tailed viper, but without doing so. Also found are the manicon (a kind of opossum), wild rabbit, wild pigeon, turtle dove, and ortolan (a small bird about six inches long, often netted and fattened as a table delicacy).

**History.** Although Christopher Columbus sighted the island in 1493, it was not until 1502, on his fourth voyage, that he visited it, leaving there some pigs and goats. Neglected by the Spaniards, who sought more material

The three principal massifs

The four vegetation zones

rewards than those the island offered, Martinique was occupied in 1635 by a Frenchman, Pierre Belain d'Es-nambuc, who established 80 settlers at Fort Saint-Pierre at the mouth of the Rivière Roxelane. A year later d'Es-nambuc, who had fallen sick, entrusted Martinique to his nephew, Jacques-Dyel du Parquet, who bought the island from the Compagnie des Isles d'Amérique and developed it into a remarkably prosperous colony.

In 1654 a group of 250 Dutch Jews, chased from Brazil by the Portuguese, introduced sugarcane. In 1660 cacao trees were planted in place of cotton. After the death of du Parquet, his widow governed the island in the name of her children, but disagreed with the settlers; and in 1658 the French king, Louis XIV, resumed sovereignty over the island, paying an indemnity to du Parquet's children. In 1664 the island was placed under the authority of the Compagnie des Indes Occidentales; in 1674 it was made part of the French crown domain, being administered, according to the Pacte Colonial, a body of principles summarized in the statement: "The mother country founds and maintains the colonies; the colonies enrich the mother country." Supplies and slaves were brought out to the French Antilles by the Compagnie du Sénégal, founded in 1664; the slave ships called at Martinique before proceeding to Guadeloupe, permitting the colony first choice of the slaves. In 1723 Arabian coffee was introduced, thus further contributing to the island's prosperity. In 1787 Louis XVI granted Martinique the right to establish a Colonial Assembly.

Attacks by  
Dutch  
and  
British

At various times Martinique was subjected to attack by various foreign fleets. An attack by the Dutch was repulsed in 1674; further attacks by the English were repelled in 1693 and in 1759. In 1762, however, the English captured the island, only to return it to France under the terms of the Treaty of Paris in 1763. The English recaptured it in 1794, and occupied it until 1802; captured once more by the English in 1809, it was definitively restored to France in 1814. Slave uprisings occurred in 1789, 1815, and 1822. The abolition of slavery in 1848 created a labour problem, as a result of which labourers from India and China were introduced. In 1848 universal suffrage was proclaimed, but was abolished once more under Napoleon III; after 1870 the French Third Republic restored representation for the island in the French Parliament.

In 1902 the volcanic eruption of Mont Pelée destroyed the town of Saint-Pierre, killing about 30,000 people. During World War II Martinique adhered to the Vichy government for three years before rallying to the Free French cause in 1943. In 1946, Martinique was granted the status of a French *département*.

**The population.** In 1658 French settlers on the island numbered about 5,000. The Carib element gradually disappeared, partly as a result of conflicts and partly as a result of assimilation. The importation of black slaves from Africa added a further ethnic component. Today the racial composition of the island is extremely mixed, although the black element is the largest. The white Creole (locally born) element, however, controls an important part of the island's economy.

	area		population

Total Martinique	431	1,116	320,000	340,000

Source: Official government figures.

Martinique's population is rapidly increasing, at a rate of 2 percent a year. The population is youthful, with more than 50 percent less than 20 years old. A Creole dialect, similar to that spoken in Haiti, is spoken, but French, which is taught in schools, is the official language.

With the exception of a few groups within the juris-

dition of the Methodist Missionary Society, and several Adventist communities, the population is in general Roman Catholic.

**The contemporary state.** *The economy.* The economy of the island is primarily agricultural; sugar, bananas, and rum are the principal exports. Although about 28 percent of the population is engaged in agriculture, this activity contributes only about 20 percent to the value of the gross domestic product. The annual agricultural output includes about 30,000 tons of sugar, 10,000 tons of pure alcohol for rum making, and more than 200,000 tons of bananas. Fresh and canned pineapples are produced. Subsistence crops include yams and cassava.

Agriculture and industry

Economic planning has laid emphasis on land reform, the diversification of agricultural crops, and industrialization. Local industrial plants include a plant for crushing clinkers, an oil refinery at Fort-de-France with a capacity of 600,000 tons a year, and a fertilizer plant with an output capacity of 100,000 tons a year. High hopes are placed on the development of tourism. An association has been formed that groups together ten *communes* (small administrative units) in the administrative district (*arrondissement*) of the island that is the most favourable to tourism.

Martinique receives a considerable amount of aid from FIDOM (Investment Fund for the Economic and Social Development of the Overseas Departments) as well as from European funds.

Martinique's predicament stems in part from the fact that the service sector of the economy accounts for only about one quarter of the domestic national product but employs nearly one third of the economically active population, which numbers about 90,000. Economic imbalance results in a significant deficit in the balance of trade. Overseas trade is essentially with France and the franc zone. An experiment in an adaptation of military service, consisting of road-building and repairing hurricane damage, has been undertaken.

*Transportation.* Martinique maintains regular air and sea links with France and North America. Sea traffic at the port of Fort-de-France amounts to about 1,500 boats a year. There is an international airport at Lamentin, to the east of Fort-de-France. The road network, which increased considerably in the 1960s, consists of about 600 miles of paved roads, and more than 500 miles of dirt roads. There are local bus services, and small coastal steamers connect various points around the island.

*Administration and social conditions.* As an overseas *département*, Martinique is divided into two *arrondissements*, comprising 34 *communes*, each of which is administered by an elected municipal council. Executive authority is represented by a prefect and other officials, and there is a legislative council of 36 elected members. Martinique is represented in the French National Assembly by three deputies and in the French Senate by two senators. The French system of justice is in force. There is a court of appeal, a judicial tribunal, and five tribunals of the first instance (the equivalent of county courts).

There are several general and maternity hospitals, as well as some dispensaries, and a hot springs station at Morne-Rouge. Martinique benefits from the same social legislation as that of metropolitan France.

There are more than 250 primary schools, as well as four secondary schools. The school enrollment of children of school age is virtually 100 percent. Higher education is usually pursued in metropolitan France, for which a number of scholarships are available. An institute of juridical studies and a higher education centre were to constitute part of the University of the Antilles, which was being formed.

Schools

*Cultural life.* The local press consists of about a dozen daily or weekly newspapers. The ORTF (Office de Radio-diffusion Télévision Française) broadcasts radio and television programs. The Fort-de-France carnival, featuring a parade with masks, is an annual event. Voodoo ceremonies are far less important on the island than they are in Haiti. Cockfighting is a popular sport.

**Prospects for the future.** The major problem faced by Martinique is demographic; it is difficult to find sufficient

food and employment for a growing population. Emigration to France has been a palliative, but not a solution. Hopes for an amelioration of economic conditions depend on the development of the tourist industry.

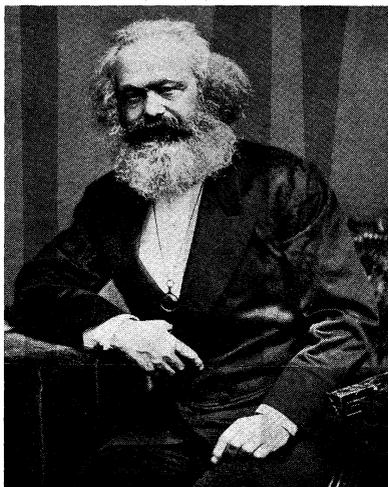

**BIBLIOGRAPHY.** EUGENE REVERT, *La Martinique: étude géographique et humaine* (1949), is the best geographical work. See also the same author's *La Magie antillaise* (1951); *Les Antilles* (1954); and *Entre les deux Amériques: le monde Caraïbe* (1958); and AUGUSTE JOYAU, *La Martinique: carrefour du monde caraïbe* (1967), a good synthesis.

(R.Co.)

## Marx, Karl

Karl Marx, revolutionist, sociologist, and economist, was the author (with Friedrich Engels) of *Manifest der Kommunistischen Partei* (1848), commonly known as *The Communist Manifesto*, the most celebrated pamphlet in the history of the Socialist movement, as well as of its most important book, *Das Kapital*. The body of thought and belief known as Marxism is based upon the writings of Marx and Engels.

Marx.

**Early years.** Karl Heinrich Marx was born on May 5, 1818, in the city of Trier (formerly Trèves) in the Rhine province of Prussia, now in West Germany, one of seven children of Jewish parents. His father Heinrich, a lawyer, was a man of the Enlightenment, devoted to Kant and Voltaire, who took part in agitations for a constitution in Prussia. His mother, born Henrietta Pressburg, was from Holland and never learned to speak German properly. A year or so before Karl was born, his father—probably because his professional career required it—was baptized in the Evangelical Established Church, and Karl was baptized when he was six years old.

Marx was educated from 1830 to 1835 at the high school in Trier. Suspected of harbouring liberal teachers and pupils, the school was under police surveillance. Marx's adolescent writings exhibited a spirit of Christian devotion and a longing for self-sacrifice on behalf of humanity. In October 1835, he matriculated at the University of Bonn. The courses he attended were exclusively in the humanities, in such subjects as Greek and Roman mythology and the history of art. He participated in customary student activities, fought a duel, and spent a day in jail for being drunk and disorderly—the only imprisonment he suffered in his life. He presided at the Tavern Club and joined a poets' club that included some political activists. A politically rebellious student culture was, indeed, part of life at Bonn. Many students had been arrested; some were still being expelled in Marx's time, particularly as the outcome of an effort by students to disrupt the session of the Federal Diet at Frankfurt. The tavern clubs at Bonn were also at odds with the more aristocratic student associations. Marx, however, left Bonn after a year and in October 1836 enrolled at the University of Berlin to study law and philosophy.

Marx's crucial experience at Berlin was his introduction to Hegel's philosophy, regnant there, and his adherence to the Young Hegelians. At first he felt a repugnance toward Hegel's doctrines; when he fell sick it was partially, as he wrote his father, "from intense vexation at having to make an idol of a view I detested." But the Hegelian circumpressure in the revolutionary student culture was powerful. Marx joined a society called the Doctor Club, whose members were intensely involved in the new literary and philosophical movement. Their chief figure was Bruno Bauer, a young lecturer in theology, who was developing the idea that the Christian Gospels were a record not of history but of human fantasies arising from men's emotional needs and that Jesus had not been a historical person. Marx enrolled in a course of lectures given by Bauer on the prophet Isaiah. Bauer taught that a new social catastrophe "more tremendous" than that of the advent of Christianity was in the making. The Young Hegelians began moving rapidly toward atheism and also talked vaguely of political action.

The Prussian government, fearful of the subversion latent in the Young Hegelians, soon undertook to drive them from the universities. Bauer was dismissed from his post in 1839. Marx's "most intimate friend" of this period, Adolph Rutenberg, an older journalist who had served a prison sentence for his political radicalism, pressed for a deeper social involvement. By 1841 the Young Hegelians had become left republicans. Marx's studies, meanwhile, were lagging. Urged by his friends, he submitted a doctoral dissertation to the university at Jena, which was known to be lax in its academic requirements, and received his degree in April 1841. His thesis analyzed in a Hegelian fashion the difference between the natural philosophies of Democritus and Epicurus. More distinctively, it sounded a note of Promethean defiance:

Philosophy makes no secret of it. Prometheus' admission: 'In sooth all gods I hate,' is its own admission, its own motto against all gods, . . . Prometheus is the noblest saint and martyr in the calendar of philosophy.

In 1841 Marx, together with other Young Hegelians, was much influenced by the publication of *Das Wesen des Christentum* (1841; *The Essence of Christianity*, 1854) by Ludwig Feuerbach. Its author, to Marx's mind, successfully criticized Hegel from the materialist standpoint, showing how the "Absolute Spirit" was a projection of "the real man standing on the foundation of nature." Henceforth Marx's philosophical efforts were toward a combination of Hegel's dialectic with Feuerbach's materialism. In January 1842, Marx began contributing to a newspaper newly founded in Cologne, the *Rheinische Zeitung*. It was the liberal democratic organ of a group of young merchants, bankers, and industrialists; Cologne was the centre of the most industrially advanced section of Prussia. To this stage of Marx's life belongs an essay on the freedom of the press. Since he then took for granted the existence of absolute moral standards and universal principles of ethics, he condemned censorship as a moral evil that could have only evil consequences; it also entailed spying into men's minds and hearts and assigned to weak and malevolent mortals powers that presupposed an omniscient mind.

On October 15, 1842, Marx became editor of the *Rheinische Zeitung*. As such, he was obliged to write editorials on a variety of social and economic issues, ranging from the housing of the Berlin poor and the theft by peasants of wood from the forests to the new phenomenon of Communism. He found his Hegelian idealism of little use in these matters. At the same time he was becoming estranged from his Hegelian friends for whom shocking the bourgeois was a sufficient mode of social activity. Marx, friendly at this time to the "liberal-minded practical men" who were "struggling step-by-step for freedom within constitutional limits," succeeded in trebling his newspaper's circulation and making it a leading journal in Prussia. Nevertheless, Prussian authorities suspended it, giving in to pressures from the government of Russia. Marx went to Paris to study French Communism.

Marx, after an engagement of seven years, had been married in June 1843 to Jenny von Westphalen. Jenny

The  
Young  
Hegelians

Newspaper  
work

was an attractive, intelligent, and much-admired girl, four years older than Karl; she came of a family of military and administrative distinction, descended on her mother's side from the rebellious Scottish earls of Argyll. Her half-brother later became a highly reactionary Prussian minister of the interior. Her father, a follower of the French Socialist Saint-Simon, was fond of Karl, though others in her family opposed the marriage. Marx's father also feared that Jenny was destined to become a sacrifice to the demon that possessed his son.

In Paris, Marx began associating with Communistic societies of French and German workingmen. Their ideas were, in his view, "utterly crude and unintelligent," but their character moved him: "the brotherhood of man is no mere phrase with them, but a fact of life, and the nobility of man shines upon us from their work-hardened bodies," he wrote in his so-called "Ökonomisch-philosophische Manuskripte aus dem Jahre 1844" (1844; *Economic and Philosophic Manuscripts of 1844* [1959]). A venture with the liberal Hegelian Arnold Ruge in the publications of "German-French Yearbooks" proved short-lived. Marx's article "Toward the Critique of the Hegelian Philosophy of Right" appeared in their pages in 1844 with its oft-quoted assertion that religion is the "opium of the people," and it was here that he first raised the call for an "uprising of the proletariat" to realize the conceptions of philosophy. Once more the Prussian government intervened against Marx; after being expelled from France by the government of Guizot, Marx left for Brussels on February 5, 1845. That year in Belgium he renounced his Prussian nationality.

**Brussels period.** The next two years in Brussels saw the deepening of Marx's lifelong collaboration with Friedrich Engels. Engels had seen at firsthand in Manchester (where a branch factory of his father's textile firm was located) all the depressing aspects of the Industrial Revolution. He had also been a Young Hegelian and had been converted to Communism by Moses Hess, who was called the "Communist rabbi." In England he associated with the followers of Robert Owen. Now he and Marx, finding that they shared the same views, combined their intellectual resources and published *Die heilige Familie* (1845; *The Holy Family*, 1956), a prolix criticism of the Hegelian idealism of the theologian Bruno Bauer. Their next work, *Die deutsche Ideologie* (written 1845-46, published 1932; *The German Ideology*, 1938), contained the first full exposition of their materialistic conception of history, but it found no publisher and remained unknown during its authors' lifetimes.

During his Brussels years, Marx developed his views and, through confrontations with the chief leaders of the working-class movement, established his intellectual standing. In 1846 he publicly excoriated the German leader Wilhelm Weitling for his moralistic appeals. Marx insisted that the stage of bourgeois society could not be skipped over; the proletariat could not just leap into Communism; the workers' movement required a scientific basis, not moralistic phrases. He also polemicized against the French Socialist thinker Pierre-Joseph Proudhon in *Misère de la philosophie* (1847; *The Poverty of Philosophy*, 1900), a mordant attack on Proudhon's book subtitled *Philosophie de la misère* (1846; *The Philosophy of Poverty*, 1888). Proudhon wanted to unite the best features of such contraries as competition and monopoly; he hoped to save the good features in economic institutions while eliminating the bad. Marx, however, declared that no equilibrium was possible between the antagonisms in any given economic system. Social structures were transient historic forms determined by the productive forces: "The handmill gives you society with the feudal lord; the steammill, society with the industrial capitalist." Proudhon's mode of reasoning, Marx wrote, was typical of the petty bourgeois, who failed to see the underlying laws of history.

An unusual sequence of events led Marx and Engels to write their pamphlet, *The Communist Manifesto*. In June 1847 a secret society, the League of the Just, composed mainly of emigrant German handicraftsmen, met in London and decided to formulate a political program. They

sent a representative to Marx to ask him to join the League; Marx overcame his doubts, and, with Engels, joined the organization, which thereupon changed its name to the Communist League and enacted a democratic constitution. Entrusted with the task of composing their program, Marx and Engels worked from the middle of December 1847 to the end of January 1848. The London Communists were already impatiently threatening Marx with disciplinary action when he sent them the manuscript; they promptly adopted it as their manifesto. It enunciated the proposition that all history had hitherto been a history of class struggles, combining this with the assertion that the victory of the proletariat would be the final struggle, putting an end to class society forever. It mercilessly criticized all forms of Socialism founded on philosophical "cobwebs" such as "alienation." It rejected the avenue of "social Utopias," small experiments in community, as deadening the class struggle and therefore as being "reactionary sects." It set forth ten immediate measures as first steps toward Communism, ranging from a progressive income tax and the abolition of inheritances to free education for all children. It closed with the words, "The proletarians have nothing to lose but their chains. They have a world to win. Workingmen of all countries, unite!"

Revolution suddenly erupted in Europe in the first months of 1848, in France, Italy, and Austria. Marx had been invited to Paris by a member of the provisional government just in time to avoid expulsion by the Belgian government. In Paris he opposed an ill-fated project of Georg Herwegh, a poet, for organizing a German legion to invade and liberate the fatherland. Marx's opposition to his venture made him unpopular among most of the German exiles. As the revolution gained in Austria and Germany, Marx returned to the Rhineland. In Cologne he advocated a policy of coalition between the working class and the democratic bourgeoisie, opposing for this reason the nomination of independent workers' candidates for the Frankfurt Assembly and arguing strenuously against the program for proletarian revolution advocated by the leaders of the Workers' Union. He concurred in Engels' judgment that *The Communist Manifesto* should be shelved and the Communist League disbanded. Marx pressed his policy through the pages of the *Neue Rheinische Zeitung*, newly founded in June 1849, urging a constitutional democracy and war with Russia. When the more revolutionary leader of the Workers' Union, Andreas Gottschalk, was arrested, Marx supplanted him and organized the first Rhineland Democratic Congress in August 1848. When the King of Prussia dissolved the Prussian Assembly in Berlin, Marx called for arms and men to help the resistance. Bourgeois liberals withdrew their support from Marx's newspaper, and he himself was indicted on several charges including advocacy of the nonpayment of taxes. On this occasion Marx gave the only speech he ever made on the Cologne streets to a crowd of workers. In his trial he defended himself with the argument that the crown was engaged in making an unlawful counter-revolution. The jury acquitted him unanimously and with thanks. As the last hopeless fighting flared in Dresden and Baden, Marx was ordered banished as an alien on May 16, 1849. The final issue of his newspaper, printed in red, caused a great sensation.

**Early years in London.** Expelled once more from Paris, Marx went to London in August 1849. Chagrined by the failure of his own tactics of collaboration with the liberal bourgeoisie, he rejoined the Communist League in London and for about a year advocated a bolder revolutionary policy. An "Address of the Central Committee to the Communist League," written with Engels in March 1850, urged that in future revolutionary situations they struggle to make the revolution "permanent" by avoiding subservience to the bourgeois party and by setting up "their own revolutionary workers' governments" alongside any new bourgeois one. Marx hoped that the economic crisis would shortly lead to a revival of the revolutionary movement; when this hope faded, he came into conflict once more with those whom he called "the alchemists of the revolution," such as August von Willich, a

Participation in the events of 1848

Revolutionary writings

Communist who proposed to hasten the advent of revolution by undertaking direct revolutionary ventures. Such persons, Marx wrote in September 1850, substitute "idealism for materialism," and regard

pure will as the motive power of revolution instead of actual conditions. While we say to the workers: "You have got to go through fifteen, twenty, fifty years of civil wars and national wars not merely in order to change your conditions but in order to change yourselves and become qualified for political power," you on the contrary tell them, "We must achieve power immediately. . . ."

The militant faction in turn ridiculed Marx for being a revolutionary who limited his activity to lectures on political economy to the Communist Workers' Educational Union. The upshot was that Marx gradually stopped attending meetings of the London Communists. In 1852 he devoted himself intensely to working for the defense of 11 Communists arrested and tried in Cologne on charges of revolutionary conspiracy and wrote a pamphlet on their behalf. The same year he also published, in a German-American periodical, his essay "Der Achtzehnte Brumaire des Louis Bonaparte" (*The Eighteenth Brumaire of Louis Bonaparte*, 1926), with its acute analysis of the formation of a bureaucratic absolutist state with the support of the peasant class. In other respects the next 12 years were, in Marx's words, years of "isolation" both for him and for Engels in his Manchester factory.

Poverty  
in London

From 1850 to 1864, Marx lived in material misery and spiritual pain. His funds were gone, and except on one occasion he could not bring himself to seek paid employment. In March 1850 he and his wife and four small children were evicted and their belongings seized. Several of his children died—including a son Guido, "a sacrifice to bourgeois misery," and a daughter Franziska, for whom his wife rushed about frantically trying to borrow money for a coffin. For six years the family lived in two small rooms in Soho, often subsisting on bread and potatoes. The children learned to lie to the creditors: "Mr. Marx ain't upstairs." Once he had to escape them by fleeing to Manchester. His wife suffered breakdowns.

During all these years Friedrich Engels loyally contributed to Marx's financial support. The sums were not large at first, for Engels was only a clerk in the firm of Ermen and Engels at Manchester. Later, however, in 1864, when he became a partner, his subventions were generous. Marx was proud of Engels' friendship and would tolerate no criticism of him. Bequests from the relatives of Marx's wife and from Marx's friend Wilhelm Wolff helped to alleviate their economic distress.

Marx had one relatively steady source of earned income in the United States. On the invitation of Charles A. Dana, managing editor of *The New York Tribune*, he became, in 1851, its European correspondent. The newspaper, edited by Horace Greeley, had sympathies for Fourierist Communism. From 1851 to 1862 Marx contributed close to 500 articles and editorials (Engels providing about a fourth of them). He ranged over the whole political universe, analyzing social movements and agitations from India and China to Britain and Spain. Dana's friendship proved helpful to Marx in another personal crisis. A liberal Swiss professor, Karl Vogt, charged in 1859 that Marx was the chief of a circle of blackmailers. Marx's reply in a seldom-read book, *Herr Vogt* (1860), included a testimonial to his character by Dana.

In 1859 Marx published his first book on economic theory, *Zur Kritik der politischen Ökonomie (A Contribution to the Critique of Political Economy, 1904)*. In its preface he described how he had arrived at the materialistic conception of history.

The mode of production in material life determines the general character of the social, political, and spiritual processes of life. It is not the consciousness of men that determines their existence, but, on the contrary, their social existence that determines their consciousness.

Marx regarded his studies at the British Museum in economic and social history as his main task, and when the German revolutionist Ferdinand Lassalle proposed in 1862 that he join with him in organizing a new workers' movement in Germany he refused. Lassalle shortly undertook the project alone.

**Role in the First International.** Marx's political isolation ended in 1864 with the founding of the International Working Men's Association. Although he was neither its founder nor its head, he soon became its leading spirit. Its first public meeting, called by English trade union leaders and French workers' representatives, took place at St. Martin's Hall in London on September 28, 1864. Marx, who had been invited through a French intermediary to attend as a representative of the German workers, sat silently on the platform. A committee was set up to produce a program and a constitution for the new organization. After various drafts had been submitted that were felt to be unsatisfactory, Marx, serving on a subcommittee, drew upon his immense journalistic experience. His "Address and the Provisional Rules of the International Working Men's Association," unlike his other writings, stressed the positive achievements of the cooperative movement and of parliamentary legislation; the gradual conquest of political power would enable the British proletariat to extend these achievements on a national scale.

As a member of the organization's General Council, and corresponding secretary for Germany, Marx was henceforth assiduous in attendance at its meetings, which were sometimes held several times a week. For several years he showed a rare diplomatic tact in composing differences among various parties, factions, and tendencies. The International grew in prestige and membership, its numbers reaching perhaps 800,000 in 1869. It was successful in several interventions on behalf of European trade unions engaged in struggles with employers.

In 1870, however, Marx was still unknown as a European political personality; it was the Paris Commune that made him into an international figure, "the best calumniated and most menaced man of London," as he wrote. When the Franco-Prussian War broke out in 1870, Marx and Engels disagreed with followers in Germany who refused to vote in the Reichstag in favour of the war. The General Council declared that "on the German side the war was a war of defence." After the defeat of the French armies, however, they felt that the German terms amounted to aggrandizement at the expense of the French people. When an insurrection broke out in Paris and the Paris Commune was proclaimed, Marx gave it his unswerving support. On May 30, 1871, after the Commune had been crushed, he hailed it in a famous address:

History has no comparable example of such greatness. . . . Its martyrs are enshrined forever in the great heart of the working class.

In Engels' judgment, the Paris Commune was history's first example of the "dictatorship of the proletariat." Marx's name, as the leader of The First International, became synonymous throughout Europe with the revolutionary spirit symbolized by the Paris Commune.

The advent of the Commune, however, exacerbated the antagonisms within the International Working Men's Association and brought about its downfall. English trade unionists such as George Odger, former president of the General Council, opposed Marx's support of the Paris Commune. The Reform Bill of 1867, which had enfranchised the British working class, had opened vast opportunities for political action by the trade unions. English labour leaders found they could make many practical advances by cooperating with the Liberal Party and, regarding Marx's rhetoric as an encumbrance, resented his charge that they had "sold themselves" to the Liberals.

A left opposition also developed under the leadership of the famed Russian revolutionist, Mikhail Alexandrovich Bakunin. A veteran of tsarist prisons and Siberian exile, Bakunin could move men by his oratory, which one listener compared to "a raging storm with lightning, flashes and thunderclaps, and a roaring as of lions." Bakunin admired Marx's intellect but could hardly forget that Marx had published a report in 1848 charging him with being a Russian agent. Marx, who had various ethnic aversions, said: "I do not trust any Russian." Bakunin felt that Marx was a German authoritarian and an arrogant Jew who wanted to transform the General Council into a personal dictatorship over the workers. To Bakunin, the mission of the revolutionist was destruction; he looked to

The Paris  
Commune

The  
struggle  
with  
Bakunin

the Russian peasantry, with its propensities for violence and its uncurbed revolutionary instincts, rather than to the effete, civilized workers of the industrial countries. The students, he hoped, would be the officers of the revolution. He acquired followers, mostly young men, in Italy, Switzerland, and France, and organized a secret society, the International Alliance of Social Democracy, which in 1869 challenged the hegemony of the General Council at the congress in Basel. Marx, however, had already succeeded in preventing its admission as an organized body into the International.

To the Bakuninists, the Paris Commune was a model of revolutionary direct action and a refutation of what they considered to be Marx's "authoritarian communism." Bakunin began organizing sections of the International for an attack on the alleged dictatorship of Marx and the General Council. Marx in reply publicized Bakunin's em- broilment with an unscrupulous Russian student leader, Nechayev, who had practiced blackmail and murder.

Without a supporting right wing and with the anarchist left against him, Marx feared losing control of the International to Bakunin. He also wanted to return to his studies and to finish *Das Kapital*. At the congress of the International at the Hague in 1872, the only one he ever attended, Marx managed to defeat the Bakuninists. Then, to the consternation of the delegates, Engels moved that the seat of the General Council be transferred from London to New York. The Bakuninists were expelled, but the International languished and died in New York.

During the next and last decade of his life, Marx's creative energies declined. He was beset by what he called "chronic mental depression," and his life turned inward toward his family. He was unable to complete any substantial work, though he still read widely and undertook to learn Russian. He became crotchety in his political opinions. Increasingly, he looked to a European war for the overthrow of Russian tsarism, the mainstay of reaction, hoping that this would revive the political energies of the working classes. He was moved by what he considered to be the selfless courage of the Russian terrorists who assassinated the tsar, Alexander II, in 1881; he felt this to be "a historically inevitable means of action." When the Lassalleans and his own followers coalesced in 1875 to found the German Social Democratic Party, Marx wrote a caustic but petty criticism of their program (the so-called Gotha Program); he even objected to such proposals as that for the abolition of child labour. The German leaders put his objections aside and tried to mollify him personally. He still retained what Engels called his "peculiar influence" on the leaders of working-class and Socialist movements. In 1879, when the French Socialist Workers' Federation was founded, its leader Jules Guesde went to London to consult with Marx, who dictated the preamble of its program and shaped much of its content. In 1881, Henry Mayers Hyndman in his *England for All* drew heavily on his conversations with Marx but angered him by being afraid to acknowledge him by name. During his last years Marx spent much time at health resorts and even travelled to Algiers. He was broken by the death of his wife on December 2, 1881, and of his eldest daughter, Jenny Longuet, on January 11, 1883. He died in London, evidently of a lung abscess, on March 14, 1883.

**Character and significance.** At his funeral in Highgate Cemetery, Engels declared that Marx had made two great discoveries, the law of development of human history and the law of motion of bourgeois society. But "Marx was before all else a revolutionist." He was "the best-hated and most-calumniated man of his time," yet he also died "beloved, revered and mourned by millions of revolutionary fellow-workers."

Marx's masterpiece, *Das Kapital*, the "Bible of the working class," as it was officially described in a resolution of the International Working Men's Association, was published in 1867 in Berlin and received a second edition in 1873. Only the first volume was completed and published in Marx's lifetime. The second and third volumes, edited by Engels, were published in 1885 and 1894. The economic categories he employed were those of the clas-

sical British economics of David Ricardo; but Marx used them in accordance with his dialectic method to argue that bourgeois society, like every social organism, must follow its inevitable path of development. Through the working of such immanent tendencies as the declining rate of profit, capitalism would die and be replaced by another, higher, society. The most memorable pages in *Das Kapital* are the descriptive passages, culled from Parliamentary Blue Books, on the misery of the English working class. Marx believed that this misery would increase, while at the same time the monopoly of capital would become a fetter upon production until finally "the knell of capitalist private property sounds. The expropriators are expropriated."

Marx never claimed to have discovered the existence of classes and class struggles in modern society. "Bourgeois" historians, he acknowledged, had dealt with them long before he had. He did claim, however, to have proved that each phase in the development of production was associated with a corresponding class structure and that the struggle of classes led necessarily to the dictatorship of the proletariat, ushering in the advent of a classless society. It is difficult to see how he could have regarded the few paragraphs he had written on these themes as constituting proof by any scientific standard.

In his character, Marx was a combination of the Promethean rebel and the helpless intellectual. He gave most persons an impression of intellectual arrogance. A Russian writer, Pavel Annenkov, who observed Marx in debate in 1846 recalled that "he spoke only in the imperative, brooking no contradiction," and seemed to be "the personification of a democratic dictator such as might appear before one in moments of fantasy." But Marx obviously felt uneasy before mass audiences and avoided the atmosphere of factional controversies at congresses. He went to no demonstrations, his wife remarked, and rarely spoke at public meetings. He kept away from the congresses of the International where the rival Socialist groups debated important resolutions. He was a "small groups" man, most at home in the atmosphere of the General Council or on the staff of a newspaper, where his character could impress itself forcefully on a small body of coworkers. At the same time he avoided meeting distinguished scholars with whom he might have discussed questions of economics and sociology on a footing of intellectual equality. Despite his broad intellectual sweep, he was prey to obsessive ideas such as that the British foreign minister, Lord Palmerston, was an agent of the Russian government. He was determined not to let bourgeois society make "a money-making machine" out of him, yet submitted to living on the largess of Engels and the bequests of relatives. He was an affectionate father, saying that he admired Jesus for his love of children, but sacrificed the lives and health of his own. He regarded "struggle" as the law of life and existence. It pervaded his vocabulary so that he thought of learning another language as acquiring another weapon in the struggle of life. Yet he remained the eternal student in his personal habits and way of life, even to the point of joining two friends in a students' prank during which they systematically broke four or five streetlamps in a London street and then fled from the police. He was a great reader of novels, especially those of Sir Walter Scott and Balzac; and the family made a cult of Shakespeare. Of his seven children, three daughters grew to maturity. His favourite daughter, Eleanor, worried him with her nervous, brooding, emotional character and her desire to be an actress. Another shadow was cast on Marx's domestic life by the birth to their loyal servant, Helene Demuth, of an illegitimate son, Frederick; Engels as he was dying disclosed to Eleanor that Marx had been the father.

Marx's most important contribution to sociological theory was his general mode of analysis, the "dialectical" model, which regards every social system as having within it immanent forces that give rise to "contradictions" (disequilibria) that can only be resolved by a new social system. Neo-Marxists, who no longer accept the economic reasoning in *Das Kapital*, are still guided by this model in their approach to capitalist society. In this sense,

Last

Kapital*

The  
"dialec-  
tical"  
model

Marx's mode of analysis, like those of Thomas Malthus, Herbert Spencer, or Vilfredo Pareto, has become one of the theoretical structures that are the heritage of the social scientist. His mode of thought has, however, been opposed by such empirically minded philosophers as Bertrand Russell, John Dewey, and Karl Popper.

#### MAJOR WORKS

*Misère de la philosophie* (1847; *The Poverty of Philosophy*, 1900); *Manifest der Kommunistischen Partei* (1848; *The Communist Manifesto*, trans. by E. and C. Paul, 1930; *Manifesto of the Communist Party*, trans. by S. Moore, new ed., 1952); *Die Klassenkämpfe in Frankreich 1848 bis 1850* (1850; *The Class Struggles in France, 1848 to 1850, 1924*); *Der Achtzehnte Brumaire des Louis Bonaparte* (1852; *The 18th Brumaire of Louis Napoleon*, trans. by E. and C. Paul, 1926); *Zur Kritik der politischen Ökonomie* (1859; *A Contribution to the Critique of Political Economy*, trans. by N.I. Stone, 1904); *Das Kapital* (vol. 1, 1867; vol. 2-3 published by Engels in 1885 and 1894; Eng. trans., *Capital: A Critique of Political Economy*, vol. 1 by S. Moore and E. Aveling, 1886; vol. 2-3 by E. Untermann, 1907 and 1909; rev. trans., 1952).

**BIBLIOGRAPHY.** The authoritative biography of Marx is FRANZ MEHRING, *Karl Marx: Geschichte seines Lebens* (1918; Eng. trans., *Karl Marx: The Story of His Life*, 1935; paperback edition, 1962). Mehring was an intense adherent to the left wing of German Social Democracy and his partisanship influenced his interpretation of such episodes as Marx's relations to Lassalle. BORIS NICHOLAEVSKY and OTTO MAENCHEN-HELFFEN, *Karl Marx: Man and Fighter* (1936), reconstructs effectively the opposition of Marx to revolutionary adventures. OTTO RUHLE, *Karl Marx: Leben und Werk* (1928; Eng. trans., *Karl Marx: His Life and Work*, 1929), is a good general biography, especially interesting for its account of Marx's psychological sense of inferiority. Of all the literature of personal recollections, the most informative is WILHELM LIEBKNECHT, *Karl Marx, zum Gedächtniss: Ein Lebensabriss und Erinnerungen* (1896; Eng. trans., *Karl Marx: Biographical Memoirs*, 1901); DAVID RYAZANOFF (ed.), *Karl Marx: Man, Thinker and Revolutionist* (1927; orig. pub. in Russian, 1919), is a well-edited collection. The documentary evidence concerning Marx's natural son was first published in WERNER BLUMENBERG, *Karl Marx in Selbstzeugnissen und Bilddokumenten* (1962); this material and other phases of Marx's personal life are also discussed in CHUSHICHI TSUZUKI, *The Life of Eleanor Marx, 1855-1898: A Socialist Tragedy* (1967); and ROBERT PAYNE, *Marx* (1968). Marx's relations to the Young Hegelians are most fully discussed in SIDNEY HOOK, *From Hegel to Marx* (1936). H.P. ADAMS, *Karl Marx in His Earlier Writings* (1940), is a useful summary. DAVID RYAZANOFF, the most scholarly of the early Soviet students of Marx, wrote a painstaking study, *The Communist Manifesto of Karl Marx and Friedrich Engels* (1930; orig. pub. in Russian, 1922). BERTRAM D. WOLFE, *Marxism: One Hundred Years in the Life of a Doctrine* (1965), has an informative account of Marx's relations to the Paris Commune. The most thorough study of Marx's attitude to the Jews is EDMUND SILBERNER, "Was Marx an Anti-Semite?" *Historia Judaica*, 11:3-52 (1949). Marx's national and racial feelings are set forth in SOLOMON F. BLOOM, *The World of Nations: A Study of the National Implications in the Work of Karl Marx* (1941). His utopian phase and his relations to Americans are dealt with in LEWIS S. FEUER, *Marx and the Intellectuals* (1969). The best short accounts of Marx's life and work are KARL KORSCH, *Karl Marx* (1938); and ISAIAH BERLIN, *Karl Marx: His Life and Environment*, 3rd ed. (1963).

*Marx's writings:* The most complete bibliography of Marx's writings is MAXIMILIEN RUBEL, *Bibliographie des oeuvres de Karl Marx* (1956), and its *Supplément* (1960). A German edition of the collected works of Marx and Engels, *Werke* (1961-68), has been published in 39 volumes and two supplementary ones. A comparative index of their writings is provided by the volume *Marx Engels Verzeichnis, Werke Schriften Artikel* (1966). The volumes of D. RYAZANOV and V. ADORATSKY (eds.), *Marx-Engels, Historisch-Kritische Gesamtausgabe* (1927-35), still remain useful. The basic works of Marx have been published in English translation; the second volume of DONALD DREW EGBERT, STOW PERSONS, and T.D. SEYMOUR BASSETT, *Socialism and American Life* (1952), provides a guide to them. Many collections of Marx's pamphlets, articles, and correspondence have been edited with reference to particular historical themes: *The American Journalism of Marx and Engels: A Selection from the New York Tribune* (1966); *The Civil War in the United States* (1937); *Revolution in Spain* (1939); *On Britain* (n.d.); *Karl Marx on Colonialism and Modernization* (1968); *On Religion*

(1964); *On Colonialism* (1960); *Marx on China, 1853-1860* (1951); *The Russian Menace to Europe* (1953); and *Marx and Engels on Malthus* (1953). KARL MARX and FRIEDRICH ENGELS, *Correspondence 1846-1895* (Eng. trans. 1934), is a useful collection, as are similar volumes of selected correspondence published in Moscow in 1955 and 1965, the last being the most inclusive.

(L.S.F.)

## Marxism

The term Marxism is used in a number of different ways. In its most essential meaning it refers to the thought of Karl Marx, sometimes extended to include that of his friend and collaborator Friedrich Engels. There is also Marxism as it has been understood and practiced by the various Socialist movements, particularly before 1914. Then there is Soviet Marxism as worked out by Lenin and modified by Stalin, which under the name of Marxism-Leninism became the doctrine of the Communist parties set up after the Russian Revolution. An offshoot of this is Marxism as interpreted by the anti-Stalinist Leon Trotsky and his followers. There is Mao Tse-tung's Chinese variant of Marxism-Leninism. There are the post-World War II nondogmatic Marxisms that have modified Marx's thought with borrowings from modern philosophies, principally from those of Edmund Husserl and Martin Heidegger, but also from Sigmund Freud and others.

#### THE THOUGHT OF KARL MARX

Karl Marx was both a man of action and a thinker. Of Jewish extraction and born into a well-to-do family in Trier in the Rhine province of Prussia on May 5, 1818, he died in exile in London on March 14, 1883. His father, a distinguished lawyer converted to Protestantism, had him baptized in 1824. The conversion of his father was to have the effect on Marx of making him independent of all religions. His adolescence was spent in the enlightened liberal Rhenish environment of that period. Later, he attached himself to a group who called themselves the Berlin Young Hegelians, who acquainted him with the historical critique of established religion and the works of Ludwig Feuerbach, a young philosopher in reaction against Hegel's thought. He turned to journalism and became editor of the *Rheinische Zeitung* in October 1842.

After his marriage in the summer of 1843, he went to live in Paris. In collaboration with Friedrich Engels, whom he came to know in 1844, he undertook a critique of the Hegelianism of the Young Hegelians, which he titled sarcastically *Die heilige Familie* (1845; *The Holy Family*, 1956). He contributed to a radical weekly, *Vorwärts*, until he was expelled from France. He then took up residence in Brussels, where he wrote *Misère de la philosophie* (1847; *The Poverty of Philosophy*, 1900), an attack on Pierre-Joseph Proudhon's book subtitled *Philosophie de la Misère* (1846; *The Philosophy of Poverty*, 1888). Together with Engels he acquired a local weekly, the *Deutsche Brüsseler Zeitung*. They established close ties with the Socialist labour movement and became members of the "League of the Just," a German secret society that had branches in London, Brussels, Paris, and Switzerland. It was for this association that they wrote the famous *Manifest der Kommunistischen Partei*, commonly known as *The Communist Manifesto*, which appeared at the beginning of 1848, the year of revolutions.

Several important studies date from this period (approximately 1843-46): "Zur Judenfrage" ("On the Jewish Question"); "Zur Kritik der Hegelschen Rechtsphilosophie" ("Toward a Critique of Hegel's Philosophy of Right"); and others which did not appear during Marx's lifetime.

From 1848 onward, the life of Marx cannot be separated from his written work and his political activity. He was expelled from Prussia in May 1849 and after a brief stay in Paris took refuge in London. In 1859, at the request of Engels, he published two chapters of *Zur Kritik der politischen Ökonomie* (*A Contribution to the Critique of Political Economy*, 1904); and in 1867 he published the first volume of *Das Kapital* (*Capital*, 1886). In 1864 he took part in the founding of the International Working Men's Association, of which he be-

Marx's writings and political activity

came the leader; it broke up in 1876. He proceeded with the preparation of the other volumes of *Das Kapital* without being able to finish them before his death.

The written work of Marx cannot be reduced to a philosophy, much less to a philosophical system. The whole of his work is a radical critique of philosophy, especially of Hegel's system and of the philosophies of the left and right post-Hegelians. It is not, however, a mere denial of those philosophies. Whereas, with Hegel, reality was made philosophy, Marx declared that philosophy must become reality. One could no longer be content with interpreting the world; one must be concerned with transforming it, which meant transforming both the world itself and men's consciousness of it. This, in turn, required a critique of experience together with a critique of ideas. For Marx, all knowledge involved a critique of ideas. He was not an empiricist. His work teems with concepts (appropriation, alienation, praxis, creative labour, value, etc.) inherited from earlier philosophers and economists, including Hegel, Johann Fichte, Kant, Adam Smith, David Ricardo, and J.S. Mill. What uniquely characterizes the thought of Marx is that, instead of making abstract affirmations about a whole group of problems such as man, knowledge, matter, nature, etc., he examines each in its dynamic relation to the others and, above all, tries to relate them to historical, social, political, and economic realities.

**The human agenda.** To go directly to the heart of the work of Marx, one must focus on his concrete program for man. This is just as important for an understanding of Marx as are *The Communist Manifesto* and *Das Kapital*. Marx's interpretation of man begins with human need. "Man," he writes in the so-called "Ökonomisch-philosophische Manuskripte aus dem Jahre 1844" (*Economic and Philosophic Manuscripts of 1844*, 1959),

is first of all a *natural being*. As a natural being and a living natural being, he is endowed on the one hand with *natural powers, vital powers . . .*; these powers exist in him as aptitudes, instincts. On the other hand, as an objective, natural, physical, sensitive being, he is a *suffering, dependent and limited being . . .*, that is, the *objects* of his instincts exist outside him, independent of him, but are the objects of his *need*, indispensable and essential for the realization and confirmation of his substantial powers.

The point of departure of human history is therefore living man, who seeks to satisfy certain primary needs. "The first historical fact is the production of the means to satisfy these needs." This satisfaction opens the way for new needs. Human activity is essentially a struggle with nature that must furnish man the means of satisfying his needs: drink, food, clothing, the development of his powers and then of his intellectual and artistic abilities. In this undertaking, man discovers himself as a productive being who humanizes himself by his labour. Furthermore, man humanizes nature while he naturalizes himself. By his creative activity, by his labour, he realizes his identity with the nature that he masters, while at the same time he achieves free consciousness. Born of nature man becomes fully human by opposing it. Becoming aware in his struggle against nature of what separates him from it, man finds the conditions of his fulfillment, of the realization of his true stature. The dawning of consciousness is inseparable from struggle. By appropriating all the creative energies, he discovers that "all that is called history is nothing else than the process of creating man through human labour, the becoming of nature for man. Man has thus evident and irrefutable proof of his own creation by himself." Understood in its universal dimension, human activity reveals that "for man, man is the supreme being." It is thus vain to speak of God, creation, and metaphysical problems. Fully naturalized, man is sufficient unto himself: he has recaptured the fullness of man in his full liberty.

Living in a capitalist society, however, man is not truly free. He is an alienated being; he is not at home in his world. The idea of alienation, which Marx takes from Hegel and Feuerbach, plays a fundamental role in the whole of his written work, starting with the writings of his youth and continuing through *Das Kapital*. The causes of alienation come to have an increasingly economic

and social content. In the *Economic and Philosophic Manuscripts*, the alienation of labour is seen to spring from the fact that the more the worker produces the less he has to consume, and the more values he creates the more he devalues himself, because his product and his labour are estranged from him. The life of the worker depends on capital; that is, on things that he has created but that are not his, so that instead of finding his rightful existence through his labour he loses it in this world of things that are external to him: no work, no pay. Under these conditions, labour denies the fullness of concrete man. "The generic being (*Gattungswesen*) of man, nature as well as his intellectual faculties, is transformed into a being which is alien to him, into a *means of his individual existence*." Nature, his body, his spiritual essence become alien to him. "Man is made alien to man." When carried to its highest stage of development, private property becomes "the product of alienated labour . . . the *means* by which labour alienates itself (and) the realization of this alienation." It is also at the same time "the tangible material expression of *alienated human life*." Though there is no evidence that Marx ever disclaimed this anthropological analysis of alienated labour, starting with *Die deutsche Ideologie* (1932; *The German Ideology*, 1938), the historical, social, and economic causes of the alienation of labour are given increasing emphasis, especially in *Das Kapital*. Alienated labour is seen as the consequence of market product, the division of labour, and the division of society into antagonistic classes.

**Alienation under capitalism.** As producers in society, men create goods only by their labour. These goods are exchangeable. Their value is the average amount of social labour spent to produce them. The alienation of the worker takes on its full dimension in that system of market production in which part of the value of the goods produced by the worker is taken away from him and transformed into surplus value, which the capitalist privately appropriates. Market production also intensifies the alienation of labour by encouraging specialization, piecework, and the setting up of large enterprises. Thus the labour power of the worker is used along with that of others in a combination whose significance he is ignorant of, both individually and socially. In thus losing their quality as human products, the products of labour become fetishes, that is, alien and oppressive realities to which both the man who possesses them privately and the man who is deprived of them submit themselves. In the market economy, this submission to things is obscured by the fact that the exchange of goods is expressed in money.

This fundamental economic alienation is accompanied by secondary political and ideological alienations, which offer a distorted representation of and an illusory justification of a world in which the relations of men with one another are also distorted. The ideas that men form are closely bound up with their material activity and their material relations: "The act of making representations, of thinking, the spiritual intercourse of men, seem to be the direct emanation of their material relations." This is true of all human activity: political, intellectual, or spiritual. "Men produce their representations and their ideas, but it is as living men, men acting as they are determined by a definite development of their powers of production." Law, morality, metaphysics, and religion do not have a history of their own. "Men developing their material production modify together with their real existence their ways of thinking and the products of their ways of thinking." In other words, "it is not consciousness which determines existence, it is existence which determines consciousness."

In bourgeois, capitalist society man is divided into citizen and economic man. This duality represents man's political alienation, which is further intensified by the functioning of the bourgeois state. From this study of society at the beginning of the 19th century, Marx came to see the state as the instrument through which the propertied class dominated other classes. "The social structure and the state issue continually from the life processes of definite individuals . . . as they are *in reality*, that is, acting and materially producing."

Existence  
and  
consciousness

Man  
as an  
alienated  
being

Ideological alienation, for Marx, takes different forms, appearing in economic, philosophical, and legal theories. Marx undertook a lengthy critique of the first in *Das Kapital* and of the second in *The German Ideology*. But ideological alienation expresses itself supremely in religion. Taking up the ideas about religion that were current in left post-Hegelian circles, together with the thought of Feuerbach, Marx considered religion to be a product of man's consciousness. It is a reflection of the situation of a man who "either has not conquered himself or has already lost himself again" (man in the world of private property). It is "an opium for the people." Unlike Feuerbach, Marx believed that religion would disappear only with changes in society.

**Historical materialism.** In 1859, in the preface to his *Contribution to the Critique of Political Economy*, Marx wrote that the hypothesis that had served him as the basis for his analysis of society could be briefly formulated as follows:

in the social production that men carry on, they enter into definite relations that are indispensable and independent of their will, relations of production which correspond to a definite stage of development of their material forces of production. The sum total of these relations of production constitutes the economic structure of society, the real foundation, on which rises a legal and political superstructure, and to which correspond definite forms of social consciousness. The mode of production in material life determines the general character of the social, political, and intellectual processes of life. It is not the consciousness of men which determines their existence; it is on the contrary their social existence which determines their consciousness.

Raised to the level of historical law, this hypothesis was subsequently called historical materialism. Marx applied it to capitalist society, both in *The Communist Manifesto* and *Das Kapital* and in other writings—for example, the articles written in the *Neue Rheinische Zeitung* and collected under the title *Die Klassenkämpfe in Frankreich 1848 bis 1850* (1895; *The Class Struggles in France, 1848–50*, 1924) or the pamphlet, written in 1852, *Der Achtzehnte Brumaire des Louis Bonaparte* (1914; *The Eighteenth Brumaire of Louis Bonaparte*, 1926). But the latter two are less systematic than *The Communist Manifesto*. Although Marx reflected upon his working hypothesis for many years, he did not formulate it in a very exact manner: different expressions served him for identical realities. If one takes the text literally, social reality is structured in the following way:

1. Underlying everything as the real basis of society is the economic structure (what in late 20th-century language is sometimes called the infrastructure) that includes (a) the "material forces of production" and (b) the overall "relations of production." Though there is a correspondence between the "material forces" of production and indispensable "relations" of production, Marx never made himself clear on the nature of the correspondence, a fact that was to be the source of differing interpretations among his later followers. Moreover, he never elucidated the difference between forces of production and relations of production.

2. Above the economic structure rises the superstructure consisting of legal and political "forms of social consciousness" that correspond to the economic structure. Marx says nothing about the nature of this correspondence between ideological forms and economic structure, except that through the ideological forms men become conscious of the conflict within the economic structure between the material forces of production and the existing relations of production expressed in the legal property relations. In other words, "the sum total of the forces of production accessible to men determines the condition of society" and is at the base of society. "The social structure and the state issue continually from the life processes of definite individuals . . . as they are *in reality*, that is acting and materially producing." The political relations that men establish among themselves are dependent on material production, as are the legal relations. This reduction of the social to the economic is not an incidental point: it colours Marx's whole analysis. It is

found in *Das Kapital* as well as in *The German Ideology* and the *Economic and Philosophic Manuscripts of 1844*.

Marx puts these methods and concepts to use in *Das Kapital*, in which he analyzes the market economy system. In this work he borrows most of the categories of the classical English economists Smith and Ricardo but adapts them and introduces new concepts such as that of surplus value.

**Analysis of the economy.** One of the distinguishing marks of *Das Kapital* is that in it Marx studies the economy as a whole and not in one or another of its aspects. His analysis is based on the idea that man is a productive being and that all economic value comes from human labour. The system he analyzes is principally that of mid-19th-century England. It is a system of private enterprise and competition that arose in the 16th century from the development of sea routes, international trade, and colonialism. Its rise had been facilitated by changes in the forces of production (the division of labour and the concentration of workshops), the adoption of mechanization, and technical progress. The wealth of the societies that brought this economy into play had been acquired through an "enormous accumulation of commodities." Marx therefore begins with the study of this accumulation. He analyzes the unequal exchanges that take place in the market. If the capitalist advances funds to buy cotton yarn with which to produce fabrics and sells the product for a larger sum than he paid, he is able to invest the difference in additional production. "Not only is the value advance kept in circulation, but it changes in its magnitude, adds a plus to itself, makes itself worth more, and it is this movement that transforms it into capital." The transformation, to Marx, is possible only because the capitalist has appropriated the means of production, including the labour power of the worker. Now labour power produces more than it is worth. The value of labour power is determined by the amount of labour necessary for its reproduction or, in other words, by the amount needed for the worker to subsist and beget children. But in the hands of the capitalist the labour power employed in the course of a day produces more than the value of the sustenance required by the worker and his family. The difference between the two values is appropriated by the capitalist, and it corresponds exactly to the surplus value realized by capitalists in the market. Marx is not concerned with whether in capitalist society there are sources of surplus value other than the exploitation of human labour—a fact pointed out by Joseph Schumpeter (*Capitalism, Socialism, and Democracy*). He remains content with emphasizing this primary source:

Surplus value is produced by the employment of labour power. Capital buys the labour power and pays the wages for it. By means of his work the labourer creates new value which does not belong to him, but to the capitalist. He must work a certain time merely in order to reproduce the equivalent value of his wages. But when this equivalent value has been returned, he does not cease work, but continues to do so for some further hours. The new value which he produces during this extra time, and which exceeds in consequence the amount of his wage, constitutes surplus value.

The introduction of machinery is profitable to the individual capitalist because it enables him to produce more goods at a lower cost, but new techniques are soon taken up by his competitors. The outlay for machinery grows faster than the outlay for wages. Since only labour can produce the surplus value from which profit is derived, this means that the capitalist's rate of profit on his total outlay tends to decline. Along with the declining rate of profit goes an increase in unemployment. Throughout his analysis, Marx argues that the development of capitalism is accompanied by increasing contradictions. The equilibrium of the system is precarious, subject as it is to the internal pressures resulting from its own development. Crises shake it at regular intervals, preludes to the general crisis that will sweep it away. This instability is increased by the formation of a reserve army of workers, both factory workers and peasants, whose pauperization keeps increasing. "Capitalist production develops the technique

*Das  
Kapital*

The crises  
of  
capitalism

and the combination of the process of social production only by exhausting at the same time the two sources from which all wealth springs: the earth and the worker."

**Class struggle.** Two basic classes, around which other less important classes are grouped, oppose each other in the capitalist system: the owners of the means of production, or bourgeoisie, and the workers, or proletariat. With the development of capitalism, the class struggle takes an acute form. "The bourgeoisie produces its own grave-diggers. The fall of the bourgeoisie and the victory of the proletariat are equally inevitable" (*The Communist Manifesto*). For

the bourgeois relations of production are the last contradictory form of the process of social production, contradictory not in the sense of an individual contradiction, but of a contradiction that is born of the conditions of social existence of individuals; however, the forces of production which develop in the midst of bourgeois society create at the same time the material conditions for resolving this contradiction. With this social development the prehistory of human society ends.

When man has become aware of his loss, of his alienation, as a universal nonhuman situation, it will be possible for him to proceed to a radical transformation of his situation by a revolution. This revolution will be the prelude to the establishment of Communism and the reign of liberty reconquered. "In the place of the old bourgeois society with its classes and its class antagonisms, there will be an association in which the free development of each is the condition for the free development of all."

Marx inherited the ideas of class and class struggle from Utopian Socialism and the theories of Saint-Simon. These had been given substance by the writings of French historians such as Adolphe Thiers and François Guizot on the French Revolution of 1789. But unlike the French historians, Marx made class struggle the central fact of social evolution. "The history of all hitherto existing human society is the history of class struggles."

But for Marx there are two views of revolution. One is that of a final conflagration, "a violent suppression of the old conditions of production," which occurs when the opposition between bourgeoisie and proletariat has been carried to its extreme point. This conception is set forth in a manner inspired by the Hegelian dialectic of the master and the slave, in *The Holy Family*. The other conception is that of a permanent revolution involving a provisional coalition between the proletariat and the petty bourgeoisie rebelling against a capitalism that is only superficially united. Once a majority has been won to the coalition, an unofficial proletarian authority constitutes itself alongside the revolutionary bourgeois authority. Its mission is the political and revolutionary education of the proletariat, gradually assuring the transfer of legal power from the revolutionary bourgeoisie to the revolutionary proletariat.

If one reads *The Communist Manifesto* carefully one discovers inconsistencies that indicate that Marx had not reconciled the concepts of catastrophic and of permanent revolution. Moreover, Marx never analyzed classes as specific groups of men opposing other groups of men. Depending on the writings and the periods, the number of classes varies; and unfortunately the pen fell from Marx's hand at the moment when, in *Das Kapital* (volume 3), he was about to take up the question. Reading *Das Kapital*, one is furthermore left with an ambiguous impression with regard to the destruction of capitalism: will it be the result of the "general crisis" that Marx expects, or of the action of the conscious proletariat, or of both at once?

**The contributions of Engels.** Friedrich Engels (1820–95), the son of a manufacturer, was Marx's closest associate and most intimate friend from 1844 to 1883. He became a Communist in 1842 and discovered the proletariat of England when he took over the management of a Manchester factory belonging to his father's cotton firm. In 1844 in Paris he became a friend of Marx. Engels was finishing his "Umriss zu einer Kritik der Nationalökonomie" ("Outline of a Critique of Political Economy")—a critique of Smith, Ricardo, Mill, and J.B. Say. This remarkable study contained in seminal form the critique

that Marx was to make of bourgeois political economy in *Das Kapital*. During the first years of his stay in Manchester, Engels observed carefully the life of the workers of that great industrial centre and described it in *Die Lage der arbeitenden Klassen in England*, published in 1845 in Leipzig (*The Condition of the Working Class in England*, 1887). This work was an analysis of the evolution of industrial capitalism and its social consequences. He collaborated with Marx in the writing of *The Holy Family*, *The German Ideology*, and *The Communist Manifesto*. The correspondence between them is of fundamental importance for the student of *Das Kapital*, for it shows how Engels contributed by furnishing Marx with a great amount of technical and economic data and by criticizing the successive drafts. This collaboration lasted until Marx's death and was carried on posthumously with the publication of the manuscripts left by Marx, which Engels edited, forming volumes 2 and 3 of *Das Kapital*. He also wrote various articles on Marx's work.

In response to criticism of Marx's ideas by a socialist named Eugen Dühring, Engels published several articles that were collected under the title *Herr Eugen Dührings Umwälzung der Wissenschaft*, which appeared in 1878 (*Herr Eugen Dühring's Revolution in Science* [Anti-Dühring], 1934) and an unfinished work, *Dialektik und Natur* (1927; *Dialectics of Nature*, 1940), which he had begun around 1875–76. The importance of these writings to the subsequent development of Marxism can be seen from Lenin's observation that he "developed, in a clear and often polemical style, the most general scientific questions and the different phenomena of the past and present according to the materialist understanding of history and the economic theory of Karl Marx." But Engels was driven to simplify problems with a view to being pedagogical; he tended to schematize and systematize things as if the fundamental questions were settled. The connections that he thus established between some of Marx's governing ideas and some of the scientific ideas of his age gave rise to the notion that there is a complete Marxist philosophy. The idea was to play a significant role in the transition of Marxism from a "critique of daily life" to an integrated doctrine in which philosophy, history, and the sciences are fused.

*Anti-Dühring* is of fundamental importance for it constitutes the link between Marx and certain forms of modern Marxism. It contains three parts: Philosophy, Political Economy, and Socialism. In the first, Engels attempts to establish that the natural sciences and even mathematics are dialectical, in the sense that observable reality is dialectical: the dialectical method of analysis and thought is imposed on men by the material forces with which they deal. It is thus rightly applied to the study of history and human society. "Motion, in effect, is the mode of existence of matter," Engels writes. In using materialistic dialectic to make a critique of Dühring's thesis, according to which political forces prevail over all the rest in the molding of history, Engels provides a good illustration of the "materialistic idea of history," which puts the stress on the prime role of economic factors as driving forces in history. The other chapters of the section on Political Economy form a very readable introduction to the principal economic ideas of Marx: value (simple and complex), labour, capital, surplus value, and ground rent. The section on Socialism starts by formulating anew the critique of the capitalist system as it was made in *Das Kapital*. At the end of the chapters devoted to production, distribution, the state, the family, and education, Engels outlines what the Socialist society will be like, a society in which the notion of value has no longer anything to do with the distribution of the goods produced because all labour "becomes at once and directly social labour," and the amount of social labour that every product contains no longer needs to be ascertained by "a detour." A production plan will coordinate the economy. The division of labour and the separation of town and country will disappear with the "suppression of the capitalist character of modern industry." Thanks to the plan, industry will be located throughout the country in the collective interest, and thus the opposition between town and country will disappear—to the profit of both industry

of  
revolution

Engels'  
critique of  
Dühring

and agriculture. Finally, after the liberation of man from the condition of servitude in which the capitalist mode of production holds him, the state will also be abolished and religion will disappear by "natural death."

One of the most remarkable features of *Anti-Dühring* is the insistence with which Engels refuses to base Socialism on absolute values. He admits only relative values, linked to historical, economic, and social conditions. Socialism cannot possibly be based on ethical principles: each epoch can only successfully carry out that of which it is capable. Marx had written this in his preface of 1859.

#### GERMAN MARXISM AFTER ENGELS

**The work of Kautsky and Bernstein.** The theoretical leadership after Engels was taken by Karl Kautsky (1854–1938), editor of the official organ of the German Social Democratic Party, *Die Neue Zeit*. He wrote *Karl Marx' ökonomische Lehren* (1887; *The Economic Doctrines of Karl Marx*, 1925), in which the work of Marx is presented as essentially an economic theory. Kautsky reduced the ideas of Marx and Marxist historical dialectic to a kind of evolutionism. He laid stress on the increasing pauperization of the working class and on the increasing degree of capitalist concentration. While opposing all compromise with the bourgeois state, he accepted the contention that the Socialist movement should support laws benefitting the workers provided that they did not reinforce the power of the state. Rejecting the idea of an alliance between the working class and the peasantry, he believed that the overthrow of the capitalist state and the acquisition of political power by the working class could be realized in a peaceful way, without upsetting the existing structures. As an internationalist he supported peace, rejecting war and violence. For him, war was a product of capitalism. Such were the main features of "orthodox" German Marxism at the time when the "revisionist" theories of Eduard Bernstein appeared.

Doctrinal  
disputes

Bernstein (1850–1932) created a great controversy with articles that he wrote in 1896 for *Die Neue Zeit*, arguing that Marxism needed to be revised. His divergence widened with the publication in 1899 of *Die Voraussetzungen des Sozialismus und die Aufgaben der Sozialdemokratie* (Eng. trans., *Evolutionary Socialism*, 1909), to which rejoinders were made by Kautsky in *Bernstein und das Sozialdemokratische Programm: Eine Antikritik* (1899; "Bernstein and the Social Democratic Program") and the Polish-born Marxist Rosa Luxemburg in *Sozialreform oder Revolution* (Engl. trans. 1951, *Reform or Revolution*), both in 1899. The critique of Bernstein focussed first of all upon the labour theory of value. Along with the economists of his time he considered it outdated, both in the form expounded by British classical economists and as set forth in *Das Kapital*. He argued, moreover, that class struggle was becoming less rather than more intense, for concentration was not accelerating in industry as Marx had forecast, and in agriculture it was not increasing at all. Bernstein demonstrated this on the basis of German, Dutch, and English statistical data. He also argued that cartels and business syndicates were smoothing the evolution of capitalism, a fact that cast doubt on the validity of Marx's theory of capitalist crises. Arguing that quite a few of Marx's theories were not scientifically based, Bernstein blamed the Hegelian and Ricardian structure of Marx's work for his failure to take sufficient account of observable reality. Finally, he appealed to the dialectic of Hegel and the philosophy of Kant.

To this, Kautsky replied that, with the development of capitalism, agriculture was becoming a sector more and more dependent on industry, and that in addition an industrialization of agriculture was taking place. Rosa Luxemburg took the position that the contradictions of capitalism did not cease to grow with the progress of finance capitalism and the exploitation of the colonies, and that these contradictions were leading to a war that would give the proletariat its opportunity to assume power by revolutionary means.

**The radicals.** One of the most divisive questions was that of war and peace. This was brought to the

fore at the outbreak of World War I, when Social Democratic deputies in the German Reichstag voted for the financing of the war. Among German Marxists who opposed the war were Karl Liebknecht and Rosa Luxemburg. Liebknecht (1871–1919) was imprisoned in 1916 for agitating against the war. On his release in 1918 he took the leadership of the Spartacist movement, which was later to become the Communist Party of Germany. Rosa Luxemburg (1871–1919) had also been arrested for her antimilitary activities. In addition to her articles, signed Junius, in which she debated with Lenin on the subject of the First World War and the attitude of the Marxists toward it (published in 1916 as *Die Krise der Sozialdemokratie* [*The Crisis in the German Social Democracy*, 1919]), she is known for her book *Die Akkumulation des Kapitals* (1913; *The Accumulation of Capital*, 1951). In this work she returns to Marx's economic analysis of capitalism, in particular the accumulation of capital as expounded in volume 2 of *Das Kapital*. There she finds a contradiction that had until then been unnoticed: Marx's scheme seems to imply that the development of capitalism can be indefinite, though elsewhere he sees the contradictions of the system as bringing about increasingly violent economic crisis that will inevitably sweep capitalism away. Luxemburg concludes that Marx's scheme is oversimplified and assumes a universe made up entirely of capitalists and workers. If increases in productivity are taken into account, she asserts, balance between the two sectors becomes impossible; in order to keep expanding capitalists must find new markets in noncapitalist spheres, either among peasants and artisans or in colonies and underdeveloped countries. Capitalism will collapse only when exploitation of the world outside it (the peasantry, colonies, etc.) has reached a limit. This conclusion has been the subject of passionate controversies.

Karl  
Liebknecht  
and Rosa  
Luxemburg

**The Austrians.** The Austrian school came into being when Austrian Socialists started publishing their works independently of the Germans; it can be dated from either 1904 (beginning of the *Marx-Studien* collection) or 1907 (publication of the magazine *Der Kampf*). The most important members of the school were Max Adler, Karl Renner, Rudolf Hilferding, Gustav Eckstein, Friedrich Adler, and Otto Bauer. The most eminent was Bauer (1881–1938), a brilliant theoretician whose *Die Nationalitätenfrage und die Sozialdemokratie* (1906; "The Nationalities Question and the Social Democracy") was critically reviewed by Lenin. In this work he dealt with the problem of nationalities in the light of the experience of the Austro-Hungarian Empire. He favoured the self-determination of peoples and emphasized the cultural elements in the concept of nationhood. Rudolf Hilferding (1877–1941) was finance minister of the German Republic after World War I in the Cabinets of Gustav Stresemann (1923) and Mueller (1928). He is known especially for his work *Das Finanzkapital* (1910), in which he maintained that capitalism had come under the control of banks and industrial monopolies. The growth of national competition and tariff barriers, he believed, had led to economic warfare abroad. Hilferding's ideas strongly influenced Lenin, who analyzed them in *Imperialism, the Highest Stage of Capitalism* (1916).

#### RUSSIAN AND SOVIET MARXISM

*Das Kapital* was translated into Russian in 1872. Marx kept up more or less steady relations with the Russian Socialists and took an interest in the economic and social conditions of the tsarist empire. The man who actually introduced Marxism into Russia was Georgi Plekhanov (1856–1918). But the man who adapted Marxism to Russian conditions was Lenin.

Lenin's  
adaptation  
of  
Marxism

**Lenin.** Vladimir Ilich Ulyanov, or Lenin, was born in 1870 at Simbirsk (Ulyanovsk today). He entered the University of Kazan to study law but was expelled the same year for participating in student agitation. In 1893 he settled in St. Petersburg and became actively involved with the revolutionary workers. With his pamphlet *What Is To Be Done?* (1902), he specified the theoretical

principles and organization of a Marxist party as he thought it should be constituted. He took part in the second Congress of the Russian Social-Democratic Workers' Party, which was held in Brussels and London (1903), and induced the majority of the Congress members to adopt his views. Two factions formed at the Congress: the *Bolshevik* (larger) with Lenin as their leader and the *Menshevik* (smaller) with Julius Martov at their head. The former wanted a restricted party of militants and advocated the dictatorship of the proletariat. The latter wanted a wide-open proletarian party, collaboration with the liberals, and a democratic constitution for Russia. In his pamphlet *One Step Forward, Two Steps Back* (1904), Lenin opposed the organizational principles of the Bolsheviks to those of the Mensheviks. After the failure of the 1905 Russian revolution, he drew positive lessons for the future in *Two Tactics of Social Democracy in the Democratic Revolution*. He fiercely attacked the influence of Kantian philosophy on German and Russian Marxism in *Materialism and Empirio-criticism* (1908). In 1912 at the Prague Conference the Bolsheviks constituted themselves as an independent party. During the first World War Lenin resided in Switzerland, where he studied Hegel's *Science of Logic* and the development of capitalism, and carried on debate with Marxists like Rosa Luxemburg on the meaning of the war and the right of nations to self-determination. In 1915 at Zimmerwald, and in 1916 at Kiental, he organized two international Socialist conferences to fight against the war. Immediately after the February 1917 revolution he returned to Russia, and in October the Bolshevik coup brought him to power.

The situation of Russia and the Russian revolutionary movement at the end of the 19th century and the beginning of the 20th led Lenin to diverge, in the course of his development and his analyses, from the positions both of "orthodox Marxism," and of "revisionism." He rediscovered the original thought of Marx by a careful study of his works, in particular *Das Kapital* and *The Holy Family*. He saw Marxism as a practical affair and tried to go beyond the accepted formulas to plan political action that would come to grips with the surrounding world.

As early as 1894, in his populist study *The Friends of the People*, Lenin took up Marx's distinction between the "material social relations" of men and their "ideological social relations." In Lenin's eyes the importance of *Das Kapital* was that "while explaining the structure and the development of the social formation seen *exclusively* in terms of its relations of production, (Marx) has nevertheless everywhere and always analyzed the superstructure which corresponds to these relations of production." In *The Development of Russian Capitalism* (1897-99), Lenin sought to apply Marx's analysis by showing the growing role of capital, in particular commercial capital—the exploitation of the workers in the factories, and the large-scale expropriation of the peasants. It was thus possible to apply to Russia the models developed by Marx for western Europe. At the same time Lenin did not lose sight of the importance of the peasant in Russian society. Though a disciple of Marx, he did not believe that he had only to repeat Marx's conclusions. He wrote:

We do not consider the theory of Marx to be a complete, immutable whole. We think on the contrary that this theory has only laid the cornerstone of the science, a science which socialists must further develop in all directions if they do not want to let themselves be overtaken by life. We think that, for the Russian socialists, an independent elaboration of the theory is particularly necessary.

Lenin laid great stress upon the dialectical method. In his early writings he defined the dialectic as "nothing more nor less than the method of sociology, which sees society as a living organism, in perpetual development (and not as something mechanically assembled and thus allowing all sorts of arbitrary combinations of the various social elements) . . ." (*The Friends of the People*, 1894). After having studied Hegel toward the end of 1914, he took a more activist view. Dialectic is not only evolution; it is *praxis*, leading from activity to reflection and from reflection to action.

**The dictatorship of the proletariat.** Lenin also put much emphasis on the leading role of the party. On the eve of the revolution of October 1917, in *State and Revolution* he set forth the conditions for the dictatorship of the proletariat and the suppression of the capitalist state. But as early as 1902 he was concerned with the need for a cohesive party with a correct doctrine, adapted to the exigencies of the period, which would be a motive force among the masses helping to bring them to an awareness of their real situation. In *What Is To Be Done?* he called for a party of professional revolutionaries, disciplined and directed, capable of defeating the police; its aims should be to establish the dictatorship of the proletariat. In order to do this, he wrote in 1905 in *Two Tactics of Social-Democracy in the Democratic Revolution*, it was necessary "to subject the insurrection of the proletarian and *non-proletarian* masses to our influence, to our direction, to use it in our best interests." But this was not possible without a doctrine: "Without revolutionary theory, no revolutionary movement."

Lenin assigned major importance to the peasantry in formulating his program. It would be a serious error, he held, for the Russian revolutionary workers' movement to neglect the peasants, even though, of course the industrial proletariat constituted the vanguard of the Revolution. But the discontent of the peasantry could be oriented in a direction favourable to the Revolution by placing among the goals of the party the seizure of privately owned land. As early as 1903 at the third Congress of the party, he secured a resolution to this effect. Thereafter, the dictatorship of the proletariat became the dictatorship of the proletariat and the peasantry. In 1917, he encouraged the peasants to seize land long before the approval of agrarian reform by the Constituent Assembly.

Among Lenin's legacies to Soviet Marxism was one that proved to be injurious to the party. This was the decision taken at his behest by the 10th Congress of the party in the spring of 1921, while the sailors were rebelling at Kronstadt and the peasants were growing restless in the countryside, to forbid all factions, all factional activity, and all opposition political platforms within the party. This decision had grave consequences in later years when Stalin used it against his opponents.

**Stalin's ideas.** It is to Joseph Stalin that we owe the body of ideas that, under the name of Marxism-Leninism, constitute the doctrine of the European Communist parties. Stalin was a man of action, in a slightly different sense than was Lenin. Gradually taking over power after Lenin's death in 1924, he pursued the development of the Soviet Union with great vigour. It was by practicing Marxism that he assimilated it; but at the same time he simplified it. Stalin's Marxism-Leninism rests on the dialectic of Hegel, as set forth in *A Short History of the Communist Party of the Soviet Union* (1938) and on a materialism that can be considered roughly identical to that of Feuerbach. His work *Problems of Leninism*, which appeared in eleven editions during his lifetime, sets forth an ideology of power and activism.

Soviet dialectical materialism can be reduced to four laws: (1) History is a dialectical development. It proceeds by successive phases which supersede one another. These phases are not separate, any more than birth, growth, and death are separate. Though it is true that phase B necessarily negates phase A, it remains that phase B was already contained in phase A and was initiated by it. The dialectic does not regard nature as an accidental accumulation of objects, of isolated and independent phenomena, but as a unified, coherent whole. Furthermore, nature is perpetually in movement, in a state of unceasing renewal and development, in which there is always something being born and developing and something disintegrating and disappearing. (2) Evolution takes place in leaps, not gradually. (3) Contradictions must be made manifest. All phenomena contain in themselves contradictory elements. "Dialectic starts from the point of view that objects and natural phenomena imply internal contradictions, because they all have a positive and a negative side." These contradictory elements are in perpetual struggle: it is this struggle that is the "internal

A plan of political action

Stalin and dialectical materialism

content of the process of development," according to Stalin. (4) The law of this development is economic. All other contradictions are rooted in the basic economic relationship. A given epoch is entirely determined by the relations of production existing among men. They are *social* relations; relations of collaboration or mutual aid; relations of domination or submission; and finally, transitory relations that characterize a period of passage from one system to another. "The history of the development of society is, above all, the history of the development of production, the history of the modes of production which succeed one another through the centuries."

From these principles may be drawn the following inferences, essential for penetrating the workings of Marxist-Leninist thought and its application: no natural phenomenon, no historical or social situation, no political fact, can be considered independently of the other facts or phenomena which surround it. It is set within a whole. Since movement is the essential fact, one must distinguish between what is beginning to decay and what is being born and developing. Since the process of development takes place by leaps, one passes suddenly from a succession of slow quantitative changes to a radical qualitative change. In the social or political realm, these sudden qualitative changes are revolutions, carried out by the oppressed classes. One must follow a frankly proletarian-class policy that exposes the contradictions of the capitalist system. A reformist policy makes no sense. Consequently (1) nothing can be judged from the point of view of "eternal justice" or any other preconceived notion and (2) no social system is immutable. To be effective, one must not base one's action on social strata that are no longer developing, even if they represent for the moment the dominant force, but on those that are developing.

Stalin's materialist and historical dialectic differs sharply from the perspective of Karl Marx. In *The Communist Manifesto* Marx applied the materialist dialectic to the social and political life of his time. In the chapter entitled "Bourgeois and Proletarians," he studied the process of the growth of the revolutionary bourgeoisie within feudal society, then the genesis and the growth of the proletariat within capitalism, placing the emphasis on the struggle between antagonistic classes. To be sure, he connected social evolution with the development of the forces of production. But what counted for him was not only the struggle but also the birth of consciousness among the proletariat. "As to the final victory of the propositions put forth in the *Manifesto*, Marx expected it to come primarily from the intellectual development of the working class, necessarily the result of common action and discussion" (F. Engels, preface to the republication of *The Communist Manifesto*, May 1, 1890).

For Stalin, on the contrary, what counted was the immediate goal, the practical result. The move was from a dialectic that emphasized both the objective and the subjective to one purely objective, or more exactly, objectivist. Human actions are to be judged not by taking account of the intentions of the actor and their place in a given historical web but only in terms of what they signify objectively at the end of the period considered.

**Trotskyism.** Alongside Marxism-Leninism as expounded in the Soviet Union there arose another point of view expressed by Stalin's opponent Leon Trotsky and his followers. Trotsky (1879-1940) played a leading role in both the Russian revolution of 1905 and that of 1917. After Lenin's death he fell out with Stalin. Their conflict turned largely upon questions of policy, both domestic and foreign. In the realm of ideas, Trotsky held that a revolution in a backward, rural country could only be carried out by the proletariat. Once in power the proletariat must carry out agrarian reform and undertake the accelerated development of the economy. The revolution must be a Socialist one, involving the abolition of the private ownership of the means of production, or else it will fail. But the revolution cannot be carried out in isolation, as Stalin maintained it could. The capitalist countries will try to destroy it; moreover, to succeed the revolution must be able to draw upon the industrial techniques of the developed countries. For these reasons the

revolution must be worldwide and permanent, directed against the liberal and nationalist bourgeoisie of all countries and using local victories to advance the international struggle.

Tactically, Trotsky emphasized the necessity of finding or creating a revolutionary situation; of educating the working class in order to revolutionize it; of seeing that the party remained open to the various revolutionary tendencies and avoided becoming bureaucratized; and finally, when the time for insurrection comes, of organizing it according to a detailed plan.

Trotsky's tactical theories

#### VARIANTS OF SOVIET MARXISM

**Maoism.** When the Chinese Communists took power in 1948, they brought with them a new kind of Marxism that came to be called Maoism after their leader Mao Tse-tung. The thought of Mao must always be seen against the changing revolutionary reality of China, from 1930 onward. His thought is complex, a Marxist type of analysis combined with the permanent fundamentals of Chinese thought and culture.

One of its central elements has to do with the nature and role of contradictions in Socialist society. For Mao, every society, including Socialist (Communist) society, contains "two different types of contradictions": (1) antagonistic contradictions; *e.g.*, contradictions between us (the people) and our enemies (the Chinese bourgeoisie faithful), between the imperialist camp and the Socialist camp, etc. These contradictions are resolved by revolution; (2) nonantagonistic contradictions; *e.g.*, between the government and the people under a Socialist regime, between two groups within the Communist party, between one section of the people and another under a Communist regime, etc. These contradictions are resolved by vigorous fraternal criticism and self-criticism.

The notion of contradiction is specific to Mao's thought in that it differs from the conceptions of Marx or Lenin. For Mao, in effect, contradictions are at the same time universal and particular. In their universality, one must seek and discover what constitutes their particularity: every contradiction displays a particular character, depending on the nature of things and phenomena. Contradictions have alternating aspects—sometimes strongly marked, sometimes blurred. Some of these aspects are primary, others secondary. It is important to define them well for if one fails to do so, the analysis of the social reality and the actions that follow from it will be mistaken. This is quite far from Stalinism and dogmatic Marxism-Leninism.

Another essential element of Mao's thought, which must be seen in the context of revolutionary China, is the notion of permanent revolution. It is an old idea advocated in different contexts by Marx, Lenin, and Trotsky. For Mao it follows from his ideas about the struggle of man against nature (held since 1938, at least); the campaigns for the rectification of thought (1942, 1951, 1952); and the necessity of struggling against bureaucracy, wastage, and corruption in a country of 600,000,000 to 700,000,000 inhabitants, where very old civilizations and cultures still permeate both the bourgeois classes and the peasantry, where bureaucracy is thoroughly entrenched, and where the previous society was extremely corrupt. It arises from Mao's conviction that the rhythm of the revolution must be accelerated. This conviction appeared in 1957 in his speeches and became manifest in 1958 in the "Great Leap Forward," followed in 1966 by the Cultural Revolution.

Mao's concept of permanent revolution rests upon the existence of nonantagonistic contradictions in the China of today and of tomorrow. Men must be mobilized into a permanent movement in order to carry forward the revolution and to prevent the ruling group from turning bourgeois (as he asserts it has in the Soviet Union). It is necessary to shape among the masses a new vision of the world by tearing them from their passivity and their century-old habits. This is the background of the Cultural Revolution that began in 1966, following upon previous campaigns but differing from them in its magnitude and, it would seem, in the mobilization of youth against the

The Chinese element in Maoism

cadres of the party. In these campaigns Mao drew upon his past as a revolutionary Marxist peasant leader, from his life in the red military and peasant bases and among the Red Guards of Yenan, seeking in his past experience ways to mobilize the whole Chinese population against the dangers—internal and external—that confronted it in the present.

The distinguishing characteristic of Maoism is that it represents a peasant type of Marxism, with a principally rural and military outlook. While basing himself on Marxism-Leninism, adapted to Chinese requirements, Mao is rooted in the peasant life from which he himself came, in the revolts against the warlords and the bureaucrats that have filled the history of China. By integrating this experience into a universal vision of history, Mao gives it a significance that overflows the provincial limits of China.

In his effort to remain close to the Chinese peasant masses, Mao draws upon an idea of nature and a symbolism found in popular Chinese Taoism, though transformed by his Marxism. It can be seen in his many poems, which are written in the classical Chinese style. This idea of nature is accompanied in his written political works by the other, Promethean idea of man struggling in a war against nature, a conception in his thought that goes back at least to 1938 and became more important after 1955 as the rhythm of the revolution accelerated.

**Marxism in Yugoslavia and Cuba.** The Titoist variant of Marxism-Leninism developed after the Yugoslav Communists, led by Josip Broz Tito, fell out with the Soviet Union in June 1948. It is a form of Marxist Socialism that in some respects is opposed to Stalinist Marxism-Leninism. Thus it emphasizes the struggle against bureaucracy and national chauvinism, along with the need for workers' control of the factories. In other respects it remains faithful to Stalinism in the unity of its leadership and in the monolithic nature of the League of Yugoslav Communists.

The Yugoslav Party claims that it has started on the road to the withering away of the state. It does not operationally direct economic and social life, as do other Communist parties that hold power. In foreign policy, Titoism refuses allegiance to either of the great power blocs; it favours self-determination and independence for the ex-colonial countries of the Third World.

The Marxism of Fidel Castro expresses itself as a rejection of injustice in any form—political, economic, or social. In this sense it is related to the liberal democracy and Pan-Americanism of Simón Bolívar in Latin America during the 19th century. In its liberalism, Castro's early socialism resembled the various French Socialisms of the first half of the 19th century. Only gradually did Castroism come to identify itself with Marxism-Leninism, although from the very beginning of the Cuban revolution Castro revealed his attachment to certain of Marx's ideas. But Castro's Marxism rejects some of the tenets and practices of official Marxism-Leninism: it is outspoken against dogmatism, bureaucracy, and sectarianism. In one sense, Castroism is a Marxist-Leninist "heresy." At the same time it aims to apply a purer Marxism to the conditions of Cuba: alleged American imperialism, a single-crop economy, a low initial level of political and economic development. One may call it an attempt to realize a synthesis of Marxist ideas and the ideas of Bolívar.

In the ideological and political conflicts that divide the Communist world, Castroism takes a more or less unengaged position. Castro is above all a nationalist and only after that a Marxist, much as is Tito in Yugoslavia.

**The fragmentation of Marxism.** By the latter part of the 20th century the ideas associated with Marx's name had been adapted to so many political and cultural conditions that it was no longer possible to define a single body of thought as Marxist. In western Europe the social democratic parties had abandoned their traditional programs and doctrines. In the Soviet Union the Leninist-Stalinist adaptation of Marxism had become the formal doctrine of a ruling party. In China, the Soviet brand of Marxism had been further modified to fit the needs of a peasant-based movement. Among certain Western intel-

lectuals Marxism enjoyed a new birth as a form of existential protest against a technological society. Some writers mixed Marxist ideas with those of other thinkers, including Nietzsche, Kierkegaard, and Freud. But the term "Marxism" in the West had come to mean certain attitudes rather than a consistent body of thought.

**BIBLIOGRAPHY.** General analyses of Marxism are contained in EMILE BURNS, *An Introduction to Marxism*, rev. ed. (1966); G.D.H. COLE, *The Meaning of Marxism*, 2nd ed. rev. (1948, reprinted 1964); and M.M. BOBER, *Karl Marx's Interpretation of History* (1948). R.N.C. HUNT, *Marxism Past and Present* (1954), is a valuable introductory work on Marx's social rather than economic doctrines. Studies of Marxism as a sociological doctrine may be found in KARL KORSCH, *Karl Marx* (1963); HENRI LEFEBVRE, *The Sociology of Marx* (Eng. trans. 1968); and in two works by SIDNEY HOOK, *Towards the Understanding of Karl Marx* (1933), and *From Hegel to Marx: Studies in the Intellectual Development of Karl Marx* (1936, reprinted 1950). GEORGE LICHTHEIM, in both *The Origins of Socialism* (1969), and *Marxism: An Historical and Critical Study* (1961), examines Marx's social and historical doctrines.

A.J. GREGOR, *A Survey of Marxism: Problems in Philosophy and the Theory of History* (1965), emphasizes philosophical problems in lieu of political or economic ones. The outstanding work on Marxist ethics is EUGENE KAMENKA, *The Ethical Foundations of Marxism* (1962).

*Marx and Modern Economics* (1968), ed. by DAVID HOROWITZ, is an excellent collection of essays by leading economic theorists. Other economic treatments of Marxism worth consulting are P.M. SWEETZ, *The Theory of Capitalist Development: Principles of Marxian Political Economy* (1942); and JOHN STRACHEY, *The Nature of Capitalist Crisis* (1935).

An account of the historical development of Marxism is HENRI CHAMBRE, *From Karl Marx to Mao-Tse-Tung: A Systematic Survey of Marxism-Leninism* (Eng. trans. 1963). G.D.H. COLE, *A History of Socialist Thought*, 6 vol. (1953-58), is a detailed study of the Marxist movement rather than the ideas; see esp. vol. 2, *Marxism and Anarchism, 1850-1890* (1954). B.D. WOLFE, *Marxism: 100 Years in the Life of a Doctrine* (1965), emphasizes the early years of the Soviet revolution; as does HERBERT MARCUSE, *Soviet Marxism: A Critical Analysis* (1958).

Of special interest is an annotated bibliography on Marxism prepared by JOHN LACHS, *Marxist Philosophy: A Bibliographic Guide* (1967).

(H.C.)

## Mary

Mary, the mother of Jesus, has been an object of veneration in the Christian Church since the apostolic age and has been a favourite subject in art, music, and literature. Her humility and obedience to the message of God have made her an exemplar for all ages of Christians. Out of the sparse details supplied in the New Testament by the Gospels about the maid of Galilee, Christian piety and theology have constructed a well-developed picture of Mary that fulfills the prediction ascribed to her in the Magnificat (Luke 1:48): "Henceforth all generations will call me blessed."

**Biblical references.** It is impossible to assemble the biblical references to Mary into a coherent biography, even though the span of time covered by these references is, in fact, longer than the life of Jesus. The first mention of her is the story of the Annunciation, which reports that she was living in Nazareth and was betrothed to Joseph (Luke 1:26 ff.); the last mention of her (Acts 1:14) includes her in the company of those who devoted themselves to prayer after the ascension of Jesus into heaven. She appears in the following incidents in the Gospels: the Annunciation; the visit with Elizabeth, her kinswoman and the mother of John the Baptist, the precursor of Jesus, (Luke 1:39 ff.); the birth of Jesus and the presentation of him in the Temple (Luke 2:1 ff.); the coming of the Magi and the flight to Egypt (Matt. 2:1 ff.); the Passover visit to Jerusalem when Jesus was 12 years old (Luke 2:41 ff.); the marriage at Cana in Galilee, although her name is not used (John 2:1 ff.); the attempt to see Jesus while he was teaching (Mark 3:31 ff.); the station at the cross, where, apparently widowed, she was entrusted to the disciple John (John 19:26 ff.). Even if one takes these scenes as literal historical accounts, they do not add up to an integrated portrait of Mary. Only in

the narratives of the Nativity and the Passion of Christ is her place a significant one: her acceptance of the privilege conferred on her in the Annunciation is the solemn prologue to the Christmas story; not only does she stand at the foot of the Cross, but in the Easter story "the other Mary" who came to the tomb of Jesus (Matt. 28:1) is not she—according to traditional interpretations, because, having kept in her heart what he was to be, she knew that the body of Jesus would not be there. On the other hand, the three incidents that belong to the life of Jesus between infancy and death all contain elements of a pronouncedly human character, perhaps even the suggestion that she did not fully understand Jesus' true mission.

Since the early days of Christianity, however, the themes that these scenes symbolize have been the basis for thought and contemplation about Mary, developing and expanding through the centuries. Christian communions and theologians differ from one another in their interpretations of Mary principally on the basis of where they set the terminal point for such development and expansion—that is, where they maintain that the legitimate development of doctrine may be said to have ended. To a considerable degree, therefore, a historical survey of that development is also an introduction to the state of contemporary Christian thought about Mary.

It should be noted that there have been various attempts to connect Christian devotion to Mary with the cult of female deities (e.g., the Great Mother of the Gods) in the Greco-Roman world. The obvious resemblances are sufficient to suggest that this was the soil in which Christian practice and thought grew, but more profound and more important than the parallels are the fundamental differences, which came from the Christian preoccupation with the historical and unrepeatable incarnation of the Son of God, as contrasted with the mythological ideas of Hellenistic religions about mother goddesses in the context of nature rather than of history.

"Born of woman"

**Dogmatic titles.** *Guarantee of the Incarnation.* Probably the earliest allusion to Mary in Christian literature is the phrase "born of woman" in the Letter of Paul to the Galatians (4:4), which was written before any of the Gospels. As parallels such as the Old Testament Book of Job (14:1) and the Gospel account of Matthew (11:11) suggest, the phrase is a Hebraic way of speaking about the essential humanity of a person. When applied to Jesus, therefore, "born of woman" was intended to assert that he was a real man, in opposition to the attempt—later seen in various systems of Gnosticism, a 2nd-century dualistic religion—to deny that he had had a completely human life; he was said by some Gnostics to have passed through the body of Mary as light passes through a window. It seems unwarranted to read anything further into the phrase, as though "born of woman" necessarily implied "but not of a man and a woman." Thus, the phrase made Mary the sign or the guarantee that the Son of God had truly been born as a man. For the ancient world, one human parent was necessary to assure that a person was genuinely human, and from the beginning the human mother of Jesus Christ, the Son of God, has been the one to provide this assurance. Some scholars have even maintained that the primary connotation of the phrase "born of the Virgin Mary" in the Apostles' Creed was this same insistence by the church upon the authentic manhood of Jesus. That insistence has been the irreducible minimum in all the theories about Mary that have appeared in Christian history. Her role as mother takes precedence over any of the other roles assigned to her in devotion and in dogma. Those who deny the virgin birth usually claim to do so in the interest of true humanity, seeing a contradiction between the idea of Jesus as the human son of a human mother and the idea that he did not have a human father. Those who defend the virgin birth usually maintain that the true humanity was made possible when the Virgin accepted her commission as the guarantee of the Incarnation (Luke 1:38): "Let it be to me according to your word." This is the original source of the title *Coredeptrix*—indicating some participa-

tion with Christ in the redemption of mankind—assigned to Mary in Roman Catholic theology, though the term has come to connote a more active role by her; the precise nature of this participation is still a matter of controversy among Catholic theologians.

*Virgin mother.* By far the most voluminous narratives about Mary in the New Testament are the infancy stories in the Gospels of Matthew and Luke. In their present form, both accounts make a point of asserting that Jesus was conceived in the womb of Mary without any human agency (Matt. 1:18 ff.; Luke 1:34 ff.); yet the many textual variants in Matt. 1:16, some of them with the words "Joseph begat Jesus," have caused some scholars to question whether such an assertion was part of Matthew's original account. The passages in Matthew and in Luke seem to be the only references to the matter in the New Testament. The Apostle Paul nowhere mentions it; the Gospel According to Mark begins with Jesus as an adult; and the Gospel According to John, which begins with his prehistorical existence, does not allude to the virgin birth, unless a variant of John 1:13, which reads ". . . who was born" rather than ". . . who were born," is followed. Matthew does not attach any theological significance to the miracle, but it is possible that the words of the angel in Luke 1:35 are intended to connect the holiness of the child with the virginity of the mother. In postbiblical Christian literature the most voluminous discussions of Mary have been those dealing with her virginity. On the basis of the New Testament, it was the unanimous teaching of all the orthodox Fathers of the Church that Mary conceived Jesus with her virginity unimpaired, a teaching enshrined in the early Christian Creeds and concurred in by the 16th-century Reformers as well as by most Protestant churches and believers since the Reformation. Only with the rise of rationalism in the 18th century and then of Protestant Liberalism in the 19th century did the teaching begin to lose the universal support it had enjoyed. One of the major points in the antiliberal reaction of Fundamentalism in the early 20th century was its insistence upon the literal accuracy of all the miracle stories in the Bible, including and especially those dealing with the miraculous conception and with the Resurrection of Jesus, without which his status as Son of God and Saviour was thought to be in jeopardy.

*Second Eve.* One of the interpretations of the person and work of Jesus Christ in the New Testament is the formulation of parallels between him and Adam: "As in Adam all die, so also in Christ shall all be made alive" (I Cor. 15:22). Decisive in the parallel is the contrast between the disobedience of Adam, by which sin came into the world, and the obedience of Christ, by which salvation from sin was accomplished (Rom. 5:12–19). Whether or not the story of the Annunciation in the first chapter of the Gospel According to Luke is intended to suggest a similar parallel between Eve and Mary, this did soon become a theme of Christian reflection. Writing at about the end of the 2nd century, the Church Father Irenaeus of Lugdunum (modern Lyon, France) elaborated the parallel between Eve, who, as a virgin, had disobeyed the word of God, and Mary, who, also as a virgin, had obeyed it;

for Adam had necessarily to be restored in Christ, that mortality be absorbed in immortality, and Eve in Mary, that a virgin, become the advocate of a virgin, should undo and destroy virginal disobedience by virginal obedience.

Irenaeus did not argue the point; he seems rather to have taken the parallel for granted, and this may indicate that it was not his own invention but belonged to tradition, for which he had a high respect. In any case, the parallel did ascribe to Mary and to her obedience an active share in the redemption of the human race: all men had died in Adam, but Eve had participated in the sin that brought this on; all men were saved in Christ, but Mary had participated in the life that made this possible.

*Mother of God.* The first widespread theological controversy over Mary had to do with the propriety of applying to her the title of *Theotokos*, "God-bearer" or "mother of God." The title seems to have arisen in devotional usage, probably in Alexandria, Egypt, sometime in

Virginity of Mary

First theological controversy over Mary

the 3rd or 4th century; it was a logical deduction from the doctrine of the full deity of Christ, which was established as a dogma during the 4th century, and those who defended that dogma were also the ones who drew the inference. Perhaps, as the 19th-century English theologian Cardinal John Henry Newman supposed, the determination of the Council of Nicaea in 325 that Christ was not merely the highest of creatures but belonged on the divine side of the line between Creator and creature was even responsible for the rapid growth of devotion and speculation attached to Mary as the highest of creatures. By the end of the 4th century, the Theotokos had successfully established itself in various sections of the church. Because it seemed to him that the supporters of the title were blurring the distinction between the divine and the human in Christ, Nestorius, the patriarch of Constantinople, objected to its use, preferring the less explicit title *Christotokos*, "Christ-bearer" or "mother of Christ." Along with other aspects of his teaching, Nestorius' objections were condemned at the Council of Ephesus in 431, and Theotokos was unconditionally approved.

In the devotion of Eastern Christendom, the Theotokos (Russian *Bogoroditsa*) has been very prominent; it was a favourite subject for icon painters and became one of the principal targets of the polemics levelled by the Iconoclasts—*i.e.*, opponents of the religious use of images—of the 8th and 9th centuries against the "idolatry" of the orthodox. Through its incorporation in the prayer Ave Maria ("Hail, Mary"), the title mother of God has been circulated throughout Western Catholicism as well. By the approval it received in both Lutheran and Reformed confessions during the period of the Reformation, the title assured itself a place in the official theology, though not in the popular piety, of orthodox Protestantism. It is as mother of God that Mary is also termed *Mediatrix* by Roman Catholics. The official teaching of the Catholic Church has sought to make clear that this latter term is intended not to detract from the glory of Christ as sole mediator but to signify that Mary mediates between Christ and mankind as she did at the marriage feast at Cana (John 2:3).

*Ever virgin.* Various corollaries could be deduced from the New Testament's assertion of Mary's virginity in the conception of Jesus, including the doctrine that she had remained a virgin in the course of his birth (the *virginitas in partu*) and the doctrine that she had remained a virgin after his birth and until the end of her life (the *virginitas post partum*). The Apostles' Creed appears to teach at least the *virginitas in partu* when it says "born of the Virgin Mary." Although this teaching about how Mary gave birth to Jesus occurs for the first time in the 2nd-century apocryphal, or noncanonical, *Protevangelium of James*, its origins and evolution are not easy to trace, and Roman Catholic and Protestant historians have come to contradictory conclusions. The growth of the ascetic ideal in the church helped to give support to this view of Mary as the model of the lifelong virgin. The doctrine is neither asserted nor denied but is simply ignored in the New Testament, and Old Testament passages adduced in support of it by Church Fathers (such as Ezek. 44:2 and S. of Sol. 4:12) were probably convincing only to those who already accepted the doctrine.

The doctrine also posed two problems of biblical interpretation, both of which were discussed in detail by defenders of the doctrine from St. Jerome to Luther. To the argument from words such as "until" (Matt. 1:25), "before" (Matt. 1:18), and "first-born" (Luke 2:7) that Mary must have borne further children, the defenders of the perpetual virginity have replied that none of these words speaks at all about what followed: an only child is a firstborn child, and although Pharaoh and his army, in the account of the Exodus, did not repent "before" the Red Sea had closed in on them, this did not mean that they suddenly became believers then. The other biblical problem was that of the "brothers" of Jesus referred to in I Cor. 9:5; Gal. 1:19; and several times in the Gospels and in the Acts of the Apostles. If they really were his brothers, it was obvious that Mary had given birth to other children after the birth of Jesus; this would seem to

be the natural interpretation. These, however, have been explained either as kinsmen (on the grounds that this is what "brothers" sometimes meant in Jewish society) or as children of Joseph by a previous marriage (his early death being an indication that he was considerably older than Mary) or as children of another Mary and of Clopas. Partly because of these biblical problems, the doctrine of the perpetual virginity of Mary has not been supported as unanimously as has the doctrine of the virgin conception or the title mother of God. It achieved dogmatic status, however, at the Council of Chalcedon in 451 and is therefore binding upon Eastern Orthodox and Roman Catholic believers; in addition, it is maintained by many Anglican, some Lutheran, and a few other Protestant theologians.

*Immaculate.* As the doctrine of the perpetual virginity of Mary implied an integral purity of body and soul, so, in the opinion of many theologians, she was also free of other sins. Attempting to prove the universality of sin against Pelagius (whose teaching was condemned as heretical by the Christian Church but who did maintain the sinlessness of Mary), Augustine, the great theologian and bishop from northern Africa, spoke for the Western Church when he wrote:

We must except the holy Virgin Mary. Out of respect for the Lord, I do not intend to raise a single question on the subject of sin. After all, how do we know what abundance of grace was granted to her who had the merit to conceive and bring forth him who was unquestionably without sin?

It was, however, the distinction between original sin (*i.e.*, the sin that all men are born with) and actual sin (*i.e.*, the sins that men commit during their life), firmly established in Western theology by the same Augustine, that eventually compelled a further clarification of what the sinlessness of Mary meant. Certain Eastern theologians in the 4th and 5th centuries were willing to attribute actual sins to her, but most theologians in both East and West came to accept the view that she never did anything sinful, a view that found expression even among the 16th-century Reformers. But was she free from original sin as well? And if so, how? Thomas Aquinas, the most important medieval theologian in the West, took a representative position when he taught that her conception was tarnished, as was that of all men, but that God suppressed and ultimately extinguished original sin in her, apparently before she was born. This position, however, was opposed by the doctrine of the Immaculate Conception, systematized by Duns Scotus, a 13th-century British Scholastic theologian, and finally defined as Roman Catholic dogma by Pope Pius IX in 1854. According to this dogma, Mary was not only pure in her life and in her birth, but

at the first instant of her conception was preserved immaculate from all stain of original sin, by the singular grace and privilege granted her by Almighty God, through the merits of Christ Jesus, Saviour of mankind.

*Assumed into heaven.* When the Immaculate Conception was promulgated, petitions began coming to the Vatican for a definition regarding the Assumption of the Virgin into heaven, as this was believed by Roman Catholics and celebrated in the Feast of the Assumption. During the century that followed, more than 8,000,000 persons signed such petitions; yet Rome hesitated, because the doctrine was difficult to define on the basis of Scripture and early witnesses to the Christian tradition. No account of the place and circumstances of Mary's death was universally accepted in the church (although paintings depicting her "dormition," or "falling asleep," in the ancient Ionian city of Ephesus were quite common); no burial place was acknowledged (although there was a grave in Jerusalem that was said to be hers); and no miracles were credited to relics of her body (although the physical remains of far lesser saints had performed many). Such arguments from silence, however, did not suffice to establish a dogma, and on the positive side even the earliest doctrinal and liturgical testimony in support of the idea has appeared relatively late in history. Finally, in 1950 Pope Pius XII made the dogma official, declaring that "the Immaculate Mother of God, the ever Virgin

definitions

Biblical  
problems

Mary, when the course of her earthly life was run, was assumed in body and soul to heavenly glory." As it was formulated, the doctrine left open to speculation the question whether, as most theologians have held, Mary had in fact died or whether she had been taken up into heaven, as had the patriarch Enoch (Gen. 5:24) and the prophet Elijah (II Kings 2:11), without first passing through physical death.

**Cultural importance.** In addition to these official prerogatives and titles given to her by Catholic Christianity, the Virgin Mary has achieved great cultural importance. Popular devotion to Mary—in such forms as feasts, devotional services, and the rosary—has played a tremendously important role in the lives of Roman Catholics and the Orthodox; at times, this devotion has pushed other doctrines into the background. Modern Roman Catholicism has emphasized that the doctrine of Mary is not an isolated belief but must be seen in the context of two other Christian doctrines: the doctrine of Christ and the doctrine of the church. What is said of Mary is derived from what is said of Jesus: this was the basic meaning of Theotokos. She has also been the type of the church, as "the first believer" and as the one in whom the humanity of the church was representatively embodied. By these emphases Roman Catholic thought has sought to reduce the extravagances of Marian cult and Mariological thought that have sometimes tended to go beyond the limits both of biblical foundation and of ecclesiastical regulations.

Mary's cultural importance, however, far transcends any dogmatic or institutional boundaries. Even the Qur'an pays tribute to her, although it appears to have confounded her with Miriam, the sister of Moses. Both in folk piety and in the speculations of philosophers and mystics, she has served to symbolize the redemption of the entire cosmos and to provide a bridge between Christianity and those religions of nature that have spoken of such a redemption. Carl Jung, founder of analytic psychology, found in the dogma of the Assumption an *Answer to Job*, in which the exaggerated and severely masculine ideas of divine transcendence proclaimed by the Hebrew prophets had themselves been transcended. Countless paintings of the Madonna and child or of the coronation of the Virgin, as well as settings of the Annunciation, the visit with Elizabeth, and the station at the Cross of Jesus have made Mary a universal theme in the history of the arts. In the secular life and literature of the West since the Middle Ages, Mary has symbolized the nobility of woman. Although the contempt for women was often depicted by the use of the story of Eve, who had been created second but had sinned first, to prove the natural inferiority of the female, the devotion to Mary could serve at least partly as a counterbalance, proving that a woman had been the first to affirm and to help make possible the redemption of the human race. Many Protestant churches that have most vigorously criticized the "Mariolatry" they claimed to find in Roman Catholicism, especially in the dogmas of the Immaculate Conception and the Assumption, have nevertheless included in their hymnals such songs as "Ye Watchers and Ye Holy Ones," written by Athelstan Riley in 1906, in which Mary is praised as "higher than the cherubim, more glorious than the seraphim"—a praise that they would hesitate to express in the prose of their sermons or dogmatic treatises. Thus, in ways that she could never have anticipated, all generations have indeed called her blessed.

**BIBLIOGRAPHY.** HILDA GRAEF, *Mary: A History of Doctrine and Devotion*, 2 vol. (1963-65), is especially instructive about the early development of the doctrine. JUNIPER CAROL (ed.), *Mariology*, 3 vol. (1955-61), deals successively with the sources of Marian doctrine, theology, and devotions. LEON J. SUENENS, *Quelle est celle-ci? essai de synthèse mariale* (1957; Eng. trans., *Mary the Mother of God*, 1959), is a brief but helpful summary. Recent theological treatments by Roman Catholics include RENE LAURENTIN, *La question mariale* (1963; Eng. trans., *The Question of Mary*, 1965); and E. SCHILLEBEECKX, *Maria, moeder van de verlossing*, 3rd rev. ed. (1957; Eng. trans., *Mary Mother of the Redemption*, 1964). The Eastern Orthodox view is presented, though from a Roman Catholic standpoint, by MAURICIO GORDILLO,

*Mariologia Orientalis* (1954). Critical, but sympathetic treatments by Protestants are GIOVANNI MIEGGE, *La Vergine Maria* (1950; Eng. trans., *The Virgin Mary*, 1955); and MAX THURIAN, *Marie, Mère du Seigneur, figure de l'Eglise* (1962; Eng. trans., *Mary, Mother of All Christians*, 1964). Technical problems are presented in the annual *Marian Studies* and in the proceedings of national and international Mariological congresses.

## Mary I of England

Queen of England from 1553 to 1558, Mary I was the first woman to rule England in her own right, but she is chiefly remembered as Bloody Mary, the instigator of a ruthless persecution of Protestants in a vain attempt to preserve Roman Catholicism in England.

Born at Greenwich Palace on February 18, 1516, daughter of King Henry VIII and the Spanish princess Catherine of Aragon, Mary as a child was a pawn in England's bitter rivalry with more powerful nations, being fruitlessly proposed in marriage to this or that potentate desired as an ally. A studious and bright girl, she was educated by her mother and a governess of ducal rank.

Mary I, painting on wood by Sir Anthony More, 1553. In the Prado, Madrid.

Betrothed at last to the Holy Roman Emperor, her cousin Charles V (Charles I of Spain), she was commanded by him to come to Spain with a huge cash dowry. This demand ignored, he presently jilted her and concluded a more advantageous match. Made princess of Wales in 1525, she held court at Ludlow Castle while new betrothal plans were made. Mary's life was radically disrupted, however, by her father's new marriage to Anne Boleyn.

As early as the 1520s Henry had planned to divorce Catherine in order to marry Anne Boleyn, claiming that, since Catherine had been his deceased brother's wife, her union with Henry was incestuous. The Pope, however, refused to recognize Henry's right to divorce Catherine, even after the divorce was legalized in England. In 1534, Henry broke with Rome and established the Church of England. The allegation of incest, in effect, made Mary a bastard. Anne Boleyn, the new queen, bore the King a daughter, Elizabeth (the future queen), forbade Mary access to her parents, stripped her of her title of princess, and forced her to act as lady-in-waiting to the infant Elizabeth. Mary never saw her mother again, though, despite great danger, they corresponded secretly.

Anne's hatred pursued Mary so relentlessly that she feared execution, but, having her mother's courage and all her father's stubbornness, she would not admit to the illegitimacy of her birth. Nor would she enter a convent when ordered to do so.

After Anne fell under Henry's displeasure, he offered to

Mary  
in the arts

Consequences of  
Henry VIII's  
divorce

pardon Mary if she would acknowledge him as head of the Church of England and admit the "incestuous illegality" of his marriage to her mother. She refused to do so until her cousin, the emperor Charles, persuaded her to give in, an action she was to regret deeply.

Henry was now reconciled to her and gave her a household befitting her position and again made plans for her betrothal. She became godmother to Prince Edward, his son by Jane Seymour, the third queen.

She was now the most important European princess. Although plain, she was a popular figure, with a fine contralto singing voice and great linguistic ability. She was, however, not able to free herself of the epithet of bastard, and her movements were severely restricted. Husband after husband proposed for her failed to reach the altar. When Henry married Catherine Howard, however, Mary was granted permission to return to court, and in 1544, although still considered illegitimate, she was granted succession to the throne after Edward and any other legitimate children who might be born to Henry.

Edward VI succeeded his father in 1547 and, swayed by religious fervour and overzealous advisers, made English rather than Latin compulsory for church services. Mary, however, continued to celebrate mass in the old form in her private chapel and was once again in danger of losing her head.

Upon the death of Edward in 1553, she fled to Norfolk, as Lady Jane Grey had seized the throne and was recognized as queen for a few days. The country, however, considered Mary the rightful ruler, and within some days she made a triumphal entry into London. A woman of 37 now, she was forceful, sincere, bluff, and hearty like her father but, in contrast to him, disliked cruel punishments and the signing of death warrants.

Insensible to the need of caution for a newly crowned queen, unable to adapt herself to novel circumstances, and lacking self-interest, she longed to bring her people back to the church of Rome. To achieve this end, she was determined to marry Philip II of Spain, the son of the emperor Charles V and 11 years her junior, though most of her advisers advocated her cousin Courtenay, earl of Devon, a man of royal blood.

Those English noblemen who had acquired wealth and lands when Henry VIII confiscated the Catholic monasteries had a vested interest in retaining them, and Mary's desire to restore Roman Catholicism as the state religion made them her enemies. Parliament, also at odds with her, was offended by her discourtesy to their delegates pleading against the Spanish marriage: "My marriage is my own affair," she retorted.

When in 1554 it became clear that she would marry Philip, a Protestant insurrection broke out under the leadership of Sir Thomas Wyatt. Alarmed by Wyatt's rapid advance toward London, Mary made a magnificent speech rousing citizens by the thousands to fight for her. Wyatt was defeated and executed, and Mary married Philip, restored the Catholic creed, and revived the laws against heresy. For three years rebel bodies dangled from gibbets, and heretics were relentlessly executed, some 300 being burned at the stake. Thenceforward the Queen, now known as Bloody Mary, was hated, her Spanish husband distrusted and slandered, and she herself blamed for the vicious slaughter. An unpopular, unsuccessful war with France, in which Spain was England's ally, lost Calais, England's last toehold in Europe. Still childless, sick, and grief stricken, she was further depressed by a series of false pregnancies. She died on November 17, 1558, in London, and with her died all that she did.

## Mary, Queen of Scots

A romantic and tragic figure to her supporters, a scheming adulteress if not murderess to her political enemies, Mary, Queen of Scots, aroused furious controversy in her own lifetime, during which her cousin Queen Elizabeth I of England aptly termed her "the daughter of debate." Her dramatic story has continued to provoke argument among historians ever since, while the public interest in this 16th-century femme fatale remains unabated.

Mary Stuart, drawing by François Clouet, 1559. In the Bibliothèque Nationale, Paris.

Mary Stuart was born at Linlithgow on December 8, 1542, the only child of King James V of Scotland and his French wife, Mary of Guise. The death of her father six days later left Mary as queen of Scotland in her own right. Although Mary's great-uncle King Henry VIII of England made an unsuccessful effort to secure control of her (Mary inherited Tudor blood through her grandmother, a sister of Henry VIII of England), the regency of the kingdom was settled in favour of her mother.

Her mother saw to it that Mary was sent to France at the age of five. There she was brought up at the court of King Henry II and his queen Catherine de Médicis with their own large family, assisted by relations on her mother's side, the powerful Guises. Despite a charmed childhood of much luxury, including frequent hunting and dancing (at both of which she excelled) Mary's education was not neglected and she was taught Latin, Italian, Spanish, and some Greek. French now became her first language, and indeed in every other way Mary grew into a Frenchwoman rather than a Scot.

By her remarkable beauty, with her tall, slender figure (she was about 5 feet 11 inches), her red-gold hair and amber-coloured eyes, and her taste for music and poetry, Mary summed up the contemporary ideal of the Renaissance princess at the time of her marriage to Francis, eldest son of Henry and Catherine, in April 1558. Although it was a political match aimed at the union of France and Scotland, Mary was sincerely fond of her boy husband, though the marriage was probably never consummated.

The accession of Elizabeth Tudor to the throne of England in November 1558 meant that Mary was, by virtue of her Tudor blood, next in line to the English throne. Those Catholics who considered Elizabeth illegitimate because they regarded Henry VIII's divorce from Catherine of Aragon and his marriage to Anne Boleyn invalid even looked upon Mary as the lawful queen. Mary's father-in-law, Henry II of France, thus claimed the English throne on her behalf. The death of Henry in 1559 brought Francis to the French throne and made Mary a glittering queen consort of France, until Francis' premature death in December 1560 made her a widow at the age of 18.

Mary as queen

Life in France

Return to  
Scotland

Returning to Scotland in August 1561, Mary discovered that her sheltered French upbringing had made her ill-equipped to cope with the series of problems now facing her. Mary's former pretensions to the English throne had incurred Elizabeth's hostility. She refused to acknowledge Mary as her heiress, however much Mary, nothing if not royal by temperament, prized her English rights. While Mary herself was a Roman Catholic, the official religion of Scotland had been reformed to Protestantism in her absence, and she thus represented to many, including the leading Calvinist preacher John Knox, a foreign queen of an alien religion. Most difficult of all were the Scottish nobles; factious and turbulent after a series of royal minorities, they cared more for private feuds and self-aggrandisement than support of the crown. Nevertheless, for the first years of her rule, Mary managed well, with the aid of her bastard half-brother James, earl of Moray, and helped in particular by her policy of religious tolerance. Nor were all the Scots averse to the spectacle of a pretty young queen creating a graceful court life and enjoying her progresses round the country.

It was Mary's second marriage in July 1565 to her cousin Henry Stewart (Stuart), earl of Darnley, son of Matthew Stewart, 4th earl of Lennox, that started the fatal train of events culminating in her destruction. Mary married the handsome Darnley recklessly for love. It was a disastrous choice because by her marriage she antagonized all the elements interested in the power structure of Scotland, including Elizabeth, who disapproved of Mary marrying another Tudor descendant, and her half-brother James, who, jealous of the Lennox family's rise to power, promptly rebelled. Nor did Darnley's character measure up to the promise of his appearance—he was weak, vicious, and yet ambitious. The callous butchery of her secretary and confidant, David Riccio (Rizzio), in front of her own eyes when six months pregnant, in March 1566, by Darnley and a group of nobles, convinced Mary that her husband had aimed at her own life. The birth of their son James in June did nothing to reconcile the couple, and Mary, armed now with the heir she had craved, looked for some means to relieve an intolerable situation.

The next eight months constitute the most tangled and controversial period of Mary's career. According to Mary's detractors, it was during this period that she developed an adulterous liaison with James Hepburn, 4th earl of Bothwell, and planned with him the death of Darnley and their own following marriage. There is, however, no contemporary evidence of this love affair, before Darnley's death, except the highly dubious so-called Casket Letters, poems and letters supposedly written by Mary to Bothwell but now generally considered to be inadmissible evidence by historians. But Mary did undoubtedly consider the question of a divorce from Darnley, after a serious illness in October 1566, which left her health wrecked and her spirits low. On the night of February 9, 1567, the house at Kirk o' Field on the outskirts of Edinburgh where Darnley lay recovering from illness was blown up, and Darnley himself strangled while trying to escape. Many theories have been put forward to explain conflicting accounts of the crime, including the possibility that Darnley, plotting to blow up Mary, was caught in his own trap. Nevertheless, the most obvious explanation—that those responsible were the nobles who hated Darnley—is the most likely one.

Whatever Mary's foreknowledge of the crime, her conduct thereafter was fatally unwise and showed how much she lacked wise counsellors in Scotland. After three months, she allowed herself to be married off to Bothwell, the chief suspect, after he abducted and ravished her. If passion is rejected as the motive, Mary's behaviour can be ascribed to her increasing despair, exacerbated by ill-health, at her inability to manage the affairs of tempestuous Scotland without a strong arm to support her. But in fact Bothwell as a consort proved no more acceptable to the jealous Scottish nobility than Darnley had been. Mary and Bothwell were parted forever at Carberry Hill on June 15, 1567, Bothwell to exile and imprisonment where he died in 1578, and Mary to incarceration on the

Darnley's  
murder

tiny island of Loch Leven, where she was formally deposed in favour of her one-year-old son James. After a brief fling of liberty the following year, defeat of her supporters at a battle at Langside put her once more to flight. Impulsively, Mary sought refuge in England with her cousin Elizabeth. But Elizabeth, with all the political cunning Mary lacked, employed a series of excuses connected with the murder of Darnley to hold Mary in English captivity in a series of prisons for the next 18 years of her life. In the meantime, Mary's brother Moray flourished as regent of Scotland.

Mary's captivity was long and wearisome, only partly allayed by the consolations of religion and, on a more mundane level, her skill at embroidery and her love of such little pets as lap dogs and singing birds. Her health suffered from the lack of physical exercise, her figure thickened, and her beauty diminished as can be seen in the best known pictures of her in black velvet and white veil, dating from 1578. Naturally, she concentrated her energies on procuring release from an imprisonment she considered unjustified, at first by pleas, and later by conspiracy. Unfortunately for her survival, Mary as a Catholic was the natural focus for the hopes of those English Catholics who wished to replace the Protestant Queen Elizabeth on the throne. It was the discovery in 1586 of a plot to assassinate Elizabeth and bring about a Roman Catholic uprising that convinced Queen Elizabeth that while she lived, Mary would always constitute too dangerous a threat to her own position.

Despite the fact that she was the sovereign queen of another country, Mary was tried by an English court and condemned; her son, James, who had not seen his mother since infancy and now had his sights fixed on succeeding to the English throne, raised no objections. Mary was executed on February 8, 1587, in the great hall at Fotheringhay Castle, near Peterborough; she was 44 years old. It was a chilling scene, redeemed by the great personal dignity with which Mary met her fate. Her body ultimately came to rest in Westminster Abbey in a magnificent monument James I raised to his mother, after he finally ascended the throne of England.

## Maryland

One of the original 13 states of the United States, Maryland lies at the centre of the Eastern seaboard, astride the great industrial-population complex that stretches from Maine to Virginia. Its small size—10,577 square miles (27,394 square kilometres), about 6 percent of which is water excluding Chesapeake Bay—belies the great diversity of its landscapes and of the ways of life that they foster: from the low-lying and water-oriented Eastern Shore and Chesapeake Bay area, through the metropolitan hurly-burly of Baltimore, its largest city, to the forested Appalachian foothills and mountains of its western reaches.

Maryland was named in honour of the wife of King Charles I by a grateful Cecil Calvert, Lord Baltimore, who in 1632 was granted charter for the land as a haven in which his fellow Roman Catholics might escape the restrictions placed on them in England. A deep sense of history still clings to many parts of the state, most notably in the quiet charm of Annapolis, its capital since 1694, and in the white-domed, pillared statehouse, built in 1772 and today the nation's oldest statehouse in continuous use. There, a 40-block area forms the city's Colonial

Captivity  
in  
EnglandGeneral  
character  
of the  
state

Historic District, the largest in the U.S. The narrow, crooked streets, the houses abutting directly on the brick-work sidewalks, the graceful tree-covered green about the statehouse, and the myriad masts of boats at dock or anchor speak more of an earlier America than of a state with a modern industrial economy and a densely clustered population of nearly 4,000,000.

Geography, too, has provided Maryland a role in American history, as a pivot between North and South. Its northern border with Pennsylvania is the famous Mason and Dixon Line, drawn in the 1760s to settle disputes between the Penn and Calvert families and traditionally regarded as the boundary between North and South. To the south, much of the boundary with Virginia is formed by the Potomac River, a symbolic barrier during the Civil War, a contest in which the sentiments and the soil of Maryland were torn asunder. On the north bank of the Potomac lies the District of Columbia, coterminous with the city of Washington, a small enclave ceded by Maryland in 1791 for the site of the national capital. East of the Chesapeake, the Eastern Shore shares the Delmarva Peninsula with Delaware on the north and Virginia on the south. In the mountainous west, Maryland's panhandle, joined to the rest of the state by a one-and-one-half-mile-wide wasp waist, forms an interlocking handclasp with the eastern panhandle of West Virginia. (For information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; CIVIL WAR, U.S.; NORTH AMERICA; and APPALACHIAN MOUNTAINS. For details on the parts of Maryland in the Washington metropolitan area, see WASHINGTON, D.C.)

#### THE HISTORY OF MARYLAND

The area's earliest human occupation is accepted as having been by roving hunters, c. 8000 BC, as the ice sheet made its final retreat. The records of this pre-Archaic, fluted-blade culture which left only the points of its weapons, remains imprecise. Later, the numerous Eastern Archaic and then Woodlands Indian populations practiced agriculture and left waterside middens as evidence of the shellfish that they consumed. During the early European settlement the tribes were Algonkian in language and politics, but were under heavy pressure from the Iroquois to the north. The English promise of support in these wars greatly smoothed relations in the early colonial years.

*The colony.* Leonard Calvert, younger brother of Lord Baltimore, landed the founding expedition on St. Clement's (now Blakistone) Island in the lower Potomac in March 1634. The first settlement and capital was St. Mary's City. Aware of the mistakes made by Virginia's first colonists, Maryland's settlers, rather than hunt for gold, made peace with the local Indians and established farms and trading posts, at first on the shores and islands of the lower Chesapeake. The field hands included indentured labourers working off the terms of their passage and, after about 1639, African slaves. The most important crop was tobacco. Roads and towns were few, and intercourse with the English-model manor houses was largely waterborne.

The religious latitude stipulated by the Calvert family was formalized by the General Assembly in 1649 in an Act Concerning Religion, later famous as the Act of Religious Toleration. It granted freedom of worship, though only within the bounds of trinitarian Christianity. Commercial disputes with Anglican Virginia and boundary quarrels with Quaker Pennsylvania and Delaware did not affect this tolerance. Puritan ascendancy in England (1648-60) caused only brief turmoil, and during an interval of crown rule (1692-1715) in Maryland the Church of England was established formally. Maryland, nonetheless, remained a haven for dissidents from sectarian rigidity in other colonies.

As the population centre shifted to the north and west, the capital was moved to Annapolis, and in 1729, Baltimore was founded. Alone among royal grants, that to the Calverts was still in force at the outbreak of the Revolution, having spanned seven generations. Maryland's dominant "country party" early resisted British efforts to make the colonies bear more of the costs of government.

Repudiation of the Stamp Act occurred in Frederick County in 1765; and in 1774, the year after the Boston Tea Party, a ship loaded with tea was burned at an Annapolis dock.

Marylanders took an active part in the war, from the siege of Boston to the surrender at Yorktown. The Continental Congress, often on the move to avoid British troops, spent a winter in Baltimore. At the close of the war it convened in Annapolis, where it accepted Washington's resignation from the army and ratified the Treaty of Paris (1783) acknowledging the independence of the colonies.

*The state.* When harassment on the high seas and other factors brought on the War of 1812, Baltimore clippers, sailing as privateers, dealt more than equal punishment to British skippers. In 1814 the British troops who had burned the principal government buildings in Washington, D.C., were repulsed in their attempts to inflict similar punishment on Baltimore. Francis Scott Key, a Georgetown lawyer and an eyewitness of the futile bombardment of Ft. McHenry in Baltimore harbour, wrote the four eight-line stanzas that, set to music, became the national anthem, the *Star-Spangled Banner*.

With peace, Maryland and the nation became occupied with "internal improvements" in transport and communication: the National Pike, first road to cross the Appalachians; the first U.S. passenger railroad, the Baltimore & Ohio; two important canals, the Chesapeake and Ohio from Washington to Cumberland and, across the top of the Delmarva Peninsula, the Chesapeake and Delaware; and the first intercity telegraph line, from Washington, D.C., to Baltimore. In 1845, the U.S. Naval Academy was founded on the Severn River in Annapolis.

The Civil War, however, arrested Maryland's progress. Landed gentry and men of the Eastern Shore supported the secessionists, while workingmen and western Marylanders stood for the Union; a third faction favoured neutrality. Federal troops occupied Baltimore and Annapolis, and martial law was imposed in this border state. The new constitution of 1864 abolished slavery and removed power from the rural aristocracy. Meanwhile, three major invasions by Confederate armies in successive summers resulted in qualified defeat at Antietam, full defeat at Gettysburg, in Pennsylvania, and dissipation of a threat to Washington, D.C., in 1864. The more cautious constitution of 1867 remains in force today, though it has been amended almost beyond recognition.

*Since 1865.* After the Civil War, Maryland prospered: first as an entrepôt for raw materials from and consumer goods to the South and Middle West and then as a growing centre of industry that rarely was controlled from within the state. Excesses that had won Baltimore the epithet "mob town" gradually were quieted; and Marylanders settled in to vote, until recent decades, for candidates of the Democratic Party. Increasingly, however, Maryland felt the impact of its proximity to the seat of national government. It became a major centre for federal installations, both military and civilian, during both world wars and after. But most significant was the radically different face of the Maryland suburbs of Washington, D.C., which reflected change not only in the greater numbers of people but also in their unusually high educational and economic status.

#### THE NATURAL AND HUMAN LANDSCAPE

*The natural environment.* *Surface features.* The Atlantic Coastal Plain covers about one-half of Maryland's land area, yielding to the Piedmont plateau at a fall line running from the tip of the District of Columbia through Baltimore and to near the northeastern corner of the state. The Catoctin ridgeline in the west forms the gateway to the Appalachians.

To the south, the Coastal Plain is sandy; to the north, it is loamy and fertile. Its water edges, called salt marshes or wetlands, exasperate mapmakers as erosion here fills in a swamp, there deletes an entire island: Blakistone, for example, is now about one-tenth its 1634 size. The Chesapeake's 23 drowned arms, or estuarial tributaries, give the state some 3,200 miles of shoreline—subject to frequent

Impact  
of the  
Civil  
War

Religious  
toleration  
in the  
colony

change. The most significant of nature-made revisions was an irruption of the ocean, during a storm in 1933, through Fenwick Island into Sinepuxent Bay, just below Ocean City. The lower portion of this barrier sand reef is now a national seashore and state park known as Assateague Island, and the inlet has become a boon to Ocean City's resort fishing fleet.

The Piedmont plateau has good farming soil save for belts of clay that are mined for brick kilns: from the beginning, the exteriors of Maryland buildings have glowed with salmon-coloured brick. To the west, paralleling the fall line, the low Parr's Ridge forms a barrier between the Potomac and Chesapeake Bay.

Maryland's share of Appalachia comprises a series of forested barriers, with many of the intervening valleys still uncleared. Backbone Mountain, hugging the West Virginia line, is the highest point in Maryland, at 3,360 feet (1,024 metres).

*Climate.* Maryland has two climates. It is continental in the west, with temperature records from  $-40^{\circ}$  F ( $-40^{\circ}$  C) to more than  $100^{\circ}$  F ( $38^{\circ}$  C). In the east, a humid subtropical climate is dependent on the Azores High, a pressure area that moderates the weather but does not prevent ice formation almost every winter on Chesapeake Bay's northern tributaries, summer calms as high as  $107^{\circ}$  F ( $42^{\circ}$  C) and nearly 100 percent humidity. Ordinarily, rains are enough to make reservoirs spill over and to enable Baltimore and Washington, D.C., to draw all the needed soft water for drinking. Storms sweep in from the west and south, except in late summer, when the fringes of passing hurricanes often drench Maryland from the east.

*Human imprints.* The most salient feature of Maryland's topography is Chesapeake Bay, which makes Baltimore a world port, divides the Eastern Shore from what was once called Maryland Main, adds picturesqueness to the Maine-to-Florida Inland Waterway, and on a summer weekend may count as many as 100,000 pleasure craft, sail or power. But it has a few drawbacks: swimmers shun its brackish, murky water after the late-summer onset of billions of small, stinging jellyfish; while the cross-bay bridge, completed in 1952, is only two lanes wide, without expansion capability; and so great is the crush of summer weekenders to and from the ocean beaches that, less than 20 years later, work was begun on a parallel bridge.

Dredging is necessary to maintain the 42-foot ship channel to Baltimore and to the Chesapeake and Delaware Canal. Finally, the bay must be defended against pollution by the cities and industries in its drainage area. Once the bay was lined with oysters; today, silt and pollutants have pushed the diminished survivors into various tributary rivers. Nonetheless, the bay, called by the Baltimore sage H.L. Mencken a "great big outdoor protein factory," still affords a living to hundreds of watermen.

Sectionalism within Maryland is dictated by terrain. The Eastern Shore farmer, in modern times, concentrates on chickens, corn, and soybeans. A mercantile appendage of Wilmington and Philadelphia until the bay was bridged, the nine-county Shore is increasingly a vacation and retirement spot for the well-to-do, who appreciate the privacy of its flat, wooded, little-posted estate areas, serpentine with creeks, guts, necks, and inlets.

Southern Maryland's five counties have built a way of life around state government, tobacco-growing, and military installations. Prince Georges County in suburban Washington has become Maryland's most populous. A nuclear-power project at Calvert Cliffs attracted attention to the marine fossils of the Miocene Epoch, where the bay has exposed dense layers of shark teeth, whale vertebrae, mollusk shells, and other ocean-floor debris from possibly 15,000,000 years ago. These fossils are deemed the world's finest accessible deposit from that period.

Central Maryland's city, Baltimore, and five counties are united only by not fitting into any of the adjoining entities. Four of the counties contain most of Baltimore's suburbs; the fifth is Montgomery, on Washington, D.C.'s northwestern edge. By 1970, only 15.7 percent of Marylanders lived outside the Census Bureau's standard metro-

politan statistical areas—and central Maryland was one long, contiguous metropolitan area.

The four counties of western Maryland owe much to road, railroad, and canal builders. The barging of coal and grain ceased in 1924, but creation of the Chesapeake and Ohio Canal National Historical Park in 1971 assured a stream of excursionists. Interstate and national roads carried city dwellers to Garrett County, where mountain-side ski runs complemented water sports on Deep Creek Lake, the largest man-made body of water in the state.

#### THE PEOPLE OF MARYLAND

*Composition of the population.* The white population, at first all from the British Isles, began to vary when German-speaking farmers and artisans spread down from Pennsylvania into western Maryland in the 1700s. The process accelerated from 1848 on as Germans and German Jews fled military conscription, and then Russian Jews, Poles, Czechs, Italians, Greeks, and others arrived at Baltimore, a major 19th-century immigration centre, and fanned out into the countryside. This ethnic diversity was one of the first characteristics setting Maryland apart from the regions below the Potomac River. In the years immediately following the Civil War, it was to some extent countered by an influx of Southerners who despaired of life in a defeated and devastated homeland.

Maryland's Indian population had been killed off or pushed westward by about 1700. All that remained from their centuries of occupancy were the campsite artifacts, still being unearthed by professional and amateur archaeologists, and place names, mangled by uncomprehending whites, that come out as Chesapeake, Patapsco, Potomac, Wicomico, Patuxent, Piscataway, Susquehanna, and many others.

*The racial picture.* African slaves were at work in Maryland under the first Calvert. The consciences of many Marylanders, particularly members of the Society of Friends (Quakers), were uneasy; and from 1783 the importation of kidnapped Africans was under prohibitive state tax. While Maryland did not formally outlaw slavery until 1864, it protected the liberty of more free blacks than any other state as slavery neared its end. After the Civil War, blacks found Maryland somewhat more congenial than the states of the Confederacy, in which, by 1900, systematic lifetime disfranchisement of blacks was under way. A corresponding effort in Maryland, led by the Democratic Party and coming to a head in 1910, was beaten in referendum by Republicans, with the aid of James Cardinal Gibbons and other leading citizens. Yet it took a U.S. Supreme Court decision in 1934 to force the University of Maryland to admit a black into its School of Law, and it was 1970 before Marylanders first sent a black to represent them in Congress—the latter in part a reflection of the fact that the population of Baltimore had become virtually half black.

*Contemporary demography.* Maryland's 1970 population was more than 80 percent white, however. The birth-rate was 15.5 per 1,000 persons, down from 24.9 in 1960, but still far above the 1970 death rate, 8.2. Rates for nonwhites in both categories were higher than for whites.

Present and foreseeable clustering is thickest in the outskirts of Washington, D.C., and Baltimore. In the Census Bureau's 1970 list of Standard Metropolitan Statistical Areas, the two ranked seventh and 11th, respectively, up from tenth and 12th in 1960. The rural stretch between the two cities, which are only 40 miles apart, diminished, particularly as the planned, unincorporated new city of Columbia progressed toward its goal of 100,000 residents in the 1980s. Because growth outward from the cities was uneven, however, fusion into a common, uninterrupted cityscape remained an indefinite prospect. To the north and east of Baltimore, the transition from farm to suburb in Baltimore and Harford counties promised ultimate juncture with the Philadelphia-Wilmington sprawl; but Cecil County, at the head of Chesapeake Bay, remained steadfastly rural.

Baltimore, with just over 900,000 inhabitants, continues to lose people to the suburbs. Calculations for runner-up city were impeded by the 20th-century tendency of the

The ethnic mix

Chesapeake Bay

The Baltimore-Washington, D.C., corridor

state's municipalities not to incorporate, making boundaries arbitrary lines drawn by census takers.

#### THE STATE'S ECONOMY

*Components.* Except for high unemployment in the early 1970s, Maryland enjoyed good economic health, with personal income at an all-time high. Federal, state, and local government employed more than 300,000 members of the civilian labour force, followed closely by manufacturing. The major industries, in order of employment, were primary metal, food and kindred products, fabricated metal, transportation equipment, apparel and related products, and electrical machinery. Most of the establishments were branches of out-of-state corporations; but wages for production workers were slightly above the national average. Coal mining, however, was at its lowest ebb in a century.

Service industries bulked large in the economy, but agriculture probably directly supported fewer than 100,000 persons, including all family members. Although the number of farms had fallen from 48,000 in 1920 to 18,000, farm income, the largest proportion from livestock, was up. Fisheries present to Maryland its one category of customary nationwide pre-eminence: oysters. The state's oyster haul rather consistently has led all others. Other saltwater staples include other shellfish, as well as perch, flounder, and other finfish.

The state has taken an increasing interest in the well being of the private sector, particularly through its Department of Economic and Community Development, which encourages outside firms to locate in Maryland, promotes tourism, and keeps close watch on the economy.

*Transportation.* Entering the 1970s, Maryland offered the traveller from the north three trunk highways into Baltimore and four highways south to Washington. It was possible to swing around Baltimore and Washington on beltways or to avoid them altogether by Eastern Shore routes. The state's main need was an alternate tunnel or bridge across Baltimore Harbor, where the existing tunnel often was unable to handle the flow of traffic. The chief remaining passenger rail service was the Penn Central service to Baltimore and the Capital Beltway. Baltimore's Friendship International Airport was augmented by 44 smaller airports about the state. For freight shipments, the Port of Baltimore had the skills and facilities to go with its standing as fifth in the nation in volume of foreign traffic handled. The port, supervised by a state agency, was especially adapted to bulk commodities, container shipments, and foreign-made automobiles.

#### ADMINISTRATION AND SOCIAL CONDITIONS

*Structure of government.* *The state level.* In spite of a provision for statewide voting every 20 years on whether to summon a constitutional convention, repeated attempts to scrap the 1867 document, with its unnecessary detail, obsolete concerns, and silence on points of current interest, have been failures. The existing document has been amended more than 100 times.

The form of state government is like that of most other U.S. states. The governor, who serves for four years, may be re-elected to an immediately succeeding term only once. A 1970-71 reorganization brought together in 11 new departments some 200 divisions, agencies, and facilities previously lacking in coherent direction.

Members of the General Assembly serve four years and may be re-elected indefinitely. Reorganization in the 1960s to assure equal voter representation in both houses brought the Senate to a membership of 43, the House of Delegates to 142. Rural domination of the legislature was effectively ended, power passing to the counties adjoining Baltimore and Washington, D.C.

Below the seven-member Court of Appeals, the highest judicial body, is an intermediate Court of Special Appeals and a series of circuit courts—known in Baltimore as the Supreme Bench. Judges are appointed by the governor and must run against their record and anyone filing in opposition—for a 15-year term—in the election following appointment.

The headquarters of the Maryland National Guard is

near the Baltimore office centre, in which the offices of some 30 percent of the state's employees are located. The guard was called out in recent years for riot duty in Cambridge, to halt civil-rights disturbances; in Baltimore, where inner-city property destruction in April 1968 (following the assassination of Dr. Martin Luther King, Jr.) was so extensive that army troops quickly replaced guardsmen; and in College Park, where in 1970 and later University of Maryland students protested U.S. military and foreign policies.

*Local government.* To avoid the greater costs that would be entailed by incorporation as governmental bodies, many of Maryland's most populous areas remain unofficial entities, their services more efficiently and economically provided on a countywide basis. As a result, the basic agency for local administration—aside from the city of Baltimore, a separate entity—is a board of county commissioners, who are elected to four-year terms. The county commissioners' power is largely executive, and most local legislation requires an act of the state legislature. A constitutional amendment allows home rule for counties, under special charter; in 1948 Montgomery County, adjoining the District of Columbia, adopted home rule, and four other counties have since followed suit. A charter county is governed by a county executive and county council, elected to four-year terms; the council is empowered to enact all local laws.

*Political life.* In the 20th century, though free of the intimidation, poll tax, and other evils practiced in some places in the South, many Maryland elections have been machine dominated. The larger group of voters consistently has registered as Democrats, and their party usually, but not always, wins. Exceptions have occurred when the Democrats split internally, when a nominee's platform was outrageous, or when a Republican presidential candidate carried the local candidates along. A Republican can usually rely on the western counties, one or two southern enclaves, and, latterly, the Eastern Shore and some affluent parts of suburbia. Baltimore, with its party-boss tradition, is a Democratic stronghold, and college-educated and consciously ethnic voters are dependably Democratic. The black vote, long staunchly Republican, switched parties during the New Deal of the 1930s.

In the early 1970s, both U.S. senators from Maryland were Republican, whereas the General Assembly remained heavily Democratic, as it had for decades. Thus, Democratic primary elections were often more important than the general election. When the nation's axis of balance was North-South, numerous presidential nominating conventions assembled in Baltimore, but none has been held there since 1912. In 1970, Marylanders chose their first Jewish governor and black congressman, but still had never elected a woman governor or member of Congress.

*The social milieu.* Through its revenues, largely from income and sales taxes, the state has assumed functions and responsibilities no longer within local capacity. It pays all full-time judges; the governor appoints the police commissioner of Baltimore; the construction of all new school buildings is a state matter; and Baltimore's airport is jointly operated by city and state. The state presents annual subsidies to Baltimore's leading orchestra, art museum, and resident theatre; and in 1971 the governor urged an annual subsidy to all nonpublic primary and secondary schools. In many instances, as population and industry moved outward, as old structures were demolished and property-tax assessments and yield dipped, municipalities took the initiative in this transfer of support and direction to the state. Maryland set no speed records, however, in the nationwide movement since 1954 toward racial nondiscrimination in schools, job opportunities, housing, and the like.

*Education.* Control of public education is vested in the state board of education and county school boards. All positions are appointive, except in Montgomery County, which elects its board. State supervision and support of county public school systems began in 1870; yet not until 1951 were 12 years of schooling uniformly required in all counties. The state in the 1970s aided local systems particularly as regards library services, vocational and reha-

of local  
financing

bilitational instruction, and utilization of federal aid; and the instructional television network opened in 1969.

In the 1960s the five state teachers' colleges were expanded into liberal arts colleges, and Morgan State College in Baltimore added a graduate school. Two-year community colleges were founded in Baltimore and in nearly one-half of the 23 counties. Crowning the state system was the University of Maryland, with its main campus in College Park and branches in Baltimore, Catonsville, and Princess Anne. Its origins date from the College of Medicine of Maryland (opened in 1807) and Maryland Agricultural College (opened in 1856). The several graduate and undergraduate schools were consolidated in 1920; and its 1970-71 enrollment made it one of the nation's ten largest universities.

Of Maryland's 22 privately operated degree-granting institutions of higher learning, the most prominent are Johns Hopkins (founded 1876), with several campuses and a world famous medical school; St. John's College (1784) in Annapolis, with its emphasis on the Great Books of the Western World; and Goucher College (1885) for women, in Towson.

**Health and welfare.** The Department of Health and Mental Hygiene, besides supervising county services, operates two tuberculosis hospitals, three chronic-disease rehabilitation hospitals, and seven hospitals for the mentally retarded or deranged. The department is also the focus for state efforts to prevent or remove pollution. Its environmental-health section monitors water supply and sewage, air quality, and solid-waste disposal. It also has assumed new responsibilities in the area of drug abuse.

The Department of Social Services is in charge of state welfare activities. Direct aid to families with dependent children comprises its largest outlay, followed by boarding care for children and aid to the elderly, the permanently and totally disabled, and the needy blind.

#### CULTURAL LIFE AND INSTITUTIONS

**The cultural milieu.** In the last third of the 20th century, Maryland had its full share of such nationwide phenomena as institutional uniformity, ebbing respect for local and regional distinctiveness, and transitoriness of residence. In addition, the setting contained sizable quantities of seediness, particularly in the close-packed monotony of many a residential neighbourhood, the garish commercialization of streets and highways, the urban waste spaces where torn-down buildings have not been replaced, and always the degradation of the slums—some of them rural.

At the same time, however, the high proportion of Marylanders who were long-time residents (some representing many generations) retained an unusual number of distinctive interests and activities. Echoes of landed gentry of England and of early Maryland were stirred by riding to hounds in pursuit of the fox and taking part in the Grand National Steeplechase and Maryland Hunt Cup races, by breeding Chesapeake Bay retrievers, by jousting on horseback with a spear at rings dangling from a crossbar, and even by appraising the girls making their debuts at cotillions. The out-of-doors looms large in the life of Marylanders: sailing and crabbing on the bay, and trolling for ocean marlin, shooting wild geese in the marshes of the Shore, playing the game of lacrosse (derived from an Indian sport), or hiking the 38-mile stretch of the Appalachian Trail across Maryland in a single day.

Sailboat and sports-car racing provide for both active and passive participation, while the annual Preakness Stakes, the horserace at Pimlico, and Baltimore's baseball Orioles, football Colts, and basketball Bullets have followings far beyond Maryland. The peculiar gastronomy of Maryland, similar to, but different from, that of the Atlantic Coast from Maine to Louisiana, focusses upon terrapin soup, steamed crabs, padded oysters, backfin lump crabcakes, and beaten biscuits, often washed down with Maryland rye and beer at parties ashore or afloat. In almost a different world are the communities of watermen on various islands of the bay, in which isolation has worked to preserve attitudes, ways of life, and accents directly out of the past.

**The arts and letters.** Among Marylanders who have made major contributions to American artistic and intellectual traditions are the critic H. L. Mencken, the Negro abolitionist-statesman Frederick Douglass, the poet and shortstory writer Edgar Allan Poe, the naturalist Rachel Carson, and the antislavery activist Harriet Tubman.

Today, Baltimore is the focus of much of the state's activity in the arts. The Baltimore Symphony Orchestra is paralleled in professional theatre by the Center Stage Theatre and numerous suburban dinner theatres. The Museum of Art and Walters Art Gallery are supplemented by similar galleries elsewhere, holding in their collections both the arts and the artifacts of the past, as well as by annual art fairs and festivals in several locations.

**Historic memorabilia.** Virtually all towns, cities, and rural areas in Maryland are marked by relics of the past. The state and the many county and local historical societies and museums offer only parts of the picture. Walking tours are needed to visit the innumerable private homes from the 17th and 18th centuries; the many old canal locks; the National Road in Garrett County that carried many of the early trans-Appalachian homesteaders westward; and the stone markers of the Mason and Dixon Line set at five-mile intervals. Historic festivals and tours are as numerous as those devoted to the products of the bay or to sporting or artistic events.

**The media.** Marylanders have only five morning newspapers, led by *The Sun* of Baltimore and *The Washington Post* from the neighbouring national capital, and only nine evening dailies. Several dozen radio stations and about 20 television stations can be picked up in Maryland, many of them from surrounding states.

#### PROBLEMS AND PROSPECTS

Entering the final decades of the 20th century, Maryland faced many of the difficulties familiar across the nation: maintaining its pleasantness as a place to live while coping with vast population growth; alleviating the deprivations of life on lower socio-economic levels; moving people swiftly between cities and between homes and jobs without paving over the entire landscape; making two-party government a working reality; reducing violent and nonviolent crime; and balancing budgets amid rising costs. The traditional evenness of Maryland ways was jeopardized still further by a clash of interests between the city, specifically Baltimore, and the bursting suburbs adjoining both Baltimore and Washington. Though steadily growing in wealth and power, the suburbs expressed unwillingness to rescue the city as its revenue sources shrank and its social-service needs expanded. Yet there was hope for a resolution of this last impasse in the visibly growing role of the state government. Assuming the role of the disinterested overseer, who requires conflicting jurisdictions to get along and promotes an all-Maryland point of view, it appeared to be leading the way toward better years to come.

**BIBLIOGRAPHY.** Books on all aspects of Maryland are legion. Fairly recent histories include M.L. RADOFF (ed.), *The Old Line State*, 3 vol. (1957); M.L. CALLCOTT, *The Negro in Maryland Politics, 1870-1912* (1969); C.B. CLARK, *The Eastern Shore of Maryland and Virginia*, 3 vol. (1950); and M. MITCHELL, *Annapolis Visit* (1969). Older works include M.P. ANDREWS, *History of Maryland* (1929, reprinted 1965); W.T. RUSSELL, *Maryland, the Land of Sanctuary: A History of Religious Toleration, 1634-1776* (1908); RAPHAEL SEMMES, *Captains and Mariners of Early Maryland* (1937); and J.M. WRIGHT, *The Free Negro in Maryland, 1634-1860* (1921). JOHN BARTH'S novel, *The Sot-Weed Factor* (1960), is an uproarious but atmospheric tale of the 17th-century colony. Maryland's landscape comes alive in such works as the FEDERAL WRITERS' PROJECT, *Maryland* (1940); H. FOOTNER, *Rivers of the Eastern Shore: Seventeen Maryland Rivers* (1944); M.V. BREWINGTON, *Chesapeake Bay: A Pictorial Maritime History*, 2nd ed. (1956), *Chesapeake Bay Log Canoes and Bugeyes* (1963); and A.A. BODINE, *Chesapeake Bay and Tidewater*, 3rd rev. and enl. ed. (1968) and *The Face of Maryland*, 3rd ed. (1970).

The Marylanders and their institutions are covered in G. BYRON, *The Lord's Oysters* (1957); G. WOLFE, *I Drove Hules on the C and O Canal* (1969); K. SCARBOROUGH, *The Homes of the Cavaliers* (1930); H.C. FORMAN, *Maryland Architect-*

## Masaccio

Though he was born poor and lived only 27 years, Masaccio, at the beginning of the 15th century, brought about the most important revolution the art of painting had known up to his time. Like his two great Florentine contemporaries, the architect Brunelleschi and the sculptor Donatello, Masaccio introduced Humanism into his art, putting man and the world at the centre of his works, rather than at the periphery, as in the theocentric universe of medieval art. Implicit in his work is confidence in human reason and knowledge; his subjects appear to have been drawn from the life he saw around him, rather than from the traditional models he inherited.

Anderson—Alinari

"The Trinity," fresco by Masaccio, c. 1427. In the church of Sta. Maria Novella, Florence.

In addition, fundamental technical advances, such as the first use of a central light source in painting and innovations in the use of perspective, are credited to him. The splendour of Italian Renaissance painting begins with Masaccio: all of its original currents derive from him and return to him.

Masaccio was born Tommaso di Giovanni di Simone Guidi on December 21, 1401, the son of Ser Giovanni di Mone Cassai and Monna Jacopa di Martinozzo, in Castel San Giovanni di Altura (now San Giovanni Valdarno, in the Tuscan province of Arezzo). His father was a notary and his mother the daughter of an innkeeper of Barberino di Mugello, a town a few miles south of Florence. His childhood must have been reasonably comfortable in the first years following his father's death in 1406, at the age of 26. Masaccio was then only five years old, and his brother Giovanni, who, under the nickname lo Scheggia, was also to become a painter, was born that year. The mother was remarried to an elderly apothecary who died in August 1417, when Masaccio was 16. That same year the boy moved to Florence.

It is not known where Masaccio received his training in art. Sources from the 16th century indicate that he served an apprenticeship with Masolino da Panicale, his frequent collaborator, but modern criticism has, on the

whole, repudiated this claim. Masolino was from the same locality as Masaccio, and this may be why they are associated in the early texts, but their association was probably a working partnership in Florence. Close ties with the late Gothic art of Gentile da Fabriano and Arcangelo di Cola da Camerino, as well as the initial influence of such Valdarno painters as Mariotto di Cristofano, also have been surmised. On the other hand, some scholars now believe it unlikely that, given the nature of his genius, Masaccio was able to make use of any influence from the past or present; others, taking into account the chronology of his works, maintain that Masaccio's idiom derived from what had been already achieved by Brunelleschi and Donatello.

On January 7, 1422, Masaccio is known to have been enrolled in Florence in the *Arte dei Medici e Speziali*; this has been learned from a document in which he is specified, for the first time, as a painter in his own right. That same year, in the church of S. Giovenale in Cascia at Reggello, near Florence, he painted a now only recently discovered triptych with the Madonna enthroned, two adoring angels, and saints. This work, probably wholly executed by Masaccio, falls within the general framework of a normal Florentine tradition, though it may not completely clarify his training as an artist. There is no trace of Masolino, a sign that the meeting with his countryman had not yet occurred, but there is, instead, much of the customary Florentine tradition. There also appear new influences from Giotto and Donatello, and Brunelleschi's revolutionary new treatment of perspective—the technique of rendering objects realistically in space—is also evident.

Masaccio's second known work, the "Madonna and Child with St. Anne," in the Uffizi, was a work begun by Masolino for the church of S. Ambrogio.

Although the contributions of the two artists have been disputed, it is probable that Masaccio painted the Madonna and child and the angel in the upper right and that Masolino painted the rest. Masaccio may be considered the independent collaborator of Masolino, who had perhaps been commissioned to execute the panel. The execution of the painting can be fixed at 1424. The Renaissance biographer Giorgio Vasari seems to assert that in the interval between the "S. Giovenale Triptych" and this painting, the artist made a trip to Rome, in 1423. Such a trip might explain certain influences that are now recognized in this work from ancient Greek and Roman art, which he might have seen there. Presumably, there must have been some trace of such influence in the lost "Sagra," a fresco celebrating the consecration ceremony of the church of Sta. Maria del Carmine in Florence, on April 19, 1422, destroyed as a result of architectural alterations to the church cloister at the end of the 16th century; some indications of it survive in drawings, including a famous one by Michelangelo.

The new Madonna is defined in a more imposing sculptural way than the one of S. Giovenale, and the child, which is taken from ancient models, blesses with a broad gesture of solemnity that is almost that of a Roman consul. Most significantly, the light, for the first time in the history of painting, comes from a single source, building every aspect of form naturalistically and truthfully and immersing it in a spatial reality in which the painter's first exercises in perspective, as developed by Brunelleschi, can perhaps be seen.

Masaccio's association with Masolino grew closer. Since Masolino was planning to visit Hungary, it is possible that he needed a collaborator for both the S. Ambrogio painting and the work he had been commissioned to do in the chapel of the Carmine, so that he could deliver them in time, collect the money required for his journey, and avoid incurring penalties for default. Masaccio might well have accepted such an arrangement, because—despite their essential differences—Masolino was the Florentine painter closest to himself. Like Masaccio, he had an objective, plastic style, though softer and smoother, and both favoured naturalism, even if for Masaccio naturalism meant a compelling obligation to construct and synthesize, while for Masolino it meant sweetness and

Association with Masolino

Early training and influences

vagueness, a feeling of springtime or the early morning to be rendered rather naively and with no necessary contact with the environment.

On February 19, 1426, Masaccio was commissioned, for the sum of 80 florins, to paint a large altarpiece for a chapel in the church of Sta. Maria del Carmine in Pisa. The execution of the work—as shown by the dates of various payments on account and the final settlement—took until December 26 of that year. The work was dismantled and dispersed in the 18th century, and so far 11 sections have been rediscovered and identified in museums and private collections. Essential for the partial reconstruction of the work was the discovery of the Madonna, now in the National Gallery in London, and of the Crucifixion, now in the Museo e Gallerie Nazionali di Capodimonte in Naples.

Another important presence in Pisa in the year 1426 was that of Donatello, who was working on a monument for Cardinal Rinaldo Brancacci to be sent to Naples. Various connections may be seen between Masaccio's art and the sculpture of Donatello, on which Masaccio's first experiments in plasticity and perspective were based, before he was exposed to Brunelleschi's more scientific approach to perspective. Donatello's influence may be seen especially in the central portion of Masaccio's Pisa polyptych and the Crucifixion above; in particular, certain contrasts in the modelling, by means of light, sharpen the edges in a manner characteristic of Donatello. Indeed, it appears that at Donatello's initial prompting the broad path of the Renaissance opened out before Masaccio.

Masaccio's most celebrated work

On December 26, 1426, the final payment of the 80 florins agreed upon for the Pisa polyptych was made. Sometime between the end of 1424 and 1427–28, when he left Florence for Rome, Masaccio painted the most celebrated work of his brief life, the frescoes of the Brancacci Chapel in the church of Sta. Maria del Carmine in Florence, one of the supreme masterpieces of painting of all time. Masaccio and Masolino divided the work, and parts begun by Masaccio were finished by Filippino Lippi. The question of attribution of the various portions of these frescoes has been one of the most discussed artistic problems of the 19th and 20th centuries. The chronology, which remains controversial, appears to have been as follows: from the first months of 1425 and until August of that year, Masaccio executed successively the "Baptism of the Neophytes," "The Expulsion," and "The Tribute Money," while Masolino worked, respectively, on "The Sermon of St. Peter," "The Original Sin," and, aided in part by Masaccio, the "Healing of the Cripple" and the "Resurrection of Tabitha." At the end of 1425 and the beginning of 1426, Masaccio executed "St. Peter Healing the Sick with His Shadow" and "St. Peter Distributing Alms," while Masolino was in Hungary, where he remained until August 1427. Masaccio was soon taken up with work on the Pisa altarpiece, for which he might easily have obtained a release from his commitment to the Brancacci Chapel, because the work was for the same sponsors. In 1427 Masaccio began the "Resurrection of the Son of Theophilus," but work on it was interrupted.

Problems arising from the authorship of these paintings were complicated by the effects of a fire in 1771 that devastated the whole church; the frescoes were saved, except for the fall of two pieces of plaster from the left side (areas of "The Tribute Money" and "Resurrection of the Son of Theophilus"), but they were blackened by smoke. The extent of the darkening was shown only recently by the removal of two small marble projections on the sides of the altar that had covered two areas of original painting in the scenes of Masaccio's "Baptism of the Neophytes" and Masolino's "Sermon of St. Peter."

Masaccio's development can be traced in his treatment of perspective in the various paintings. In the first frescoes of the Brancacci Chapel, from the "Baptism of the Neophytes" to "The Tribute Money," it is rather similar to the intuitive perspective of Donatello, as it appears in his St. George bas-relief (c. 1415); in the final phase of the work ("Resurrection of the Son of Theophilus"), however, the feeling is more in keeping with that of Brunelleschi. This new grasp of perspective is fully realized

in "The Trinity," with the Virgin, St. John the Evangelist, and two donors, in the church of Sta. Maria Novella; the spatial scheme, showing a barrel-vaulted hall, is the first use of linear perspective in the art of fresco painting.

As has been mentioned, Masaccio seems to have returned from Pisa in 1427 to work again in the Carmine. Having begun the "Resurrection of the Son of Theophilus," he interrupted his work when he was called to Rome by Masolino, who had presumably been there since the autumn of 1427.

Attempts by critics to detect Masaccio's hand in Masolino's frescoes of S. Clemente in Rome have been unsuccessful. Nevertheless, he may have made at least a contribution to what was Masolino's polyptych of the altar in Sta. Maria Maggiore in the panel with SS. Jerome and John the Baptist, now in the National Gallery in London.

Masaccio died in Rome in the autumn of 1428. An old and unconfirmed report speaks of death by poisoning. All of his known works derive from a period of eight years.

Masaccio's significance for modern painting has never been doubted through the ages. In his own century, such eminent men of the arts as Leon Battista Alberti and Leonardo da Vinci paid homage to him, and all painters native to or working in Florence studied his Carmine frescoes in order "to learn the precepts and rules for painting well," in the words of Vasari, who specifically enumerated Fra Angelico, Filippo Lippi, Michelangelo, Raphael, and many others. Similarly, artists and writers of later periods have continued to study and to be influenced by him down to the present. Although consistently praised for the profoundly human nature of his art, he has also been variously credited with qualities that reflect the predisposition of each period or the personal biases of the critics. Thus, his work has been called pure, unadorned, and classic, on the one hand, and expressive, plastic, and highly chromatic, on the other; it has been praised by some for being rationalistic and ideologically proletarian or anti-bourgeois, while others have found it anti-intellectual and intuitive. This power to compel careful scrutiny in each succeeding age, while evading any definitive explanation, is the hallmark of only the greatest works of art.

#### MAJOR WORKS

"Giovenale Triptych" (dated 1422; Uffizi, Florence); "Madonna and Child with St. Anne" (c. 1424; Uffizi); Frescoes in the Brancacci Chapel, Sta. Maria del Carmine, Florence (c. 1424–28): "The Expulsion," "Baptism of the Neophytes," architecture (in the "Resurrection of Tabitha"), "The Tribute Money," "St. Peter Distributing Alms and the Death of Ananias," "St. Peter Healing the Sick with His Shadow," "Resurrection of the Son of Theophilus and St. Peter Enthroned"; "SS. John the Baptist and Jerome" (c. 1426; National Gallery, London); sections of the Pisa polyptych (1426): "St. Paul" (Museo Nazionale di San Matteo, Pisa), "Crucifixion" (Museo e Gallerie Nazionali di Capodimonte, Naples), "St. Andrew" (Lanckoronski Collection, Vienna), "St. Augustine" (Staatliche Museen Preussischer Kulturbesitz, Berlin), "St. Jerome" (Staatliche Museen Preussischer Kulturbesitz, Berlin), "The Virgin and Child" (National Gallery, London), "The Martyrdom of SS. Peter and John the Baptist" (Staatliche Museen Preussischer Kulturbesitz, Berlin), "The Adoration of the Magi" (Staatliche Museen Preussischer Kulturbesitz, Berlin); "St. Julian Murdering His Parents and the Miracle of St. Nicholas" (Staatliche Museen Preussischer Kulturbesitz, Berlin); "Prayer in the Garden and the Communion of St. Jerome" (c. 1426–27; Staatliches Lindenau-Museum, Altenburg); "The Trinity" (c. 1427; Sta. Maria Novella, Florence); "St. Julian's Story" (1427; Museo Horne, Florence).

**BIBLIOGRAPHY.** The extensive literature on Masaccio was gathered by O.H. GIGLIOLI in his exhaustive annotated bibliography in *Bollettino del Reale Istituto di Archeologia e Storia dell'Arte* (1929); it has been updated to 1963–64 by LUCIANO BERTI, *Masaccio* (1964). Certain contributions after 1945 are noted in ALESSANDRO PARRONCHI's small monograph, *Masaccio* (1966), in Italian. Other basic texts are MARIO SALMI, *Masaccio* (1934, 1947); UGO PROCACCI, *Tutta la pittura di Masaccio* (1951; Eng. trans., *All the Paintings of Masaccio*, 1962); UMBERTO BALDINI in the *Encyclopedia of World Art*, vol. 9, col. 509–520 (1964); and LUCIANO BERTI, *Masaccio* (1967).

Masaccio's continuing significance

## Masaryk, Tomáš

Tomáš Garrigue Masaryk, philosopher, chief founder, and first president of Czechoslovakia, first won international fame for Czech and Slovak independence during World War I. As a philosopher Masaryk was an unrelenting critic of the Czech bourgeoisie; having rebelled against the Roman Catholic Church in his youth, he fought from the 1880s onward for the revival of the puritan ethic of the Bohemian religious reformer Jan Hus.

From the collections of the National Gallery in Prague

Tomáš Garrigue Masaryk, painting by Vojtěch Hynais, 1919. In the Národní Galerie, Prague.

The son of a Slovak coachman, Masaryk was born on March 7, 1850, on an Austrian imperial estate on the Hungarian-Moravian border near Göding (now Hodonín, Czechoslovakia). His mother, a maid, came from a Germanized Moravian family. Though he was trained to be a teacher, he briefly became a locksmith's apprentice but then entered the German high school in Brno in 1865. Continuing his studies at the University of Vienna, he obtained his doctorate in 1876. He studied for a year in Leipzig, where he met an American student of music, Charlotte Garrigue, whom he married in 1876.

He was appointed lecturer in philosophy in Vienna in 1879. Masaryk was a Neo-Kantian, but he was also strongly influenced by the English puritan ethics and the austere teaching of the Hussites. At the same time, he showed a critical interest in the self-contradictions of capitalism—e.g., in his first major work, a study of suicide as a mass phenomenon of modern civilization. In 1882 Masaryk was appointed professor of philosophy in the Czech university of Prague.

His early works on the Czech Reformation and the Czech revival of the early 19th century were intended to remind the Czechs of the "religious meaning" of their heritage. His treatise on the work of the Czech historian František Palacký, who favoured equal rights for Slavs within the Austrian state, was a profound analysis of Austrian-Czech tensions. Masaryk founded two periodicals, in one of which he proved after a bitter debate that two ostensibly early medieval Czech poems, regarded as Slavic counterparts of the German *Nibelungenlied*, were in fact patriotic forgeries by an early-19th-century Czech poet.

In 1889 Masaryk entered upon his political career after transforming a journal into a political review. In the early 1890s he began to turn his attention to the Slovaks in northern Hungary. By criticizing both the feudal nature of Hungarian sovereignty and the antiquated Pan-Slav tendencies of the Slovak politicians, he became the idol of the young Slovak progressives who played a decisive role in the Czech-Slovak union in 1918-19. After unmasking the forged medieval Czech poems, he demonstrated his willingness to risk unpopularity in pursuit of moral righteousness once again when he succeeded in

1899 in proving the innocence of Jews accused in a ritual-murder case. Although deeply involved in political controversies, Masaryk published two monumental works before 1914. In his work on Marxism (1898) he discussed the immanent contradictions of both capitalism and Socialism. In *Russia and Europe* (1913) he provided a critical survey of the Russian religious, intellectual, and social crises—the contradictions and confusions of the "Byzantine retardation of Russian society by the Orthodox Church and reactionary ideas.

As a politician he was at first an adherent of the federative Austro-Slavism in 1848. But as a democrat he gradually became estranged from the loyal, conservative, and Catholic concept of the Old Czech Party and accepted the invitation of the liberal, bourgeois Young Czech Party. In 1891 he was elected to the Austrian Reichsrat, but, after disagreeing with the Young Czechs' emotional nationalism, he resigned his seat in 1893. In March 1900 he founded his own Realist Party, and, after his re-election in a more democratic Reichsrat, he became an outstanding figure of the left Slav opposition there. In both the Reichsrat and the standing committee of the Austrian and Hungarian parliaments he attacked Austria-Hungary's alliance with Germany and its imperialistic politics in the Balkans. He defended the rights of the Serbs and Croats—especially at the time of the annexation of Bosnia-Herzegovina by Austria.

In early 1915, after the outbreak of World War I, Masaryk made his way to western Europe, where he was recognized as the representative of the underground Czech liberation movement and conducted a vigorous campaign against Austria-Hungary and Germany. His British and French friends helped him to establish contact with the Allied leaders, to whom he delineated the Czech aims: restitution of Bohemia's independence on a democratic basis; the establishment of Czech-Slovak unity; dismemberment of Austria-Hungary according to ethnic principles, and establishment of new states between Germany and Russia as a cordon sanitaire against German imperialism. After the overthrow of the autocratic tsarist regime in 1917, he transferred his activities to Russia in order to organize the Czechoslovak Legion, formed by Czechoslovak war prisoners, and to develop contacts with the new government. After the Bolshevik Revolution he set out for the United States, where he was welcomed by Czech and Slovak groups and negotiated the terms of Czechoslovak independence with Pres. Woodrow Wilson and Secretary of State Robert Lansing. The Lansing Declaration of May 1918 expressed the sympathy of the United States government with the Czechoslovak freedom movement, and Czechoslovakia's liberation became one of Wilson's Fourteen Points for the post-World War I peace settlement. Masaryk also concluded the so-called Pittsburgh Convention with the Slovak associations in the United States, which promised the Slovaks a large measure of home rule; the interpretation of this declaration led to controversies between the Slovak opposition and the Czechoslovak government during the life of the first Czech republic.

On June 3, 1918, Czechoslovakia was recognized as an Allied power, and its frontiers were demarcated according to Masaryk's outline. As Masaryk had promised, the new multinational state respected the minority rights of its large German and Hungarian ethnic groups. On November 14, 1918, he was elected president of Czechoslovakia and re-elected in 1920, 1927, and 1934. As a true "liberator" and "father of his country," he was constantly occupied in settling the crises resulting from the conflicts between the Czech and the Slovak parties, as well as from Slovakia's minority status. A philosopher and democrat, Masaryk was among the first to voice his anxiety over central Europe's fate after the Nazis came to power in Germany in 1933. He resigned his post in December 1935 and died in Castle Lány on September 14, 1937.

**BIBLIOGRAPHY.** For an anthology of Masaryk's political essays and speeches, see *Cesta demokracie*, 2 vol. (1933-34). Studies of Masaryk's life and politics include: KAREL ČAPEK, *Hovory s T.G. Masarykem*, 3 vol. (1926-28; 1 vol., 1936; Eng. trans., *President Masaryk Tells His Story*, 1934, reprinted

The best summation of Masaryk's views and philosophy may be found in the *Festschrift Th. G. Masaryk zum 80. Geburtstag*, ed. by B.V. YAKOVENKO, 2 vol. (1930), a collection of essays honouring him on his 80th birthday; see especially EMANUEL RADL'S study.

(L.V.G.)

## Mashriq, Cultures of the

The Mashriq may be defined as the region extending from the western border of Egypt through to the western border of Iran. Countries included in the area are thus Egypt, the Sudan, Saudi Arabia, Yemen (Ṣan'ā'), Yemen (Aden), and Oman; Kuwait and the small Persian Gulf states; and Israel, Jordan, Lebanon, Syria, and Iraq. The total land area is approximately 2,700,000 square miles (7,000,000 square kilometres) and the total population some 80,000,000. The area has, in the 20th century, been given other appellations, including Levant, Near East, and Middle East.

From the perspective of its cultural geography, the Mashriq may be divided into two types of region: the arid, infertile desert areas that are the home of the nomadic Bedouin and the fertile, cultivated river valleys of the settled agriculturalists.

The great plateau of the Arabian Peninsula comprises most of the desert area. Barren, except for occasional oases and the Najd, a pastoral tableland in the north, the peninsula is fronted to the west by mountains rising in the Hejaz, the holy land of Islām, to some 9,000 feet (3,000 metres) and further south, in the Yemen, to some 14,000 feet. The south central portion of the peninsula, an area of some 40,000 square miles (100,000 square kilometres), is known locally as ar-Rub' al-Khali (the Empty Quarter). Here, average summer temperatures are in excess of 120° F.

The outstanding geographical feature of the remainder of the Mashriq is the Fertile Crescent, an arc of territory stretching from the Nile Valley of Egypt through present-day Israel, Lebanon, Jordan, and Syria, into Iraq. At each horn of the Fertile Crescent there is a river valley—to the east that of the Tigris and Euphrates rivers, in Iraq, and to the west that of the Nile, in Egypt. These valleys are composed of rich and fertile masses of alluvium deposited year after year on a substratum of sand and rock. In Egypt this deposit is almost 40 feet deep. As they are annually replenished, these valleys are continually re-fertilized. They also provide irrigation and drinking water.

### PEOPLES AND LANGUAGES

The Mashriq has the longest cultural history of any region in the world and was in fact the birthplace of human civilization. Three monotheistic religions—Judaism, Christianity, and Islām—originated there. As a land bridge connecting Asia, Africa, and Europe, it has been traversed by numerous peoples, many of whom left small groups in the region. Its cultural evolution has been such that, until recently, minority groups were permitted to retain separate and distinct entities, so that the most conspicuous fact about the Mashriq has been its demographic heterogeneity; its population is a mosaic of peoples.

Among the earliest inhabitants of the region were the Sumerians, believed to have been of an Armenoid physical type—roundheaded, of moderate height, and of heavy build. They spoke a language with certain agglutinative features suggestive of the Mongoloid family of languages. The ancient Egyptians were of the Mediterranean physical type—longheaded, dark-haired, relatively slender, and of moderate stature, speaking a separate language classified as Hamitic.

Additional early peoples in the area were the Akkadian, Babylonian, and Assyrian invaders and conquerors of Mesopotamia, the Amorites of northern Syria, the Aramaeans of inner Syria, the Canaanites of the Levant coast, and the Hebrews of the hill country. All of these peoples are generally classified as Semites—not because they possessed any unique physiological feature but because they all spoke languages assigned to the North Semitic family and because they are generally believed to have originated somewhere in the central Arabian Peninsula. Arabic, the primary contemporary South Semitic language, was apparently originally spoken by a small group of traders, townsfolk, and desert nomads in the district of Mecca and Medina. Arabic was the language of Muḥammad and his early followers, and, with the rise and expansion of Islām in the 7th century, it quickly replaced most other languages of the Mashriq. Within the region, Egyptian, Palestinian, Syrian, Iraqi, and Yemeni dialects of Arabic are spoken today. Some of these differ only in pronunciation, while in other instances the colloquial forms may be quite wide apart. Other languages spoken in the region are Hebrew, which is one of the official languages of Israel (the other is Arabic); Aramaic, which is reputed to be still spoken in a few villages of Syria; and Kurdish, an Indo-European language spoken by the approximately 1,000,000 Kurds resident in Iraq and Syria.

The Kurds, a semi-nomadic pastoral group, practice transhumance (movement between summer pastures on the mountain slopes and winter quarters in the valleys and lowlands). Kurdistan, their homeland, is a rugged mountainous region lying in Syria, Iraq, Iran, and Turkey. The Kurds have lived in the region since they invaded it, perhaps in the 2nd millennium BC, and to this day the Kurds have maintained their distinct tribal independence. Invaders of the Kurds' region—from Alexander the Great to the present-day Iraqi militia—have attested to the Kurdish reputation of being a "fierce and predatory people."

### TRADITIONAL CULTURE PATTERNS

**Settlement patterns and economic organization.** *The fellahin* ("villagers"). Agriculture has long been and still continues to be the predominant way of life of the majority of the peoples of the Mashriq. Spread along the Fertile Crescent and in the isolated oases of the deserts, the overwhelming majority of the people were—and still are—peasants. Despite widespread urbanization, more than two-thirds of the people may still be classified as fellahin.

Family solidarity and the need for security have always precluded a pattern of isolated farmsteads. Instead, the peasants gather together in villages, ranging from modern and well-off communities in Lebanon (particularly among the Christians) to the miserable mud and kerosine-can huts of semi-nomadic tribesmen. Despite such disparities, however, a broad cultural pattern can be discerned, especially in the Arabic-speaking regions.

Landownership in the Mashriq is complicated by the fact that landed property, or the right to work other people's landed property, is divided among the children, with boys sharing equally but with a girl's share equalling only half that of a boy. Complex fragmentation of agricultural land results, with the dispersed small plots, sometimes termed "dwarf holdings," rarely economically feasible. High-interest loans are often not met, and as a result the accumulation of large tracts of land in the hands of a few wealthy landowners is quite common; many debt-ridden peasants are consequently forced into sharecropping. In virtually all of the newly independent nations of the Mashriq, land reform is one of the basic tenets of revolutionary programs. Much, however, still remains to be accomplished.

Throughout the region village layout is strikingly similar. At the centre is the mosque, or church, bordered by a few small shops of the grocer, blacksmith, and cobbler. Some five to ten twisted alleys, just wide enough for a donkey with its side baskets, wind between the walls of low, flat-roofed houses and then narrow into even smaller

Linguistic basis of the Semitic ethnic classification

The traditional village

lanes that generally end where the fields begin. The village square functions as a marketplace for itinerant peddlers and is the scene of village ceremonial events.

The homes, whether of stone blocks or sunbaked bricks, consist of a few rooms and a courtyard. When a son marries, a new room is added along the side of the house, on the roof, or in the courtyard. Stables are uncommon, and the fellahin share with their animals the same dirt-and dung-littered courtyard and, in winter, the same room for sleeping.

Furniture among the peasants is limited and strictly utilitarian. Since squatting on the floor is the normal position, whether doing the housework or eating with the fingers or with a piece of bread dipped into a common bowl, there is no need for tables and chairs or forks, knives, and spoons.

A chest, a pile of bedding stored away during the day in a recess in the wall, a cradle, a few straw mats, a kerosene lamp, and perhaps one or two cheap carpets constitute the essential furniture. Kitchen needs are met by a few clay jars for keeping the drinking water, a large grain bin coated with clay and sealed at the top but open at the bottom for access to the daily need, a copper kettle, a few handwoven baskets, some locally made earthen jars, and a variety of imported bowls and basins. A few coffee cups on a tray for occasional visitors, a few photographs of the sons (daughters are rarely photographed, and their pictures are certainly not on view), some religious prints or calligraphed verses of the Qur'an, and a newspaper photograph of the local national leader complete the inventory of the typical village home.

Water is generally a scarce commodity. If the peasants are fortunate, they may have a well in the courtyard. Generally, however, water is obtained from common village wells, springs, or ponds. When these dry up during the long arid summer months, animals and humans share the same distant, often polluted, ponds or streams. Piped water to the courtyards or to the village centre is not uncommon among wealthy villagers or in areas in which the government has embarked on special rural development programs. In some regions of Iraq and Egypt and along the rivers of the Levant, although water may be readily available, it often is a source of malaria and other diseases. Flush toilets are very rare, as are outhouses. Urine is generally disposed of in the courtyards, along the paths, or in the fields. Fecal matter is spread in the fields.

Animal dung, in treeless regions, is the prime source of fuel. Women and children carefully gather the dung, shape it, dry it in the sun, and store it on the roof or in the courtyard. The family oven, in which bread is baked, is generally in the courtyard and is a dome-shaped mud affair with a low opening.

The diet is simple and generally monotonous. Its mainstays consist of unleavened bread, accompanied by rice and a few vegetables, usually onions and garlic, and, depending on the region, olives or dates. In season, small amounts of fresh fruit and green vegetables may be added. Tea and coffee are luxury items paid for out of a limited budget. Meat and fat are eaten, by most, only at special ceremonies such as a wedding, birth of a son, or great holidays or in honour of a distinguished visitor.

Standards of health and education well demonstrate the poverty of the peasants. Malnutrition is chronic, and infectious diseases are endemic. It is estimated that perhaps nine-tenths of the fellahin suffer from a variety of dysfunctional or debilitating diseases such as trachoma, typhoid, dysentery, intestinal worms, and tuberculosis. Western-type medical aid is still not widely available among peasants, and their main recourse continues to be the traditional village practitioners. Schooling, despite the fact that most countries of the Mashriq have enacted compulsory-education laws, is uneven and sporadic. Illiteracy among rural adults, particularly women, is still the rule.

The way of life for the early Zionist farmers working the marginal lands of Palestine often was as difficult as that of their fellow Arabs. It was the attempt to break out of that pattern that led to the development among the Jews of collective forms of agriculture—variants of the

kibbutz and the moshav—designed to maximize their financial and labour input, to raise their agricultural returns, and to improve their collective standard of living.

*The Bedouin.* The Bedouin, as one observer has put it, are more glamorous than numerous. They have rarely constituted more than 15 percent of the total population of the Mashriq, and in the 1970s their numbers were rapidly decreasing, even in the Arabian Peninsula, as they voluntarily migrated to the towns to work for the oil industry or to settle on government-sponsored tracts of land.

The homeland of the classical, traditional Bedouin is an area of the northern Arabian Desert, stretching into Iraq, Syria, and Jordan. The Bedouin are nomads in varying degrees, but the true Bedouin are those who possess only camels and who spend their summer months camped around wells or streams and the rest of the year ranging the desert. In kinship they trace their origin back either to Qaḥṭān, an ancient patriarch who lived before Abraham, or to Ishmael, son of Abraham and Hagar. Collectively they constitute the *aṣīlīn*, a closed circle of about 18 tribes or tribal confederations.

The material culture of the Bedouin is limited. The chief possession is the home—a long, low, black tent of woven goat hair. Men and women have separate divisions within the tent. The male side, away from the wind, is left open; it has a carpet, spread before a portable stove, or coffee hearth, with a mortar for grinding the coffee, a coffeepot, and cups. This is the social centre of the household, the meeting place for guests, and the site for the transaction of all tribal affairs.

Clothing is simple: a long robe of thick material, a large headcloth wound around the head and held in place by a black goat-hair cord and rawhide, and heelless sandals.

Water is generally too scarce to be used for washing, and sand or animal urine is substituted for use in daily ablutions. The diet is limited, consisting of a variety of milk products such as curds, buttermilk, and cheese, dried fruit, particularly dates, and, when obtainable from the fellahin, grains such as wheat, barley, or rice. Meat, as among the peasants, is a luxury eaten only when an animal has died a natural death or for a special ceremony. The meals are served first to the older men of the tent, then to the younger men and boys, and finally to the women and the girls. The sexes do not intermingle during mealtime. The inadequate diet and low standard of nutrition result in a people who are small, even stunted, and slightly built. By the age of 40, particularly among the women, old age has begun.

Raiding was the traditional means of supplementing the deficiencies of life in the arid zone. The Bedouin took by force from the peasants what they lacked in foodstuffs, material goods, and even women and children. Successful leadership in raids could be a most effective means of developing reputation and power, a practice that to this day has not been completely curtailed.

**Social organization.** In certain respects the fellahin and the Bedouin share a similar social structure, and thus the pattern traditionally common to both can be broadly sketched. The model described is that of the classical, idealized, Arab way of life.

*The family.* The family is the most fundamental and important feature of Arab social structure. The family is extended—that is, it is headed by an elderly man and consists of his wife, or wives, his married sons and their wives and children, his unmarried sons, and his unmarried daughters. Daughters, when they marry, leave their own extended families and become incorporated into the extended families of their husbands, even though their moral conduct continues to be the responsibility of the original family.

The extended family may total a dozen or more persons, all of whom live in one house or in a number of adjoining houses or, as among the Bedouin, in a number of tents pitched next to each other. The extended family functions as one entity in economic, political, and military ventures.

The family is patrilineal—*i.e.*, an individual belongs only to the family of his father—and patrilocal (young

Bedouin  
raiding

Health  
and  
education  
among the  
fellahin

couples when they marry take up residence in or near the house of the bridegroom's father). It is also patriarchal: the father is the head of his family, and the elderly male who is head of the entire extended family is the absolute ruler over the entire group, traditionally. Even to this day, in certain respects, he has jurisdiction over life and death.

Pride in descent forms one of the most significant traits in the ethos of the peoples of the Mashriq. Emphasis on noble ancestry and lineage is a matter of great importance among the Bedouin and to a lesser extent among the fellahin. Tribal and village genealogists trace an individual back from his individual extended family to his sub-*hamūlah* (a cluster of extended families) to his *hamūlah* (a large group of families tied together by an actual or assumed genetic relationship) and to his subtribe (*ashirah*) and tribe (*qabilah*). Beyond his tribal affiliation, a man's lineage will be traced to his supposed progenitor dating back to early biblical sources. This tribal pedigree, even among the villagers, can play a fundamental role in determining and justifying positions of traditional authority and political power.

*Marriage and divorce.* There is a strong tradition of endogamous marriage (that is, of marriage within a very small social circle), ideally with the father's brother's daughter or, failing that, within the same village or tribe or having the same social status. A man may be married to more than one wife simultaneously (polygyny).

Prevalence of polygyny

The prevalence of polygyny among the Arabs has been greatly exaggerated by Western commentators, and the practice has always been the exception rather than the rule, especially in modern times. The simple biological problem of acquiring a surplus of young females plus the economic cost of paying their bride-prices and then adequately supporting them and their offspring all have prevented any more than 4 to 5 percent of the married men from having more than one spouse.

Traditionally marriages are arranged and consummated when the women are still in their teens. This is considered highly proper and beneficial. An old Arab saying holds that there are only three things in life a man must do quickly: bury the dead, serve a guest, and marry off a marriageable daughter.

Great prestige is attached to the male's procreative ability and to the regular delivery of live, preferably male, children. Status is achieved through the production of large families; a childless couple is regarded with contempt. Only the extended family with many children, preferably boys, can be a strong family, providing economic and political security. The injunction to "be fruitful and multiply" thus provides a constant goal.

Term, or temporary, marriage, usually referred to as *mu'ah*, dates back to pre-Islamic days and still survives in certain parts of the Mashriq. Term marriages were contracts made with women by soldiers, traders, and travelers under which the couple were legally married for the day, the length of the caravan journey, or for another defined time period. At the stated end of the period the contract was no longer binding. Children born of *mu'ah* marriages held all the rights of the offspring of ordinary marriages, but the term wife could not inherit from her husband nor he from her.

The announcement of the birth of a child to the father is based upon long-standing Mashriq traditions. If the infant is a boy, the father will be told *bishārah*, meaning "good tidings" or "reward." The father will ordinarily give a modest gift to the individual who first brings him this news. Among those who can afford it, a sacrifice of a sheep or a feast is also common. If the infant is a girl, no reward will be given for the announcement, neither will there be a celebration.

Traditional divorce in Arab Muslim society is extremely simple. The male is the sole initiator of such an action. The wife can neither oppose a divorce nor initiate one on her own behalf. The husband pronounces the traditional formula, "I divorce thee," in the presence of two witnesses, and the divorce is effected. The wife must return to her father's (or brother's) family and can claim only that portion of the bride-price that was stipulated in the original marriage contract to be paid in the event of such an

occurrence. If a wife should leave her husband and he later agrees to a divorce, she forfeits any part of the bride-price. After the divorce a man may marry immediately, but the woman must wait three months to make sure that she is not pregnant. If she is pregnant, she cannot remarry until she has given birth to the child and reared it, during which time the father (her former husband) must support her. All children belong to the father and, in the event of a divorce, must be delivered up to him.

Among the Arab Muslims no stigma is attached to divorce, and divorced women as a rule remarry as soon as they are permitted to do so.

*Socialization.* Shortly after birth, the infant will be rubbed with salt and oil, not only to cleanse him but also to enable him to grow up to be modest and courteous. The infant will then be wrapped in swaddling clothes for a time period ranging from 40 days to six months.

Nursing may last for 18 months to three years. A mother is traditionally prohibited from weaning her child before two years. The extended nursing period postpones another pregnancy (suckling periods are generally connected with an abstinence from intercourse), and it is believed to make the child strong.

To mothers it is said: "pampering a girl disgraces thee; pampering a boy makes thee rich." The boy will therefore be nursed longer than the girl. As soon as the child shows the slightest signs of restlessness, he will be breast fed. As a consequence, the female is seen as sympathetic and the woman's breast as a symbol of compassion.

If for some reason, such as illness, a child is nursed by a woman other than its mother, certain protocol must be observed. A woman may not give her milk to another child or have another woman give her child milk without her husband's permission; for the child belongs to the husband's patrilineage, and that important decision rests with him. Furthermore, a boy and a girl nursed by the same woman are considered to be brother and sister and can never marry. Nursing relationships can also be a method of adoption (especially of an orphan): if a woman wishes to adopt a strange child or even an adult, she does so by offering her breast.

One of the most important events in a Muslim and Jewish boy's life, not only for himself but also for his parents, is circumcision. The rite of circumcision is a religious duty, and no male can enter heaven uncircumcised. The age at which circumcision is carried out varies: it may be done shortly after birth or in childhood, but it must be done before marriage. Fathers will ordinarily have their sons circumcised soon after birth, not only because it is less painful then but also because of fear that the boy might die before the father has fulfilled the commandment of circumcising his son.

The religious rite of circumcision

Among Muslims, the rite of circumcision proceeds in a program similar to that of a wedding. It is preceded by an evening of joy in village festivities, henna (a dye) is put on by the woman, and a new outfit is provided for the child. Festival garments decorated with flowers and leaves are worn, and, in similar fashion to a bride, the boy is led in procession around the village in his new outfit. After the ceremony there is a feast at which presents are given. Several boys may be circumcised at once, or the circumcision may be combined with a wedding to save expenses. There is a further connection between circumcision and marriage, for, as it is the duty of the father to marry his children before his death, he attempts to find a suitable mate for them as soon as possible. A boy thus often acquires his bride at his circumcision ceremony, although he will not marry her until sometime after puberty.

The early socialization of a boy and a girl into the traditional family of the Mashriq differs profoundly. The growing boy is trained to become an obedient member of his family, able to subordinate his wishes to those of his father and elder brothers. The fact is impressed upon him that the interests of his family always come first and that he must govern his actions to enhance the collective strength of his family. The girl, on the contrary, is not only weaned earlier than the boy but, by the age of five or

six, is already being consciously prepared for moving out of the home of her parents and into the home of her mother-in-law. There, she will fill a subordinate and even a servant role—a role that will be improved only as she bears sons.

**Religion and health.** A discussion of the predominant religion of the area, Islām, can be found in such articles as ISLAM; ISLAMIC MYSTICISM; and ISLAMIC THEOLOGY AND PHILOSOPHY. But some understanding of the function of religion in the traditional Mashriq can be grasped from an analysis of its role in the peoples' approach to health, disease, and death.

*Philosophy of illness.* The essential philosophy underlying the traditional system of medicine in the Mashriq is that illnesses and injuries are subjective affairs arising from one's own acts or omissions or caused by someone or something possessed with power. Illnesses or injuries do not just occur—they befall a certain victim, at a given time and in a definite manner, because of specific causal actions.

Evil spirits  
and the  
evil eye

Two essential elements of this philosophy are belief in animism and animatism, or, more specifically, the belief in the existence of evil spirits (animism) and of the "evil eye" (animatism), or the power of certain persons or objects to affect and influence the human body—and nature as well, in certain circumstances.

Evil spirits abound in the environment, ready to pounce on the unsuspecting victim. Strong, healthy, mature individuals are the least susceptible to such attacks; the most susceptible are infants and children, the weak, the ill, the aged, and normally healthy individuals in certain circumstances (women during menstruation, pregnancy, or while giving birth, for example).

The presence of strong, healthy, mature individuals near the susceptible person is a strong deterrent to evil spirits. As one cannot rely on such persons to be constantly on duty, however, various inanimate objects with strong power to repel the evil spirits are called into play. Common objects of this nature are the Hand of Fāṭimah (beloved daughter of Muḥammad), which may have inscribed on it holy words in Arabic or Hebrew and which is generally worn around the neck (Cochin Jews may put it around the abdomen); the shield of David (a six-pointed star); and blue beads, pieces of jewelry, or bits of cloth that are worn around the neck or attached to the clothing (blue is particularly repugnant to the evil spirits and the evil eye). Sometimes a concoction of evil-smelling herbs will be placed in a bag and worn close to the body, or various religious phrases will be written on paper and sewed into the clothing or put into a bag and worn on the body.

The Bible also possesses the power to repel evil spirits, and thus some Jewish mothers place a copy of it beneath the pillow. Another practice, but less common, is to preserve the foreskin cut off during the *ber-it mila* (the ceremony of circumcision conducted on every Jewish male child when he is eight days old), by drying the piece of skin and powdering it. It is then sewn into a piece of cloth and kept under the pillow or among the blankets of the child's bed.

Evil spirits fear the name of Allāh, which strikes terror into their hearts and weakens them and forces them to withdraw or repels them completely. Consequently, his name is uttered frequently while a person is engaged in the everyday routine of life. Otherwise healthy individuals must, in certain circumstances, be particularly careful to invoke Allāh's name. When, for example, a Muslim couple is about to engage in sexual intercourse, the male must first say a prayer: "I seek refuge in Allāh, from the accursed Satan, in the name of Allāh, the Beneficent, the Merciful." If this is not said, the evil spirit will enter the woman, and her child will be evil, bad, or a devil, or the woman herself might fall ill. A prayer to Allāh also ensures conception—the mere physical act of intercourse is no guarantee.

*Vulnerability of women.* From the moment of conception until the last birth pang, the pregnant woman is especially sensitive to evil spirits. Each of her actions is carefully watched by them, and, should she commit a

transgression or not constantly invoke the power of Allāh, retribution will be certain to follow. The afterbirth provides powerful protection for the newborn child and must be saved. It may be left attached to the child for some hours or overnight, and it then must be preserved in or near the house.

Women during menstruation are very dangerous. They are not only considered impure and unclean but also, if not actually possessed by a spirit, likely to be transmitters of the actions of evil spirits. They must therefore be separated from others, particularly from the ill and women in labour. Women during menstruation sometimes must leave the home and live in a menstruation hut or tent for the entire period, returning to their homes only after they have been purified. When a woman is permitted to remain in the home, she is subject to numerous restrictions: She must sleep on the floor or on a low bed, must have no sexual relations with her husband, must not even touch him or his bed, and should not prepare any meals or enter a home in which there is an ill person or a woman in labour. Such restrictions are only practicable within the extended family, and disintegration of the extended family leads to forced abandonment of many such practices. The beliefs themselves, however, may persist, as may anxieties when the taboos are broken.

Restrictions  
on  
menstruating  
women

*Safeguards against the evil eye.* The prevention of illness to the inner body by the evil eye—as distinct from the prevention of illnesses caused by evil spirits—is based on the principle of misleading, deceiving, and deluding the evil eye. The evil eye is particularly feared, and more than half of all deaths are attributed to it. It is attracted to the healthy, the beautiful, the happy, and to children.

In the Mashriq, possessors of the evil eye are often women. Psychologists have argued that the evil eye is in reality an envious eye, and the entire corpus of preventive measures seems to be based upon the principle of not attracting its attention (or envy). The youngest are a particular attraction to the evil eye. Thus children, esteemed the greatest blessings, are kept dirty, ragged, and unkempt, particularly when out in public. The child may be called "Oh, dirty one" or "Oh, evil one" and similar names, in order to disguise the true feelings of the parent. The child may be given a false name, and its true name kept a secret, in order that the real name may not be overheard and utilized for negative purposes. The child will never be praised in public or boasted about; on the contrary, it will constantly be decried and complained about. A male child may be dressed as a girl and referred to in the feminine, since females have less prestige. Such practices against the evil eye are especially likely to be followed if there have been previous infant deaths in the family or if there is only one child.

To arouse disgust in the eye of the beholder is far healthier than to arouse admiration; and praise when given must be denied or deprecated. Inquiries about personal or family health, business, or status should be responded to with shaking heads and gloomy predictions. Boasting is considered the fool's way of courting disaster, as is the disclosure of one's future plans. It is possible, however, to accept praise or note good looks, good health, or good fortune if one is careful to constantly invoke the name of Allāh and to deny the force of the evil eye.

Particularly valuable as a defense against the evil eye are amulets. Blue beads are the most common type, and they may be worn on the person or placed in the house or on a dog, horse, cart, or automobile.

If, despite such precautions, evil spirits do gain access to the body and illness sets in, medicine is brought into play. Curative practices are clearly recognized, however, as being less successful ultimately than preventive measures, and their purpose is partly to provoke emotional comfort and security to the patient and his family.

Curative  
practices

The local practitioner gives the family his undivided attention, identifies and names the disease, makes a positive prognosis, and initiates certain measures to evict the evil spirits or draw away the evil eye. These include smoking, drinking, chanting, praying, burning, bloodletting, emetics, purgatives, and massages. A burning blue

rag may be snuffed and the smoke inhaled to weaken or frighten out the evil spirits, especially during childbirth. Charms and holy phrases written on paper may be soaked in a liquid and then drunk in order to internalize the holy power. The spittle of a holy man may be applied to the disturbed organ of the body. The patient's name may be changed so that the evil spirit may somehow be misled and lose the patient or never find him.

Drastic, painful measures may be taken to force out the spirit. A red-hot nail may be pressed against the abdomen of an infant a number of times to force out the evil causing dysentery; it may be pressed against other parts of the skin to evict the evil spirit causing smallpox or rheumatism, or it may be pressed against a "boil" under the tongue to enable the baby to take the breast. The entire family may be required to chant special prayers, songs, or phrases or to fast or suffer other discomforts. Parents may have to abstain from sexual relations, and members of the family may have to travel on a pilgrimage. There may be bargaining on the part of the family, and precious animate or inanimate objects may be sacrificed to appease the evil spirit. The patient, recipient of this rich fund of strength, is emotionally able to endure the physical discomfort during the prescribed course of curative treatment and is mentally prepared for possible death should the treatment not succeed.

If the patient should die it is because he or his family, consciously or unconsciously, committed offenses and attracted the evil eye or permitted evil spirits to enter the body to the extent that no power was able to avert the evil and save the patient.

It is clear that both patient and practitioner operate within a cultural framework of knowledge, beliefs, and values that explain their respective actions. The patient and his family search their thoughts and actions to ascertain how the misfortune could have occurred or by whom it could have been inflicted. The practitioner, on his part, listens to the family's statements and the patient's complaint and then formulates his diagnosis and treatment. The success in such treatment in a certain number of cases inspires further faith in the system. There are few cynics among the patients and few charlatans among the practitioners.

Within this medical system may be distinguished three or four types of local practitioners specializing in particular areas and methods of treatment. Their sex, role, or status may vary, or they may specialize in cures for external complaints such as sores and wounds; or they may practice preventive and curative medicine for the internal body. The latter is generally a male of senior years and of religious-medical standing. To fulfill his role he must be well versed in the concepts of animism and animatism. Such knowledge alone, however, is not sufficient; he must also have a personality that will inspire confidence and elicit information from the patient and his family. In addition, he must be aware of the significance of symptoms and complaints, certain of which may or may not be expressed. He must possess to a high degree the quality of sensitivity and intuitiveness, for many of his diagnoses will be based upon implicit understanding and tacit agreement. He must have the ability to quickly analyze and evaluate the relations between the patient, his family, and his community.

#### MODERNIZATION OF THE CULTURES

A process of Westernization, modernization, and development has come to dominate the Mashriq. The evolution of the traditional folk culture of the fellahin and the Bedouin is being radically altered, and even rural peasants want to live the supposed good life made possible by Western technology. The town in the Mashriq is the focal centre of this Westernization process, and from there it is dispersed throughout the countryside and into the desert. It is useful, therefore, to examine the traditional town and the ways in which it is changing.

**Classical urban pattern.** Urban life began in this area of the world, and it is not uncommon to still find towns that have been occupied continuously or intermittently over the past 4,000 years. While the Bedouin and the

fellahin have long remained rather constant in their culture, the towns have constantly reflected the effects of political changes, military invasions, and population movements. Thus, whereas the nomads and villagers were comparatively homogeneous in both population and occupational structure, the towns contained separate quarters (*harat*) for various ethnic and religious populations and also a range of occupations and social classes.

The typical Arab town of the Middle Ages consisted of a mosque, a palace, a bathhouse, a school, a *khān* (hostelry for foreign merchants), a hospital, and a *maydān* (an open field for the horse and cattle market). Two main thoroughfares ran through the town at right angles to each other, leading from the four gates of the thick and heavily fortified walls. From the centre a network of narrow streets and alleys radiated into the residential quarters. Each of these quarters was also walled, frequently with its own bathhouse and school, as well as a mosque, church, or synagogue. The cemeteries and the *maydān* were outside the town walls.

Such was the typical town of the Mashriq during the classical Arab period. With the conquests of the Ottoman Turks in the 16th century came urban poverty, exodus, and decay. Only within the 20th century has there been a redevelopment of the urban centres.

**20th-century urbanization.** Rapid, unplanned, and uncontrolled urbanization is a marked feature of the contemporary Mashriq. The 3 percent annual rate of population growth (the population of the region is apparently growing faster than any other major region of the world, except for Latin America) is causing great pressure on available agricultural land and is pushing the excess population into the urban centres. The growing difficulty in finding additional land for cultivation and the chronic weaknesses in the implementation of agricultural reforms are aggravating the already serious situation of large numbers of a redundant, underemployed rural labour force.

Other factors are also at work in accelerating the urbanization process: improved roads and transportation have made the towns increasingly accessible; increased communications, particularly by radio and television, have spread the attraction of the cities as centres of education, health, employment, recreation, and a totally different way of life; and the discovery and exploitation of oil have brought thousands of workers into the cities in search of employment. The flow of capital from oil revenues has revolutionized the cultures of some of the countries of the Mashriq, particularly Saudi Arabia and Kuwait, and has had a direct impact on the economy of cities in nearby countries—in particular, Beirut, Lebanon, which, as an oil-pipeline terminus, has benefitted greatly from Kuwait's annual oil income of over \$150,000,000.

Israel holds third place in the world in proportion of urban dwellers to total population (some 76 percent). In Kuwait, some half of the total population lives in localities of 100,000 and more inhabitants, and, in Lebanon and Syria, the proportion is one-third. This large-scale urbanization has been primarily a 20th-century movement, particularly since World War II.

**Growth and crowding.** Urbanization has resulted in a series of physical changes and problems. The uncontrolled growth of what were for the most part medieval towns has led to their mushrooming over surrounding areas at a rapacious rate. Most cities have doubled in size within the past few decades, and some—Beirut, for example—have incorporated surrounding towns. Greater Baghdad and Kuwait have spilled over their city walls. In Israel, almost the entire coastal plains from Haifa in the north to below Tel Aviv in the south is gradually evolving into one continuous metropolitan area. The megalopolis, as well as the metropolis, is becoming a significant term in the Mashriq.

As in many other regions of the world, acute urban problems have accompanied this movement. Traffic in urban land, with building for quick, speculative profit, has become a major economic activity and has often had the result of greatly modifying traditional values and behaviour. Slums and shantytowns, a hallmark of metro-

The traditional Arab town

Problems accompanying urbanization

Types of medical practitioner

politan growth in underdeveloped countries, are extensive. In the Mashriq, rural migrants build simple one-room shacks. Lacking sanitary amenities, these are crowded next to each other and quickly deteriorate into unhealthy and unsightly slums. Sections of greater Baghdad, for example, are ringed by slum dwellings mainly of the *sharifah* type—a one-room house constructed mainly of reed matting. It is estimated that there are more than 44,000 *sharifahs* in greater Baghdad—nearly 45 percent of the total number of houses. Their inhabitants are estimated at 250,000, more than a quarter of the total population of the city.

The emergence of a large and rapidly growing unskilled (and therefore underemployed or unemployed), illiterate, and unhealthy peasant population in the towns may create a new version of the lumpenproletariat. With little to lose and much to gain, these people may profoundly and radically alter traditional religious and familial values and behaviour. Juvenile delinquency, petty thievery, prostitution, and mob violence frequently accompany such changes. Violence, of course, may be aggravated by political figures. Acute xenophobia, directed particularly at traditional “imperialist” powers, and the brutal elimination of incumbent leaders are two of the more obvious by-products. During the July 1958 revolution in Iraq, for example, street mobs ran amok in Baghdad, pillaging and burning at will. Scores were slaughtered, including King Faysal II and Prime Minister Nuri as-Said.

In certain respects the general life of the majority of the people has been materially improved. The traditional scourges of the Mashriq—disease, poverty, and ignorance—are slowly weakening their grip. Clothing, housing, household effects, kitchen utensils, communication equipment such as radio and television, and transportation facilities are becoming increasingly available from the cities of the coast to the towns and villages of the interior and even to the peoples of the desert.

*Changes in class structure.* New social classes have developed, and the traditional cleavage of a small wealthy class supported by a mass of poverty-stricken peasants and nomads has been somewhat modified. The upper classes are frequently educated in the West, and their financial resources, their educational interests, and their way of life all orient them away from their own country's traditions. The wealthy of Cairo and Beirut, for example, are as much at home in Switzerland and France as in Egypt or Lebanon.

A new and increasingly numerous middle class has developed. The traditional class of craftsmen, merchants, artisans, and professionals has been augmented by a rapidly growing white-collar population of educated persons who go into law, politics, journalism, clerical and higher administration, and religious and teaching positions. This class frequently manifests an aversion to rural life and any type of labour associated with earning a living by one's hands.

As a result, the emerging middle class of the Mashriq, it has been argued, is lopsided when judged by Western standards. It has a profusion of white-collar workers and “intellectuals,” many of whom are chronically unemployed or underemployed and underpaid. Conversely, this class lacks a sufficient number of doctors, engineers, architects, chemists, and technicians.

Disenchantment with many of their own cultural values and with many aspects of their way of life and disillusionment with much of what the West has to offer have resulted in pronounced dissatisfactions and frustrations. To the extent that such general discontent prevails, one might predict a continuation of the social and political instability characteristic of much of the area for the greater part of the 20th century.

**BIBLIOGRAPHY.** CARLETON S. COON, *Caravan: The Story of the Middle East*, rev. ed. (1958); MOSHE ZELTZER, *Aspects of Near East Society* (1962); GABRIEL BAER, *Population and Society in the Arab East* (1964; orig. pub. in Hebrew, 1960); and RAPHAEL PATAI, *Golden River to Golden Road: Society, Culture and Change in the Middle East*, 3rd ed. (1969), are four basic sources on the cultures of the Mashriq. Important textbooks include AILON SHILOH (ed.), *Peoples and Cultures of the Middle East* (1969); LOUISE E. SWEET (ed.), *Peoples*

*and Cultures of the Middle East: An Anthropological Reader*, 2 vol. (1970), and *The Central Middle East: A Handbook of Anthropology and Published Research on the Nile Valley, the Arab Levant, Southern Mesopotamia, the Arabian Peninsula and Israel*, 2 vol. (1968); and ABDULLA M. LUTFIYYA and CHARLES W. CHURCHILL (eds.), *Readings in Arab Middle Eastern Societies and Cultures* (1970). STEPHAN and NANDY RONART, *The Concise Encyclopaedia of Arabic Civilization: The Arab East* (1960), is an extremely broad and useful reference text.

Specific national studies, particularly on the village ethnographic level, include HAMED AMMAR, *Growing Up in an Egyptian Village: Silwa, Province of Aswan* (1954); HENRY H. AYROUT, *Moeurs et coutumes des fellahs* (1938; rev. Eng. trans., *The Fellaheen*, 1945; as *The Egyptian Peasant*, 1963); ABDULLA M. LUTFIYYA, *Baytūn, a Jordanian Village: A Study of Social Institutions and Social Change in a Folk Community* (1966); LOUISE E. SWEET, *Tell Toqaan, a Syrian Village* (1960); JOHN GULICK, *Social Structure and Cultural Change in a Lebanese Village* (1955); ANNE H. FULLER, *Buarji: Portrait of a Lebanese Muslim Village* (1961); S.M. SALIM, *Marsh Dwellers of the Euphrates Delta* (1962); and the collected works of HILMA GRANDQUIST: *Marriage Conditions in a Palestinian Village*, 2 pt. (1931–35); *Birth and Childhood Among the Arabs: Studies in a Muhammadan Village in Palestine* (1947); *Child Problems Among the Arabs: Studies in a Muhammadan Village in Palestine* (1950); and *Muslim Death and Burial* (1965). While urbanization is considered in many of the above-cited general studies, it is important to note at least the following three works: MORROE BERGER (ed.), *The New Metropolis in the Arab World* (1963); JANE HACKER, *Modern Amman: A Social Study* (1960); and JOHN GULICK, *Tripoli: A Modern Arab City* (1967). Modernization is also considered in many of the above-cited general studies, but again, it is important to note more detailed studies, which include DANIEL LERNER, *The Passing of Traditional Society: Modernizing the Middle East* (1958); JOHN GULICK (ed.), “Dimensions of Cultural Change in the Middle East,” *Human Organization*, 24:1–104 (1965); and BENJAMIN RIVLIN and JOSEPH S. SZYLIOVICZ (eds.), *The Contemporary Middle East: Tradition and Innovation* (1965). Cultural studies on selected populations of contemporary Israel include ABNER COHEN, *Arab Border-Villages in Israel: A Study of Continuity and Change in Social Organization* (1965); ALEX WEINGROD, *Reluctant Pioneers: Village Development in Israel* (1966); and EMANUEL MARX, *Bedouin of the Negev* (1967). Volumes that are regularly brought up to date and that contain a wealth of information on the general features of the contemporary Middle East include the latest editions of publications of the Royal Institute of International Affairs on this subject; *The Middle East and North Africa*, published by Europa Publications, Ltd. (annual); and W.B. FISHER, *The Middle East: A Physical, Social and Regional Geography*, 6th ed. (1971).

(An.S)

## Mask

Simply defined, a mask is a form of disguise. It is an object that is frequently worn over or in front of the face to hide the identity of a person and by its own features to establish another being. This essential characteristic of hiding and revealing personalities or moods is common to all masks. As cultural objects they have been used throughout the world in all periods since the Stone Age and have been as varied in appearance as in their use and symbolism.

### GENERAL CHARACTERISTICS

Masks have been designed in innumerable varieties, from the simplest of crude “false faces” held by a handle to complete head coverings with ingenious movable parts and hidden faces. Mask makers have shown great resourcefulness in selecting and combining available materials. Among the substances utilized are woods, metals, shells, fibres, ivory, clay, horn, stone, feathers, leather, furs, paper, cloth, and cornhusks. Surface treatments have ranged from rugged simplicity to intricate carving and from polished woods and mosaics to gaudy adornments.

Masks generally are worn with a costume, often so complete that it entirely covers the body of the wearer. Fundamentally the costume completes the new identity represented by the mask, and usually tradition prescribes its appearance and construction to the same extent as the mask itself. Costumes, like the masks, are made of a great

The new middle class

Carl Frank

Anthropomorphic and theriomorphic masks

variety of materials, all of which have a symbolic connection with the mask's total imagery. Ideally the costume should be seen with the mask while the wearer is in action.

The morphological elements of the mask are with few exceptions derived from natural forms. Masks with human features are classified as anthropomorphic and those with animal characteristics as theriomorphic. In some instances, the mask form is a replication of natural features or closely follows the lineaments of reality, and in other instances it is an abstraction. Masks usually represent supernatural beings, ancestors, and fanciful or imagined figures and can also be portraits. The localization of a particular spirit in a specific mask must be considered a highly significant reason for its existence. The change in identity of the wearer for that of the mask is vital, for if the spirit represented does not reside in the image of the mask, the ritual petitions, supplications, and offerings made to it would be ineffectual and meaningless. The mask, therefore, most often functions as a means of contact with various spirit powers, thereby protecting against the unknown forces of the universe by prevailing upon their potential beneficence in all matters relative to life.

**The making of masks.** With few exceptions, masks have been made by professionals who were either expert in this particular craft or were noted sculptors or artisans. In societies in which masks of supernatural beings have played a significant ceremonial role, it is presumed that the spirit power of the created image usually is strongly felt by the artist. A primary belief involved in both the conception and the rendering of these objects was that spirit power dwelled in all organic and inorganic matter, and therefore the mask will contain the spirit power of whatever material was used to make it. This power is considered a volatile, active force that is surrounded by various taboos and restrictions for the protection of those handling it. Certain prescribed rituals frequently have to be followed in the process of the mask's creation. A spirit power is also often believed to inhabit the artist's tools so that even these have to be handled in a prescribed manner. As the form of the mask develops it is usually believed to acquire power increasingly in its own right, and again various procedures are prescribed to protect the craftsman and to ensure the potency of the object. If all the conventions have been adhered to, the completed mask, when worn or displayed, is regarded as an object suffused with great supernatural or spirit power. In some

The mask maker

cultures it is believed that because of the close association between the mask maker and the spirit of the mask, the artist absorbs some of its magic power. A few West African tribal groups in Mali believe, in fact, that the creators of masks are even potentially capable of using the object's supernatural powers to cause harm to others.

Aesthetically, the mask maker has usually been restricted in the forms he can use since masks generally have a traditional imagery with formal conventions. If they are not followed, the artist can bring upon himself the severe censure of his social group and the displeasure or even wrath of the spirit power inherent in the mask. This requirement for accuracy, however, does not restrict artistic expressiveness. The mask maker can and does give his own creative interpretation to the traditionally prescribed general forms, attributes, and devices. The artist, in fact, is usually sought out as a maker of masks because of his known ability to give a vitally expressive or an aesthetically pleasing presentation of the required image.

**The wearing of masks.** The wearer is also considered to be in direct association with the spirit force of the mask and is consequently exposed to like personal danger of being affected by it. For his protection, the wearer, like the mask maker, is required to follow certain sanctioned procedures in his use of the mask. In some respects he plays the role of an actor in cooperation or collaboration with the mask. Without his performing dance and posturing routines, which are often accompanied with certain sounds of music, the mask would remain a representation without a full life-force. The real drama and power of its form is the important contribution of the wearer. When he is attired in the mask, there is a loss of his previous identity and the assuming of a new one. Upon donning the mask, the wearer sometimes undergoes a psychic change and as in a trance assumes the spirit character depicted by the mask. Usually, however, the wearer skillfully becomes a "partner" of the character he is impersonating, giving to the mask not only an important spark of vitality by the light flashing from his own eyes but also bringing it alive by his movements and poses. But it would seem that the wearer often becomes psychologically completely attached to the character he is helping to create. He loses his own identity and becomes like an automaton, without his own will, which has become subservient to that of the personage of the mask. It appears, however, that at all times there remains some important, even if *sub rosa*, association between the mask and its wearer.

**The role of the spectator.** It is as consecrated objects imbued with supernatural power that masks are viewed by the spectators or participants at ceremonials where their presence is required. Whatever their specific identity may be, the masks usually refer back to early times, when their initial appearance occurred. This basic aspect of the mask is understood at least in essence by everyone. A paramount role of the mask is to give a sense of continuity between the present and the beginnings of time, a sense that is of vital importance for the integration of a culture with no written history. Psychologically the spectators become associated with the past through the spirit power of the mask, and this often leads the participants to a state of complete absorption or near-frenzy. This is not, however, a consistent reaction to masked ceremonials. That depends on the character whose presence the mask represents. In some cases, the spirit or supernatural being depicted is viewed with rejoicing and almost a familiarity, which leads to gaiety that has a cathartic aspect. Even so, the mask has a spirit content that is respected and revered, even if it is not showing a being with malignant potential. All of these forms have spirit and magical qualities and are thus esteemed as agents for the accomplishing of superhuman acts.

Some masks, however, do represent malignant, evil, or potentially harmful spirits. These are often used to keep a required balance of power or a traditional social and political relationship of inherited positions within a culture. The characters depicted are also prescribed by tradition and enact roles to achieve the desired ends. The drama involving these masks is often associated with

The mask wearer

secret societies, especially in Africa, where the greatest range of mask forms and functions can be observed. These forms are often used in very restricted performances, where only select persons can view them. This is also true in other areas where masks are used, such as in Oceania, the Americas, and even in some of the folk-mask rites still performed in Europe.

**Meaning and aesthetic response.** On the basis of present knowledge, it would appear that there is not or has not been any set response or reaction by any one of the three groups involved with the mask: the artist, the wearer, the spectator. There is, however, a reaction of a very particular kind common to every culture, a response such as awe, delight and pleasure, fear and even terror: these are as traditionally determined as the forms and costumes of the masks themselves. This is a learned and inherent pattern of conduct for each culture. Masks, therefore, that have a closely comparable appearance in several unrelated groups in quite different parts of the world often have totally dissimilar meanings and functions. It is thus practically impossible to determine either the meaning or use of a mask by its appearance alone. For example, some masks in Africa, as well as in Oceania and East Asia, have such a grotesque or frightening appearance as to lead one to suspect that they represent evil spirits with an intent to terrorize the spectators; actually they may have the opposite character and function. The significance of masks can be determined only by reference to accounts or personal observations of the masks in the setting of their own culture.

The aesthetic effects of masks, on the other hand, since they derive from the forms and their disposition within the design, can readily be evaluated as art objects. But this evaluation is based on elements very different from those appraised within the mask's own culture. This is partly because the total artistic qualities of a mask derive both from its exterior forms and from its meaning and function within its cultural context. There exist, however, in all cultures criteria for determining the quality of objects as art. These criteria differ from one culture to another, and they may be known only from investigations carried out within the varying cultures.

**Preservation and collecting.** The preservation or disposal of masks is often decreed by tradition. Many masks and often their form and function are passed down through clans, families, special societies, or from individual to individual. They are usually spiritually reactivated or aesthetically restored by repainting and redecorating, without destroying the basic form and symbolism. In many instances, however, the mask is used only for one ceremony or occasion and then is discarded or destroyed, sometimes by burning.

The collecting of masks has largely been of recent origin. Not until the late 19th and early 20th century were they seriously appreciated as art objects or studied as cultural artifacts. Most masks have been obtained through archaeological excavations or in field expeditions, that is, in their place of origin.

#### THE FUNCTIONS AND FORMS OF MASKS

Masks are as extraordinarily varied in appearance as they are in function or fundamental meaning. Many masks are primarily associated with ceremonies that have religious and social significance or are concerned with funerary customs, fertility rites, or curing sickness. Other masks are used on festive occasions or to portray characters in a dramatic performance and in re-enactments of mythological events. Masks are also used for warfare and as protective devices in certain sports, as well as frequently being employed as architectural ornament.

**Social and religious uses.** Masks representing potentially harmful spirits were often used to keep a required balance of power or a traditional relationship of inherited positions within a culture. The forms of these masks invariably were prescribed by tradition, as were their uses. This type of mask was often associated with secret societies, especially in Africa, where the greatest range of types and functions can be found. They were also widely used among Oceanic peoples of the South Pacific and the

American Indians and are even used in some of the folk rites still performed in Europe.

Masks have served an important role as a means of discipline and have been used to admonish women, children, and criminals. Common in China, Africa, Oceania, and North America, admonitory masks usually completely cover the features of the wearer. It is believed among some of the African Negro tribes that the first mask was an admonitory one. A child, repeatedly told not to, persisted in following its mother to fetch water. To frighten and discipline the child, the mother painted a hideous face on the bottom of her water gourd. Others say the mask was invented by a secret African society to escape recognition while punishing marauders. In New Britain, members of a secret terroristic society called the Dukduk appear in monstrous five-foot masks to police, to judge, and to execute offenders. Aggressive supernatural spirits

Upper portion is basketwork with faces modelled of red earth mixed with coconut oil, trimmed with shells, feathers, and a skirt of bark fibres. Height 1.79 m.

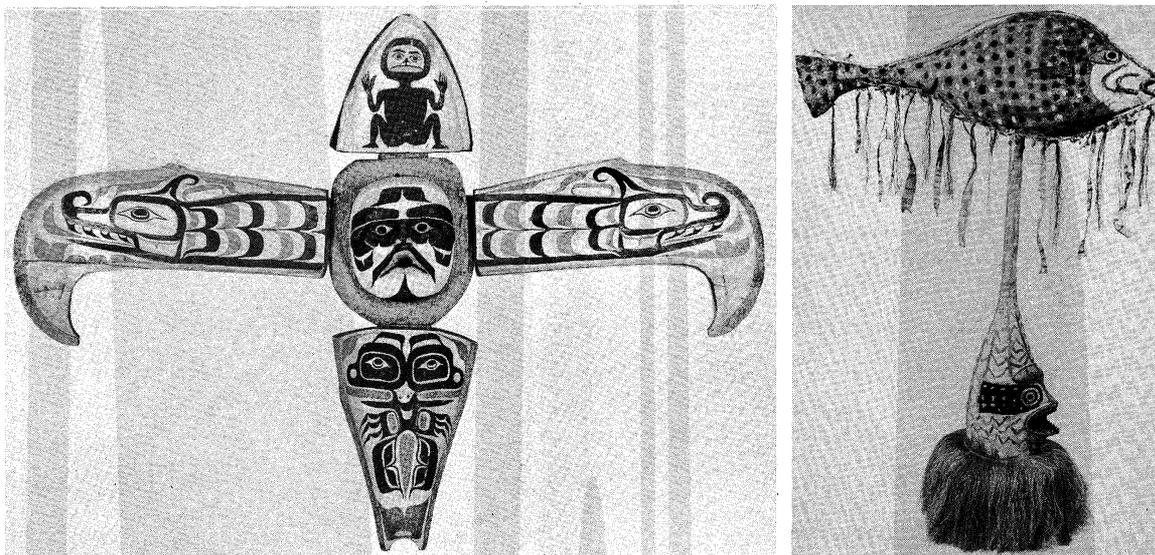

of an almost demonic nature are represented by these masks, which are constructed from a variety of materials, usually including tapa, or bark cloth, and the pith of certain reeds. These materials are painted in brilliant colours, with brick red and acid green predominating.

In many cultures throughout the world, a judge wears a mask to protect him from future recriminations. In this instance, the mask represents a traditionally sanctioned spirit from the past who assumes responsibility for the decision levied on the culprit.

Rituals, often nocturnal, by members of secret societies wearing ancestor masks are reminders of the ancient sanction of their conduct. In many cultures, these masked ceremonials are intended to prevent miscreant acts and to maintain the circumscribed activities of the tribe. Along the Guinea coast of West Africa, for instance, many highly realistic masks represent ancestors who enjoyed specific cultural roles; the masks symbolize sanction and control when donned by the wearer. Among some of the Dan and Ngere tribes of Liberia and Ivory Coast, ancestor masks with generic features act as intermediaries for the transmission of petitions or offerings of respect to the gods. These traditional ancestral emissaries exert by their spirit power a social control for the community.

Particularly among Oceanic peoples, American Indians, and Negro tribes of Africa, certain times of the year are

set aside to honour spirits or ancestors. Among nonliterate peoples who cannot record their own histories, masked rituals act as an important link between past and present, giving a sense of historic continuity that strengthens their social bond. On these occasions, masks usually recognizable as dead chieftains, relatives, friends, or even foes are worn or exhibited. Gifts are made to the spirits incarnated in the masks, while in other instances dancers wearing stylized mourning masks perform the prescribed ceremony.

In western Melanesia, the ancestral ceremonial mask occurs in a great variety of forms and materials. The Sepik River area in north central New Guinea is the source of an extremely rich array of these mask forms mostly carved in wood, ranging from small faces to large fantastic forms with a variety of appendages affixed to the wood, including shell, fibre, animal skins, seeds, flowers, and feathers. These masks are highly polychromed with earth colours of red and yellow, lime white, and charcoal black. They often represent supernatural spirits as well as ancestors and therefore have both a religious and a social significance.

#### Initiation masks

Members of secret societies usually conduct the rituals of initiation, when a young man is instructed in his future role as an adult and is acquainted with the rules controlling the social stability of the tribe. Totem and spiritualistic masks are donned by the elders at these ceremonies. Sometimes the masks used are reserved only for initiations. Among the most impressive of the initiation masks are the exquisitely carved human faces of west coast African Negro tribes. In western and central Zaire, in Africa, large, colourful helmetlike masks are used as a masquerading device when the youth emerges from the initiation area and is introduced to the villagers as an adult of the tribe. After a lengthy ordeal of teaching and initiation rites, for instance, a youth of the Pende tribe appears in a distinctive colorful mask indicative of his new role as an adult. The mask is later cast aside and replaced by a small ivory duplicate, worn as a charm against misfortune and as a symbol of his manhood.

#### Totem masks

Believing everything in nature to possess a spirit, man found authority for himself and his family by identifying with a specific nonhuman spirit. He adopted an object of nature; then he mythologically traced his ancestry back to the chosen object; he pre-empted the animal as the emblem of himself and his clan. This is the practice of totem, which consolidates family pride and distinguishes social lines. Masks are made to house the totem spirit. The totem ancestor is believed actually to materialize in its mask; thus masks are of the utmost importance in se-

curing protection and bringing comfort to the totem clan.

The Papuans of New Guinea build mammoth masks called *hevehe*, attaining 20 feet in height. They are constructed of a palmwood armature covered in bark cloth; geometric designs are stitched on with painted cane strips. These fantastic man-animal masks are given a frightening aspect. When they emerge from the men's secret clubhouse, they serve to protect the members of the clan. The so-called "totem" pole of the Alaskan and British Columbian Indian fulfills the same function. The African totem mask is often carved from ebony or other hard woods, designed with graceful lines and showing a highly polished surface. Animal masks, their features elongated and beautifully formalized, are common in western Africa. Dried grass, woven palm fibres, coconuts, and shells, as well as wood are employed in the masks of New Guinea, New Ireland, and New Caledonia. Represented are fanciful birds, fishes, and animals with distorted or exaggerated features.

The high priest and medicine man, or the shaman, frequently had his own very powerful totem, in whose mask he could exorcise evil spirits, punish enemies, locate game or fish, predict the weather, and, most importantly, cure disease.

The Northwest Coast Indians of North America in particular devised mechanical masks with movable parts to reveal a second face—generally a human image. Believing that the human spirit could take animal form and vice versa, the makers of these masks fused man and bird or man and animal into one mask. Some of these articulating masks acted out entire legends as their parts moved.

**Funerary and commemorative uses.** In cultures in which burial customs are important, anthropomorphic masks have often been used in ceremonies associated with the dead and departing spirits. Funerary masks were frequently used to cover the face of the deceased. Generally their purpose was to represent the features of the deceased, both to honour them and to establish a relationship through the mask with the spirit world. Sometimes they were used to force the spirit of the newly dead to depart for the spirit world. Masks were also made to protect the deceased by frightening away malevolent spirits.

From the Middle Kingdom (c. 2040–1786 BC) to the 1st century AD, the ancient Egyptians placed stylized masks with generalized features on the faces of their dead. The funerary mask served to guide the spirit of the deceased back to its final resting place in the body. They were commonly made of cloth covered with stucco or plaster,

which was then painted. For more important personages, silver and gold were used. Among the most splendid examples of the burial portrait mask is the one created c. 1350 BC for the pharaoh Tutankhamen. In Mycenaean tombs of c. 1400 BC, beaten gold portrait masks were found. Gold masks also were placed on the faces of the dead kings of Cambodia and Siam. The mummies of Inca royalty wore golden masks. The mummies of lesser personages often had masks made of wood or clay. Some of these ancient Andean masks had movable parts, such as the metallic death mask with movable ears found in the Moon Pyramid at Moche, Peru. The ancient Mexicans made burial masks that seem to be generic representations rather than portraits of individuals.

In ancient Roman burials, a mask resembling the deceased was often placed over his face or was worn by an actor hired to accompany the funerary cortege to the burial site. In patrician families these masks or *imagines* were sometimes preserved as ancestor portraits and were displayed on ceremonial occasions. Such masks were usually modelled over the features of the dead and cast in

wax. This technique was revived in the making of effigy masks for the royalty and nobility of Europe from the late Middle Ages through the 18th century. Painted and with human hair, these masks were attached to a dummy dressed in state regalia and were used for display, processions, or commemorative ceremonies. From the 17th century to the 20th, death masks of famous persons became widespread among European peoples. With wax or liquid plaster of paris a negative cast of the human face could be produced that in turn acted as a mold for the positive image, frequently cast in bronze. In the 19th century, life masks made in the same manner became popular. Another type of life mask had been produced in the Fayyum region of Egypt during the 1st and 2nd centuries AD. These were realistic portraits painted in encaustic on wood during a person's lifetime; at death, they were attached directly to the facial area on the mummy shroud.

The skull mask is another form usually associated with funerary rites. The skull masks of the Aztecs, like their wooden masks, were inlaid with mosaics of turquoise and

lignite, and the eye sockets were filled with pyrites. Holes were customarily drilled in the back so the mask might be hung or possibly worn. In Melanesia, the skull of the deceased is often modelled over with clay, or resin and wax, and then elaborately painted with designs that had been used ceremonially by the deceased during his own lifetime.

**Therapeutic uses.** Masks have played an important part in magico-religious rites to prevent and to cure disease. In some cultures, the masked members of secret societies could drive disease demons from entire villages and tribes. Among the best known of these groups was the False Face Society of the North American Iro-

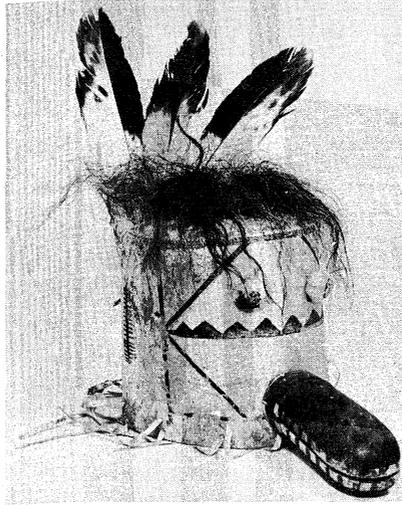

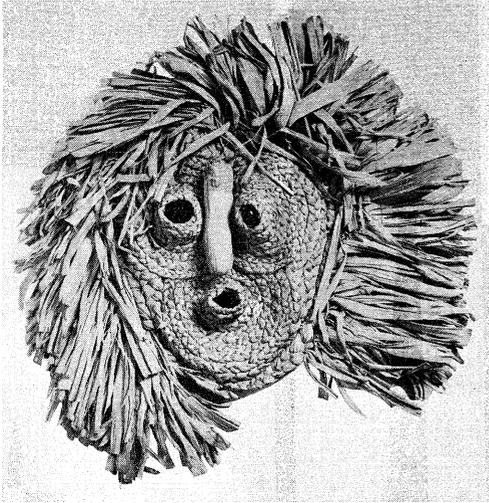

quois Indians. These professional healers performed violent pantomimes to exorcise the dreaded *Gahadogoka gogosa* (demons who plagued the Iroquois). They wore grimacing, twisted masks, often with long wigs of horse-hair. Metallic inserts often were used around the eyes to catch the light of the campfire and the moon, emphasizing the grotesqueness of the mask.

Masks for protection from disease include the measles masks worn by Chinese children and the cholera masks worn during epidemics by the Chinese and Burmese. The disease mask is most developed among the Sinhalese in Sri Lanka (Ceylon), where 19 distinct *rakasa*, or disease devil masks, have been devised. These masks are of fero-

**Uses in warfare and sport**

Masks have long been used in military connections. A war mask will have a malevolent expression or hideously fantastic features to instill fear in the enemy. The ancient Greeks and Romans used battle shields with grotesque masks or attached terrifying masks to their armour, as did the Chinese warrior. Grimacing *menpo*, or mask helmets, were used by Japanese samurai.

Many sports require the use of masks. Some of these are merely functional, protective devices such as the masks worn by fencers, baseball catchers, or even skiers. To protect their faces in sports events and tournaments of arms, horsemen of the Roman army attached highly decorative and symbolic masks to their helmets.

Perhaps the earliest use of masks was in connection with hunting. Disguise masks were seemingly used in the early Stone Age in stalking prey and later to house the slain animal's spirit in the hope of placating it. The traditional animal masks worn by the Altaic and Tungusic shamans in Siberia are strictly close to such prehistoric examples as the image of the so-called sorcerer in the Cave of Les Trois Frères in Ariège, France.

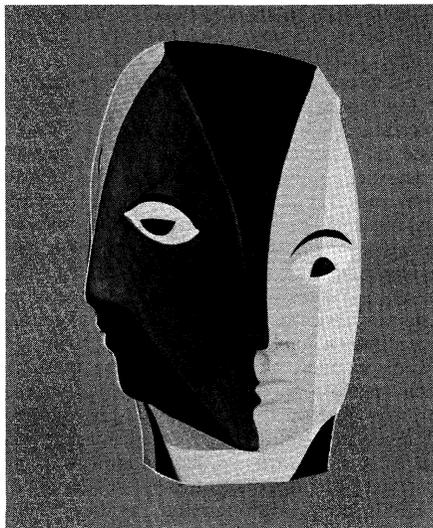

Since agricultural societies first appeared in prehistory, the mask has been widely used for fertility rituals. The Iroquois, for instance, used corn husk masks at harvest rites held by American Indians are those still performed by the Hopi and Zuni Indians of the Southwest U.S. Together with masked dancers representing clouds, rain spirits, stars, Earth Mother, sky god, and others, the shaman takes part in elaborate ceremonies designed to assure crop fertility. Spirits called *kachinas*, who first brought rain to the Pueblo tribes, are said to have left their masks behind when sent to dwell in the bottom of a desert lake. Their return to help bring the rain is incarnated by the masked dancer. Cylindrical masks, covering the entire head and resting on the shoulders, are of a primal type. They are made of leather and humanized by the addition of hair and a variety of adjuncts. Eyes are represented by incisions or by buckskin balls filled with deer hair and affixed to the mask. The nose is often of rolled buckskin or corncob. Frequently the mask has a projecting wooden cylinder for a bill or a gourd stem cut with teeth for a snout. Horns are attached to some masks. Many colours are used in their painting; plumes and beads are attached, and the sex of the mask is distin-

**Uses in fertility ceremonies**

guished by its shape: round head for male and square for female. In the western Sudan area of Africa many tribes have masked fertility ceremonials. The *segoni-kun* masks of the Bambara tribes in Mali are aesthetically among the most interesting. Antelopes, characterized by their elegant simplicity, are carved in wood and affixed to woven fibre caps that are hung with raffia and cover the wearer. The antelope is believed to have introduced agriculture, and so when crops are sown, members of Tji-wara society cavort in the fields in pairs to symbolize fertility and abundance.

**Festive uses.** Masks for festive occasions are still commonly used in the 20th century. Ludicrous, grotesque, or superficially horrible, festival masks are usually conducive to good-natured licence, release from inhibitions, and ribaldry. These include the Halloween, Mardi Gras, or "masked ball" variety. The disguise is assumed to create a momentary, amusing character, often resulting in humorous confusions, or to achieve anonymity for the prankster or ribald reveller.

Throughout contemporary Europe and Latin America, masks are associated with folk festivals, especially those generated by seasonal changes or marking the beginning and end of the year. Among the most famous of the folk masks are the masks worn to symbolize the driving away of winter in parts of Austria and Switzerland. In Mexico and Guatemala, annual folk festivals employ masks for storytelling and caricature, such as for the Dance of the Old Men and the Dance of the Moors and the Christians. The Eskimo make masks with comic or satiric features that are worn at festivals of merrymaking, as do the Ibos of Nigeria.

**Theatrical uses.** Masks have been used almost universally to represent characters in theatrical performances. Theatrical performances are a visual literature of a transient, momentary kind. It is most impressive because it can be seen as a reality; it expends itself by its very revelation. The mask participates as a more enduring element, since its form is physical.

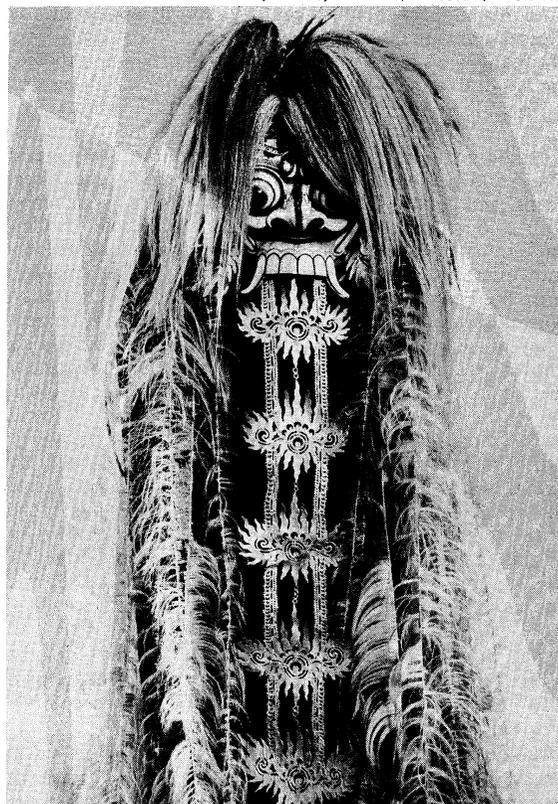

The mask as a device for theatre first emerged in Western civilization from the religious practices of ancient Greece. In the worship of Dionysus, god of fecundity and the harvest, the communicants' attempt to impersonate the deity by donning goat skins and by imbibing wine eventually developed into the sophistication of masking. When a literature of worship appeared, a disguise, which consisted of a white linen mask hung over the face (a device supposedly initiated by Thespis, a 6th-century-BC poet who is credited with originating tragedy), enabled the leaders of the ceremony to make the god manifest. Thus symbolically identified, the communicant was inspired to speak in the first person, thereby giving birth to the art of

drama. In Greece the progress from ritual to ritual-drama was continued in highly formalized theatrical representations. Masks used in these productions became elaborate headpieces made of leather or painted canvas and depicted an extensive variety of personalities, ages, ranks, and occupations. Heavily coiffured and of a size to enlarge the actor's presence, the Greek mask seems to have been designed to throw the voice by means of a built-in megaphone device and, by exaggeration of the features, to make clear at a distance the precise nature of the character. Moreover, their use made it possible for the Greek actors—limited by convention to three speakers for each tragedy—to impersonate a number of different characters during the play simply by changing masks and costumes. Details from frescoes, mosaics, vase paintings, and fragments of stone sculpture provide most of what is known of the appearance of these ancient theatrical masks. The tendency of the early Greek and Roman artists to idealize their subjects throws doubt, however, upon the accuracy of these reproductions. Some authorities maintain that the masks of the ancient theatre were crude affairs with little aesthetic appeal.

In the Middle Ages, masks were used in the mystery plays of the 12th to the 16th century. In plays dramatizing portions of the Old and New Testaments, grotesques of all sorts, such as devils, demons, dragons, and personifications of the seven deadly sins, were brought to stage life by the use of masks. Constructed of papier-mâché, the masks of the mystery plays were evidently marvels of ingenuity and craftsmanship, being made to articulate and to belch fire and smoke from hidden contrivances. But again, no reliable pictorial record has survived. Masks used in connection with present-day carnivals and Mardi Gras and those of folk demons and characters still used by central European peasants, such as the *Perchten* masks of Alpine Austria, are most likely the inheritors of the tradition of medieval masks.

The 15th-century Renaissance in Italy witnessed the rise of a theatrical phenomenon that spread rapidly to France, to Germany, and to England, where it maintained its popularity into the 18th century. Comedies improvised from scenarios based upon the domestic dramas of the

Javanese *tupeng* mask representing the witch Rangda. Lacquered wood, cloth, metal, and horsehair.

ancient Roman comic playwrights Plautus (254?–184 BC) and Terence (186/185–159 BC) and upon situations drawn from anonymous ancient Roman mimes flourished under the title of *commedia dell'arte* (*q.v.*). Adopting the Roman stock figures and situations to their own usages, the players of the *commedia* were usually masked. Sometimes the masking was grotesque and fanciful, but generally a heavy leather mask, full or half face, disguised the *commedia* player. Excellent pictorial records of both *commedia* costumes and masks exist; some sketches show the characters of Arlecchino and Colombina wearing black masks covering merely the eyes, from which the later masquerade mask is certainly a development.

#### Modern

Except for vestiges of the *commedia* in the form of puppet and marionette shows, the drama of masks all but disappeared in Western theatre during the 18th, 19th, and first half of the 20th centuries. In modern revivals of ancient Greek plays, masks have occasionally been employed, and such highly symbolic plays as *Die versunkene Glocke* (*The Sunken Bell*; 1897) by the German Gerhart Hauptmann (1862–1946) and dramatizations of *Alice in Wonderland* have required masks for the performers of grotesque or animal figures. The Irish poet-playwright W.B. Yeats (1865–1939) revived the convention in his *Dreaming of the Bones* and in other plays patterned upon the Japanese *Nō* drama. In 1926 theatregoers in the United States witnessed a memorable use of masks in *The Great God Brown* by the American dramatist Eugene O'Neill (1888–1953), wherein actors wore masks of their own faces to indicate changes in the internal and external lives of their characters. Oskar Schlemmer (1888–1943), a German artist associated with the Bauhaus, became interested in the late 1920s and '30s in semantic phenomenology as applied to the design of masks for theatrical productions. Modern art movements are often reflected in the design of contemporary theatrical masks. The stylistic concepts of Cubism and Surrealism, for example, are apparent in the masks executed for a 1957 production of *La favola del figlio cambiato* (*The Fable of the Transformed Son*) by the Italian dramatist Luigi Pirandello (1867–1936). A well-known mid-century play using masks was *Les Nègres* (1958; *The Blacks*, 1960) by the French writer Jean Genet (1910– ). The mask, however, has unquestionably lost its importance as a theatrical convention in the 20th century, and its appearance is exceptional rather than general.

#### East Asian

In many ways akin to Greek drama in origin and theme, the *Nō* drama of Japan has remained a significant part of national life since its beginnings in the 14th century. *Nō* masks, of which there are about 125 named varieties, are rigidly traditional and are classified into five general types: old persons (male and female), gods, goddesses, devils, and goblins. The material of the *Nō* mask is wood with a coating of plaster and lacquered and gilded. Colours are traditional. White is used to characterize a corrupt ruler; red signifies a righteous man; a black mask is worn by the villain who epitomizes violence and brutality. *Nō* masks are highly stylized and generally characterized. They are exquisitely carved by highly respected artists known as *tenka-ichi*, "the first under heaven." Shades of feeling are portrayed with beautifully sublimated realism. When the masks are subtly moved by the player's hand or body motion, their expression appears to change.

In Tibet, sacred dramas are performed by masked lay actors. A play for exorcising demons called the "Dance of the Red Tiger Devil" is performed at fixed seasons of the year exclusively by the priests or lamas wearing awe-inspiring masks of deities and demons. Masks employed in this mystery play are made of papier-mâché, cloth, and occasionally gilt copper. In Sikkim and Bhutan, where wood is abundant and the damp climate is destructive to paper, they are carved of durable wood. All masks of the Himalayan peoples are fantastically painted and are usually provided with wigs of yak tail in various colours. Formally they often emphasize the hideous.

Masks, usually made of papier-mâché, are employed in the religious or admonitory drama of China; but for the greater part the actors in popular or secular drama make up their faces with cosmetics and paint to resemble masks,

as do the Kabuki actors in Japan. The makeup mask both identifies the particular character and conveys his personality. The highly didactic sacred drama of China is performed with the actors wearing fanciful and grotesque masks. Akin to this "morality" drama are the congratulatory playlets, pageants, processions, and dances of China. Masks employed in these ceremonies are highly ornamented, with jewelled and elaborately filigreed head-gears. In the lion and dragon dances of both China and Japan, a stylized mask of the beast is carried on a pole by itinerant players, whose bodies are concealed by a dependent cloth. The mask and cloth are manipulated violently, as if the animal were in pursuit, to the taps of a small drum. The mask's lower jaw is movable and made to emit a loud continuous clacking by means of a string.

In Java and Bali, wooden masks, *tupeng*, are used in certain theatrical performances, called *wayang wong*. These dance dramas developed from the shadow puppet plays of the 18th century and are performed not only as amusement but as a safeguard against calamities. The stories are in part derived from ancient Sanskrit literature, especially the Hindu epics, although the Javanese later became Muslims. The brightly painted masks are made of wood and leather and are often fitted with horsehair and metallic or gilded paper accoutrements. They are ordinarily held in the teeth by means of a strap of leather or rattan fastened across the inside. Occasionally an actor interrupts the unseen narrator, the *Dalang*, who is speaking the play. The mask is then held in front of the face while the player says his line. The use of masks in Java is exceptional; for masks, being forbidden under the prohibition of images, are practically unknown in the Islamic world.

In the 20th century, with the breaking down of primitive and folk cultures, the mask has increasingly become a decorative object, although it has long been used in art as an ornamental device. In India, Indonesia, Japan, Kenya, and Mexico, masks are largely produced for tourists. The collecting of old masks has been a part of the current interest in so-called primitive and folk arts. Masks also have exerted a decided influence on modern art movements, especially in the first decades of the 20th century, when painters in France and Germany found a source of inspiration in the tribal masks of Africa and western Oceania.

**BIBLIOGRAPHY.** "Masks" in the *Encyclopedia of World Art*, vol. 9, col. 520–570 (1964), a good historical survey; WILLIAM N. FENTON, "Masked Medicine Societies of the Iroquois," *Smithsonian Institution, Annual Report for 1940*, pp. 397–429 (1941), a very good general discussion of Iroquois masks, with illustrations; MARCEL GRIAULE, *Masques Dogons* (1938), a profusely illustrated classic study of the masks of the Dogon, a people of Mali, within their cultural setting; GEORGE W. HARLEY, *Masks as Agents of Social Control in Northeast Liberia*, Peabody Museum Papers 32, no. 2 (1950), a useful, illustrated article; E.A. KENNARD, *Hopi Kachinas* (1938), an important study of the masks of the Hopi, the westernmost Pueblo Indians; *Le Masque*, an exhibition catalogue, December 1959–May 1960, Musée Guimet, Paris (1959), an excellent text with superb plates; DOROTHY J. RAY, *Eskimo Masks: Art and Ceremony* (1967), one of the best studies of masks with many fine plates and bibliography; HANS HIMMELHEBER, *Afrikanische Masken, ein Brevier* (1960), a brief but good résumé, with excellent plates; F.E. WILLIAMS, *Drama of Oroko* (1940), a classic study of masks of the Gulf of Papua, New Guinea, with fine illustrations and bibliography; LEON UNDERWOOD, *Masks of West Africa* (1948), a small book but important for the subject, with good plates.

(P.S.W.)

## Masonry Construction

Masonry construction includes building and fabricating in stone, clay, brick, and concrete. Masonry materials have long been favoured by architects for their colour, scale, texture, pattern, and look of permanence. Engineers have valued them for their durability and compressive (weight-bearing) strength. Because of their own considerable deadweight and their lack of tensile strength (ability to resist pulling force), however, masonry materials now have been largely, though not entirely, replaced in structural functions by steel, reinforced concrete,

Indo-  
nesian

wood, and plastics. Today masonry is employed chiefly as an external wall material in applications in which aesthetics and weatherability are deciding factors.

#### HISTORY

The art of masonry originated when early man sought to supplement his valuable but rare natural caves with artificial caves made from piles of stone. Circular stone huts, partially dug into the ground, dating from prehistoric times have been found in the Aran Islands, Ireland. By the 4th millennium BC, Egypt had developed an elaborate stonemasonry technique, culminating in the most extravagant of all ancient structures, the Pyramids.

**Geological influences.** The choice of masonry materials has always been influenced by the prevailing geological formations and conditions. When monumental aesthetics and durability were sought for religious and governmental buildings, natural stone was preferred. Egyptian temples were constructed of limestone, sandstone, alabaster, granite, basalt, and porphyry quarried from the hills along the Nile. The Greeks lacked Egypt's variety of natural stones, but they possessed rich quarries of unrivalled marble and coated their coarse-grained limestone with a layer of marble-stucco. The Romans, though they imported stones from both Egypt and Greece, depended heavily on their own limestone deposits, both travertine (a hard variety) and tufa (a porous variety), of which the hills of Rome are mainly composed. They also used peperino and lava stones, both of volcanic origin.

Another ancient centre of civilization, the area of western Asia between the Tigris and Euphrates, lacked stone outcroppings but was rich in clay deposits. As a result, the masonry structures of the Assyrian and Persian empires were constructed of sun-dried bricks faced with kiln-burned, sometimes glazed, units. In this area pitch or bitumen, as well as plastic, calcareous earth, was used for mortar. Both the Assyrians and Persians constructed buildings with massive brick walls, adorning the openings with alabaster or limestone masonry.

Stone and clay continued to be the primary masonry materials through the Middle Ages and later. Brick was widely employed in the lowlands of northwest Europe and in the regions of southern Europe under the influence of Byzantine architectural ideas originating in Constantinople. Special forms of clay (terra-cotta and mosaic) ornamented Byzantine and Roman buildings. Terra-cotta pieces made of a fired clay that was frequently glazed were used to create decorative cornices, gutters, or base course moldings. Mosaics, either coloured stone or glazed glassware, decorated flat surfaces.

**Roman concrete and arches.** A significant development in masonry construction in ancient times was the invention of concrete by the Romans. Although well-cut blocks of stone masonry could be erected without benefit of mortar, the Romans recognized the value of cement, which they made from pozzolanic tuff, a volcanic ash. Mixed with water, lime, and stone fragments, the cement was expanded into concrete. Walls of this concrete, faced with various stone or fired clay materials (see Figure 1),

From B. Fletcher, *A History of Architecture on the Comparative Method*, 17th ed. rev., R.A. Cordingley (1961); Athlone Press of the University of London

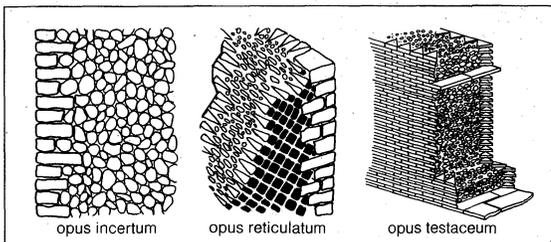

Figure 1: Roman methods of wall construction.

were more economical and faster to erect. Opus incertum required irregularly shaped stones. Opus reticulatum was arranged in diagonal lines, using tuff (limestone) studding to resemble meshes of net. Opus testaceum was faced with bricks triangular in plan. Unfaced concrete could be effectively utilized for foundation work.

Because it provided more freedom in shaping structures, concrete helped the Romans develop the arch, long-known but little-used, into one of the great basic construction forms. Prior to the arch, all builders in stone had been handicapped by the material's fundamental lack of tensile strength—that is, its tendency to break under its own weight when supported on widely separated piers or walls. The Egyptians had roofed temples with stone slabs but had been forced to place the supporting columns close together. The Greeks had used wooden roof beams covered with thin stone; such beams were subject to weather and fire. The Roman arch avoided tension entirely, keeping all the masonry in compression, from the keystone to the piers. Stone in compression has great strength, and the Romans built huge bridges and aqueducts in large numbers. Extending their arch into a tunnel, they invented the barrel vault, with which they successfully roofed such buildings as the Temple of Venus in Rome. Several arches intersecting at a common keystone could be used to form a dome, such as that of the Pantheon in Rome. Two intersecting barrel vaults gave rise to the groin vault, which was used in some of the great public baths.

Roman arches and vaults were invariably semicircular in shape, making them massive and rigid. The shape and mass of Roman construction generally avoided problems of horizontal thrust, the horizontal pressure resulting from the arch type of construction. The Pantheon had a diameter of 142 feet, a span not equalled in magnitude until the introduction of modern steel and reinforced-concrete construction.

**Gothic masonry.** The Roman arch underwent a significant modification in the Middle Ages in the evolution of the pointed arch, which provided a strong skeleton resting on well-spaced piers. The massive, rigid construction of the Romans gave way to soaring vaults supported by external flying buttresses (external bracing). The use of smaller-sized stones and thick mortar joints created an elastic slender structure that stressed the masonry to its fullest. The bearing of unit upon unit required the use of mortar to distribute the contact stresses. In the Beauvais Cathedral the builders exceeded the stress limit, and the choir vault, more than 157 feet high, fell. Rebuilt after AD 1337, it remains today the loftiest structure of its kind in Europe.

With the advent of Gothic forms, masonry construction in a historic sense had solved the problem of spanning space entirely by material in compression, the only design formula suitable to stone. With the advent of the truss in the 16th century, the rise of scientific structural analysis in the 17th century, and the development of high-tensile resistant materials (steel and reinforced concrete) in the 19th century, the importance of masonry as a practical material for spanning space declined. It owes its revival largely to the invention of portland cement, the principal ingredient of concrete, which in the 20th century returned masonry to its essentially pre-Roman role of forming vertical wall enclosures, partitions, and facings.

#### MINING AND MANUFACTURING

Masonry construction begins with extractive materials, such as clay, sand, gravel, and stone, usually mined from surface pits or quarries. Geologically, all masonry materials come from a common source, rock, the solidified state of the molten material called magma, which still exists within the earth's interior.

Igneous rocks are created directly from the molten interior, frequently without seams, layers, or grain in massive formations that are difficult to quarry. In time, igneous rock is weathered by temperature, wind, and water, and once decomposed, it is called mantle. Particles of this rock range from fine-sized clays to large-sized gravel and stones. When deposited in compressed layers, mantle hardens into a sedimentary rock that is relatively easy to quarry because it is layered and has grain. When igneous and sedimentary rocks have been subjected to tremendous heat and pressure with the contraction and thrust of the earth's crust, they have changed into a material called metamorphic rock.

The pointed arch

**Stone sources.** The most widely used igneous rock is granite, a massive rock less difficult to quarry because it has grain and rift (natural seams). Typically, igneous rock is strong, hard, and durable. Composed primarily of quartz (silicon dioxide) and feldspar (aluminosilicate), it has a characteristic peppery, coarse-grained appearance predominantly gray in hue. Other igneous rocks, such as syenite (feldspar with hornblende) and diorite (feldspar with pyroxene), are excellent fine-grain rocks. Because of their massive formation (no rift and grain) and brittle behaviour, however, they cannot be commercially quarried. The porphyry rock used by the ancients is actually a form of igneous rock characterized by a dense, compact groundmass in which are embedded large, perfectly formed crystals of quartz or feldspar. Gneiss granite, a metamorphic granite form stratified during its formation, has not been commercially exploited even though its layered deposits permit easier quarrying.

Limestone  
and  
sandstone

Limestone and sandstone are the two most widely used sedimentary rocks. Limestone is primarily calcium carbonate, called calcite; most deposits are of marine origin, chiefly in the form of shells, as, for example, in a coral reef. The double carbonate of calcium and magnesium is called dolomite limestone. It is easier to quarry than the granites because it is softer, occurs in sedimentary layers, and has well-defined rift and grain. The most common colour is gray, with gradations of buff or brown. Limestone formed at the surface by precipitation from hot spring waters is called travertine. Sandstone consists of sand-sized particles of weathered rock cemented together by sedimentary action. Though the composition is frequently quartz, weathered particles of granite or feldspar have produced valuable sandstones. Hues range from white to gray, coloured with pink, red, yellow, buff, brown, or green, depending on the cementing material. Like limestone, sandstone is easy to quarry.

The major metamorphic rock of commercial value is marble, primarily a recrystallized limestone that has been subject to heat and pressure during formation. Marbles containing iron oxides display pink, red, or yellow colours; those containing carbonaceous matter (organic remains) display blue-gray, gray, or black shades. Vermont marbles, containing talc, are green.

**Manufacturing.** The cement used in concrete blocks is created by heating a blend of limestone and clay in rotary kilns. Clays are chemically composed of about 60 percent quartz and 20 percent aluminum oxide, with varying amounts of metallic oxides, chiefly iron, calcium, magnesium, sodium, and potassium. The aggregates in concrete blocks may be either dense, using sand and gravel, or crushed rock, or lightweight, using sand and expanded shale, pumice, cinders, or blast-furnace slag (see also CEMENT; CONCRETE).

Concrete blocks are shaped by vibrating a very dry plastic concrete mix in an automated mold. When the blocks have been hardened sufficiently to hold their shape on release from the mold, they are transferred to a curing process to minimize shrinkage. Curing may be simply slow drying over a period of two to four weeks in open sheds, with precautions against freezing. The most effective method is steam curing under high pressure. A typical concrete mix for blocks is one part cement to six parts aggregate by volume. When water is added, a chemical reaction called hydration takes place, producing a hardened mass.

Bricks and other clay construction units are essentially plastic clay fired in a fused ceramic. Screened and ground clays are blended into a mill with water to create a plastic mass called stiff-mud, which is then forced through a die. The clay column, generally cored to produce the desired geometric voids, is cut by taut, rotating wires to the desired lengths (see also BRICK AND TILE PRODUCTION). Clays that are either too wet or too harsh (nonplastic) to be formed by the stiff-mud process are subjected to a process called soft-mud, which molds wet clays. High-pressure steel molds are used on such harsh clays.

After the units are formed, they are dried in ovens and heated to moderate temperatures for one to two days. Excess water is removed, and air shrinkage of the clay

mass (2 to 8 percent) takes place. The dried units are then burned in kilns. Clay properties, the type of unit, and the required specifications of the final product determine the kiln burning time and temperature, which range from two to five days and from 1,600° to 2,400° F (about 870° to 1,315° C). During firing, further shrinkage occurs, increasing the total shrinkage from 4 to 16 percent. Differential shrinkage, a major cause of rejects in older kilns, has been reduced by improved firing control in modern long-tunnel kilns that provide uniform heating.

The dimension stone industry has also adopted machine operations, but the rock mass must first be broken into pieces that can be handled by power equipment. Traditionally, rocks have been broken into sections that can be cleaved along natural seams and cracks. Today, however, wedges are inserted in pneumatic-drilled holes to cleave hard, igneous rocks. For limestone and marble, a channelling machine makes parallel cuts in the quarry face, and the channelled block is split from its bed by wedges placed in horizontal holes in the block. In another method, a wire saw (a steel cable stretched over pulleys like a band saw) cuts downward like the channelling machine. Long blocks split off from the quarry face are broken into shorter blocks by drilling and wedging. When taken to the fabricating mills, quarry blocks are generally cut into thin slabs by gang saws. To profile the stones and give them surface treatment, lathing, planing, grinding, and polishing machines are employed just as in metalworking. Hand methods employing hammers and chisels are now largely obsolete, except for special custom work.

Rock  
cleaving

#### MODERN CONSTRUCTION PRACTICE

**Work methods.** *Masonry tools.* The installation of masonry units is primarily a skilled hand operation. The tools needed are used for three major activities: (1) laying out the work; (2) placing the mortar; and (3) shaping the units.

The major tools are the rule, level, and line. A mason's rule, which resembles a carpenter's folding rule, has vertical coursing scales to measure the thickness of the mortar joint. The corners of a wall are constructed first, and a plumb level is used to align the work. A mason's line (a special heavy twine) is then stretched between the corners. During construction the level is continuously used to plumb the corners of window and door openings and to check the level of horizontal joints (called bed joints). Pins on a corner block hold the line in place. A support called a tingle plate is used to keep the line from sagging over a long length of wall.

Mortar is handled with a brick trowel, a tool measuring nine to 11 inches in length. To finish the joints after the units have been placed and the mortar has stiffened, the jointing tool is slid along the face of the joint. The pointing trowel fills joints to a depth of about one-half inch. On new work, this procedure makes it possible to use coloured or dense mortars. On old work, the pointing trowel is used to replace weathered mortar, to ensure greater life, and to waterproof the construction—a process called tuck-pointing.

To cut and trim brick units, a brick hammer and brick set are employed. The cold chisel cuts holes in all kinds of masonry. Traditionally, the stonemason was equipped with many hammers and chisels to create a variety of finishes. With the advent of mill fabrication, however, such tools are no longer required on the job site. Concrete block and glazed facing tile are frequently cut by a circular, diamond-blade, portable saw. Modern masonry technology attempts to minimize trimming and cutting on the site by supplying special shapes, such as half, corner, jamb, or lintel units.

Brick  
hammer  
and brick  
set

**Mortar mixing.** Mortars are generally mixed by volume, using one part cement paste and three parts sand aggregate. Sufficient water is added to provide workable consistency. The paste may vary from all cement to all lime. Cement-rich mortars are strong but difficult to work, whereas lime-rich mortars are weak but plastic to work. Masonry cements containing ground limestone

blended with cement can produce a workable mortar. For an all-purpose mortar, a 1:1:6 (cement: lime: and sand aggregate) mix has proved to be both workable and relatively strong. High-bond mortars include plastic organic additives and fine aggregates (aggregate that has been pulverized), such as marble dust, to maintain workability. To reduce water permeability through the joint, stearates (fatty acids) are added for water repellency. Mortars can be safely coloured with the earthy hues of iron oxides or the black of carbon. White can be achieved with white sand and cement. Highly absorptive masonry units, such as common brick, may remove sufficient water from the mortar to reduce strength and bond measurably. Such units must be wetted prior to laying.

**Bonding patterns.** The common bonding patterns of brick are shown in Figure 2. The different patterns (run-

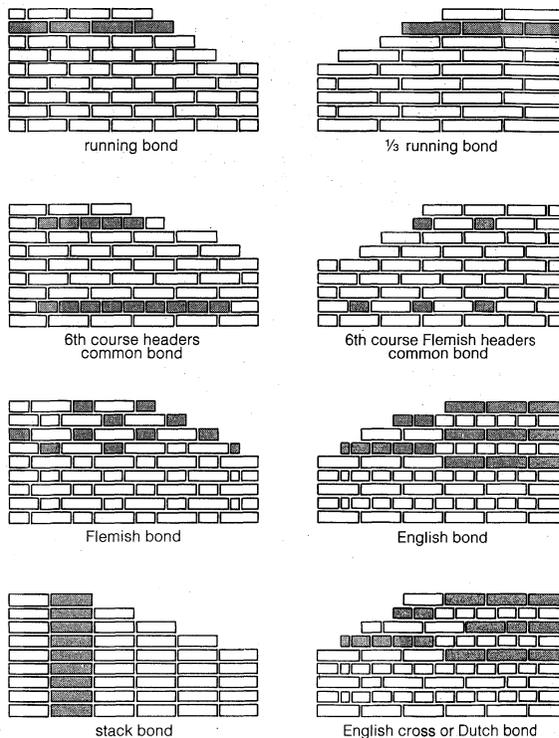

Figure 2: Common brick-bonding patterns.

ning bond, common bond, etc.) result from different arrangements of stretchers (brick with the long dimension parallel to the wall) and headers (brick with the long dimension toward the face of the wall). Where two or more vertical courses (layers) are constructed across the wall thickness, they must be tied by header units or light-gauge metal ties to provide structural stability. Mortar joints are made as narrow as the dimensional accuracy of the units will permit. Generally, this ranges from  $\frac{1}{4}$  inch to  $\frac{1}{2}$  inch.

**Physical properties of materials.** Although masonry is among the oldest of building materials, only recently has it been subjected to rational engineering analysis. With the advent of modern steel and concrete, masonry has ceased to be the prime structural support and instead serves as a weather enclosure for the building system; and even this use has been challenged by modern composite material systems, such as glass walls, metal sheets, reinforced plastics, and cast architectural concrete. Since 1950 masonry industries have engaged in materials and structural testing in a search for designs based in rational engineering analysis, permitting a return to the structural use of masonry materials.

The primary physical properties of engineering interest are structural resistance; durability; volume changes; and fire, acoustical, and thermal resistance.

**Structural resistance.** The basic structural compressive strength of masonry materials (in pounds per square inch) ranges as follows: concrete block 1,000–5,000; clay

products 3,000–15,000; dimension stone 5,000–25,000. The tensile strength is about one-tenth the compressive value. The composite strength when used with mortar is below that of the parent masonry material, the value depending on the geometry of the unit, joint thickness, mortar strength and stiffness, and the bonding used in construction.

The deadweight of masonry varies from 90 pounds per cubic foot for lightweight concrete block, to 120 for brick masonry, to 150 for dense concrete block or natural stone. Some dense marbles and granites reach 175 pounds per cubic foot.

**Durability.** Traditionally, masonry materials have been valued for their permanence. The agents that cause deterioration are freezing-thawing of absorbed water, chemical action of atmospheric water containing dissolved industrial pollutants, and abrasive wear. For external use in the ground, materials of very low absorption and high strength are used, such as dense concrete block, highly fired bricks, or dense igneous rocks. The softer limestones and marbles need protection against corrosive atmospheres; they wear easily under foot and vehicular traffic.

**Volume changes.** Expansion and contraction due to temperature changes and to moisture changes are important concerns to the designer. Compared with most building materials, masonry materials as a class have relatively low thermal expansion. Fired clay products and igneous rocks have the least. Concrete products and sedimentary rocks approach that of mass concrete.

As a class, clay products and igneous rocks have negligible dimensional movement with moisture changes. Concrete products have substantial shrinkage upon loss of water, necessitating their careful curing, as noted earlier. Such shrinkage can be ten times greater than thermal changes. Autoclaved concrete block may reduce this movement to one-third or less. Natural stone contains "quarry sap," or absorbed water, which, when dried out, increases the strength measurably, and the stone becomes stabilized against future shrinkage. Generally, materials that shrink upon loss of absorbed water will swell and lose strength upon reabsorption.

**Fire, acoustical, and thermal resistance.** Fire resistance of masonry materials is generally superior to that of other building materials, even concrete. Certain igneous rocks (e.g., granite) crack or spall under high temperature but do not completely disintegrate, thus providing substantial protection against collapse. Fires may reach temperatures above the softening point of steel (1,200° F). Thus, masonry is able to provide superior fire protection. Highly vitrified clay products containing fire clays can withstand temperatures in excess of 2,000° F.

The mass of masonry enhances its resistance to the transmission of airborne sound. When employed as a separating wall between noisy and quiet activities, it provides superior sound insulation. As an enclosing wall to reduce street noises, it is also effective. High-density masonry walls provide excellent protection against the noise of jets at airports.

Except for lightweight concrete blocks, most masonry materials and units are relatively poor insulators against the steady transfer of heat, as compared with rock wool, glass fibre, or Styrofoam. When the heat source is periodic, however, as during the daily summer heat-gain cycle, the high density and low specific heat of masonry acts as a heat sink of high capacity. The heat of the exterior building surface never reaches the interior before nocturnal cooling can take place. Such heat capacity (time-lag effect) explains the cool interiors of heavy fortresses or churches located in desert or tropic climates.

**Modern applications.** *Brick-veneer walls.* In housing, masonry is often used as a veneer over wood-stud construction. Most of the brick used in housing is applied in this manner.

*Cavity walls.* The most water-resistant wall construction is a masonry cavity, using an exterior course, an air space, and an interior course. Wire ties increase lateral stability. Weep holes (drainage holes) formed at the bottom of the wall allow the cavity to drain to the exterior

Dead-weight of masonry

Fibre glass  
insulation

when moisture penetrates the outside course. To reinforce the superior thermal resistance of this construction, the cavity may be filled with glass fibre or other insulation to create a degree of resistance to heat flow equal to the best of wood construction.

**Concrete block foundations.** House foundations are frequently built with dense concrete block as the basement wall material.

**Exterior curtain walls.** Brick and stone are valued aesthetically when used as weather enclosures for fenestration (window construction), particularly in high-rise commercial buildings. Such walls are usually backed up by concrete block for wind, weather, and fire resistance. They are built solid, with the exterior finish masonry bonded to the backup, using header construction, metal wire ties, or metal ladder reinforcing.

**Fire walls.** Most building codes require fire walls capable of resisting fire for a specified length of time, to prevent the spread of fire. The walls may be located between adjacent town houses, the major divisions of floor areas in factories, and at certain intervals in apartment construction. These walls are thick, of solid construction, and usually without openings.

**Glazed-tile walls.** Where low maintenance, high sanitation, and aesthetics are desired, structural glazed facing tile, a fireclay product produced in a wide colour range, is often used, typically in surgical rooms, commercial kitchens, radiation laboratories, and rest rooms. Glazed tile is not usually satisfactory for exterior use because of surface crazing (cracking) during freeze-thaw cycles.

**Interior-partition walls.** Lightweight concrete-block units, sometimes glazed with plastic colours, are widely used in school, commercial, and industrial walls. Economical, they provide the fire and sound resistance generally needed in such applications.

**Load-bearing walls.** The most significant new application is actually an old one: load-bearing use of masonry. Using modern data on material strength and modern principles of structural engineering, all interior and exterior vertical, opaque walls can be made to support floors against gravity forces. While skeleton framing of steel and reinforced concrete has dominated construction since the beginning of the 20th century, such construction has frequently employed opaque masonry materials under beams and between columns. The modern application of structural masonry can eliminate the structural frame. Eight inches of masonry can safely hold a height of ten stories. In Europe and the United States, load-bearing buildings with walls not more than 12 inches thick have been carried to about 20 stories. To withstand the horizontal forces of wind or earthquakes, load-bearing construction is braced by building high shear walls, vertical cross walls that buttress the building.

**Reinforced walls.** The resistance of unreinforced masonry walls is dependent on the tensile bond of the mortar. A low-tensile bond value is adequate for ordinary wind loads on walls one story high, but for high walls, steel reinforcing is required. In brick construction, a cavity wall is constructed and the air space is filled with grout (thin mortar) containing embedded steel bars. In concrete wall construction, bars inserted into vertical cells are grouted in position. This form of construction is common where earthquake or severe-wind resistance is needed.

**Screen walls.** Clay and concrete units, available in a wide variety of open-through-the-wall designs, create attractive screening walls. They are used as outside fences, inside divider walls, or above fenestration as shading against sunlight.

(1963), a comprehensive architectural history text on classical masonry buildings of the past, including Oriental buildings; TALBOT HAMLIN, *Architecture Through the Ages*, rev. ed. (1953), a source that especially emphasizes primitive structures and pre-Columbian buildings; GEORGE P. MERRILL, *Stones for Building and Decoration*, 3rd rev. ed. (1903), though dated, a comprehensive statement of the geology of dimension stone in the United States; JAMES G. CROSS and HARRY C. PLUMMER, *Principles of Clay Masonry Construction* (1970), a resource text for teaching masonry to architectural and civil engineering students.

(C.B.Mo.)

## Massachusetts

Like others of the 13 British colonies along America's Atlantic Seaboard in the 17th and 18th centuries, Massachusetts was founded by men seeking in a wilderness for a new way of life involving such then untried notions as freedom of religion and self-government. These and other ideals were severely tested during more than 150 years of colonial life, but they came to provide much of the ideological underpinning of the American Revolution, from which Massachusetts emerged as one of the founding and leading members of the new United States.

One of the six New England states lying in the northeastern corner of the nation, the Commonwealth of Massachusetts, as it is known officially, is bounded on the north by Vermont and New Hampshire, on the east and southeast by the Atlantic Ocean, on the south by Rhode Island and Connecticut, and on the west by New York. Its 8,257 square miles (21,386 square kilometres) rank it 45th in area nationally. The nearly 5,690,000 residents counted in the 1970 census represented an amalgamation of the prototypal Yankee spirit of an earlier America and the energies of the later immigrants who flocked to its cities in the 19th century.

Massachusetts has been, nearly from its founding, a leading force in American education. During the 19th century, Boston, its capital, became synonymous nationally with the highest attainments in America's cultural and artistic life, and the state as a whole provided industrial and financial leadership for the nation. Though these latter positions have long since been yielded to larger and faster growing states and regions, the history and people of Massachusetts have left an indelible mark on the development of the American consciousness. (For information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; BOSTON; NORTH AMERICA; and APPALACHIAN MOUNTAINS.)

### THE HISTORY OF MASSACHUSETTS

History is woven into the very fabric of life in Massachusetts and has become the state's most valuable resource. The Pilgrims' landing and the American Revolution were the most heralded events, but the elements of struggle and survival were the main lessons for posterity from those two eras.

**Cornerstones of the colony.** The arrival of the Pilgrims on December 21, 1620, was significant, yet the Indians had found this corner of the country some 3,500 years earlier, and Leif Eriksson and his Norsemen probably landed somewhere in the Cape Cod region in 1003. European seafarers tapped the fertile fishing areas throughout the 1500s, the French explorer Samuel de Champlain mapped the area in 1605, and in 1614 Capt. John Smith of Virginia drafted a detailed map of the New England coast from Penobscot Bay in Maine to Cape Cod. He even fought the Indians at Plymouth, stealing their canoes and trading them back in exchange for beaver skins.

At the time of the landing at Plymouth, most of the Pilgrims were at Provincetown, where they had arrived several days earlier and where the "Mayflower" was still anchored. An expedition of a dozen Pilgrims and six crewmen was sent to scout for a suitable settling place, which they found at Plymouth. The "Mayflower" did not arrive until the day after Christmas.

The Mayflower Compact, signed five weeks earlier by 41 men while still at sea, was hardly democratic. Basically, it called for rule by the elite, but it established an

Character  
and  
location of  
the  
common-  
wealthShear  
walls

elective system and a basis for limited consent of the governed as the source of authority. The Compact for "the general good of ye Colonie" agreed that the "civill body politick" would abide by "just and equal laws." Nearly 170 years later, the framers of the United States Constitution adopted that theme.

Early  
struggle  
for  
survival

During that first winter the Pilgrims lived aboard ship and suffered the loss of 47 colonists. Probably they were victims of the same epidemic that was believed to have killed 95,000 Indians from 1615 to 1617, leaving only about 5,000 along the coast. The "Mayflower" returned to England in the spring, leaving a hardy band atop Cole's Hill, where they buried their dead and then planted seed to conceal their tragedy.

In March a tall, nearly naked Indian named Samoset confronted the haggard settlers with the peace cry in English, "Much welcome, Englishmen! Much welcome, Englishmen!" Both races had been weakened by the plague and needed one another. Their common efforts at survival gave rise after the autumn harvests to the feast of Thanksgiving, the first and since 1621 the most characteristic celebration of the peoples of the United States. Samoset, a Pemaquid from Maine, introduced his friend Massasoit, chief of the Wampanoags, and 20 braves. Among them was Squanto, once sold into slavery in Spain and later a resident at the home of an English gentleman, where he learned English. By a quirk of history, he became the interpreter, guide, and teacher of the first white settlers.

Settlers had feared Massachusetts for its hostile Indians, but, until 1675, relative peace prevailed because of a pact with Massasoit. This accord was ended by King Philip (Metacom), Massasoit's son. His open warfare (King Philip's War [1675-76]) ended in his own death, but only after 300 settlers had been killed, 600 dwellings levelled, and 50 towns raided in southeastern and central Massachusetts.

**Revolutionary period.** A new struggle against new obstacles was touched off 100 years later by "the shot heard 'round the world." The colonists' fight was not so much against the British Redcoats as it was for an ideal, and the struggle actually had begun several years earlier, when a new spirit grew out of years of physical sacrifice and radical ideas involving such concepts as equality, freedom, and unity.

Leadership  
in  
fomenting  
the  
Revolution

From a tragic moment of that period—the Boston Massacre of 1770, in which British soldiers killed five civilians after a snowball-throwing incident that got out of hand—came one of the finest moments in the annals of the American judicial system. John Adams, later to be president, and Josiah Quincy successfully defended the soldiers against the outcries of an enraged citizenry bent on retribution. Three years later, another (but unrelated) Adams, Samuel, led the raid known as the Boston Tea Party, dumping chests of taxable tea into the harbour, forcing the British to close the port of Boston, and striking a kindred nerve of resistance in other colonies. Events occurred in rapid-fire sequence after that—the battles of Lexington and Concord and Bunker Hill and the evacuation of Boston, inspiring song and verse that came to typify the spirit and events of the Revolutionary era.

**The state.** The state's contributions to the nation were many as it was being born, and they continued as it matured. It has contributed four presidents—John Adams, John Quincy Adams, Calvin Coolidge, and John F. Kennedy—as well as many cabinet officers, career officers, diplomats, and congressional leaders. It has supported most of America's wars but opposed others, such as the War of 1812, the Mexican War (1846-48), and the Vietnamese war.

The middle and late 19th century saw pronounced changes in the state, spurred by the factories spawned by the Industrial Revolution, a golden age of literature, and immigration, particularly by the Irish. The older, established classes remained dominant during this period, taking advantage of this new, cheap work force. A large segment of the rural population migrated westward, however, where the opportunities were greater and the discrimination less.

Grass roots agitation prompted legislation in 1820 that removed property requirements for voters, and in 1833 the church was separated from the state. This set the stage for the Jacksonian Democrats, who advocated giving more power to the people. The large immigrant voting bloc soon achieved this, mainly through the Democratic Party.

New England lost its textile leadership to the South and much of its shoe business to the Middle West in the first half of the 20th century, but it continued its financial, educational, and cultural prominence while branching into the fields of electronics and communications.

#### THE NATURAL AND HUMAN LANDSCAPE

**The natural environment.** A walk along the Massachusetts coast would register about 1,500 miles, yet the cross-country distances are only 190 miles from east to west and 110 miles north to south. The jagged coast winds from Rhode Island around Cape Cod, in and out of scenic harbours along the shore south of Boston, through Boston Harbor and up the North Shore, finally swinging around the painters' paradise of Cape Ann before reaching New Hampshire.

**Surface features.** The indented coasts of Massachusetts were formed by the great glaciers that in places covered the land with several thousand feet of ice. Ocean tides licked away the last ice some 11,000 years ago, revealing massive chunks of rocks along the shore. Hard, flat land stretches out beyond, becoming stony upland pastures near the central part of the state and bulging into a gently hilly country in the west. Except toward the west, the land is rocky, often sandy, and not fertile.

In the southeast, Cape Cod juts out into the ocean. This 65-mile-long appendage is rectangular in shape except at its easternmost point, where it hooks northward. Its offshore waters are among the most treacherous in the country. Henry David Thoreau wrote that, to the people of Provincetown, at the tip of the cape, the sea is their garden, and the dog that growls at their door is the Atlantic Ocean. Tufts of grass spring up along the sand dunes, and gnarled jack pines and scrub oaks, some only head high, grow in bunches. Off the southeastern coast lie the islands of Nantucket and Martha's Vineyard, lashed by the gray Atlantic in winter but in summer alive with thousands of tourists and longtime seasonal residents.

Cape Cod  
and the  
offshore  
islands

Central Massachusetts comprises rolling plains fed by innumerable streams. Beyond lies the broad and fertile Connecticut Valley and then the Berkshire Hills. The now-paved Mohawk Trail crosses the Berkshires, the Taconic Range on the west and the Hoosac Range on the east. The state's highest point, 3,491 feet (1,064 metres), is Mt. Greylock on the Taconic side near Adams. In North Adams a natural bridge of white marble has been formed by the wind and water, and at nearby Sutton is a half-mile-long gorge that knifes through the rock, exposing 600,000,000 years of geological history.

The land is veined with rivers—19 main systems, the best known of which are the Connecticut, Charles, and Merrimack. More than 1,200 ponds or lakes lie among the hollows of the hills, one in almost every one of the 365 communities. Many bear long Indian names, most notably Lake Chargoggagoggmauchuaggogggchaubungamaugg (which, translated, means "You fish on your side; I fish on my side; nobody fish in the middle"). The best known small body of water, however, is Walden Pond, immortalized by Thoreau.

Rivers  
and lakes

Nearly all the rivers and many lakes are now too polluted for swimming. This has long been true of the meandering Charles, which separates Boston and Cambridge and which now is favoured by college rowing crews, canoers, and sailboat enthusiasts.

**Vegetation and animal life.** Despite its industrialization, Massachusetts has managed to preserve many of its forests, and it has 108 state forests and reservations.

Not far from downtown Boston is the Arnold Arboretum, which has the largest collection of trees and shrubs in the United States. Along the shores the sandpiper, blue heron, American egret, sanderling, and turnstone are seen. Water birds include the gull, scoter, cormorant, and

loon, while those most often seen on land are the kingfisher, warbler, bobwhite, brown thrasher, sparrow hawk, yellow-shafted flicker, and whippoorwill. Game birds include ruffed grouse, wild turkey, and pheasant.

Public hunting grounds amount to about 23,000 acres. Three national wildlife refuges and Cape Cod National Seashore allow further contact with nature, but few animals remain. Of the larger animals, deer, snowshoe hare, red fox, woodchuck, muskrat, otter, and chipmunk still may be seen.

*Climate.* Statewide, a temperate climate prevails. The climate is colder but drier in western Massachusetts, although its winter snowfalls may be more severe than those nearer the coast. July and August are the hottest months, averaging about 70° F (21° C), in contrast to the 30° F (−1° C) average of winter.

*Patterns of settlement.* In the early days the most populated seacoast towns lay at the mouth of rivers. The settlers fanned inland along these streams, drawing on them at first for farming and later for the power to run the mills.

Today, the lure of the sea results in nearly equal popularity for all the towns along the coast, where sunbathing, swimming, yachting, and fishing are a way of life. Among these are Plymouth, with its long harbour; Duxbury, Marshfield, Scituate, and Cohasset, where the first suburbs sprang up in colonial days; the boating bays from Hingham to Boston; the beaches at Revere and Lynn; the famous fishing off Gloucester and Cape Ann; and Marblehead, the yachting capital of the world.

Boston is surrounded by communities many of whose residents work in the city by day, sleep in the suburbs by night, and clog the highways commuting back and forth. Other urban cores include Springfield, Worcester, Fall River–New Bedford, and Lowell–Lawrence. These cities, which grew large during the Industrial Revolution, continue to act as magnets to large numbers of people.

#### THE PEOPLE OF MASSACHUSETTS

*Ethnic composition.* Boston and San Francisco often are referred to as sister cities because of such similarities as busy oceanside ports, good restaurants, emphasis on culture, prominence of religion in civic and social life, fine architecture in public and private buildings, and echoes of a colourful history. Their ethnic mix is comparable as well. The blend of peoples in Boston has spread across the state. Although Boston is heavily Irish, so too are the urban areas in western Massachusetts, and the native brogue of Ireland is more likely to be heard around Springfield, Westfield, and Holyoke than in Boston. In the first half of the 20th century large numbers of Italians followed the Irish immigrations of the 1800s, while in the late 1960s and early 1970s the newcomers have been mostly Spanish speaking, from Cuba and Puerto Rico.

The English stock that still forms the backbone of the population is intermingled with Slovaks, Poles, Canadians, Russian Jews, Greek, Scandinavians, Syrians, Germans, French, and Chinese. Fall River and New Bedford are the homes of many Portuguese and Cape Verde Islanders. Descendants of the Indians are few, though the state was named by Capt. John Smith for the Massachusetts tribe, whose name meant “near the great hill,” believed to refer to the Blue Hill Range that rises south of Boston in an otherwise flat area. Blacks are concentrated mainly in the old and deteriorating Roxbury and Dorchester sections of Boston and in New Bedford and Springfield.

*Demographic trends.* Although the state’s population increased by about 10.5 percent from 1960 to 1970, Boston’s dipped by nearly 10 percent. Six cities had populations of 100,000 or more, while Suffolk and Middlesex counties, in and around Boston, held more than one-third of the population.

Better roads and environmental problems contributed to a growing tide of migrants away from the urban core after the early 1950s. The building of a wheellike pattern of highways with Boston at the centre started the first exodus. The second began in 1970 with the completion of

a new outer rim several miles from the first one. The accessibility of both highways drew many electronics and engineering firms to these areas, providing a new nucleus for suburban and exurban employment and living.

*Religious development.* Massachusetts is largely Roman Catholic, with over 2,700,000 adherents, though its religious foundation was solidly Protestant. The Mayflower colonists were Separatists who fled to Amsterdam from England to practice their religion without official interference. Hardship and a desire to establish an identity free of Dutch influence prompted them to seek out America in 1620. The Puritans, who came to Massachusetts in 1630, believed in reform but only within the church structure. (They were not believers in religious freedom, a fact that other Protestant groups, such as the Anabaptists and Quakers, soon discovered, to their discomfort.)

From this socioreligious framework evolved a theocracy in which government officials attempted to act as clergy, interpreting the will of God for the people. The arrangement fell short of its purpose. When in 1634 Gov. John Winthrop refused to call a meeting of the legislature, or General Court, the freemen demanded to see the charter. He acceded, divulging his infringement on the rights of the legislature, and a bill was quickly passed vesting governmental power in the people. The establishment religion was whittled at constantly by scores of radicals. Many of them were banished—including Roger Williams from Salem and Anne Hutchinson from Boston—for their independent views.

During its subsequent development, Massachusetts remained very religious. Following colonial patterns, churches often are found in the most prominent places of the towns and villages, symbolizing their traditional role in social life.

*Social hierarchies.* All the people of Massachusetts may be created equal, but some gained an edge earlier than others. The variety of peoples in the state, exceeded only by that of New York, fails to alter the fact that the major concentration of wealth and power continues to be controlled by the 800 or so families who trace their pedigrees to the “Mayflower” and the handful who in the following centuries so successfully trod the winding avenues of commerce, finance, and culture that they came to be considered among the ranks of that still relevant cadre, the Proper Bostonians. Many descendants of later immigrants also have found their way to the top of the financial—and often political—ladder. The proud tradition of family participation in the building of the state extends also to those of less exalted position: a large proportion of the residents of small-town Massachusetts, especially in the west, can claim many generations of Yankee background.

#### THE STATE’S ECONOMY

*Manufacturing.* Massachusetts has been a manufacturing state since the early 1640s, when John Winthrop, Jr. (son of Governor Winthrop), opened a saltworks in Beverly and ironworks in Saugus and Quincy. Francis Cabot Lowell was largely responsible, however, for raising the state to its manufacturing eminence, which now accounts for one-half of New England’s manufacturing income. Lowell went to England to study methods of textile operations and built a power loom in Waltham in 1814. He died in 1817, but his associates developed the brick city of Lowell, with its mills driven by the Merrimack River.

Yankee ingenuity fostered much early handicraft-based industry, though the influx of unskilled, low-paid labourers from Europe during the 19th century was the necessary ingredient for the mass production that developed in the state’s shoe and textile factories. One of the first and largest shoe plants in America was the United Shoe Machinery Corporation in Beverly, while the building of the Springfield armory in 1777 boosted industry in western Massachusetts at the same time that it aided the Revolutionary cause. Other well-known goods from Massachusetts factories include watches from Waltham, Salem, and Boston; rockers from Gardner; cutlery and hand

Religious separatists and other dissenters

The old families and the new

tools from Greenfield; guns and motorcycles from Springfield; leather goods from Peabody; shovels (used by the '49ers in the California Gold Rush) from North Eaton; envelopes from Worcester; paper from Holyoke; silverware from Newburyport; and razor blades from Boston.

Today, the electronics and communications industries draw heavily upon the many educational institutions in and around Boston. The western suburbs of Boston have become world famous for their research-and-development facilities, which contributed significantly to space technology in the 1960s.

*The sea and the soil.* Foreign trade, fishing, and agriculture long buoyed the economy. Salem sailors brought exotic goods from China, the West Indies, and other faraway lands. Fishing was lucrative, adventuresome, and dangerous—more than 10,000 Gloucester fishermen have lost their lives over the centuries. Fishing and shipbuilding went hand in hand. Between 1789 and 1810 the Massachusetts fleet grew tenfold, some of it to aid in defense against British and French aggressions on the high seas. Yankee sailors also found much “black gold” in the slave trade between West Africa and Southern ports.

At the height of the whaling boom in the 19th century, 329 whaling vessels sailed from New Bedford, in addition to others from Nantucket and other ports, bringing in \$10,000,000 worth of cargo each year in their holds. This great industry was not to last, however, and, by the turn of the century, its contribution to the state's economy had dwindled to only a fraction of its former importance. Fishing later suffered substantial reverses, as well. A \$42,000,000 annual business in the early 1960s, fishing began to wane, late in the decade, because of foreign competition in the traditional Atlantic fishing grounds and the depletion of such species as haddock and lobster from overfishing.

The generally rocky soils support only truck gardening, although the purple sandy bogs of southeastern Massachusetts and Cape Cod produce about 60 percent of the world—and 70 percent of the U.S.—cranberry supply. Poultry accounts for about one-third of the agricultural income.

*Finance.* Since colonial days, Boston has been a financial centre. Its investments contributed heavily to developing the American West, while the shipping industry made it the first insurance capital of the nation.

*Tourism.* Tourists know Massachusetts for the haddock, cod, and shellfish of its restaurants, as well as for its rich heritage of American history. The state has some 8,500,000 visitors annually, who pump well over \$1,000,000,000 into its economy.

*Transportation.* “Never, in these United States, has the brain of man conceived, or the hand of man fashioned, so perfect a thing as the clipper ship,” wrote historian Samuel Eliot Morison in *Maritime History of Massachusetts*. All clipper ships were built between 1850 and 1855, and from then on a kind of World Series of ship racing began. The champion was Donald McKay's “Flying Cloud,” which sailed to San Francisco in 89 days, went 374 miles in one day, and averaged 13.5 knots (nautical miles per hour) an hour over four days. Records were not the only motivating factor: the clippers carried 1,700 tons of cargo. Long before this, however, in 1716, Boston Light had been built off the busy port, the first lighthouse in the United States.

Water formed the Bay State's highway system for 200 years. Rivers such as the Connecticut and Merrimack and man-made canals such as the Middlesex served early needs well. The Boston Post Road and Mohawk Trail were the most heavily travelled early roadways. Opened to Boston–New York mail in 1673, the Post Road consisted of three routes. The Mohawk, an Indian footpath converted to an ox road by the settlers, became the first interstate toll-free road, called Shunpike, in 1786.

In 1826, the nation's first railroad brought granite from the quarries of Quincy and Charlestown for the building of the Bunker Hill Monument in Charlestown. The cars were horse drawn. A steam railroad connected Springfield and Worcester in 1839, and 15 systems were shut-

ting freight among western Massachusetts cities by 1855. Among the most impressive feats of early railroad building was the 4½-mile Hoosac Tunnel, drilled under the Hoosac Range between 1851 and 1875. The first electric street railway began in Brockton, and Boston had America's first passenger subway, as well as an elevated system.

Boston's Logan International Airport, stretching parallel to the harbour, is one of the few large air terminals in close proximity to a major city. It also is the nation's only airport owned and operated by the state. In spite of the general modernity of the state's transportation system, however, the sleek high-speed trains and the supersonic jets have yet to match the aesthetic perfection of the Yankee clipper.

#### ADMINISTRATION AND SOCIAL CONDITIONS

*Government. Traditions of self-government.* From the Mayflower Compact, drawn up by the Pilgrims in 1620 when the concept of “the divine right of kings” dominated Europe and the idea of self-government was little more than an exotic notion, a form of government evolved of which the people could feel themselves a part. In 1630, when the Puritans of the Massachusetts Bay Company settled Boston and other surrounding towns, John Winthrop and 18 assistants formed the governing body known as the Great and General Court. In a dispute over a stray pig, the Court became bicameral in 1644, the assistants forming the Senate and two deputies elected from each town making up the House.

After independence was declared, the General Court drew up a state constitution. The people rejected it, however, wanting a share in the drafting, and they elected a constitutional convention. Meeting in Cambridge in 1779, it gave the writing task to John Adams, and the people ratified his work in 1780. One of its extraordinary provisions permits the governor and his council or the legislature to seek advisory opinions on questions pertaining to the scope of gubernatorial or legislative power from justices of the Supreme Judicial Court. Today, Massachusetts is the only one of the 13 original states still governed under its first constitution, though the document has been updated many times by amendment.

The first meeting of the General Court as the legislative body of the new state took place in October 1780, exactly 150 years after the first meeting of the Puritans' Great and General Court. At present it comprises 40 senators and 240 representatives, but in the 1960s political battles began over whether the House was too unwieldy in size for efficient action. The state's judiciary mainly divides into the district courts for handling minor matters, superior courts for trial by jury, and the Supreme Judicial Court.

*Local government.* Another phenomenon that grew up shortly after the settlers arrived was the town meeting, which started as a forum for settling local quarrels and grew to what is in many smaller towns the community event of the year. (As the poet James Russell Lowell observed, “Puritanism, believing itself quick with the seed of religious liberty, laid without knowing it, the egg of democracy.”) The first recorded meeting was in Dorchester in 1633, when citizens were summoned by the roll of a drum. A year later Charlestown organized the first Board of Selectmen, the emergence of such local government balancing the power of the colony's executive. A county system also was developed patterned after the English model, in which the greater powers reside in townships and cities rather than in the counties, which serve chiefly for judicial purposes. A major need of Massachusetts in the 1970s was in the redefinition of the roles of municipal, county, and state governments.

*Political life.* The legislature tends to be dominated by Democrats, but it is not surprising for Republicans to win the governorship or seats in the U.S. Congress. The Boston Irish politician has become legendary, mostly because of Mayor James Michael Curley, a skillful orator from a lowly background who was jailed twice, once while in office. During the late 19th and early 20th centuries, politics became a means to a better life—to a place alongside the “Boston Brahmins” of Mayflower heritage—for the

The golden age of Yankee seafarers

Waterways and highways in the past

Irish, who were discriminated against in employment advertisements that carried the letters "N.I.N.A."—No Irish Need Apply.

**The social milieu.** Discrimination was practiced from time to time in Massachusetts against such groups as the Indians, religious sects, and women, but the state also provided leaders in major fights to improve social conditions: Roger Williams and Anne Hutchinson for religious freedom; William Lloyd Garrison and Horace Greeley for the abolition of slavery; Horace Mann for public secondary education; Mary Lyon for women's education; and Francis Cabot Lowell, whose brick housing near his factories, though grim by today's standards, was better than the workers' ghettos he had seen in England.

Women and children were exploited at the start of the Industrial Revolution, but Massachusetts was a pioneer in devising laws to protect them. State boards, under the supervision of the governor, later grew out of the need to improve conditions in health, education, welfare, labour, banking, insurance, prisons, and the like.

**Health and welfare.** Massachusetts is one of the chief medical centres of the world, particularly in the area of specialists and specialty hospitals. It also has been a leader in research, notably at Boston's Children's Cancer Research Foundation. An urgent contemporary challenge is the delivery of medical services to the poor, who have been victimized by urbanization and the gradual disappearance of the family physician. Care for the mentally ill, the alcoholic, the addict, and the juvenile delinquent remain problems, even though the state recognized its responsibility as early as 1818, when it opened an asylum for the insane.

Welfare was the province of the cities and towns until taken over by the state in 1970. Although the new program was fraught with difficulty, it was an improvement over the system that existed in the mid-19th century, when 3,000 citizens were imprisoned annually for indebtedness.

**Social tensions.** Except among the intellectual elite, little concern was shown for the Negroes before 1850 for fear of alienating Southern cotton producers. Boston had a separate school for blacks, but otherwise they were denied schooling. The Know-Nothing Party emerged in 1845 primarily to combat growing Irish immigration but also to fight slavery, which the party considered an outgrowth of indifference by the rich toward human rights.

In the 1960s the urban areas experienced racial unrest similar to that throughout the country. Little had been resolved by the early 1970s, but the blacks were making some advances through political and economic means. Bussing of school children was more of a dilemma in Massachusetts cities than in the South during the 1960s and 1970s. The blacks had little encouragement, however, to "pull themselves up by their bootstraps"—as they were constantly reminded that the Irish and Italians did.

The Yankees, meanwhile, continue to run most of the banks, most of the law firms, and many of the businesses. They still represent the rock-ribbed solidarity in the state, built up through generations and epitomized by their contributions to the entire nation.

**Education.** Close to the heart of Massachusetts' social and cultural life lies education. Harvard College (now Harvard University), founded in 1636 in New Towne (now Cambridge), was long the major factor, although it was designed originally to provide the wilderness colony with a continuing supply of trained clergy rather than an educated lay population. Its graduates became community leaders, and schooling soon was provided colony-wide. In 1647, towns with 50 householders were required to support an elementary school; those with 100, a secondary school.

Massachusetts became the pioneer as well in kindergarten and secondary education and developed a uniform state public-school system in 1840. The state has numerous private preparatory schools of national ranking. Roxbury Latin School, founded in 1645, is among the nation's oldest, while others are located in Andover, Groton, Milton, Mount Hermon and Northfield, and Deerfield.

Many of America's oldest and most prestigious institutions of higher learning, in addition to Harvard, are in Massachusetts. Some 300,000 students were in its public and private institutions in 1971, about 160,000 in Boston alone, where Boston University (1839) and Northeastern University (1898) were the largest. Nearby were the Massachusetts Institute of Technology (Cambridge; 1861) and Tufts (Medford; 1852) and Brandeis (Waltham; 1948) universities. Amherst (Amherst; 1821) and Williams (Williamstown; 1791) colleges perpetuated traditions of academic excellence at small schools, while Mount Holyoke (South Hadley; 1837), Wellesley (Wellesley; 1870), Smith (Northampton; 1871), and Radcliffe (Cambridge; 1879) colleges were pioneers in women's education. Boston College (Chestnut Hill; 1863) and Holy Cross (Worcester; 1843) are major Roman Catholic institutions. The University of Massachusetts (Amherst and Boston; 1863) has raised its academic standing significantly in recent decades.

#### CULTURAL LIFE AND INSTITUTIONS

The blending of an Old World heritage and a New World spirit produced a bountiful cultural environment in Massachusetts.

**The arts.** Literature was virtually lost in the leaden language of the early writings and sermons, though poets such as Anne Bradstreet and Edward Taylor rose well above the level of dogmatizing, and Jonathan Edwards combined taut language and a brilliant theological mind with an unemotional pulpit delivery. During what has been called the American renaissance, however, beginning around the time of the Revolution and lasting through much of the 19th century, the state nourished many writers who might be said to have founded the bases of American literature—and who brought it recognition outside the new nation.

The group of writers who brought fame to Concord are an indication of the inspiration of this period. A deep sense of both community responsibility and individualism may be traced through the writings of Ralph Waldo Emerson, Henry David Thoreau, Nathaniel Hawthorne, and Louisa May Alcott, all of whom were neighbours. The eloquence of Emerson, preacher, philosopher, and poet, carried his concepts of individual spiritual freedom to faraway lands while Hawthorne found tranquillity in the small town after growing up in the shadows of Salem witches near the House of Seven Gables.

The mountains of Pittsfield also provided a congenial working environment for Hawthorne as well as for Herman Melville, Oliver Wendell Holmes, and Henry Wadsworth Longfellow (the latter two combining, respectively, medicine and scholarship with their writings). Among other famous writers of the era were John Greenleaf Whittier and James Russell Lowell, as well as Emily Dickinson, today generally acclaimed as the finest American poet of the 19th century.

The universities have become central to many of the performing arts (theatre, dance, and music) in Massachusetts, although the Boston Symphony Orchestra generally is regarded as among the finest musical ensembles in the world. Its Tanglewood concerts under the stars at Lenox in the Berkshires (begun in 1937) are, with the Jacob's Pillow Dance Festival at nearby Lee, among the major attractions of the New England summer. The museums, libraries, and historical societies of Boston are among the most distinguished in the nation. These and other cultural aspects of that city are covered in greater detail in the article BOSTON.

**Monuments to history.** Historical sites in Boston draw the most tourists. A Freedom Trail provides a whirl through yesteryear that includes Boston Common, the old and new (1795) state houses, Park Street Church, the Old Granary Burying Ground, Old Corner Bookstore, Faneuil Hall, Paul Revere House, the Old North Church, and the *uss* "Constitution," better known as "Old Ironsides."

Outside the capital, the past seems still alive in three villages: Plimoth Plantation, Old Sturbridge Village, and Shaker Village in Hancock, where the sect established its

Leaders of social consciousness

Place in American arts and letters

Educational pioneering

communal-church concept in the 1780s. Harvard Square in Cambridge is a favourite tourist stop for its potpourri of people, its proximity to Harvard and Massachusetts Institute of Technology, and the history imbedded in the cobblestone atmosphere along its narrow side streets: the Harvard Yard, Christ Church, the Fogg Art Museum, Longfellow House (one of seven making up Tory Row), and innumerable other attractions of the city.

Salem prefers to forget its witch-hunting period of the late 17th century, but visitors to the House of Seven Gables and other "haunted houses" keep the memories alive. In the elm-shrouded Chestnut Street area are Federal-style homes that reflect the days of prosperity for merchants, shipowners, diplomats, congressmen, and writers.

Along the South Shore are Quincy, where the humble homes of the eminent Adams family are next door to one another, and Hingham, where the Old Ship Church is the oldest surviving church in the 13 colonies. The Whaling Museum in New Bedford includes a half-size reproduction of a whaling vessel and some 600 log books, and the Seamen's Bethel (chapel) there was immortalized by Melville in *Moby Dick*.

Westward of Boston lies Concord and its Old Manse, home of the Emersons' grandfather and for four years, of the Hawthornes.

Historic  
western  
Massachu-  
setts

Past the Old Mill and Longfellow's Wayside Inn in Sudbury are Worcester and then Springfield, where the armoury and arsenal are reminders of the city's famous rifle. In nearby Pelham, the Town Hall complex has the oldest continuously used meeting house in the country and a monument to Capt. Daniel Shays, who led a rebellion of poor farmers in 1786. Chesterwood in Stockbridge was the site of the studio of Daniel Chester French, sculptor of the great seated Lincoln statue in Washington's Lincoln Memorial. Some of the doors of houses in Old Deerfield bear the marks of Indian tomahawks wielded during the raids of the early 18th century.

**Recreation.** Private clubs, both social and athletic, long have been Massachusetts institutions, especially for golf, tennis, and yachting. Among the most exclusive were the Brookline Country Club and the Longwood Cricket Club in Brookline, the Myopia Hunt Club in Hamilton, and various yacht clubs along the North Shore above Boston, particularly in Marblehead.

Athletics have come in recent decades to form a subculture among all social classes. The professional teams—Boston's Red Sox in baseball, Bruins in hockey, and Celtics in basketball and the Foxboro-based New England Patriots in football—attract the most attention, but the state gives considerable emphasis to high school and college activity as well.

**The communications media.** Boston's Freedom Trail passes the now-defunct Newspaper Row, where before World War II seven newspapers competed daily. The survivors in the early 1970s were the *Boston Globe* and *Boston Herald Traveler* and *Record American*. The *Springfield Republican* under Samuel Bowles was one of America's prominent papers during the 19th century, along with the *Worcester Telegram-Gazette*, a pioneer in modern printing technology. Both are still in operation. Among the broadcast media that blanket the state, educational television station WGBH in Boston achieved a wide reputation for its innovative programming.

#### PROBLEMS AND PROSPECTS

To many persons Massachusetts faces the future with a need for regeneration in many areas of its public life. Its forefathers set a straight course that resulted in prosperity and freedom, while Yankee ingenuity helped hurdle the rough places in the road. Now their ideals of freedom and equality are in practice, and the challenge that faces the beneficiaries of this groundwork is whether they can cope with the luxury bequeathed them. The physical revitalization of Boston continues, but cutbacks in federal programs hurt the defense-oriented electronics and research industries. Governmental leaders must continue to reform the political mechanisms while continuing to conform with the inspired direction of John Adams' Constitution.

**BIBLIOGRAPHY.** The history of Massachusetts runs back into the history of England, and the early literature is massive. Both WILLIAM BRADFORD and JOHN WINTHROP, early colonial governors, wrote journals. The early divines were prolific. The Adams family has been called "the writingest family" in American history, and their papers make up over 80 volumes without touching the 20th century. For a study of the Puritan mind, the works of FERRY MILLER are most authoritative. The intellectual history from the Puritan fathers through the Transcendentalists is thoroughly documented. Modern political history is less well covered, but it has become increasingly subject to scholarly scrutiny. A history of Harvard University is central to an understanding of the commonwealth. The following merely touches the surface of a vast literature.

*General reading:* FEDERAL WRITERS' PROJECT, *Massachusetts: A Guide to Its Places and People*, new ed. (1971); VAN WYCK BROOKS, *The Flowering of New England, 1815-1865* (1936) and *New England: Indian Summer, 1865-1915* (1940); CLEVELAND AMORY, *The Proper Bostonians* (1947).

*History:* A.B. HART (ed.), *Commonwealth History of Massachusetts: Colony, Province and State*, 5 vol. (1927-30); CHARLES M. ANDREWS, *The Fathers of New England: A Chronicle of the Puritan Commonwealths* (1920) and *The Colonial Period of American History*, 4 vol. (1934-38); SAMUEL ELIOT MORISON and HENRY STEELE COMMAGER, *The Growth of the American Republic*, 4th ed. rev. (1950); SAMUEL ELIOT MORISON, *The Maritime History of Massachusetts, 1783-1860* (1921) and *Builders of the Bay Colony* (1930); OSCAR HANDLIN, *Boston's Immigrants, 1790-1880*, rev. ed. (1959). Periodicals include *Proceedings and Collections* of the Massachusetts Historical Society, Boston; the *Proceedings* of the American Antiquarian Society, Worcester; publications of the Essex Institute, Salem; publications of the Colonial Society of Massachusetts; and the *New England Quarterly*.

*Physical description:* B.K. EMERSON, *Geology of Massachusetts and Rhode Island* (1917); HENRY F. HOWE, *Salt Rivers of the Massachusetts Shore* (1951); WALTER MUIR WHITEHILL, *Boston: A Topographical History* (1959); ARTHUR B. TOURTELLOT, *The Charles* (1941); WALTER R. HARD, *The Connecticut* (1947).

*Government and politics:* OSCAR and MARY F. HANDLIN, *Commonwealth: A Study of the Role of Government in the American Economy: Massachusetts, 1774-1861* (1947); L.A. FROTHINGHAM, *A Brief History of the Constitution and Government of Massachusetts* (1925).

(J.S.D.)

## Mass Production

The term mass production refers to methods of organizing manufacturing processes so as to attain high rates of output at decreasing unit cost. Mass-production methods are based on two general principles: (1) division and specialization of human labour, and (2) the use of tools and machines in the production of standard, interchangeable parts. The term automation defines a mass production technique in which certain operations are carried on automatically under the direction of programmed controls. The following article treats mass production from the technological point of view; for a treatment in terms of economic theory, see PRODUCTION, THEORY OF.

**Historical survey.** The principle of the division of labour and the specialization of skills that results from its application can be found in many human activities, and there are records of its application to manufacturing in ancient Greece. The first unmistakable examples of manufacturing operations carefully designed to reduce production costs by specialized labour and the use of machines appeared in the 18th century. The French Academy of Sciences' classic work entitled "The Description of Arts and Crafts" described the manufacture of pins in 1762 and clearly illustrated the careful division of labour and the use of specialized tools to reduce production costs. In *The Wealth of Nations* (1776), Adam Smith also used pin manufacture to exemplify improvements in human productivity by the application of mass-production techniques. In 1832 Charles Babbage published "On the Economy of Machinery and Manufactures" emphasizing the economy and excellence that can be obtained by the proper planning and division of labour in producing goods.

Another major advance was made in 1798 when Eli Whitney, inventor of the cotton gin, proposed the manu-

Inter-changeable parts

facture of flintlocks with completely interchangeable parts in contrast to the older method under which each gun was the individual product of a highly skilled gunsmith, and each part was hand-fitted. Whitney obtained a contract to produce 10,000 guns; in what was perhaps one of the first examples of planned tooling for manufacture, he used standard patterns for parts, specially designed guides for tools, and jigs for holding materials during fabrication. The resulting production equipment could be run by relatively unskilled boys instead of the highly skilled gunsmiths normally required.

During the same period similar ideas were being tried out in Europe. In England, Marc Brunel, French-born inventor and engineer, established a production line to manufacture pulley blocks for sailing ships, using the principles of division of labour and standardized parts. Brunel's machine tools were designed and built by Henry Maudsley, who has been called the father of the machine-tool industry. Maudsley recognized the importance of precision tools that could produce identical parts; he and his student, Joseph Whitworth, also manufactured interchangeable, standardized metal bolts and nuts.

By the middle of the 19th century the general concepts of division of labour, machine-assisted manufacture, and assembly of standardized parts were well established. In 1881 at the Midvale Steel Company in the United States, Frederick W. Taylor began studies of the organization of manufacturing operations that subsequently were to form the foundation of modern production planning. By making detailed stop-watch measurements of the time required to perform each step of manufacture, Taylor brought a quantitative approach to the organization of production and created the "scientific management" of production functions.

At the same time, Frank B. Gilbreth and his wife, Lillian M. Gilbreth, U.S. industrial engineers, began their pioneering studies of the movements by which people carry out tasks. Using the new technology of motion pictures, the Gilbreths analyzed the design of motion patterns and work areas with a view to achieving maximum economy of effort. The "time and motion" studies of Taylor and the Gilbreths provided important tools for design of modern mass-production lines.

Much of the credit for bringing these early concepts together in a coherent form, and creating the modern, integrated mass-production operation, belongs to the U.S. industrialist Henry Ford and his colleagues at the Ford Motor Company, where in 1913 a moving-belt conveyor was used in the assembly of flywheel magnetos. With it assembly time was cut from 18 minutes per magneto to five minutes. The approach was then applied to automobile body and motor assembly. The design of these production lines was highly analytical and sought the optimum division of tasks among work stations, optimum line speed, work height, and careful synchronization of simultaneous operations.

The success of Ford's operation led to the adoption of mass production principles by industry in the U.S. and Europe. The methods made major contributions to the large growth in manufacturing productivity that has characterized the 20th century, and produced phenomenal increases in material wealth and improvements in living standards in the industrialized countries.

#### GENERAL PRINCIPLES

**Basic considerations.** The efficiencies of mass production result from the following basic considerations:

1. The careful division of the total production operation into specialized tasks comprised of relatively simple, highly repetitive motion patterns and a minimum handling or positioning of the work piece. This permits the development of human motion patterns that are easily learned and rapidly performed with a minimum of unnecessary motion or mental readjustment.

2. The simplification and standardization of component parts to permit large production runs of parts which are readily fitted to other parts without adjustment. The imposition of other standards (*e.g.*, screw dimensions and locations, material types, stock thickness, etc.) on all

parts further increases the economies that can be achieved.

3. The development and use of specialized machines, materials, and processes. The selection of materials and development of tools and machines for each operation minimizes the amount of human effort required, maximizes the output per unit of capital investment, and reduces raw material costs.

4. The systematic engineering and planning of the total production process permit the best balance between human effort and machinery, the most effective division of labour and specialization of skills, and the total integration of the production system to optimize productivity and minimize costs.

Careful skilled production engineering is required to achieve the maximum benefits that application of these principles can provide. Planning begins with the original design of the product; component parts must be adaptable to production and assembly by mass techniques. The entire production process is planned in detail, including the flow of material and subassemblies through the line. Production volume must be carefully estimated because the selection of techniques will depend upon the volume to be produced and anticipated short-term changes in demand. Volume must be large enough first, to permit the task to be divided into its subelements and assigned to different individuals; second, to justify the substantial capital investment often required for specialized machines and processes; and third, to permit large production runs so that human effort and capital will be efficiently employed.

The need for detailed advance planning extends beyond the production line itself. The large, continuous flow of product from the factory requires equally well-planned distribution and marketing operations to bring the product to the final consumer. Advertising, market research, transportation problems, licensing, and tariffs must all be considered in establishing a mass-production operation. Thus, mass-production planning implies a complete system plan from raw material to consumer.

**Continuous and batch production.** There are two basic types of mass-production facilities, continuous and batch. On a continuous production line, components and subassemblies pass by steps through a series of operations and emerge at the end of the line as a completed product. The automobile final assembly line is an example.

In a batch process a given quantity is moved as a batch through one or more process steps and the total volume emerges simultaneously at the end of the production cycle. Batch processing is widely used in the chemical industry.

Many mass-production operations combine continuous and batch processes. In semiconductor integrated-circuit production, for example, many thousands of circuits are batch processed together on several slices of silicon single crystal through more than a hundred different process steps. The circuits, each a fraction of an inch (a few mm) on a side, are then separated and individually assembled with other circuit elements on a continuous line to produce a final product.

**Other considerations.** In addition to lowering cost, the application of the principles of mass production has led to major improvements in uniformity and quality. The large volume, standardized design, and standardized materials and processes, facilitate statistical control and inspection techniques to monitor production and control quality. This leads to a reliable assurance that quality levels are achieved without incurring the large costs that would be necessary if detailed inspection of all products was required.

Mass-production techniques are not very flexible, however. Since maximum efficiency is desired, tools, machines, and work positions are often quite precisely adapted to details of the parts produced. Changes in product design may thus render expensive tooling and machinery obsolete. One answer has been to design machinery with flexibility built in; for relatively little extra cost, tooling can be changed to adapt the machine to accommodate design changes.

Similarly, a production line is usually designed to oper-

ate most efficiently at a specified rate (Figure 1). If the required production levels fall below that rate, operators and machines are being inefficiently used; and if the rate

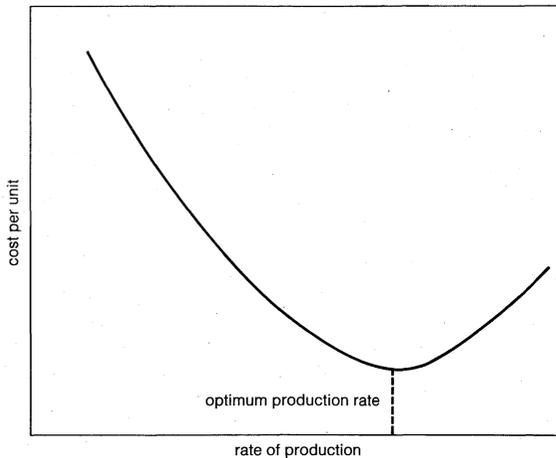

Figure 1: Curve showing relationship of unit cost to production rate.

goes too high operators must work overtime, machine maintenance cannot keep up, breakdowns occur, and the costs of production rise. Thus, it is extremely important to anticipate production demands accurately. Planning can alleviate the problems of increased demand by incorporating some excess capacity in the facilities that would require the longest time to procure and install. Then, if production loads increase, it will be easier to bring the entire line up to the new level. Similarly, if large fluctuations in demand cannot be avoided, flexibility to accommodate these changes economically must be planned into the system.

The functional relationship pictured in Figure 1 applies broadly to the economies of scale associated with mass production as a whole. At any given stage of technological development, the economies obtained by increasing production volume are largest in the initial stages of growth and level off as volumes are further increased. Indeed, if volumes grow too large, unavoidable breakdowns of facilities, failures of coordination, or other strategic factors may cause costs to rise. Advances in technology or changes in other factors can shift the optimum point to higher volume levels. For these reasons planners limit the maximum size of a single production facility and construct an independent facility if greater production is necessary.

#### PLANNING FOR MASS PRODUCTION

**Design.** Planning begins with the concept of the product and the assessment of its market. Market estimates establish the volume levels that must be initially produced, the anticipated growth of the market, and periodic changes in expected demand. Design must reflect a proper balance between the product's functional and production aspects. In the marketplace the customer is principally interested in function and appearance. Changes in detailed design may greatly simplify manufacture without affecting function or appearance. Internal parts may be shaped for easier handling during assembly. The kinds of materials readily available at low cost, and the processes available by which these can appropriately be fabricated, must also be considered during the product-design phase. The closest interaction between the product designer and manufacturing engineer from the earliest stages of design are critical in achieving a marketable product at lowest cost.

**Manufacturing sequence.** As the details of product design become firm, a manufacturing sequence is established. Materials are selected. Fabrication processes are chosen. Planners determine which production steps will be manual and which will be mechanized or automated (see AUTOMATION). A general layout for the production line is established on the factory floor. The manner in

which material will flow through the production line is of particular importance; decisions are made between the manual transport of materials and assemblies between some production points and the mechanized or conveyORIZED handling of materials and parts in other areas (see MATERIALS HANDLING). Planners decide at which points in the production process control by measurement and inspection are to be required.

A critical aspect of planning is the design of information flows that insure coordination of various elements of the line, and assure that necessary materials and facilities will be available when needed. Increasingly, the information flows are provided by production control systems using electronic computers to keep track of materials and parts and plan future operations.

As the manufacturing sequence begins to take final form, detailed studies are made of each manual and machine operation. Manual operations are studied in minute detail in order to determine the most efficient operator position, the best design of tools and jigs, and the most effective motion patterns with which to perform the operation. The number of operators and their skill levels are defined, and the means by which parts and subassemblies are brought to, and carried from, each operator are determined.

For the mechanized operations, a detailed study is made of each machine and machine motion. This includes machines used in fabrication, in testing, and in material-transport systems. Frequently, prototypes of new machines are built and tested under simulated production conditions. The results of this testing are used to perfect the final production machinery. Machinery maintenance requirements and schedules are also determined.

The detailed integration of the various production-line components proceeds simultaneously with the specialized studies of the various operations. The rate of output of each manual and mechanized position is carefully measured; the number of positions for each operation is determined in order that the total line will be well balanced. Without this detailed line balancing, partially assembled products might accumulate at bottleneck positions so that the faster portions of the line will have to reduce speed or shut down until the slower portions are able to catch up.

**Training personnel.** In parallel with this planning, anticipated human-resource requirements are translated into recruiting and training programs so that a nucleus of appropriately skilled operators will be available as the machinery is installed. Specialized groups are established with responsibility for support activities such as equipment maintenance, plant services, production scheduling, and control operations, etc. Proper personnel planning is critical in assuring that expensive capital equipment will not stand idle and that early operations will not be wasteful of effort, time, and materials.

If the production line is especially complex or the production processes are new and untried, it is probable that a "pilot line" will be established to determine whether the procedures will function satisfactorily and as planned. The pilot line may be a scaled-down version of the total production process or of those portions of the process about which the greatest uncertainty may exist. Experience gained from pilot-line operation can be invaluable in assuring success of the full scale operation. Often, further changes in product design are made during this period to improve ease of manufacture. In addition, the pilot-line operations provide an opportunity to train a nucleus of operators and managers for the full-scale production line.

When planning and facilities are complete, and trained operators are ready, production may begin. Normally, the line starts up slowly with all operations working well below their planned capacities. Engineering designers constantly observe how their plans are functioning and make changes as required. As experience is gained, processes are speeded up until planned output levels have been achieved. Even a manufacturing line that has operated successfully for a considerable period requires continuing engineering attention to improve processes, layouts, and material flow and to search for cost-reduction

Information flows

and quality-improvement opportunities. When operators on the line find ways to improve their efficiency, these are incorporated in normal operating procedures. All of the learning processes that take place continuously on both the engineering and operating levels are major components of the continual improvements in productivity typical of well-run mass-production operations.

**Manufacturing progress function.** Because of the enormous complexity of a typical mass-production line and the almost infinite number of changes that can be made and alternatives that can be pursued, a body of quantitative theory of mass-production manufacturing systems has not yet been developed. The volume of available observational data is, however, growing, and qualitative facts are emerging that may eventually serve as a basis for quantitative theory. An example is the "manufacturing progress function." This was first recognized in the airframe industry. Early manufacturers of aircraft observed that as they produced increasing numbers of a given model of airplane, their manufacturing costs decreased in a predictable fashion. As shown in Figure 2, if the logarithm of the cost per unit is plotted as a function of the logarithm of the total number of units produced, the resulting data points almost form a straight line. Over the years similar relationships have been found for many products manufactured by mass-production techniques. The slope of the straight line varies from product to product. For a given class of products and a given type of production technology, however, the slope appears remarkably constant.

Manufacturing progress functions can be of great value to the manufacturer. It is a consequence of the mathematical relationship portrayed in Figure 2 that the cost of a unit decreases by a constant percentage every time the cumulative volume of production is doubled. The actual percentage depends on the slope of the line. (Figure 2 is a

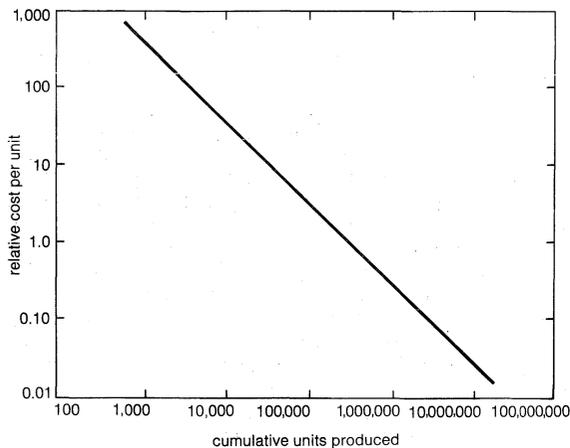

Figure 2: Manufacturing progress function relating cost per unit produced to number of units.

25 percent progress function; *i.e.*, the cost per unit decreases by 25 percent when the cumulative volume of production has doubled.) Thus the progress function can serve as a useful tool in estimating future costs. Furthermore, the failure of costs to follow a well-established progress function may be a sign that more attention should be given to the operation in order to bring its cost performance in line with expectation.

Though manufacturing progress functions are sometimes called "learning curves," they reflect much more than the improved training of the manufacturing operators. Indeed, although improved operator skill is important in the early start up of production, the major portion of the long-term cost improvement is contributed by improvements in product design, in machinery, and in the overall engineering planning of the production sequence.

In the early 1970s the manufacturing progress function was still an empirical tool. It is dangerous to place too much reliance on such a tool until there is a better basis for understanding the complex processes that give rise to this simple relationship. There exists, however, a substan-

tial incentive to develop a quantitative body of manufacturing theory that would permit more certain optimization of manufacturing systems.

#### EXAMPLES OF MASS PRODUCTION

**Automobile industry.** The traditional example of mass production is the automobile industry, which has continued to refine the basic principles originally laid down by Henry Ford. By the early 1970s automotive assembly lines differed considerably from early ones.

Today's automobile is the result of a large number of mass-production lines established in a multitude of factories. The assembly plant from which the finished automobile emerges is only the final element of a geographically distributed mass-production operation. Into the final assembly plant flow large subassemblies such as the automobile chassis, the engine, major body components such as doors, panels, upholstered seats, and many electrical and hydraulic accessories such as brakes, lighting systems, radios, etc. Each of these, in turn, is usually the product of a mass-production line in another factory. Stamping plants specialize in producing the formed metal parts that constitute the body of the automobile. Radio assembly plants, in turn, depend upon other assembly plants for components such as transistors. There are glass plants for windows, transmission plants, tire plants, and many others, each specializing in the mass production of their own product, which will, in turn, feed the final assembly plant. The control of the flow of material into and out of final assembly plants, including the scheduling of production from feeder plants and the timing of rail and truck shipments, are among the major engineering tasks that make the total mass-production system for automobiles work.

In the final assembly line one can see clearly how human effort in assembly is divided among many specialized skills. The special tooling and machinery developed to handle assembly parts and to aid operators in their tasks can also be observed. At a given point on the line an operator may specialize in mounting seats. At another position the motor is mounted on the chassis. In other places body panels and doors are assembled to the chassis, dashboard instruments and wiring are added. Each operator learns his task in detail and uses tools specialized for that task. The total operation is paced by the speed of movement of the conveyor that carries the partially assembled automobiles. The number of operators, machine stations, and the flow of materials to the conveyor have all been planned so that the conveyor can maintain an essentially constant speed with each operator and machine functioning near optimum effectiveness.

In Ford's early lines, parts and product were precisely standardized. Only one car model was manufactured, and each unit was identical to every other unit in all aspects, including colour—black. Today's automotive manufacturing engineers have learned to mass produce a highly customized product. The same assembly line may turn out a variety of models with all kinds of colours and options. This is achieved by continued insistence on standardization of critical elements such as the methods by which parts are held together internally. Thus, the operator who specializes in assembling doors can handle a variety of models and colours equally well. In addition, the flow of materials to the various line positions is carefully scheduled and controlled so that the specific part required for a given model, colour, or option list arrives at the line at the moment that the partially assembled unit requiring the part has arrived along the conveyor. The exquisitely designed production-control systems operating in the automotive and other industries make it possible for the consumer to obtain a greatly enhanced variety of product without sacrificing the cost advantages of mass-production techniques.

**Telephone industry.** Similar benefits have been realized in producing smaller and less expensive items. The telephone set is an example of a relatively inexpensive product that is available in a wide variety of models and colours and whose production has been carefully engineered to achieve the optimum of mass-production econ-

Manufacturing progress function

Product variety on single line

omies. One telephone-set manufacturing plant employs approximately 8,000 people and each year produces 6,000,000 telephone sets in more than 1,000 different varieties and colour combinations. This factory, in turn, receives materials and components from over 3,000 suppliers. The manufacturing operation consists of a varied but precisely designed mixture of manual assembly effort and mechanized production processes with major operations of both continuous and batch types. In many cases, the partially assembled product moves between operations on conveyors. In other cases, materials are moved in batches by small motorized trucks that operate along factory aisles. Again, an intricate production-control system is employed to schedule the ordering and arrival of parts and the work load of the various production sections.

**Other applications.** The mass-production principles of the division and specialization of labour and the use of standardized parts and processes have been applied to a wide area of productive activity. In agriculture the development of specialized machines for plowing, seeding, cultivating, and harvesting followed by factories for preparing, preserving, and packaging food products has drawn heavily on mass-production principles. There are specialized manual tasks supplementing the specialized machines both in the fields and in the processing plants.

In the service industries, such as transportation, the division and specialization of skills can be observed among ticket agents, pilots, navigators, baggage handlers, stewardesses, maintenance crews, and traffic controllers. All major engineering projects in both design and manufacture generally require a complement of engineering specialties including chemical, mechanical, and electrical engineers and further subdivisions of these professions such as semiconductor engineers, circuit designers, etc.

Thus, as industry becomes more complex at each level, the division of labour and specialization become necessary. At the same time, the need for coordination and communication between specialized members of the team becomes greater.

#### MASS PRODUCTION AND SOCIETY

**The employee.** Both the quantity and the variety of material goods in industrialized countries have resulted directly from the application of mass-production principles. At the same time the environment and circumstances of those employed by, and associated with, the production of material goods have changed. The benefits that have arisen from the greatly improved productivity made possible by mass-production techniques have been shared by employees, investors, and customers. The working environment has greatly changed, however. Similarly, the complexities of management have increased substantially and the investment requirements and risks faced by owners and investors have become much greater.

Before the introduction of mass-production techniques, goods were produced by highly skilled craftsmen who often prepared their basic raw materials, carried the product through each of the stages of manufacture, and ended with the finished product. Typically, the craftsman spent several years at apprenticeship learning each aspect of his trade; often he designed and made his own tools. He was identified with his product and his craft, enjoyed a close association with his customers, and had a clear understanding of his contribution and his position in society.

In contrast, the division of labour, the specialization of narrow skills, the detailed engineering specification of how each task is to be carried out, and the assemblage of large numbers of employees in great manufacturing plants has greatly diluted the identification of the employee with his productive function and has obscured his view of his role and position in society. In addition, the division and specialization of labour may lead to such narrowly defined skills and highly repetitive operations, paced by the steady progression of a machine or conveyor line, that tedium and fatigue may arise to reduce the sense of satisfaction inherent in productive work.

These physical and psychological factors have been the subject of numerous studies by industrial psychologists and others. Special attention has been paid to work fac-

tors that affect the psychological motivation that is a prime determinant of employee productivity. The psychological effects of the repetitive aspects of some mass-production tasks have been examined in great detail. Tasks that are precisely paced by the rhythm of machine operation or conveyor-line movement appear to be particularly fatiguing. For this reason, efforts are made to structure each job so that the operator can vary his pace by working ahead of the line for a period and then slowing down, and by interspersing work breaks with productive periods. Some individuals prefer tasks that are sufficiently repetitive and narrowly skilled that they do not require any substantial amount of mental concentration once the function is mastered. Most fatiguing are those tasks whose pace is out of the operator's control, are repetitive, but also require moderate mental concentration.

With this understanding in mind, work tasks can be structured to produce a minimum of mental and physical fatigue, an important part of the overall planning required for a successful production operation.

The highly repetitive, tightly paced production operations are usually the most easily automated. Thus, as technology advances, that part of the production operation that is most fatiguing, least satisfying, and that takes minimum advantage of the mental and physical flexibility of human effort is replaced by automatic machinery. Not only is productivity improved, but the remaining functions that require human effort can provide a more satisfying experience.

There is also increasing study of the interaction of workers with the tools and machines that assist their efforts. Working together, engineers and physicians are making quantitative biomechanical studies of how the human body functions in performing physical tasks. This has led to the improved design of tools and work positions, and is a part of the broader field of human-factors engineering, which considers the abilities and limitations of people in productive functions, and seeks out ways in which machines can be designed to provide the best allocation of function between human effort and machine assistance. These studies are especially important as automated manufacture becomes more common.

The problem of the loss of employee identification with his job has been of special concern. Progressive industrial organizations work to strengthen this identification in many ways, such as by using job rotation and educational programs to diversify the employee's experience and to acquaint him with various aspects of the manufacturing process. This can give each employee a concept of the total manufacturing task and the importance of his specific function within that task. Employee suggestion systems provide further opportunity for the individual to have a direct effect on the productive process; the employee is given other opportunities to help structure the manner in which the job is performed. Thoughtful programs of this type can substantially ameliorate the feeling of anonymity that may otherwise result. Clearly employers must be willing to compromise on the division and specialization of work tasks that technical considerations alone might suggest as desirable. Job content and employee participation must be expanded so that the employee feels significant and retains his motivation and identification.

In addition to this increased attention to the structure of the job itself, increases in productivity and resulting increases in wages have reduced working hours and provided employees with opportunities and resources to develop interests outside the work place. Forward-looking employers, aware of these needs, frequently support these activities through employees' clubs and other means.

**Economic effects.** Mass production, with its heavy dependence upon mechanized facilities and high levels of production volume, presents great challenges for industrial leadership. The importance of advanced planning and the coordinated control of the large human and capital resources associated with mass production have been described. The day-to-day problems of monitoring the status of a major manufacturing complex are also immense. Up-to-the-minute knowledge of status is essential

to effective response when difficulties such as the breakdown of a machine, the shortage of required materials or components, or the absence of important employees occurs. Many aids to management have been devised for collecting data, analyzing it, and presenting alternatives for management decision. The electronic computer, with its great capability for collecting, analyzing and comparing data, is becoming especially important as a management aid, both in the initial planning and simulation of production facilities and in computer-based production and resource-control systems. In this way, the management of mass-production operations is rapidly becoming a quantitative technology in its own right.

The need for substantial investment is another result of the application of mass-production principles. Much of the increase in productivity that has been achieved by mass production is a direct result of the development and use of automatic machinery and processes to supplement human effort. This, in turn, requires the support of a sizable technical staff in advance of production and later substantial capital investment for production facilities. Increased levels of capital, which must often be committed years before production begins, and before the true market for the product has been established, greatly increase the risks that investors must assume and have markedly affected the investment climate in manufacturing industries.

As capital needs have grown, the nature of ownership and investment in industry has changed dramatically. Economies of scale favour large, high-volume operations that require capital investment levels often well beyond the means of an individual owner. This has been the prime stimulant for corporate ownership of major manufacturing firms. Furthermore, the direct managers of the manufacturing enterprise seldom possess ownership control of the enterprise. This has created a new spectrum of relationships between the owners, the managers, and the employees of large manufacturing firms. Frequently the owners are principally concerned with the profits on their investments and leave the planning and managerial operations to professional managers.

At the same time the large capital needs of growing industries place special emphasis on the ability to acquire the necessary capital resources. Thus, the financial markets become extremely important in determining the general directions in which manufacturing industry will grow. This emphasizes the importance of profit incentives to encourage private investment, which is vital to achieve the productivity advances possible in mass-production operations.

Similarly, industrial nations are strongly encouraged to retain and reinvest a significant fraction of their gross national product if national industries are to grow and to compete successfully in international markets. These problems of capital formation have been especially troublesome in introducing mass production in the developing nations.

Other consequences of a mass-production economy have recently become apparent. The increased consumption associated with low-cost production has created problems of conservation of natural resources and the disposal or reconversion of the wastes of production and of goods whose utility is ended. There are technological solutions for the resulting problems of solid wastes and air and water pollution, but the political and economic problems of how the costs will be distributed must be solved.

**BIBLIOGRAPHY.** Early studies of the organization of human effort for production are treated in classics of the 18th and 19th centuries, including *Descriptions des arts et métiers, faites ou approuvées par messieurs de l'Académie royale des sciences*, 45 vol. (1761-89); ADAM SMITH, *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776); and CHARLES BABBAGE, *On the Economy of Machinery and Manufacture* (1832).

More recent historical views of developments leading to modern mass-production methods are J.K. FINCH, *Engineering and Western Civilization* (1951), *Story of Engineering* (1960); and F. KLEMM, *Technik: eine Geschichte ihrer probleme* (1954; Eng. trans., *A History of Western Technology* 1964). Technical descriptions of mass-production techniques are

given by E.P. DE GARMO, *Materials and Processes in Manufacturing* (1969). The classical technical works on time and motion studies in manufacturing are F.W. TAYLOR, *The Principles of Scientific Management* (1911); and F.B. GILBRETH, *Motion Study: A Method for Increasing the Efficiency of the Workman* (1911). R.M. BARNES, *Motion and Time Study* (1968), describes modern industrial engineering methods; E.J. MCCORMICK, *Human Factors Engineering* (1964), provides a broad study of the physiological aspects of engineering design.

Books written about human and societal problems and adjustments to the industrial milieu include: R. BURLINGAME, *Backgrounds of Power* (1949), a popular history and commentary; and W.A. FAUNCE, *Problems of an Industrial Society* (1968), on the sociological effects. Others have focussed on the problems of individuals and how they may be approached. Among these are: W.J. DICKSON and F.J. ROETHLISBERGER, *Counseling in an Organization* (1966); R.N. FORD, *Motivation Through the Work Itself* (1969); F. HERZBERG, *Work and the Nature of Man* (1966); and C.R. WALKER and R.H. GUEST, *Man on the Assembly Line* (1952).

(M.T.)

## Mass Society

Mass society is a term intended by its proponents to connote the main features that distinguish modern industrial societies from feudal, peasant, or tribal societies. A mass society, they argue, is one in which the most important institutions are large, centralized, bureaucratic, and impersonal; in which most human relationships are shallow, partial, and transitory; and in which individuals tend to be lonely, anxious, rootless, and in search of a sense of community.

### EVOLUTION OF IDEAS CONCERNING MASS SOCIETY

Widespread use of the idea of "the mass" or "masses" originated in the ideological struggles of political and economic groups in Europe prior to the French Revolution. With the victory of the bourgeoisie, what had previously been part of the antibourgeois rhetoric of the aristocrats became transformed and redirected at the lower orders. At first, there was a happy confidence in the masses, as expressed in the essays of such radical and Utilitarian writers as Condorcet and Jeremy Bentham. But then, in the course of the 19th century, the term masses came to be used pejoratively to refer to urban industrial workers and discontented lower classes. Gradually, the demands of these "masses" for social, cultural, and political equality became identified as a threat to a stable bourgeois social order. The fear of the majority expressed in the writings of Alexis de Tocqueville and John Stuart Mill represented a retreat from the confidence of Condorcet and Bentham. Nineteenth-century liberalism became a philosophy of retrenchment and nostalgia, with concomitant fear of and disillusion with the masses. Karl Marx, too, emphasized this social division by applying the idea of the masses to that stratum of society engaged in industrial production but excluded from the ownership or control of the instruments of production—that is, the proletariat.

In addition to its links with 19th-century liberalism, the theory of mass society also has significant roots in Romanticism. Broadly speaking, Romanticism led in two principal directions: a celebration of the free individual on the one hand and a celebration of the national, local, or folk community on the other. Sociological Romanticism combined these strands of 19th-century thought in idealizing the *Gemeinschaft*, or traditional community, and in emphasizing the unhappiness of the individual liberated from traditional society only to be thrust into the impersonal and abstract world of "the city." This theme was elaborated in the late 19th and early 20th centuries by such social scientists as Ferdinand Tönnies, Sir Henry Maine, Georg Simmel, Émile Durkheim, and Max Weber in their attempts to account for the transition from traditional to modern industrial societies. These thinkers shared a focus on "social disorganization," the breakdown of the primary, or intimate, group; the erosion of traditional social bonds of family, local community, and religion; the emergence of large-scale industrialized society, and the increasing concentration of population in urban centres. They also postulated a necessary

Liberalism  
and  
Romanticism  
in the  
idea of the  
masses

Change in  
nature of  
ownership  
and  
investment

historical development, an evolution from the simple to the complex, the homogeneous to the heterogeneous. Out of this concern for the disappearance of older forms of community, the theory of mass society emerged as

. . . a presumed scientific statement concerning the disorganization of society created by industrialization and by the demand of the masses for equality. . . . Behind the theory of social disorganization lies a romantic notion of the past that sees society as having once been made up of small "organic" close-knit communities that were shattered by industrialism and modern life, and replaced by a large impersonal "atomistic" society which is unable to provide the basic gratifications and call forth the loyalties that the older communities knew. . . . The revolutions in transport and communications have brought men into closer contact with each other and bound them in new ways; the division of labor has made them more interdependent; tremors in one part of the society affect all others. Despite this greater interdependence, however, individuals have grown more estranged from one another. The old primary-group ties of family and local community have been shattered; ancient parochial faiths are questioned; few unifying values have taken their place. Most important, the critical standards of an educated elite no longer shape opinion or taste. As a result, mores and morals are in constant flux, relations between individuals are tangential or compartmentalized rather than organic. At the same time greater mobility, spatial and social, intensifies concern over status. Instead of a fixed or known status symbolized by dress or title, each person assumes a multiplicity of roles and constantly has to prove himself in a succession of new situations. Because of all this, the individual loses a coherent sense of self. His anxieties increase. There ensues a search for new faiths. The stage is thus set for the charismatic leader, the secular messiah, who, by bestowing upon each person the semblance of necessary grace, and of fullness of personality, supplies a substitute for the older unifying belief that the mass society has destroyed. (Daniel Bell, "The Theory of Mass Society"; reprinted from *Commentary*, by permission; copyright © 1956 by the American Jewish Committee.)

The theory of mass society was prompted not only by philosophers and social scientists, however, but also by such poets as W.H. Auden, who called the modern era "the age of anxiety," and by novelists as diverse as Ernest Hemingway and Ford Madox Ford. T.S. Eliot's poems *The Waste Land* and "The Love Song of J. Alfred Prufrock" stand out as attempts to give expression to the idea of modern society as a desert and the individual within it as lost, disconnected, and insubstantial.

**Democracy, political ideology, and culture.** It was equality and the prospect of democratization that provided the opening theme for the concept of the mass and of mass society. Contemporary observers in the decades following the French Revolution and the revolutionary industrialization that began in England came to find in democracy and in the human products of industrialization a serious threat to social order. The prospect of democracy—a word that had only come into the general political vocabulary at the end of the 18th century—was not appealing. "Democracy" conjured up the picture of violent mobs. Even the authors of the United States Constitution in 1787 were uneasy about involving the people at large in the political process. One of them, Elbridge Gerry, called democracy "the worst of all political evils." Almost half a century later, when Alexis de Tocqueville, a French aristocrat and civil servant, made his celebrated observations on democracy in the United States, these sentiments were just as current. Tocqueville, like others of his time and station, saw the first two goals of the French Revolution—equality and liberty—as incompatible. He took the passion for equality to be the outstanding characteristic of democratic nations, the young American nation in particular, and, correspondingly, the preservation of liberty to be such a nation's most difficult task. He believed that people in an egalitarian society lost faith in one another and lost respect for the superior person or superior class. Instead, they placed faith only in the public as a whole and in the nation-state as its embodiment. In language that Tocqueville did not use but that he might well have used, classes became masses and the individual became all too willing to subordinate his

own opinion to that of the majority. This emphasis foreshadowed contemporary thought about mass society in its concern not only for political and social life but for culture. When the individual is the object of attention in contemporary theories of mass society, there is a fear that a society of atomized individuals will lead to majority tyranny or submission to totalitarian government. When the precarious status of social and cultural elites in mass society is considered, the debasement of culture is seen as the threat. Writers such as Karl Mannheim and T.S. Eliot held that the preservation of a strong cultural tradition lay in the maintenance of a small and relatively exclusive class of persons who produce it. These fears of cultural democratization were not new. Tocqueville commented on the effect of democracy on the arts, holding that in democratic nations "the productions of artists are more numerous, but the merit of each production is diminished" (*Democracy in America*).

Whereas Tocqueville argued his fear of the majority in terms of the logical consequences of equality, others argued from their notion of the debased character and criminality of the European "masses." Recent scholarship suggests that those who participated in mobs and riots and thus elicited the fear and hostility of the powerful were actually not the criminal, the vagrant, the poorest of the city's poor but rather the sober artisans, servants, labourers, and others from stable districts and with steady jobs. But 19th-century liberals nonetheless often believed the worker and the criminal to be one and the same. They supported political and economic reforms to the extent that such reforms favoured elements of the middle class rather than the growing and presumably irresponsible urban masses. The English Reform Act of 1832 enlarged the electorate only from 4.4 to 7.1 percent of the adult population and retained property holding as a qualification for the franchise. Liberal middle class reformers in the various German states, as in England, feared the "dangerous" lower classes and, until the revolutions of 1848, looked upon the idea of manhood suffrage with horror. Socialist thinkers, of course, called these "dangerous" classes "the industrial classes" and thus portrayed in a positive light the same people whom the bourgeoisie considered so frightful.

It should be remembered that, in the early 19th century, ideological conflict was more significant than actual changes in social structure. Germany, France, and the United States, after all, experienced the same fears of the mob that England did and at roughly the same time, even though they lagged well behind England in the degree of industrialization. It was equality and the prospect of democratization, then, that provided an important initial element in the ideas of the mass and of mass society.

**Formation of mass society and the Industrial Revolution.** The rapidity of social change after the early 19th century created a world in which the major institutions affecting individual lives were quite novel. In primarily agrarian societies, work had centred on the family as the economic and social unit. When commerce and manufacturing supplanted agriculture as the focus of the economy, this changed. Although the cottage industry of the early industrial era had permitted work to be performed in the home, the development of the factory brought masses of individuals together in a single work place outside their homes. In the 19th and 20th centuries, massive shifts in population from farm to city took place in all the industrialized countries as a result of the enormous increases in agricultural productivity and the concomitant expansion of the manufacturing and services sectors of the economy.

There were more people in the world by 1900: the population of Europe had doubled in the preceding century and a half, and the population of the United States had risen from 4,000,000 in 1790 to 75,000,000. Not only did people move to the cities and work for others rather than for themselves, but the organizations they worked for grew in size, each of them employing more and more workers. Small proprietors and partnerships similarly gave way to corporations, corporations in turn grouping into cartels and monopolies. Bureaucratization every-

Concept of the "dangerous" masses

The presumed threats of liberty and equality

Urbanization and modernization

where tended to shift the emphasis in human relations from family and communal groups to impersonal, contractual groups.

Not only were there more people but they were more easily linked to one another through technological advances such as the railroad and, later, the telephone and the automobile. The invention of the printing press in the 15th century had been the beginning of a movement that spread with the growth of literacy and technological innovations in printing and marketing. The circulation of books and pamphlets spread, and literacy levels in Europe advanced markedly, both a cause and a result of the increased use of print. In England in 1841, 33 percent of bridegrooms could not sign their names to their marriage certificates; almost all could do so by 1900. In France the percentage who could not sign their names dropped from 32 percent in 1855 to 5 percent in 1900. Between 1840 and 1882 the monthly issue of newspapers in Paris jumped from 3,000,000 to 44,000,000 copies.

Sociologists, as well as poets and novelists, tried to come to grips with the contradictions of urban life as expressed in the contrast between the old German proverb that "city air makes one free" and the perception of the powerlessness of the individual in the face of urban sprawl, poverty, and corruption. Although the German sociologist Georg Simmel did argue that the city offered the individual "a kind and an amount of personal freedom which has no analogy whatsoever under other conditions," he also held that it enforced a fearful impersonality in social relations, a calculating frame of mind, a blasé attitude, an incapacity to react to new sensations, and a perception of the world as flat and grey, all of which he explained as "the faithful subjective reflection of the completely internalized money economy."

Whereas Simmel saw the city man becoming calculating and blasé, his most influential American student, Robert Park, viewed the outlook of the urban dweller as rational and practical, modelled on the machine and the application of science to life. But if this was true of the individual in the city, it was not true of the crowd. Park's pioneering textbook, *Introduction to the Science of Sociology* (1921), written in collaboration with Ernest W. Burgess, reported on the work of European psychologists who stressed the irrational aspect of the modern world and who saw modern man attaching himself to crowds that were brutal, highly emotional, and suggestible. Modern economic conditions had broken down family and local ties, freeing the individual, but "the effect," Park wrote, "has been to loosen all the social bonds and reduce society to its individual atoms. The energies thus freed have produced a world-wide ferment. Individuals released from old associations enter all the more readily into new ones. Out of this confusion new and strange political and religious movements arise, which represent the groping of men for a new social order."

It would be difficult to judge whether or not, as some writers assumed, mass political action had increased and intensified. What is more certain is that the nature of collective action had changed. People were grouped into large homogeneous blocs in factories and in working class neighborhoods; special interest groups such as the labour union and the political party, capable of mobilizing people quickly, had developed; and people were concentrated in the urban seats of power, thus encouraging authorities to react more quickly to dissidence. It would also be difficult to know whether to emphasize the increased rationality of individuals in the machine age or to emphasize their increased susceptibility to collective irrationalities. It may be wiser simply to note that the context for the expression of reason and enthusiasm had changed. The great expansion of public education was instructing ever greater numbers of people in rational processes, and the great extension of the franchise was providing them the opportunity to exercise these rational processes. On the other hand, the possibility of order and rationality was being questioned. A new mood of scientific thought was denying not only the old truths of religion but the possibility of objective science as well. This was evident in the works of Kierkegaard and Nietzsche. Marx and

Freud, while they remained in a scientific tradition, contributed to the skepticism of science by unearthing the social and psychological sources of human beliefs and behaviour, revealing the subjective roots even of science itself.

**The mass and totalitarianism.** The concept of mass society included the ideas of democratization and the splintering of community, but these in turn were deemed by some writers as prime causes of 20th-century totalitarianism, especially in Nazi Germany. The concept was fundamental in the works of such émigré German intellectuals as Hannah Arendt, Erich Fromm, and Karl Mannheim. Although critics of mass society continued to appear among aristocratic liberals and conservatives in the mid-20th century, notably José Ortega y Gasset and T.S. Eliot, the more sustained analysis appeared on the left. Indeed, it was primarily the contribution from the left that established "mass society" in the language of social science.

In trying to comprehend Nazism in Germany, the theorists of mass society emphasized the social and psychological preconditions of totalitarianism. Arendt stressed that totalitarianism built on masses, not classes—on people who "either because of sheer numbers, or indifference, or a combination of both, cannot be integrated into any organization based on common interest, into political parties or municipal governments or professional organizations or trade unions." She distinguished the 19th-century mob, which had class origins, from the 20th-century mass, which was shaped "by all-pervasive influences and convictions which were tacitly and inarticulately shared by all classes of society alike" (*The Origins of Totalitarianism*). Thus Arendt stressed not the decline of family and community so much as the isolation of huge numbers of people from participation in major social and political processes. Not all theorists would agree. Another émigré, Franz L. Neumann, did not make Arendt's sharp distinction between classes and masses but saw instead the mass as the extreme consequence of the processes of modern industrial capitalism and mass democracy. What characterized mass society in pre-Nazi Germany was not so much the psychological unwillingness of large numbers to participate in social life but the inappropriateness of the increasingly bureaucratic organs of society for satisfying human relations. To Neumann, the bureaucratic trade unions, political parties, athletic organizations, radio networks, birth-control associations, consumers' cooperatives, and food chain stores of the Weimar Republic all represented depersonalized control over the life of the individual. Such organs failed to provide proper leadership; and it was this, not the psychological susceptibility of mass man to extremism, that contributed to the rise of Hitler.

The theory of mass society, nevertheless, has been more closely associated with a more psychological view, emphasizing that a certain kind of social character is prominent in modern society and is unusually susceptible to the appeals of demagogues. The psychological condition of the individual in mass society has been described in terms of isolation, loneliness, yearnings for a personal or collective identity, impersonal human relations, the privatization of personal emotion. It has been suggested that whereas a communal society is regulated by shame and honour, and a liberal democratic society such as that of 19th-century England is governed by self-reliance and guilt, mass society is dominated by suggestibility and anxiety. This point of view—which was developed by such writers as Erich Fromm in a number of important works before, during, and just after World War II—had a profound influence on social science. Although these studies were primarily a response to the rise of Nazism and an attempt to explain the phenomenon, they also represented a more general approach to the psychological dimension of life in industrial society. Much influenced by Fromm was American sociologist David Riesman's evocative description of the change in the social character of the American middle class individual from "inner-directed" to "other-directed." The "inner-directed" person, broadly speaking, was the rational, individualistic person

Presumed preconditions of totalitarianism

Psychological view of mass society

Questions of rational behaviour of the masses

of the 19th century, driven by an internal sense of direction and destiny. The "other-directed" character, a product generally of capitalism, industrialization, and urbanization, finds his sense of direction—if he finds one at all—in cues from other people. He is not concerned with mastery of the environment; that has been taken care of. For him, "other people are the problem" (*The Lonely Crowd*). Finally, a considerable literature on "alienation" grew out of the concern among various writers for the quality of social life under industrialism (see ALIENATION).

Influence  
of war

From another point of view, it may be that mass society is characterized more by powerful new organs of mobilization rather than by an unusual psychological readiness to be mobilized. Indeed, the enlargement of the franchise in Germany and in England at the end of the 19th century brought with it vigorous efforts to organize the new voters of the working class into political parties. Not only did parties and unions grow more important but the state itself grew more centralized and more powerful, especially through involvement in war. War, as Tocqueville observed, increases the centralization of the state, or, as a contemporary sociologist has written, "if there is any single origin of the institutional State, it is in the circumstances and relationships of war" (Robert Nisbet, *The Quest for Community*).

Here, as before, the question concerns the relationship between totalitarianism and mass society. It seems true that modern societies today are dominated by the influence of the centralized state. The expenditures of the government of the United States, for example, rose from \$9,000,000,000 in 1940 to \$69,000,000,000 in 1957; by 1970 the defense budget alone was \$80,000,000,000. The influence of war and the military is visible not only in public expenditures but in the nature of modern institutions. The organizational techniques used in World War I provided the models for dealing with the Great Depression of the 1930s in both Europe and America. Intelligence testing, developed for classifying huge numbers of soldiers, was adopted by school systems to deal with the burgeoning school populations. Even charities were consciously organized in a military style based on war experience. Both world wars advanced the use of the mass media as systems of control—the propaganda of World War I being described as "the first modern effort at systematic, nationwide manipulation of collective passions." (Jack Roth, in *World War I: A Turning Point in Modern History* [1967]).

#### EVALUATIONS OF MASS SOCIETY

**Criticism of the idea of mass society.** The idea of mass society is open to criticism on at least two levels. First, one might ask, is modern industrial society accurately described as a mass society? In other words, are societies with large numbers of people, large cities, industrialized economies, bureaucratic organization of institutions, and widespread use of mass media of communications—are these societies characterized by the weakness of human social relations, loneliness, and the debasement of culture? Second, is the "mass-ness" of a society closely linked to tendencies to totalitarianism? In other words, are highly urbanized, industrialized, and bureaucratized societies inhabited by lonely, highly suggestible individuals who are especially prone to accept totalitarianism?

Signifi-  
cance  
of  
"human  
relations"  
in modern  
society

The extent to which atomism, loneliness, and anxiety characterize individuals in modern society can be questioned. Despite rapid urbanization, industrialization, and bureaucratization, close personal relationships are still basic to the individual's style of life and provide a human link between the individual and mass communications and large organizations. The now-famous Hawthorne project, spanning the late 1920s and early 1930s, offered early evidence of the possibility of creating personal ties in an industrial setting. Researcher Elton Mayo and his colleagues, studying the productivity of workers at a Western Electric Company plant outside Chicago, found that no matter what variations they made in lighting, temperature, rest periods, or working hours, the output of the workers kept rising. Only later did they realize what

had happened: the special attention that had been given to the workers in the course of the experiment had contaminated the experiment, the result being a "Hawthorne effect." The experiment had created a group among the individuals working in the test room, resulting in a new esprit de corps and mutual identification that was crucially related to the increase in output. The factory organization of work was not, as some had thought, a simple transaction between the requirements of the employer and the needs of the individual worker; rather, it operated through the work group, which established its own "informal" rules and expectations concerning behaviour, including productivity. Similarly, studies of American soldiers in World War II indicated, to the surprise of researchers accustomed to thinking of modern society as a mass society, that small-scale interpersonal relations are strong and significant even in such large-scale organizations as the military. Attachment to an informal group of "buddies" was more important as a factor in a soldier's willingness to enter combat than either ideological goals or, for that matter, the system of discipline and formal orders.

The individual in the city, too, is not as deprived of substantial personal attachments to family and small groups as the idea of mass society would suggest. Urban dwellers spend a significant share of their lives with family, friends, and relatives; many live in neighbourhoods that retain a sense of community based on ethnic, racial, or class lines. Studies in the United States, England, and elsewhere indicate that even in highly urbanized, industrialized, and bureaucratized societies there is reason to doubt that atomization and the absence of normal social relations characterize social experience.

Is the mass society totalitarianism-prone? This, too, may be questioned. Surely it would be difficult to conceive of totalitarian rule or, for that matter, of the welfare states of western Europe without cities, industry, bureaucracy, and mass communications. But to explain totalitarianism by the appeal of demagoguery to atomized masses is another matter. First, the idea of mass society, since it is designed to apply to modern industrial societies generally, is much too broad to explain why only some of these societies develop powerful extremist social movements, why such movements arise at some times and not at other times, and why only some of them succeed in gaining power. It does not explain why some societies that seem to fit the picture of mass society best—such as England or the United States—have not developed lasting extremist social movements, or why one major instance of totalitarianism, the Soviet Union, began to resemble a mass society only after establishing totalitarian rule.

**The past and future of mass society.** In his classic essay on "Urbanism as a Way of Life" (*American Journal of Sociology*, July 1938) the American sociologist Louis Wirth summarized the then prevailing view concerning the nature of urban life in a way that reflects the preoccupations of the theorists of mass society:

Inade-  
quacy  
of early  
views of  
urbanism  
and mass  
society

The distinctive features of the urban mode of life have often been described sociologically as consisting of the substitution of secondary for primary contacts, the weakening of bonds of kinship, and the declining social significance of the family, the disappearance of the neighborhood, and the undermining of the traditional basis of social solidarity.

As noted earlier, this conception has been subjected to criticism. With respect to the importance of family and kinship, for example, recent research tends to indicate that the extent and intensity of kin relationships and the frequency of interaction among kin remains quite persistent. Patterns of neighbourhood and kinship ties appear to be stronger than Wirth had supposed. On the other hand, there is perhaps at least one area to which Wirth's conceptions seem applicable, and that is to the area—sometimes referred to as the "inner city"—in which are concentrated a number of disadvantaged groups whose range of choice in housing and life-styles is restricted by income, age, ethnicity, or race and whose lives are especially subject to stress and disruption. Indeed, Wirth's formulation still seems applicable not only

"Masses"  
in the  
Third  
World

to residents of the American inner city, for example, but also to the citizens of some newly developing countries undergoing the strains of rapid modernization. Detribalized and declassed populations on the fringes of great urban centres in Asia, Latin America, and Africa, concentrated in shantytowns, clustered on the hillsides of Rio de Janeiro or Lima or Calcutta, may exhibit some of the same characteristics reflected in the Wirth formulation and in the classical idea of "mass society." One must therefore confront the paradox that the idea of mass society may have greatest relevance for the newly developing countries in the throes of industrialism, where the problems of 19th-century Europe are being re-created at an intensified pace over a period of time far shorter than that within which Europe and North America absorbed the strains of economic development. This also suggests that an ideology such as that represented by the idea of mass society may become most relevant to the peoples of the "Third World" precisely at the time when its relevance for the peoples of the United States, western Europe, and the other highly industrialized nations is being challenged. Both the unemployed peasant in the Brazilian shantytown, or *favela*, and the rural farm worker in Kenya who can multiply his salary six times by going to Nairobi and getting a job may ultimately find themselves enmeshed in a complex of problems envisioned by the theorist of mass society.

On the other hand, some social scientists have argued that even in newly developing countries the strains of migration to the urban centres have been exaggerated. Moreover, even though tribalism and traditionalism in Africa, Asia, and Latin America are giving way under the pressure of commercial and industrial development and the social changes associated with them, it is also true that many of these changes are giving rise to an expansion of the available alternatives that many people perceive as liberating. In reflecting on these alternatives, the British anthropologist Lucy Mair has written:

the changes that non-Western societies are going through, though they were imposed on them at the outset, are now essential for the realization of aims that they have made their own. In terms of individual actions the process can be seen as one of response to new opportunities, which include freedom to choose one's way of life and dispose of one's own earnings. Women, as well as men, seek this freedom, in the non-Western as well as in the Western world. (From *New Nations*, University of Chicago Press, 1963.)

Perpetual  
elusiveness  
of the  
idea  
of mass  
society

Ultimately, the ideology of mass society emphasizes the negative effects of the rise of industrial society; and, since only a part of the answers to the questions raised by the theory of mass society can be answered by empirical research, part of the issue will always remain in the form of stubborn ideological differences concerning the good, the true, and the beautiful, and the most desirable way of life. What one thinker will deplore as the decline of the folk community might be conceptualized by another as the creation of new communities based on a new conception of the good life, new roles, and new life-styles.

In one respect, the perspective of theorists of mass society has received support from those who have pointed to a number of undesirable features of modern industrial society. Apart from the threat of nuclear, chemical, and biological warfare, there is widespread concern for the unchecked growth of population in relation to resources, giving rise to a neo-Malthusian and sometimes apocalyptic vision of the future. And considerable attention also has been given to the unanticipated consequences of technological development in the form of the pollution of the air, the earth, and the waters on a global scale. These ecological factors may be cited in the context of a discussion of mass society since they will inevitably exert a profound influence.

Finally, it should be said that precisely because of its ideological elements, the idea of mass society will continue to have appeal for social scientists interested in specific problems associated with modernization, urbanization, and industrialism. The best one may hope for is a productive tension between these ideological elements on the one hand and an empirical concern for what is really happen-

ing, what is actually the case, on the other—in the best tradition of modern social science. Freedom of inquiry concerning the nature of modern societies may be one of the important safeguards against the pessimistic view of modern life suggested by the theory of mass society.

**BIBLIOGRAPHY.** For an early analysis of mass society, see ALEXIS DE TOCQUEVILLE, *De la démocratie en Amérique*, 2 vol. (1835; Eng. trans., *Democracy in America*, 2 vol., 1945, reprinted 1961). For the idea of mass society at the turn of the century, see GUSTAVE LE BON, *The Crowd* (Eng. trans. 1903); GEORG SIMMEL, "The Metropolis and the Mental Life," in *The Sociology of Georg Simmel* (1950); and ROBERT E. PARK, *Human Communities* (1952). For more recent theory, see especially KARL MANNHEIM, *Man and Society in an Age of Reconstruction* (1940); HANNAH ARENDT, *The Origins of Totalitarianism* (1951); ERICH FROMM, *Escape from Freedom* (British title, *The Fear of Freedom*: 1942); and JOSE ORTEGA Y GASSET, *La Rebelión de las masas* (1929; Eng. trans., *The Revolt of the Masses*, 1932). See also RAYMOND WILLIAMS, *Culture and Society: 1780–1950* (1958), for a survey of English intellectual criticism of modern society; and RICHARD HOGGART, *The Uses of Literacy* (1957). Political aspects of mass society are the focus of WILLIAM KORNHAEUSER, *The Politics of Mass Society* (1959); and ROBERT NISBET, *The Quest for Community* (1953), emphasizes the role of the state. Critical reviews of the idea of mass society may be found in DANIEL BELL, *The End of Ideology* (1960); and LEON BRAMSON, *The Political Context of Sociology* (1961). The debate concerning mass culture may be reviewed in BERNARD ROSENBERG and DAVID MANNING WHITE (eds.), *Mass Culture* (1957); DAVID RIESMAN, *The Lonely Crowd* (1950); and EDWARD SHILS, "Daydreams and Nightmares: Reflections on the Criticisms of Mass Culture," *Sewanee Review*, 65:587–608 (1957). T.S. ELIOT's essay *Notes Toward A Definition of Culture* (1948) also remains relevant. Recent works focussing on American society are PHILLIP OLSON (ed.), *America As a Mass Society* (1963); WILLIAM H. WHYTE, *The Organization Man* (1956); C. WRIGHT MILLS, *White Collar* (1951) and *The Power Elite* (1956); KENNETH KENISTON, *The Uncommitted: Alienated Youth in American Society* (1965); and ARTHUR VIDICH and JOSEPH BENSMAN, *Small Town in Mass Society*, rev. ed. (1968), and *The New American Society* (1971). The historical sociology of the masses is discussed in GEORGE RUDE, *The Crowd in History: A Study of Popular Disturbances in France and England, 1730–1848* (1964); and CHARLES TILLEY, "Collective Violence in European Perspective," in H. GRAHAM and T. GURR (eds.), *The History of Violence in America* (1969).

## Mass Spectrometry

Mass spectrometry, or mass spectroscopy, denotes that field of physics in which the motion of ions (charged atoms, molecules or fragments of molecules) in electric and magnetic fields is used to sort ions according to their mass-to-charge ratios. The instruments used in these studies are called mass spectrometers and mass spectrographs, and they operate on the principle that moving ions may be deflected by electric and magnetic fields. The two instruments differ only in the way in which the sorted charged particles are detected. In the mass spectrometer they are detected electrically; in the mass spectrograph by photographic or other nonelectrical means, and the term mass spectroscopy is used to include both kinds of devices; a person who specializes in their use is called either a mass spectrometrists or a mass spectroscopist.

Mass spectroscopes consist of five basic parts: high vacuum system; a sample handling system, through which the sample to be investigated can be introduced; an ionization chamber (ion source), in which a beam of charged particles characteristic of the sample can be produced; an analyzer, in which the beam can be separated according to its mass components; and a detector or receiver by means of which the separated ion beams can be observed or collected.

Many investigations have been conducted with the help of mass spectroscopy. These include the identification of the isotopes of the chemical elements and determination of their precise masses and relative abundances, the dating of geological samples, the analysis of inorganic and organic chemicals especially for small amounts of impurities, structural formula determination of complex organic

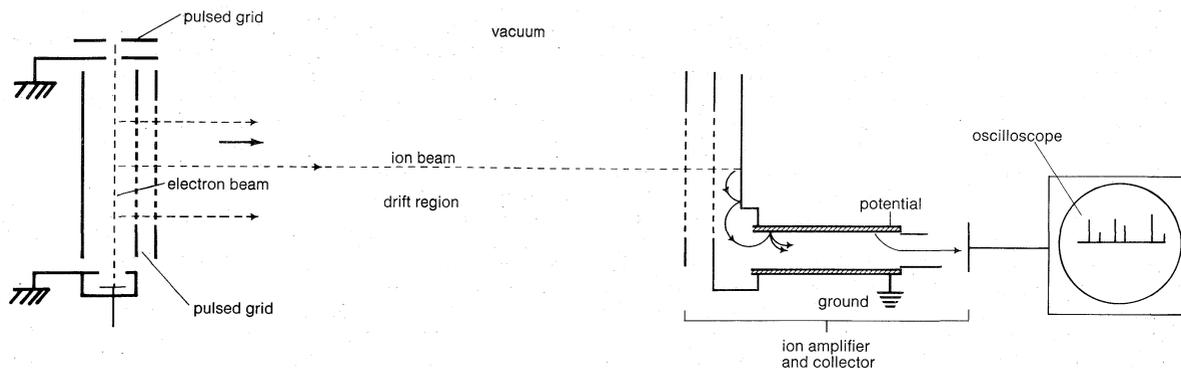

Figure 1: Linear time-of-flight mass spectrometer.

A pulse of electrons ionizes the sample and a pulsed grid draws ions out of ionizing region and accelerates them along a drift region. Since all ions acquire the same energy of acceleration, the lighter ions arrive at the collector first. The separated ion beams can be displayed on an oscilloscope.

substances, the strengths of chemical bonds and energies necessary to produce particular ions, the identification of products of ion decomposition, and the analysis of unknown materials, such as moon samples, for their chemical and isotopic constituents. Mass spectrometers are employed also to separate isotopes and to measure the abundance of concentrated isotopes when used as tracers in chemistry, biology, and medicine.

#### HISTORY OF MASS SPECTROSCOPY

The foundation of mass spectroscopy was laid in 1898, when Wilhelm Wien, a German Nobel Prize winner, discovered that beams of charged particles could be deflected by a magnetic field. In more refined experiments carried out between 1907 and 1913 by J.J. Thomson, the great English physicist who discovered the electron, a beam of positively charged ions was passed through a combined electrostatic and magnetic field. Charged particles such as ions deflect as they pass through electrostatic and magnetic fields; the two fields in Thomson's tube were situated so that the ions were deflected through small angles in two perpendicular directions. The net result was that the ions produced a series of parabolic curves on a photographic plate placed in their paths. Each parabola corresponded to ions of a particular mass-to-charge ratio and the lengths of the parabolic curves provided a measure of the range of ion energies contained in the beam. Later, in an attempt to estimate the relative abundances of the various ion species present, Thomson replaced the photographic plate by a metal sheet in which was cut a parabolic slit. By varying the magnetic field, he was able to scan through a mass spectrum and measure a current corresponding to each separated ion species. Thus he may be credited with the construction of the first mass spectrograph and the first mass spectrometer.

The most noteworthy observation made with the parabola spectrograph was the spectrum of rare gases present in the atmosphere. In addition to lines due to helium (mass 4), neon (mass 20), and argon (mass 40), there was a line corresponding to an ion of mass 22 that could not be attributed to any known gas. The existence of different mass forms of the same element had been suspected since it had been found that many pairs of radioactive materials could not be separated by chemical means. The name isotopes was suggested by Frederick Soddy in 1913 for these different radioactive forms of the same chemical species since they could be classified in the same place in the periodic table of the elements. The ion of mass 22 was, in fact, a stable heavy isotope of neon.

**Focussing spectroscopes.** The spectroscopes discussed so far are analogous to the pinhole camera in optics because no focussing of the ion beams is involved. The introduction of focussing types of mass spectroscopes came in the years 1918–19 and was due to F.W. Aston and to A.J. Dempster.

In Aston's version, successive electric and magnetic fields were arranged in such a way that all perfectly collimated ions of one mass were brought to a focus independent of their velocity, thus giving rise to what is known

as velocity focussing. Aston's design was the basis of his later instruments with which he systematically investigated the accurate masses of the isotopes of many of the elements. He chose  $^{16}\text{O}$  (the isotope of oxygen of mass 16) as his standard of mass.

Dempster's spectrometer utilized only a magnetic field, which deflected the ion beam through an arc of  $180^\circ$ . In Dempster's machine, an ion beam homogeneous in mass and energy, but diverging from a slit, could be brought to a direction focus. This spectrometer was employed by Dempster to make accurate abundance determinations of the isotopes of magnesium, lithium, potassium, calcium, and zinc, laying the foundation for similar measurements of the isotopes of all the elements.

The resolving power of a mass spectroscope is a measure of its ability to separate adjacent masses that are displayed as peaks on the detector. If two peaks due to mass  $m$  and  $(m + \Delta m)$  can just be separated, the resolving power is  $m/\Delta m$ . The early machines had resolving powers of only a few hundred. In 1935 and 1936, Dempster, K.T. Bainbridge, and Josef Mattauch working independently, developed instruments with electric and magnetic fields arranged in tandem in such a way that ion beams that emerged from the source slits in divergent directions and with different velocities were refocussed. Such focussing is termed double focussing. It was thus possible to achieve a resolving power of about 60,000.

**Alternating field spectrometers.** The spectrometers described so far employ steady electric and magnetic fields. In 1932 the use of alternating electric fields to separate ions of different mass was introduced by Henry D. Smyth. Instruments employing this technique are known as radio-frequency mass spectrometers, and by 1950, developments had improved them so that a resolving power of 100,000 was possible. Nonfocussed spectrometers were introduced that did not require deflecting fields but operated on the principle of the pulsed beam. Typical of these is the "time-of-flight" spectrometer, shown in Figure 1, which depends upon the fact that an accelerated bunch of ions will separate during its flight through the drift tube and arrive at the collector as a series of ion pulses, the lighter ions arriving first.

In 1953, Wolfgang Pauli and Helmut Steinwedel described the development of a quadrupole mass spectrometer. The application of superimposed radio-frequency and constant potentials between four parallel rods can be shown to act as a mass separator in which only ions within a particular mass range will perform oscillations of constant amplitude and be collected at the far end of the analyzer. This device, like the others, has the advantage of high transmission.

#### ION PRODUCTION AND DETECTION

**Ion sources.** The electron bombardment ion source was first used by Dempster. Its operation depends on the fact that an electron, when colliding with a molecule, may transfer a sufficient amount of its energy to eject one of the electrons in the molecule, thus forming a positively charged ion. A bombarding electron can transfer much

Resolving power

more than the minimum amount of energy necessary to produce an ion and the excess energy can cause the ion to decompose in various ways with the loss of neutral fragments, thus giving rise to a mass spectrum. A simplified electron bombardment ion source consists of a heated filament, generally of tungsten or rhenium, which emits electrons in copious numbers. The electrons are attracted by slits having a high positive charge and pass through the ionization chamber containing the gaseous sample to be analyzed; here they are constrained to move in a narrow beam by a magnetic field in a direction along their lines of motion. Positive ions are formed in the ionization chamber along the length of the electron beam and are ejected from the chamber by positively charged, or repeller, electrodes. The ions leaving the source have a spread in energy of only a fraction of an electron volt. A sample is required in gaseous form at extremely low pressure, and a sample consumption of less than a thousandth of a microgram each second is typical. The source is frequently used for examination of organic compounds, which can be vaporized without decomposition, as well as for gas analysis.

Use of photons

Instead of electrons, photons in the far ultraviolet region may be used, as they have sufficient energy to produce positive ions in a sample gas or vapour to be analyzed. A discharge in a capillary tube through which is passed a suitable gas, such as helium, is a good source for such radiation. Photo-ionization sources usually produce fewer ions than electron bombardment sources but have advantages when the ionization chamber must be held at low temperature.

In the vacuum spark source a pulsed, high-frequency potential of about 50 kilovolts is built up between two electrodes until electrical breakdown occurs. Hot spots appear on the electrodes, and electrode material is evaporated and sputtered, some of which is ionized by bombardment from electrons present between the electrodes. The principal merit of the vacuum spark source is its ability to produce copious quantities of ions of all elements present in the electrodes.

To obtain large ion currents a low voltage arc source can be used. The sample vapour, contained in a capillary, starts a low-current discharge in the filament chamber, the walls of which act as the anode. Electrons from this discharge ionize the vapour within the capillary and strike an arc to the anode, the ion density within the capillary being particularly high. When a magnetic field is used parallel to the direction of the primary electrons, the discharge is constrained without the use of a capillary. A weak electrostatic accelerating field extracts ions from the arc plasma and these can be collimated and focussed. Ion beams of one milliampere (a million times greater than those from the sources described above) can be obtained and collected to give usable amounts of separated isotopes. The surface ionization source depends upon the fact that when an atom of low ionization potential is heated on a surface of high work function, it is likely to evaporate as a positive ion. Neutral atoms striking the hot filament may also be re-emitted as ions. The ionization efficiency is so high in favourable cases that samples less than a millionth of a microgram (*i.e.*,  $2 \times 10^{-13}$  g) may be analyzed with a precision of a few percent. This type of source has been widely used in the age determination of rocks. Substances that are adsorbed on a surface can be desorbed as positive ions under the action of a sufficiently strong electric field. Intense fields of the order of  $10^8$  volt per centimetre can be generated in the neighbourhood of sharp points and edges and these have been used as field emission sources. This source is becoming popular in the study of organic compounds, which can be introduced as vapours and ionized in the intense fields. The ions are formed with very little excitation energy so that there is little fragmentation of the molecular ions, making molecular formulas easier to determine.

**Types of ions.** When mass spectra are produced using any of the ion sources described, the various ion species can be classified into the following categories: Parent ions or molecular ions are ions that have been formed from complete molecules by removal of one or more electrons

without fragmentation. One can represent, in equation form, the addition of an electron  $e$  to a neutral molecule  $M$  to produce an ion and two electrons (electron bombardment), or the addition of a photon  $h\nu$  to produce an ion and one electron (photo-ionization). Almost all organic compounds are held together by bonds, each of which contains two electrons; so the neutral molecule contains an even number of electrons. When an odd number of electrons is removed, the ion so formed will contain an odd number of electrons which can be symbolized by a dot placed beside the positive charge. The equation for electron bombardment is thus  $M + e = M^{\cdot+} + 2e$ , and for photo-ionization,  $M + h\nu \rightarrow M^{\cdot+} + e$ . These ions may contain an energy considerably in excess of the minimum required for fragmentation and may break into a variety of fragment ions and neutral species. Thus the molecular ions are the "parent" ions of the mass spectrum. Molecular ions may carry one or more charges because transfer of a large amount of energy by a bombarding electron (or photon) may expel two or more electrons from the molecule; thus, for example, processes such as are represented by the equation  $M + e \rightarrow M^{2+} + 3e$ , or  $M + e \rightarrow M^{3+} + 4e$  can occur. These are examples of the formation of multiply charged ions.

Most of the research carried out in mass spectroscopy is concerned with positive ions; that is to say, ions formed by removing an electron from a neutral molecule. Electrons having a low kinetic energy can attach to molecules, forming *negative ions* and these can also be studied by mass spectroscopy.

The fragmentation of a molecular ion  $ABCD^+$  can occur in several ways. For example, the expressions  $ABCD^+ \rightarrow AB^+ + C \cdot D \cdot$  represents simple cleavage, and  $ABCD^+ \rightarrow AC^+ + B \cdot D \cdot$  a rearrangement reaction, when the ion  $AC^+$  is called a rearrangement ion. The fraction or moiety B has transferred during fragmentation to combine with moiety D. Such rearrangements are commonly found in the mass spectra of organic compounds and involve transfer of hydrogen atoms, or occasionally, small groups of atoms.

Ions that make up a mass spectrum also can be classified according to their stability. Ions that undergo fragmentation within the ionization chamber are classified as unstable, ions (both molecular and fragment ions) that leave the ionization chamber and reach the detector without fragmentation are classified as stable ions, and ions that undergo fragmentation between the ionization chamber and the detector are said to be metastable. Metastable ions that decompose in field-free regions of the flight tube can give rise to diffuse peaks in the mass spectrum. The positions and shapes of these "metastable peaks" can be used to give information about the individual steps in the fragmentation processes.

**The detection and identification of ions.** The two most widely used detection systems for energetic ions are the photographic plate and the secondary electron multiplier.

Special high-sensitivity photographic plates are employed to take account of the low penetrating power of the ions. It has proved possible with these to detect an element over a sensitivity range of 1 part in 1,000,000,000. In addition to the sensitivity, a major advantage of the photographic plate arises when it is used in a double-focussing mass spectroscope in which the whole, or a major part, of the mass spectrum is focussed in a plane (see the design of Mattauch and Richard Herzog shown in Figure 4 and described below). In this case, one can make use of the integrating action of the plate and compare the densities of lines due to different elements.

The basic electrical detector is the so-called Faraday cage. The current due to ions striking the cage is usually measured with an electrometer amplifier. The stability of electrometer amplifiers is such that the ion current issuing from the ionization chamber, minute as it is, permits intensity measurements of ten parts per million. An ion-collector system can be built with two or more slits and a corresponding number of Faraday cages that allows the simultaneous collection of two or more ion beams. Such a system allows the ratio of two ion beams to be measured continuously; it is particularly valuable in

Fragmentation of ions

measuring the abundance ratios of the isotopes of an element and in detecting small changes in these ratios.

Secondary electron multipliers of the conventional kind are used to detect the smallest currents and to reduce the time constant, thus increasing the plotting rate of spectra. They can give a measurable current for the arrival of a single ion and be used for single ion counting. A scanning time of one second for several hundred mass peaks can be achieved if one sacrifices the accuracy of measurement of relative peak heights for the smallest peaks.

Another method of detecting the positive ions in a beam is to allow them to strike a phosphor, thus producing scintillations that can be detected by a photomultiplier. A more sensitive method is to allow the ion beam to impinge upon a secondary emitting electrode, maintained at a high negative potential. The secondary electrons produced are accelerated to a phosphor that is optically coupled to a photomultiplier. In this way, high sensitivity is attained and the photomultiplier is never exposed to the atmosphere yet is conveniently located outside the vacuum system.

#### THE ANALYSIS OF IONS

**Magnetic field analysis.** Ions of mass  $m$  and charge  $e$  moving *in vacuo* with a velocity  $v$  in a direction perpendicular to a magnetic field  $H$  will follow a radius  $R$  given by

$$R = mv/He.$$

Therefore, all ions with the same charge and momentum entering the magnetic field from a common point will move in the same radius  $R$  and will come to a first order focus after  $180^\circ$  as shown in Figure 2, no matter what their masses. Hence, the mass spectrometer used by Dempster can be referred to as a "momentum spectrometer." If all ions of charge  $e$  enter the magnetic field with an identical kinetic energy  $eV$ , due to their acceleration through a voltage drop  $V$ , a definite velocity  $v$  will be associated with each mass and the radius will depend upon the mass. Since  $eV = \frac{1}{2}mv^2$ , substitution in the previous equation will give  $m/e = H^2R^2/2V$ . This formula shows that the radius of curvature  $R$  for ions in this spectrometer depends only on the ratio of the ions' mass to charge, as long as their kinetic energy is the same. Thus, a magnetic field can be used to separate a monoenergetic ion beam into its various mass components. A magnetic field will also exert a focussing action on a monoenergetic beam of ions of mass  $m$  as is shown in Figure 2. In this figure an ion beam emerges from a point

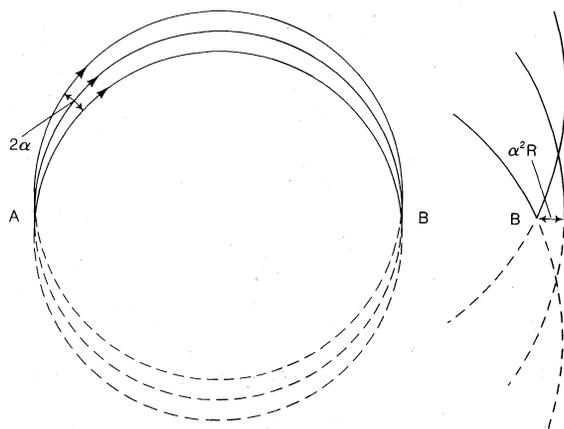

Figure 2: Paths of monoenergetic ions moving in a plane perpendicular to a magnetic field, passing through focal point B after originating at point A (see text).

A with a spread in direction  $2\alpha$  that then comes to an approximate focus at B after traversing  $180^\circ$ . When a molecular ion of mass  $m_1$ , carries a single positive charge, it may decompose in front of the magnetic sector to form a fragment ion of mass  $m_2$  and a neutral fragment. If there is no kinetic energy of separation of the fragments, the ion  $m_2$ , and also the neutral fragment, will con-

tinue along the direction of motion of  $m_1$  with unchanged velocity. The equation of motion for the ion  $m_2$  entering the magnetic sector can now be written from a previous relationship,  $R = m_2v/He$ . In this equation  $v$  is the initial velocity appropriate to  $m_1$  and given by  $\sqrt{2eV/m_1}$ . Multiplying both sides of the equation  $v = \sqrt{2eV/m_1}$  by  $m_2$ , one obtains  $m_2v = \sqrt{2eV}(m_2^2/m_1)$ . Since the general momentum equation for any mass  $m$  can be written  $mv = \sqrt{2eVm}$ , it is apparent from the former equation that the momentum  $m_2v$  is appropriate to an ion of mass  $m_2^2/m_1$ . Thus, the decomposition of the metastable ion will give rise to a peak at an apparent mass  $m^* = m_2^2/m_1$ , not necessarily an integral number. This peak is known as a metastable peak. Generally, metastable peaks occur at non-integral mass numbers, and because there usually is a kinetic energy of separation during fragmentation of the polyatomic ion, they tend to be more diffuse than the normal mass peaks and thus are recognized easily. For any value of  $m^*$  a pair of integers  $m_1$  and  $m_2$  can be found such that  $m^* = m_2^2/m_1$ . Thus, the action of the magnetic field on the charged metastable-ion decomposition product can be used to give information on the individual fragmentation processes taking place in a mass spectrometer.

**Electrostatic field analysis.** An electrostatic field that attracts ions toward a common centre—that is, a radial field—will also exert a focussing action on a divergent beam of ions as shown in Figure 3. The radial force on

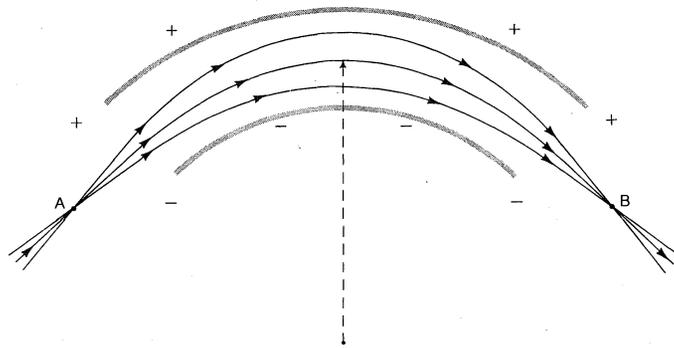

Figure 3: Focussing action of a radial electrostatic field produced by two semicylindrical charged electrodes on a monoenergetic beam of ions. The ions diverging from point A are brought to a focus at point B.

the ions due to the electrostatic field will be  $Ee$ , the product of the field  $E$  and the ionic charge  $e$ , and is equal to the centripetal force  $mv^2/R$ , of mass  $m$  moving with velocity  $v$  about a radius  $R$ . Thus, one may write the equation

$$Ee = mv^2/R \text{ or } R = \frac{1}{2}mv^2/1/2Ee.$$

The radius traversed by the ions will be proportional to their kinetic energy and an electric sector will thus produce an energy spectrum of the ions passing through it. Alternatively, if narrow collimating slits are placed at either end of the sector a monoenergetic beam of ions can be selected.

The possibility of using an electric wedge or sector to obtain a monoenergetic beam of ions, which is then separated for mass analysis by a magnetic sector is an obvious possibility. General equations for combined electric and magnetic sectors have been developed which show that a suitable combination of fields will give direction focussing for an ion beam of given mass-to-charge ratio, even though the beam may be heterogeneous in energy. The term double focussing is used for those combinations in which the angular and velocity aberrations effectively cancel.

Two of the best examples of double-focussing mass spectroscopes, both of which have been used in a variety of commercial instruments, were built by Mattauch and Herzog and by Alfred O. Nier and his collaborators. The Mattauch-Herzog geometry is shown in Figure 4 and has the remarkable property of being double focussing for all masses. Ions of all masses focus along a line that coincides with the second magnetic field boundary. Many ver-

focussing

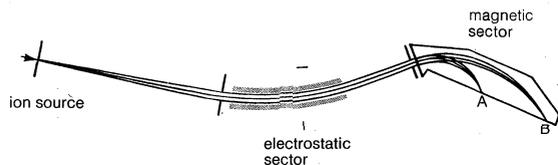

Figure 4: Arrangement of the electrostatic and magnetic sectors in the Mattauch-Herzog double-focussing mass spectrometer.

The ions are deflected in opposite directions in the electrostatic and magnetic fields. The divergent monoenergetic beam contains two ion species of different mass to charge ratio. All ions are brought to a focus along the plane AB.

sions of this design have been used when high resolution (up to  $10^5$ ) is desired for accurate mass and abundance measurements and general analytical work. It can give good spectra, even for a spread of 5 percent in energy of the ion beam, and can be used with virtually any ion source. The resolved ion beams can be recorded electrically or with a photographic plate.

The design due to Nier is illustrated in Figure 5. In a second instrument, Nier was able to achieve high sensitivity as well as high resolution. Using an electron-bom-

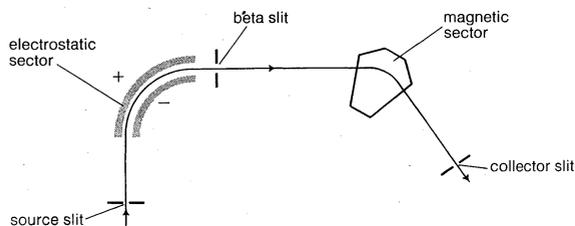

Figure 5: Arrangement of the electrostatic and magnetic sectors in the Nier double-focussing mass spectrometer. The angle of the electrostatic sector is  $90^\circ$  and that of the magnetic sector  $80^\circ$ . The direction of deflection of the ion beam is the same in both sectors.

bardment ion source, a resolving power of  $2 \times 10^5$  has been attained in a commercial instrument. The design has yielded mass measurements of the highest precision for a very large number of the isotopes and it has also been the most popular design for high resolution work in organic chemistry.

A few methods of attaining perfect double focussing are known. The simplest is to allow ions to move in a plane perpendicular to a homogeneous magnetic field. If the ions originate at a point, each ion will travel in a circular path appropriate to its momentum and will pass exactly through its point of origin after each revolution. In any practical system it is necessary to modify the arrangement so as to produce mass dispersion. This was first done by injecting a beam of positive ions into crossed homogeneous magnetic and electric fields. An ion moving in the plane of the electric field  $E$  and normal to the magnetic field  $H$  will describe a trochoid (the locus of a point on a wheel moving in a straight line) as shown in Figure 6, and all ions originating at the source or point A will be brought to a focus at the collector slits at point B. The

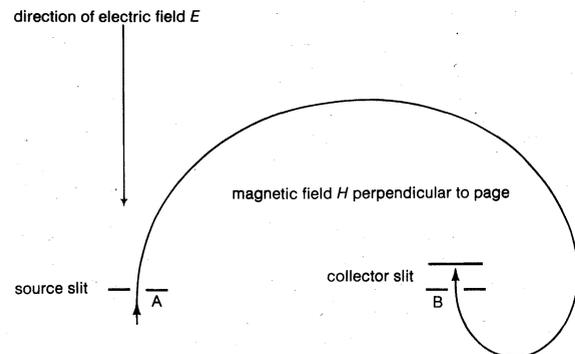

Figure 6: Ion path in the cycloidal mass spectrometer. The magnetic field  $H$  is in a direction perpendicular to the plane of the diagram.

separation distance AB of the source and collector can be written  $AB = (2\pi E/H^2) (m/e)$ . Neither the initial velocity nor direction of motion of the ions appears in this expression; so these factors do not affect the focus. In a commercial design, a resolving power of about 30,000 has been achieved.

All the designs described so far use electric and magnetic fields that are invariant with time. Several other designs, however, have been constructed in which alternating or pulsed fields are used. A method of obtaining mass separation by the use of crossed magnetic and radio-frequency fields makes use of the principle of cyclotron resonance. The "omegatron" spectrometer is illustrated in Figure 7.

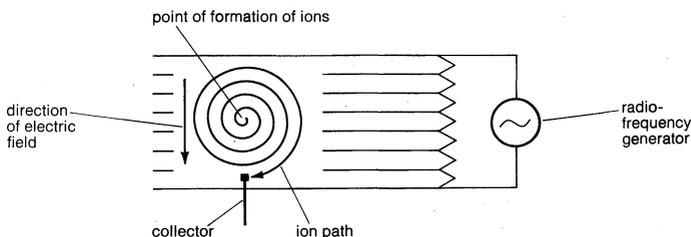

Figure 7: Path of the ions in the omegatron radio-frequency mass spectrometer. A magnetic field is in a direction perpendicular to the plane of the diagram.

Positive ions are produced by a stream of electrons moving along the direction of the magnetic field. If the time of revolution of an ion is equal to the period of the radio-frequency field (in phase), the ion can gain energy from the field and, as its energy increases, it will travel outward in an Archimedean spiral towards a collector. An ion of slightly different mass will be out of phase with the radio-frequency field and pass successively through maximum and minimum radii as it attains its maximum and minimum velocities. Ions of mass  $m$ , which are in phase, will be collected, and those ions of mass  $(m + \Delta m)$  will be prevented from reaching the collector. The resolving power  $m/\Delta m$  can be shown to be  $\pi n/2$ , in which  $n$  is the number of revolutions made by the ion before arriving at the collector. The resolving power attainable in practice is limited by ion scattering over the very long path length, which dictates a small instrument. The absence of limiting slits makes the instrument very sensitive and therefore useful in such studies as residual gas analysis.

Two other types of mass spectrometer, neither of which makes use of a magnetic field, have been developed into successful commercial instruments. The first of these is the linear time-of-flight spectrometer illustrated in Figure 1. Ions are formed in the source region and pulses of ions are injected into a region where there is no accelerating force, the so-called drift region. Since all ions enter the drift region with essentially the same kinetic energy  $K.E.$ , it can be seen from the equation  $K.E. = \frac{1}{2}mv^2$ , or  $v = \sqrt{2K.E./m}$ , that their velocities  $v$  will be inversely proportional to the square root of their masses  $m$  and they will take different times to traverse the drift region. A detector at the end of the drift region detects the arrival of the separated ion beams. Each pulse of ions thus gives rise to a complete mass spectrum, and spectra can be produced at rates as high as  $10^5$  per second, making the instrument particularly suitable for the study of fast reactions and transient species.

The basic concept of the quadrupole mass spectrometer is to provide a potential field distribution, periodic in time, which will allow ions of a selected mass to pass along an axis. The field is produced, ideally, between four hyperbolic electrodes, a cross section of the ideal arrangement being shown in Figure 8. In practice, four cylindrical electrodes are used, and combinations of dc and radio-frequency potentials are fed to opposite pairs of electrodes. Modern versions of the quadrupole mass spectrometer are compact and versatile instruments, offering a resolving power of the order of 500, plus a high ion transmission and sensitivity. It has been used to detect microscopic traces of gases and complete spectra can be obtained about once every second. The ion mass transmitted by a

Cyclotron resonance

Quadrupole field

quadrupole mass spectrometer can be selected with high precision merely by adjusting the radio frequency, thus making the instrument suitable for computer control and automatic data presentation.

#### PRINCIPAL APPLICATIONS

**Studies with stable isotopes.** The mass spectrometer is widely used to measure the masses of isotopes and to record the relative abundances with which they occur in nature or in artificially enriched samples. Mass spectrometers giving separated ion currents of several milliamperes are known as calutrons and these have been employed to produce relatively large and pure samples of particular isotopes. Separated isotopes are useful as targets in accelerators and reactors, and as labels in tracer studies.

Isotopic  
labelling

A variety of compounds is commercially available in which the molecules are chemically labelled with a specific isotope. Labelling with the heavy isotopes  $^2\text{H}$ ,  $^{13}\text{C}$ ,  $^{15}\text{N}$ ,  $^{17}\text{O}$ , and  $^{18}\text{O}$  is of particular importance in organic chemistry and in biology and medicine. The stable isotopes of nitrogen and oxygen are used for labelling, as no suitable radioactive isotopes of these elements exist. In the so-called isotopic dilution method a known amount of a labelled compound is added to a complex mixture containing some of the same (but unlabelled) compound (see also RADIOISOTOPES, APPLICATIONS OF). Measurement with a mass spectrometer of the percentage labelling in a small sample of the compound extracted from the mixture establishes the original amount of the compound present. Important advances have been made in such fields as metabolism studies, plant respiration, photosynthesis, the direct utilization of oxygen in biological oxidations, enzymic hydrolyses, phosphate transfer reactions. Stable isotopes of elements beyond oxygen are also commonly employed. For example,  $^{59}\text{Fe}$  has been used to follow hemoglobin cycles in the body.

**Exact measurement of atomic masses.** Over two-thirds of all exact atomic masses are now based on mass spectroscopic determinations. Large double-focussing mass spectrometers are employed for the highest accuracy. The standard used is the mass of the  $^{12}\text{C}$  isotope taken as 12 units exactly, and relative to the standard, many isotopic masses have been measured to better than 1 part in  $10^7$ . It is possible to deduce the composition of a polyatomic ion solely on the basis of an accurate measurement of its mass. This information is of particular importance in organic chemistry and is discussed below.

Organic chemists nowadays use mass spectrometers routinely to determine the structural formulas of organic compounds. Any compound that can be heated to give a vapour pressure without decomposing can be examined by this technique. Both high-resolution (20,000 to 100,000) and low-resolution (500 to 5,000) mass spectrometers are used. With a high-resolution mass spectrometer it is possible to carry out mass measurements on the molecular ion (or any other ion in the spectrum) to an accuracy of 1 part in 1,000,000, or so. This mass provides the best index for determining ionic formulas. The accurate masses of the ions  $\text{C}_6\text{H}_{12}^+$  and  $\text{C}_6\text{H}_8\text{O}_2^+$  are, for example, 84.0939 and 84.0211, respectively, and these ions can easily be distinguished solely on the basis of their

masses. Once the molecular formula is known it is possible to deduce the total of rings and double bonds making up the molecular structure and to begin to speculate on possible structural formulas. In order to deduce structural formulas from molecular formulas it is essential to study the fragment ions in the mass spectrum. It is still not possible to predict fragmentation patterns for organic molecules, but many semi-empirical rules of fragmentation are known and it is usually possible to pick out peaks in the spectrum that are characteristic of particular chemical groups. The technique is valuable in that it is generally not necessary to know any details of the composition of the unknown compound in order to deduce a complete or partial structure. Only a small quantity of compound, a hundred micrograms or less, is necessary for an analysis.

Structural  
formulas

Using a computer coupled to a high-resolution mass spectrometer, about 1,000 mass peaks per minute can be plotted at a resolving power of up to 20,000, accurate measurements can be made on each peak, and peak heights and ion compositions printed out in the form of an "element map" to aid in the interpretation of the spectrum. It is also possible for the computer to carry out many of the logical steps in reducing the data that lead to structural elucidation.

Continuous sampling of the materials contained in a reaction vessel, followed by analysis with a mass spectrometer, has been used to identify and measure the quantity of intermediate species formed during a reaction as a function of time. This kind of analysis is important, both in suggesting the mechanism by which the overall reaction takes place, and enabling the detailed kinetics of reactions to be resolved.

Isotopic labelling is widely used in such studies. It can indicate which particular atoms are involved in the reaction; in rearrangement reactions it can show whether an intramolecular or intermolecular process is involved; in exchange reactions it can show that particular atoms of, say, hydrogen, are exchanging between the reacting species. Labelling is also widely used in mass-spectrometric research to give information about the fragmentation reactions occurring in the mass spectrometer.

There are appreciable "isotope effects" by which isotopes may be distinguished apart from their difference in mass. It has been found, for example, that differences can be measured in the oxygen-18 content of the shells of marine animals that depend upon the temperature of the water in which the shells were formed. Such differences are preserved for millions of years and they have been used to obtain information concerning oceanic temperatures in paleolithic times.

Paleolithic  
temperatures

**Analysis of other chemical substances.** Using the high-frequency spark source already described, many less volatile substances can be examined by mass spectrometry. The usual method of sample preparation is to construct the electrodes for the high-frequency spark source out of the pure substance to be examined, or if the sample is a powder, to mix it with, say, pure nickel powder and to compress the mixture into the form of the electrodes. The combination of high temperature and high electric field within the spark produces ions characteristic of the sample. The method has found particular application in the analysis of inorganic substances, alloys, minerals, and the highly purified materials used in atomic-energy research, and semiconductor technology. It is possible to detect impurities of the order of one part in 100,000,000, or lower by this technique.

If a monoenergetic beam of electrons or photons is used as the ionizing radiation and if the energy in the beam is slowly increased from a low value, the bombarding energy at which ions begin to appear gives the ionization potential. As the energy is increased further, fragmentation of molecular ions will occur. The energy at which a particular ion appears gives the appearance potential for that ion. Appearance potentials of fragment ions can be used in conjunction with ionization potentials and calorimetric data to estimate various thermodynamic quantities such as latent heats and bond strengths.

Appear-  
ance  
potentials

The absolute time scale of geologic history can be con-

structed by the use of various isotopic clocks based on the radioactive decay of relatively long-lived isotopes (see DATING, RELATIVE AND ABSOLUTE). For example, uranium occasionally is found in fairly high local concentrations in radioactive rocks, along with the stable isotopes of lead-206 and lead-207, which are decay products of uranium-238 and uranium-235. Hence, knowing the decay rates of uranium-238 and uranium-235, the relative abundances of the uranium and radiogenic lead isotopes can be measured to give an estimate of age. Other natural radioactive processes that have been used in age determinations include the decay of potassium-40 to argon-40 and the decay of rubidium-87 to strontium-87.

**Vacuum techniques.** A type of small spectrometer adjusted for helium detection is commonly associated with vacuum systems in laboratories and industry. Connected to an evacuated system, it is an efficient and reliable aid for locating air leaks. In searching for a leak, a small jet of helium is played over the exterior of the system at the suspected joint or leakage area. When the exact point is reached, helium is sucked in along with the air, and the spectrometer sounds an alarm. The sensitivity of the technique is so great that an air leak can be detected, even if hundreds of thousands of other leaks of the same magnitude are present.

## Mas'ūdī, al-

Al-Mas'ūdī (full name: Abū al-Ḥasan 'Alī al-Mas'ūdī), the Arab historian and traveller known as the Herodotus of the Arabs, was the first Arabic writer to combine history and scientific geography in a single large-scale work. He thus pioneered a way of writing history that provided an alternative to the year-by-year chronology exemplified in the *Tarīkh* ("History") of al-Ṭabarī (c. 839–923).

Born in Baghdad toward the end of the 9th century, he soon showed an extraordinary love of learning, an excellent memory, a capacity to write quickly, and a boundless curiosity that led him to study a wide variety of subjects, ranging from history and geography—his main interests—to comparative religion and science. Mas'ūdī was not content to learn merely from books and teachers but travelled widely to gain firsthand knowledge of the countries about which he wrote. His travels extended to Syria, Iran, Armenia, the shores of the Caspian Sea, the Indus Valley, Ceylon, Oman in Arabia, and the east coast of Africa as far south as Zanzibar, at least, and, possibly, Madagascar.

The titles of more than 20 books attributed to him are known, including several about Islāmic beliefs and sects and even one about poisons, but most of his writings have been lost. His major work was *Akhbār az-zamān* ("The History of Time") in 30 volumes. This seems to have been an encyclopaedic world history, taking in not only political history but also many facets of human knowledge and activity. A manuscript of one volume of this work is said to be preserved in Vienna, but its projected publication has not, in the early 1970s, materialized. If this manuscript is genuine, it is all that has remained of the work. Mas'ūdī followed it with *Kitāb al-awsaṭ* ("Book of

the Middle"), variously described as a supplement to or an abridgment of the *Akhbār az-zamān*. The *Kitāb* is undoubtedly a chronological history. A manuscript in the Bodleian Library, Oxford, may possibly be one volume of it.

Neither of these works made much impact on scholars—in the case of *Akhbār az-zamān*, possibly because of its daunting length. So Mas'ūdī rewrote the two combined works in less detail in a single book, to which he gave the fanciful title of *Murūj adh-dhahab wa ma'ādin al-jawāhir* ("The Meadows of Gold and Mines of Gems"). This book quickly became famous and established the author's reputation as a leading historian. Ibn Khaldūn, the great 14th-century Arab philosopher of history, describes Mas'ūdī as an *imam* ("leader, example") for historians. Though an abridgment, *Murūj adh-dhahab* is still a substantial work. In his introduction, Mas'ūdī lists more than 80 historical works known to him: but he also stresses the importance of his travels to "learn the peculiarities of various nations and parts of the world." He claims that, in the book, he has dealt with every subject that may be useful or interesting.

The work is in 132 chapters. The second half is a straightforward history of Islām, beginning with the Prophet Muḥammad, then dealing with the caliphs down to Mas'ūdī's own time, one by one. While it often makes interesting reading because of its vivid description and entertaining anecdotes, this part of the book is superficial. It is seldom read now, as much better accounts can be found elsewhere, particularly in Ṭabarī. The first half, in contrast, is of great value, though somewhat sprawling and confused in its design. It starts with the creation of the world and Jewish history. Then it intersperses chapters describing the history, geography, social life, and religious customs of non-Islāmic lands, such as India, Greece, and Rome, with accounts of the oceans, the calendars of various nations, climate, the solar system, and great temples. Among particularly interesting sections are those on pearl diving in the Persian Gulf, amber found in East Africa, Hindu burial customs, the land route to China, and navigation, with its various hazards, such as storms and waterspouts. The relative positions and characteristics of the seas are explained.

Mas'ūdī's approach to his task was original—even eccentric. He made no attempt to write a methodical history and gave as much weight to social, economic, religious, and cultural matters as to politics. Moreover, he utilized information obtained from sources not previously regarded as reliable. He retailed what he learned from merchants, local writers, including non-Muslims, and others he met on his travels. He displayed interest in all religions, including Hinduism and Zoroastrianism, as well as Judaism and Christianity. But he tended to reproduce uncritically what he heard: thus, his explanations of natural phenomena are often incorrect. Yet he was no worse, in this respect, than medieval European travellers such as Marco Polo and Sir John Mandeville.

Mas'ūdī had no settled abode for most of his adult life. In 945 he settled in Damascus. Two years later, he left there for al-Fuṣṭāṭ (old Cairo), where he remained until his death in 957.

It was there, in the last year of his life, that he wrote his "swan song," *Kitāb at-tanbīh wa al-ishrāf* ("The Book of Notification and Verification"), in which he summarized, corrected, and brought up-to-date the contents of his former writings, especially the three historical works.

**BIBLIOGRAPHY.** For an appreciation of Mas'ūdī as a historian within the wider context of Arabic historical writing as a whole, see FRANZ ROSENTHAL, *A History of Muslim Historiography* (1952), especially pp. 95–97 and 107–118. Little is known of Mas'ūdī's life except the little he tells us himself. About one quarter of the *Murūj adh-dhahab* can be read in English translation, with a useful preface, by ALOYS SPRENGER: *El-Mas'udi's Historical Encyclopaedia Entitled "Meadows of Gold and Mines of Gems,"* vol. 1 (1841). See also R.A. NICHOLSON, *A Literary History of the Arabs*, 2nd ed., pp. 352–354 (1930); and C. FIELD, *Tales of the Caliphs* (1909), based on Mas'ūdī.

## Materialism

Especially since the 18th century, the word Materialism has been used to refer to a family of metaphysical theories (*i.e.*, theories on the nature of reality) that can best be defined by saying that a theory tends to be called Materialism if it is felt sufficiently to resemble a paradigmatic theory that will here be called mechanical Materialism.

### TYPES OF MATERIALIST THEORY

Mechanical Materialism is the theory that the world consists entirely of hard, massy material objects, which, though perhaps imperceptibly small, are otherwise like such things as stones. (A slight modification is to allow the void—or empty space—to exist also in its own right.) These objects interact in the sort of way that stones do: by impact and possibly also by gravitational attraction. The theory denies that immaterial or apparently immaterial things (such as minds) exist or else explains them away as being material things or motions of material things.

#### Types distinguished by departures from the paradigm.

In modern physics (if interpreted realistically), however, matter is conceived as made up of such things as electrons, protons, and mesons, which are very unlike the hard, massy, stonelike particles of mechanical Materialism. In it the distinction between matter and energy has also been broken down. It is therefore natural to extend the word Materialist beyond the above paradigm case (of mechanical Materialism) to cover anyone who bases his theory on whatever it is that physics asserts ultimately to exist. This sort may be called physicalistic Materialism. Such a Materialist allows the concept of material thing to be extended so as to include all of the elementary particles and other things that are postulated in fundamental physical theory—perhaps even continuous fields and points of space-time. Inasmuch as some cosmologists even try to define the elementary particles themselves in terms of the curvature of space-time, there is no reason why a philosophy based on such a geometrized cosmology should not be counted as Materialist, provided that it does not give an independent existence to nonphysical things such as minds.

Another sort of departure from the paradigm leads in the direction of what might be called a deistic Materialism. In this view it would be allowed that, although there is a spiritual Creator of the universe, he does not interfere with the created universe, which is itself describable in terms of mechanical or physicalist Materialism.

Still another departure from the paradigm is the theory that holds that everything is composed of material particles (or physical entities generally) but also holds that there are special laws applying to complexes of physical entities, such as living cells or brains, that are not reducible to the laws that apply to the fundamental physical entities. (To avoid inconsistency, such a theory may have to allow that the ordinary laws of physics do not wholly apply within such complex entities.) Such a theory, which could be called “emergent Materialism,” can shade off, however, into theories that one would not wish to call Materialist, such as hylozoism, which ascribes vital characteristics to all matter, and panpsychism, which attributes a mindlike character to all constituents of material things.

Another common relaxation of the paradigm is that which allows as compatible with Materialism such a theory as epiphenomenalism, according to which sensations and thoughts do exist in addition to material processes but are nonetheless wholly dependent on material processes and without causal efficacy of their own. They are related to material things somewhat in the way that a man’s shadow is related to the man. A similar departure from the paradigm is a form of what might be called “double-aspect Materialism,” according to which in inner experience men are acquainted with nonphysical *properties* of material processes, though these properties are not causally effective. A form of double-aspect theory in which these properties were allowed to be causally effective would be a species of emergent Materialism.

Physicalistic, deistic, emergent, and epiphenomenal types

Of course, more than one of these qualifications might be made at the same time: thus a person might wish to speak of “physicalist deistic epiphenomenalist Materialism.” If no other qualifications are intended, it is convenient to use the word extreme and to speak, for example, of “extreme physicalist Materialism”—which is probably the type most discussed among professional philosophers in English-speaking countries.

**Type distinguished by its view of history.** In the wider world, however, the word Materialism most commonly brings to mind dialectical Materialism, which is the orthodox philosophy of Communist countries. This is most importantly a theory of how changes arise in human history, though a general metaphysical theory lies in the background. Dialectical Materialists contrast their view with what they call “vulgar” Materialism; and it does, indeed, appear that their theory is not an extreme Materialism, whether mechanical or physicalist. They seem to hold merely that mental processes are dependent on or have evolved from material ones. Though they might be akin to emergent Materialists, it is hard to be sure; their assertion that something new emerges at higher levels of organization might refer only to such things as that a wireless receiver is different from a mere heap of the same components. And if so, even an extreme physicalistic Materialist could acquiesce in this view. The distinctive features of dialectical Materialism would, thus, seem to lie as much in its being dialectical as in its being Materialist. Its dialectical side may be epitomized in three laws: (1) that of the transformation of quality into quantity, (2) that of the interpenetration of opposites, and (3) that of the negation of the negation. Nondialectical philosophers find it hard, however, to interpret these laws in a way that does not make them into either platitudes or falsehoods (see MARXISM; see also RELATED ENTRIES UNDER MATERIALISM in the *Ready Reference and Index*).

Perhaps because of the historical determinism implicit in dialectical Materialism, and perhaps because of memories of the mechanical Materialist theories of the 18th and 19th centuries, when physics was deterministic, it is popularly supposed that Materialism and determinism must go together. This is not so. As indicated below, even some ancient Materialists were indeterminists, and a modern physicalist Materialism must be indeterministic because of the indeterminism that is built into modern physics. Modern physics does imply, however, that macroscopic bodies behave in a way that is effectively deterministic, and, because even a single neuron (nerve fibre) is a macroscopic object by quantum mechanical standards, a physicalistic Materialist may still regard the human brain as coming near to being a mechanism that behaves in a deterministic way.

**Types distinguished by their account of mind.** A rather different way of classifying Materialist theories, which to some extent cuts across the classifications already made, emerges when the theories are divided according to the way in which a Materialist accounts for minds. A central-state Materialist identifies mental processes with processes in the brain. An analytical behaviourist, on the other hand, argues that, in talking about the mind, one is not talking about an actual entity, whether the brain or an immaterial soul, but, rather, one is somehow talking about the way in which people would behave in various circumstances. According to the analytical behaviourist, there is no more of a problem for the Materialist in having to identify mind with something material than there is in identifying such an abstraction as the average plumber with some concrete entity. Analytical behaviourism differs from psychological behaviourism, which is merely a methodological program to base theories on behavioral evidence and to eschew introspective reports. The analytical behaviourist usually has a not too plausible theory of introspective reports according to which they are what are sometimes called “avowals”: roughly, he contends that to say “I have a pain” is to engage in a verbal surrogate for a wince. Epistemic Materialism is a theory that can be developed either in the direction of central-state Materialism or in that of analytical behaviourism and that rests on the contention that the only

Dialectical Materialism

Central-state Materialism and analytical behaviourism

statements that are intersubjectively testable are either observation reports about macroscopic physical objects or statements that imply such observation reports (or are otherwise logically related to them).

Before leaving this survey of the family of Materialistic theories, a quite different sense of the word Materialism should be noted in which it denotes not a metaphysical theory but an ethical attitude. A person is a Materialist in this sense if he is interested mainly in sensuous pleasures and bodily comforts and hence in the material possessions that bring these about. A man might be a Materialist in this ethical and pejorative sense without being a metaphysical Materialist, and conversely. An extreme physicalistic Materialist, for example, might prefer a Beethoven record to a comfortable mattress for his bed; and a person who believes in immaterial spirits might opt for the mattress.

#### HISTORY OF MATERIALISM

**Greek and Roman Materialism.** Though Thales of Miletus (c. 580 BC) and some of the other Pre-Socratic philosophers have some claims to being regarded as Materialists, the Materialist tradition in Western philosophy really begins with Leucippus and Democritus, Greek philosophers who were born in the 5th century BC. Leucippus is known only through his influence on Democritus. According to Democritus, the world consists of nothing but atoms (indivisible chunks of matter) in empty space (which he seems to have thought of as an entity in its own right). These atoms can be imperceptibly small, and they interact either by impact or by hooking together, depending on their shapes. The great beauty of atomism was its ability to explain the changes in things as due to changes in the configurations of unchanging atoms. The view may be contrasted with that of the earlier philosopher Anaxagoras (c. 480 BC), who thought that when, for example, the bread that a person eats is transformed into human flesh, this must occur because bread itself already contains hidden within itself the characteristics of flesh. Democritus thought that the soul consists of smooth, round atoms and that perceptions consist of motions caused in the soul atoms by the atoms in the perceived thing (see ATOMISM).

Because Epicurus' philosophy was expounded in a lengthy poem by Lucretius, a Roman philosopher of the 1st century BC, Epicurus (died 270 BC) was easily the most influential Greek Materialist. He differed from Democritus in that he postulated an absolute up-down direction in space, so that all atoms fall in roughly parallel paths. To explain their impacts with one another, he then held that the atoms are subject to chance swerves—a doctrine that was also used to explain free will. Epicurus' Materialism therefore differed from that of Democritus in being an indeterministic one. Epicurus' philosophy contained an important ethical part, which was a sort of enlightened egoistic hedonism (see EPICUREANISM). His ethics, however, was not Materialistic in the pejorative sense of the word.

**Modern Materialism.** Materialism languished throughout the medieval period, but the Epicurean tradition was revived in the first half of the 17th century in the atomistic Materialism of the French Catholic priest Pierre Gassendi. In putting forward his system as a hypothesis to explain the facts of experience, Gassendi showed that he understood the method characteristic of modern science, and he may well have helped to pave the way for corpuscular hypotheses in physics. Gassendi was not thoroughgoing in his Materialism inasmuch as he accepted on faith the Christian doctrine that men have immortal souls. His contemporary, the English philosopher Thomas Hobbes, also propounded an atomistic Materialism and was a pioneer in trying to work out a mechanistic and physiological psychology. Holding that sensations are corporeal motions in the brain, Hobbes skirted, rather than solved, the philosophical problems about consciousness that had been raised by another contemporary, the great French philosopher René Descartes. Descartes's philosophy was dualistic, making a complete split between mind and matter. In his theory of the physical world,

however, and especially in his doctrine that animals are automata, Descartes's own system had a mechanistic side to it that was taken up by 18th-century Materialists, such as Julien de La Mettrie, the French physician whose appropriately titled *L'Homme machine* (1747; Eng. trans., *Man a Machine*, 1750) applied Descartes's view about animals to man himself. Denis Diderot, an 18th-century French Encyclopaedist, supported a broadly Materialist outlook by considerations drawn from physiology, embryology, and the study of heredity; and his friend Paul, baron d'Holbach, published his *Système de la nature* (1770), which expounded a deterministic type of Materialism in the light of evidence from contemporary science, reducing everything to matter and to the energy inherent in matter. He also propounded a hedonistic ethics as well as an uncompromising atheism, which provoked a reply even from the Deist Voltaire.

The 18th-century French Materialists had been reacting against orthodox Christianity. In the early part of the 19th century, however, certain writers in Germany—usually with a biological or medical background—reacted against a different orthodoxy, the Hegelian and Neo-Hegelian tradition in philosophy, which had become entrenched in German universities. Among these were Ludwig Büchner and Karl Vogt. The latter is notorious for his assertion that the brain secretes thought just as the liver secretes bile. This metaphor of secretion, previously used by P.-J.-G. Cabanis, a late-18th-century French Materialist, is seldom taken seriously, because to most philosophers it does not make sense to think of thought as a *stuff*. The Hobbesian view, also espoused by Büchner, that thought is a *motion* in the brain is usually viewed as a more promising one.

The synthesis of urea (the chief nitrogenous end product of protein metabolism), discovered in 1828, broke down the discontinuity between the organic and the inorganic in chemistry, which had been a mainstay of nonmaterialistic biology. Materialist ways of thinking were later strengthened enormously by the Darwinian theory of evolution, which not only showed the continuity between man and other living things right back to the simplest organisms but also showed how the apparent evidences of design in natural history could be explained on a purely causal basis. There still seemed to be a gap, however, between the living and the nonliving, though E.H. Haeckel, a 19th-century German zoologist, thought that certain simple organisms could have been generated from inorganic matter and, indeed, that a certain simple sea creature may well be in process of generation in this way even now. Though Haeckel was wrong, 20th-century biologists have proposed much more sophisticated and more plausible theories of the evolution of life from inorganic matter. Haeckel and his contemporary, the British zoologist T.H. Huxley, did much to popularize philosophical accounts of the world that were consonant with the scientific thought of their time, but neither could be regarded as an extreme Materialist.

**Contemporary Materialism.** Perhaps because recent developments in biochemistry and in physiological psychology have greatly increased the plausibility of Materialism, there has lately been a resurgence of interest in the philosophical defense of central-state Materialism. Central-state Materialists have proposed their theories partly because of dissatisfaction with the analytical behaviourism of the Oxford philosopher Gilbert Ryle. Ryle himself is reluctant to call himself a Materialist, partly because of a dislike of all "isms" and partly because he thinks that the notion of matter has meaning only by contrast with that of mind, which he thinks to be an illegitimate sort of contrast. Nevertheless, it would seem that analytical behaviourism could be used to support a physicalist Materialism that would go on to explain human behaviour by means of neural mechanisms. (Ryle himself is suspicious of mechanistic accounts of biology and psychology.) Analytical behaviourism has been felt to be unsatisfactory, however, chiefly because of its account of introspective reports as avowals (see above), which most philosophers have found to be unconvincing.

Philosophers have distinguished two forms of central-

Democritus and Epicurus

Darwin, Haeckel, and Huxley

Gassendi through Büchner and Vogt

state Materialism, namely, the translation form and the disappearance form. The translation form is the view that mentalistic discourse can be translated into discourse that is neutral between physicalism and dualism, so that the truth of a man's introspective reports is compatible with the objects of these reports being physical processes. The disappearance form is the view that such a translation cannot be done and that this fact, however, does not refute physicalism but shows only that man's ordinary introspective reports are contaminated by false theories.

Feigl,  
Place,  
Smart,  
Arm-  
strong

*Translation central-state theories.* Among the philosophers who have advocated the translation form is the U.S. philosopher Herbert Feigl, earlier a member of the Vienna Circle, who, in an influential monograph (see *Bibliography*), did the most to get contemporary philosophers to treat central-state Materialism as a serious philosophical theory. Against the objection that, for example, "visual sensation" does not mean "process in the visual cortex," advocates of the translation form point out that "the morning star" does not mean the same as "the evening star," and yet the morning star as a matter of fact is the evening star. The objection confuses meaning and reference. Against the objection that a purely physical process (a dance of electrons, protons, and so on) cannot have the sensory quality of greenness that is observed in a visual experience of seeing grass, say, they reply that to talk of the sensory experience of something looking green (or having a green mental image) is not to talk of anything that is literally green, but is simply to report that some internal process is of the sort that normally goes with seeing something, such as a lawn, which really is green. Though an immaterialist might say that the sort of process in question is a spiritual process, the Materialist can equally claim that it is a material process in the brain. The analysis of the introspective report is neutral between these two contentions; the Materialist, however, opts for his contention on various grounds. The British Materialist U.T. Place does so on the ground of normal scientific methodology; and the Australian Materialist J.J.C. Smart does so with a metaphysical application of the principle (called "Ockham's razor") that entities should not be multiplied beyond necessity. A physicalistic Materialist has, of course, an obligation to go on to give a suitable account of such apparently nonphysicalist qualities as the greenness of grass. At one time Smart analyzed colours in terms of the discriminatory behaviour of human beings. Another Australian Materialist, D.M. Armstrong, holds, on the other hand, that colours are as a matter of fact properties of objects, such properties being of the sort describable in the theoretical terms of physics. Feigl, in turn, is to some extent (and rather reluctantly) a double-aspect theorist. He qualifies the position taken by the other translation theorists, conceding that the translations do leave something out, viz., the immediately introspectable properties of "raw feels," such as that of hearing the tone of middle C. He holds, however, that such properties are irrelevant to causal explanations of phenomena. The translation form of central-state Materialism thus has some affinities with the earlier epistemic Materialism of the Positivist philosophers Rudolf Carnap and Hans Reichenbach, Germans who settled in the United States. Thus Carnap has suggested that mental predicates be treated as applying to material entities: for example, "Carnap sees green" could be taken as meaning "the body Carnap is in the state of green-seeing," the state of green-seeing being a purely physical state that explains the behavioral facts that led one to ascribe the predicate "sees green" to Carnap in the first place.

*Disappearance central-state theories.* David K. Lewis, a United States philosopher of science and language, has developed a translation form of central-state Materialism on the basis of a theory regarding the definition of theoretical terms in science. According to this theory, entities such as electrons, protons, and neutrons are defined in terms of the causal roles that they play in relation to observational phenomena—e.g., phenomena in cloud chambers—but the method of definition is able to do justice to the causal and other interrelations between the theoretical entities themselves. Lewis applies this account to com-

monsense psychology. Since mental entities, such as pains, are defined in commonsense psychology in terms of their causal roles (in relation to observable behaviour) and since there is empirical reason to ascribe the same causal roles to brain processes, Lewis identifies mental events, processes, and states with brain events, processes, and states. The disappearance form of central-state Materialism is the sort of theory held by P.K. Feyerabend, a U.S. philosopher, who denies that the Materialist can give a neutral analysis of introspective reports. In Feyerabend's view, commonsense introspective reports are irreducibly immaterialist in content. He argues, however, that this admission does not show the untenability of Materialism. Ordinary mentalistic discourse, he holds, is comparable to the medieval discourse about epileptics as being "possessed by the devil." If one now "identified" demon possession with a certain medical condition of the brain, this would really be an assertion that there is no such thing as a demon-possessed state: the medieval way of looking at the matter is thus rejected. It is in this sort of way that Feyerabend wants to "identify" the mind with the brain: he simply rejects the ordinary mentalistic conceptual scheme and so feels no obligation to show its compatibility with Materialism.

The influential American philosophers W.V. Quine and Wilfrid Sellars also hold theories that could be regarded as disappearance forms of physicalistic Materialism, though there is a Kantian twist to Sellars' philosophy that makes it hard to classify. Sellars holds that mentalistic concepts cannot be eliminated from man's commonsense picture of the world, which he calls "the manifest image." In a way reminiscent of Kant he holds that, although the manifest image is inescapable, it does not give metaphysical truth about the world as it really is in itself. This truth is given, instead, by "the scientific image"—i.e., by theoretical science, which is physicalist. In the case of Quine, there is a certain Platonism in that he believes in the objective reality of nonspatiotemporal entities, viz., those that are the subject matter of pure mathematics. Because he holds that the reason for believing mathematics is that it is needed as part of physical theory, his reasons for believing in numbers and the like are not in principle different from those for believing in electrons; thus Quine's Platonism does not really compromise his physicalism.

The Austrian philosopher Ludwig Wittgenstein, who lived to the mid-20th century and was professor of philosophy at Cambridge University, has sometimes been interpreted as a behaviourist, though his insistence that an inner process stands in need of outward criteria could possibly be interpreted as a sort of epistemic and central-state Materialism. Nevertheless, to count Wittgenstein as a Materialist would be to take considerable liberties with him; for, while displaying at times a certain mystical attitude, he also held very strongly that the business of a philosopher is not to put forward any metaphysical theory but to clear up conceptual confusions—to show the fly the way out of the fly bottle.

**Eastern Materialism.** This historical survey has been concerned with Materialism in Western philosophy. On the whole, Materialism is contrary to the spirit of both Indian and traditional Chinese philosophy, though the Cārvāka school of Materialists flourished from the 6th century BC until medieval times in India. Mention should also be made of the strong naturalistic tendency in Theravāda Buddhism, as also in certain schools of Chinese philosophy that exalt *ch'i* ("ether" or "material force") above principle and mind.

#### SUBSTANTIVE ISSUES IN MATERIALISM

**Reductionism, consciousness, and brain.** The main attraction of Materialism today is the way in which it fits in with a unified picture of science—a picture that has become very plausible. Thus, chemistry is reducible to physics inasmuch as there is a quantum-mechanical theory of the chemical bond. Biology is mainly an application of physics and chemistry to the structures described in natural history (including the natural history that one can explore through powerful microscopes). Increasingly, biological explanations resemble explanations in engineer-

Feyera-  
bend,  
Quine,  
Sellars,  
Wittgen-  
stein

Unified  
science  
and  
physical-  
mental  
laws

ing, in which material structures are described and then the laws of physics and chemistry are used to explain the behaviour of these structures. (In the biological case, of course, these structures are often dynamic in the sense that their molecules are continually being replaced.) Through the influence of neurophysiology and also cybernetics (the science of information and control, which can be applied also to artificial automata), scientific psychology is also fitting well into the same mechanistic scheme. The recalcitrant residue appears in the phenomena of consciousness. Here mental events seem, indeed, to be correlated with physical events; but, if the mental events are not the very same as the physical events, one is left with apparently ultimate (or irreducible) physical-mental laws that do not fit happily into unified science, and one is thus faced with a situation unlike that of the rest of science. Looking at science generally, one expects *ultimate* laws to relate simple entities, such as fundamental particles. A physical-mental law, however, would have to refer to something very complex—a brain process involving perhaps millions of neurons, with each neuron being itself an almost fantastically complex entity. There would be a multitude of physical-mental laws, which would look like excrescences on the face of science. Because they would not fit into the network of scientific laws, Herbert Feigl has called them “nomological danglers.” To get rid of these danglers is one of the chief attractions of Materialism. Of course, an immaterialist might assert that mental entities exist and also that there are no physical-mental laws. But it might be hard for him to reconcile this position with the empirical evidence; and in any case he would be faced with the problem of how to distinguish the free exercise of such anomalous physical-mental interaction from mere chance behaviour.

The development of computers and other devices to take over much of the more routine sort of human behaviour has led to attempts on the part of scientists and technologists, such as the American M.L. Minsky, to develop real artificial intelligence. So far, the success that these scientists hoped for has not been achieved. An American linguistic theorist, Noam Chomsky, has argued on the basis of his theories of generative grammar that the brain is quite unlike any already-understood type of mechanism. Indeed, any physicalistic Materialist must certainly concede that there are very deep problems about the brain, which apparently can no longer be thought of as a bundle of conditioned reflex mechanisms or the like, as it often has seemed to be to many psychologists. The physicalist can stress, however, that the investigator's ignorance need not lead him to assume that he will never be able to find an explanation of intelligence and of linguistic abilities in terms consonant with his present notion of a physical mechanism. (There is also the possibility that physical laws not yet discovered might be needed to explain the workings of the brain. So long as these turned out to be basic laws of physics, such discoveries would not imply a shift to emergentist Materialism.)

**Logic, intentionality, and psychical research.** Some philosophers, such as the Oxford philosopher J.R. Lucas, have tried to produce positive arguments against a mechanistic theory of mind by employing certain discoveries in mathematical logic, especially Gödel's theorem, which implies that no axiomatic theory could possibly capture all arithmetical truths. In general, philosophers have not found such attempts to extract an antimaterialist philosophy from mathematical logic to be convincing. Nevertheless, the problems of mechanizing intelligence, including the mathematical abilities of human beings, do pose unsolved problems that the Materialist is obliged to take seriously.

Perhaps the most common challenge to Materialism comes from philosophers who hold that it cannot do justice to the concept of intentionality, which Franz Brentano, a pre-World War I German philosopher, made the distinguishing mark between the mental and the non-mental (see MIND, PHILOSOPHY OF: *The search for a criterion of the mental: Intentionality*; PHENOMENOLOGY: *Origin and Development of Husserl's phenomenology*:

*Basic concepts*). (A related objection is that Materialism cannot do 'justice to the distinction between behaviour and mere bodily movements.) Brentano held that mental events and states somehow point toward objects beyond themselves (or have a “content”). Many contemporary philosophers agree with Brentano that purely physical entities cannot have this property. If it is said, for example, that punched holes on the tape of a computer can refer beyond themselves in the way that thoughts do, then it is commonly replied that, in themselves, the holes on the tape have no reference or content—for this belongs only to the thoughts in the mind of a person who reads the tape. The Materialist reply may be to argue, however, that there is a fundamental unclarity in the very notion of intentionality (this is roughly Quine's position) or else to argue that purely physical systems can, after all, possess intentionality.

The alleged spiritualistic and other phenomena reported in psychical research are sometimes adduced against Materialism. The Materialist, however, can well afford to postpone discussion of these phenomena until such time as they are accepted by the general scientific community, which on the whole still remains skeptical of them.

At present, there are reputable philosophers who accept Materialism, and there are also reputable philosophers who either reject it as false or hold that it is not the business of a philosopher to propound any sort of metaphysical system. Perhaps Materialists are still in a minority; but at any rate there is much less tendency than there was a generation ago for this type of theory to be thought philosophically naïve.

**BIBLIOGRAPHY.** For the period up to about 100 years ago, see F.A. LANGE, *Geschichte des Materialismus und Kritik seiner Bedeutung in der Gegenwart*, 2 vol. (1902; Eng. trans., *History of Materialism and Criticism of Its Present Importance*, 3rd ed., 3 vol. (1925)). For more recent times, see JOHN PASSMORE, *A Hundred Years of Philosophy*, 2nd ed. (1966). There are excellent articles by KEITH CAMPBELL and H.B. ACTON on “Materialism” and “Dialectical Materialism” in the *Encyclopedia of Philosophy*, vol. 5, pp. 179–188 and vol. 2, pp. 389–397 (1967), which also contains excellent articles on nearly all of the noncontemporary philosophers here mentioned. Examples of work by most of the contemporary writers are given in JOHN O'CONNOR (ed.), *Modern Materialism: Readings on Mind-Body Identity* (1969); and C.V. BORST (ed.), *The Mind-Brain Identity Theory* (1970). See also HERBERT FEIGL, *The “Mental” and the “Physical”*: *The Essay and a Postscript* (1967); J.J.C. SMART, *Materialism and Scientific Realism* (1963); D.M. ARMSTRONG, *A Materialist Theory of the Mind* (1968); and WILFRID SELLARS, *Science, Perception and Reality* (1963), especially ch. 1. A rather difficult book defending Materialism from the difficulties about intentionality is D.C. DENNETT, *Content and Consciousness* (1969). For two very different styles of antimaterialist argument, see J.R. LUCAS, *The Freedom of the Will* (1970); and NORMAN MALCOLM, *Problems of Mind* (1971). Another interesting critique of Materialism is in JOHN BELOFF, *The Existence of Mind* (1962). A mainly mechanistic philosophy of biology is presented by the German biologist B. RENSCH in *Biophilosophie auf erkenntnistheoretischer Grundlage (Panpsychistischer Identismus)* (1968; Eng. trans., *Biophilosophy*, 1971), though Rensch's philosophy is also panpsychist.

Some classic Materialist works are: LUCRETIVS, *On the Nature of the Universe*, trans. by R.E. LATHAM (1951); THOMAS HOBBS, *Body, Mind and Citizen: Selections*, ed. by R.S. PETERS (1962); RENE DESCARTES, *Philosophical Writings*, trans. and ed. by ELIZABETH ANSCOMBE and P.T. GEACH (1954); and A. VARTANIAN, *La Mettrie's “L'Homme Machine”*: *A Study in the Origins of an Idea* (1960), which is a critical edition with introductory monograph and notes.

## Materials Handling

Materials handling is the process of applying human, animal, or other energy to the movement of raw materials from their native site to a point of use; the manipulation of materials in the production process as an aid to manufacture; and the transfer of finished goods to the final user. The major emphasis of materials handling falls at the points of contact among these three types of basic economic activities. A secondary aspect of materials handling is the transportation and storage function of industry.

In the world today, various stages of materials-handling development can be seen, often in proximity. In such countries as Turkey, ancient systems involving human and animal power interconnect with modern systems involving rail and truck facilities.

**Modern trends.** Modern materials handling considers the entire movement of goods from their beginnings as raw materials to processing points and to customers, in contrast to the former approach that considered each part of the system separately. In early systems, for example, vegetables might be picked one at a time, stored temporarily, placed in a package or loose in a cart, moved to an assembly point, handled again individually, put into a bag, box, or basket, placed in a larger vehicle in packaged units, moved to a wholesaler in bags, broken down into individual portions for delivery to the retailer, and, finally, sold to the consumer.

This situation still exists to a large extent in many areas, not only of the underdeveloped world but in developed countries. The only difference in the handling of many products is the level of technology applied. Australian wool is handled between 50 and 60 times before it reaches the consumer as a garment. The typical agricultural product may be handled 20 times before it reaches the store shelf.

**Examples of modern techniques.** The first applications of the flow concepts of materials handling occurred in large bulk industries such as those processing iron ore, coal, and petroleum. Iron ore, for example, has been moved in bulk on the Great Lakes of the United States since the beginning of the 20th century. Large earthmoving equipment removes the ore from open pits in northern Minnesota, transfers it to special trains that haul it to port, where large cranes or automatic dumping mechanisms place it in huge holding bulkheads that, in turn, transfer it by means of gravity or by cranes to the ship. The ship then steams to a lake port near a steel mill, where the process is reversed. The entire system is geared to anticipate mill needs with a continuous flow of the ore from mine to mill.

Modern materials-handling systems are also employed in assembly-line production, such as automobile manufacturing. When operating at full capacity, a large-scale auto assembly plant can produce one car every 40 seconds; a full 24-hour production schedule results in a maximum daily production of 2,160 cars. This level of production can be maintained for long periods despite differentiation in colour, style, accessories and trim that make it possible to produce a year's output of cars with no two identical. Materials handling in such productive industries must be highly organized. Arrival of raw materials at the plant site is carefully coordinated with scheduled production needs, thus reducing storage to a minimum. Finished cars cannot be economically stored at the plant and are therefore moved to distribution points as quickly as possible. Raw materials are scheduled to arrive within 96 or even 48 hours of use, and finished cars are moved away within a few hours.

The key to scheduling materials supply and handling in the assembly line for each automobile manufactured is the customer order, or purchase specification, which is converted to punch-card form and placed in the production schedule. Materials and parts necessary to complete the car in precisely the way the purchaser has specified are placed in subassembly lines; when the chassis arrives at a station, the correct part is available for assembly. Plants that employ this type of operation are not really manufacturing plants but materials-handling plants.

Practically all manufacturing of parts and components is done away from the assembly line, often at a distant point.

Another example of modern materials-handling techniques is the processing of wheat into consumer products. Harvested by large combines, the grain is moved in bulk via truck to an elevator, in which it is placed by conveyor or by an air-pressure system; from the elevator it is gravity fed to a railroad car, shipped to a flour mill, and stored again in silos. From the silos it moves to the mill via a quantity-feed conveyor or an air slide. The finished flour coming from the end of the line is either packaged for the consumer market or shipped in bulk by rail and truck to bakeries or other large industrial users. At the bakery the flour is again placed in a silo or hopper, conveyed to a mixing unit for dough preparation, baked into bread or another product, sent to an automatic wrapping machine, and wheeled to trucks for delivery. In many cases the first time the product is handled as a single unit is when the consumer takes it from the shelf. Such an integrated distribution system is made possible by meticulous attention to required materials-handling systems within each process and to the transfers of material between processes.

### TYPES OF MATERIALS-HANDLING SYSTEMS BY PROCESS

In bulk movements of any type, emphasis is on an integrated flow from source of raw materials to final user. Three principles underlie operations: (1) the best handling system involves no actual handling at all, or minimal handling; (2) the larger the volume handled the lower the unit cost; and (3) movement of materials as a unit should be maintained as far toward the ultimate point of use as possible.

**Raw-materials and parts supply.** Raw-materials and parts supply both have various economic and physical characteristics that affect materials handling. There are three main classes: large-volume, low-value, flowable products, such as petroleum; large-volume bulk products that do not flow, such as iron ore; and high-volume manufactured parts and components.

**Flowable bulk commodities.** Sources of supply for raw materials of this kind usually are located at a distance from the market. Petroleum fields in the southwest United States, in the Persian Gulf region, and in North Africa supply oil and gas to the northeast United States, Europe, and Japan—thousands of miles away. Handling of petroleum products begins with collection of crude oil in the field. Though much crude oil in the past moved by rail tank car to refineries and by tank car or truck to market, today pipelines dominate petroleum handling. Pipe of relatively small dimension is attached to each producing well. A network of these pipes serving a specified geographic area connects to bulk collecting stations, which, in turn, serve large terminal areas with storage tanks capable of holding hundreds of thousands of gallons. From these large bulk terminals, the crude petroleum is placed in a pipeline the diameter of which may reach 36 inches (91 centimetres). Since crude oil comes in various grades, minimum quantities of about 50,000 barrels (one barrel equals 55 gallons or about 220 litres) at one time are put into the pipeline system.

After refining, the finished product is either stored in bulk terminals for later pipeline delivery to smaller markets in the area or is carried by tank truck for local delivery to gasoline stations. Fuel oil moves directly to large users or distributors by pipeline.

Oil tankers typically carry petroleum and its products across large bodies of water. In the past few decades, supertankers with dead weight up to 300,000 tons have taken over most international oil movements. While increasing the risk of spills of very large magnitude, these tankers have substantially reduced the cost of handling and moving oil, acting, in effect, as extensions of the pipeline system.

Like oil, natural gas flows, and pipelines are typically employed for its transmission. Since natural gas can be

Handling  
iron ore

Auto-  
matized  
bread  
baking

compressed, it is frequently stored near markets under pressure in large circular tanks or underground. Above-ground tanks have movable upper halves that rise and fall as stored content varies. This feature of natural-gas handling allows close to 100 percent utilization of the pipeline in spite of large seasonal changes in demand. Another important feature of natural gas is its ability, when subjected to extremely low temperatures, to shrink substantially in volume. Thus, natural gas at low temperatures may be shipped in containers over long distances by rail, motor truck, or ship and may at the receiving point be permitted to expand to normal operating temperature and volume.

Moving slurries

A slurry consists of finely ground solid material suspended in a liquid carrier, usually water. Coal, pulverized and mixed with water, can be moved by pipeline. Major users of coal slurries are electric utilities. Slurries have also been moved via pipeline for short distances and can then be partially dried at terminal points before pumping onto a ship. Water is again added after the material leaves the ship so that it can be sent by pipeline to the final user. The advantage of this system is that it minimizes handling costs between pipeline and ship.

In the case of coal, gasification is sometimes employed as a basic materials-handling technique. In this process, the coal is burned in the ground and the products of combustion collected, or the coal is heated to form gas. These gases may then be burned to produce electrical energy that is transmitted over power lines. Alternatively, the gas is injected into a pipeline.

*Nonflowable bulk commodities.* Items in this category include iron ore, coal, limestone, cement, phosphate, potash, and sulfur. While some of the above can be made to flow, discussion here is limited to their nonflowable forms.

Most production in this category involves materials-handling systems tied to water movements by ship or barge or to rail and motor-truck movements. Because of the large volumes moving at any one time, large-scale materials-handling equipment is typical at terminal points.

Coal is handled in much the same way as iron ore. The advantage of large-scale handling systems of the type used to transport coal and iron ore is their greater efficiency. While an ordinary freight train carrying carloads of several different types of merchandise typically averages about 3 to 6 miles (5 to 10 kilometres) per hour, a train transporting coal only may average 30 to 50 miles (50 to 80 kilometres) per hour because it moves directly from the source to point of use with no intermediate stops. Thus, the use of open-pit mining methods, combined with modern materials handling, can bring a fivefold increase in the productivity of the train. Because of the higher capital cost of materials-handling equipment, however, the total system saving is considerably less, but still substantial.

Another example of this type of materials-handling system is the synthetic fertilizer industry. The principal ingredients of fertilizer—phosphate, potash, and nitrogen, plus an inert carrier—are brought together at a single processing plant and mixed to specifications. While nitrogen is extracted from the atmosphere at numerous locations, phosphate and potash are taken from mines. Furthermore, fertilizer demand is subject to wide seasonal variations. After its extraction from the earth, phosphate is moved by truck or conveyor to a rail siding for shipment to a mixing plant. The typical large fertilizer company has a network of mixing plants centred in large agricultural areas. The product is mixed close to market because rail bulk shipment of its ingredients is the cheapest part of the entire handling and distribution process. After mixing, the finished product is placed in hoppers for loading into covered railcars or trucks equipped with self-unloading equipment. Some large farms have their own fertilizer hoppers and dump the product directly into a mechanical applicator.

*High-volume manufactured-parts supply.* The materials-handling system for this category of goods, which typically includes automobile parts and other durable consumer goods, revolves around four basic needs: ar-

rival of the product at the processing point as close to scheduled need as possible; designing the materials-handling system, including packaging, to fit production processes as closely as possible; compatibility with transport types employed; and finished product availability at minimum cost. Great attention to the details of materials-handling equipment design is focussed in these areas, with unitization the basic principle employed. Unitization involves the handling of large volumes as a unit; thus, several thousand automobile parts may be packaged together on one warehouse pallet and not be unpacked again until they are put into the assembly line. The optimum size of package and pallet or container is crucial to handling efficiency and to the use of space in storage and transportation.

Values of unitization

**Continuous-processing systems.** In continuous processing, work progresses through the production system at a fixed rate. The flour and baking industries employ continuous-processing techniques, as do certain chemical producers and makers of textiles and agricultural products. The process need not depend upon the flowable characteristics of the product. The auto assembly plant is a case in point, as are steel mills. In these kinds of continuous processing, the materials-handling function is highly automated, with relatively high capital investment in automatic systems. In the most sophisticated continuous-process systems, the work function consists largely of electronically or mechanically controlling automated product flow over continuously operating equipment. Sometimes the system includes computerized control that requires simple monitoring only.

In the work-station processing system, materials move from one work station to the next in sequence, stopping at each. The role of materials handling in this type of operation involves assuring maximum productivity at each work station (see AUTOMATION; MASS PRODUCTION) and smoothing the flow of semifinished goods from one work station to the next.

#### MATERIALS-HANDLING EQUIPMENT

Materials-handling equipment may be classified in terms of the type of product handled, thus including machinery for bulk products in large continuous volumes; continuous processing based on industrial-parts movement; discontinuous processing of a wide variety of goods; and order filling of large varieties of goods.

A second classification relates to the mobility characteristics of the materials-handling equipment and includes both stationary and movable facilities.

A third classification, which identifies the type of equipment itself, includes wheeled carts, power and lift trucks, trailer trains, racks and pallets, bins and boxes, mono-rails and conveyors, containers, unit loads, and cranes and hoists.

*Wheeled carts.* Though they are among the more primitive materials-handling-equipment types, carts with two or four wheels are still quite widely used. A cart merely permits a man to move a larger volume of goods at one time and is generally used where distances are short and labour costs low. Shifting of a product from a storage area adjacent to the production line is a case in point. Laundries, bakeries, wholesalers, and other industries of this type characteristically use carts.

*Power trucks.* This equipment improves the productivity of labour by increasing both the speed and the size of load. Forklifts are among the most common power trucks now used. Trucks for general packaged merchandise usually are designed to convey from 2,000 to 4,000 pounds (900 to 1,800 kilograms). Power trucks of larger capacity are designed for special product handling. Lumber yards, for example, have large-capacity trucks usually of a straddle type that can lift 10,000 to 20,000 pounds (4,500 to 9,000 kilograms) of lumber.

Straddle trucks

*Trailer trains.* As their name implies, trailer trains consist of a single powered tractor with one or more four-wheeled carts attached. These usually follow a specific route covering a number of loading and unloading stations and are particularly useful where the flows of packaged materials are large and continuous.

**Racks and pallets.** Racks consist of stationary wood or steel frames designed to store a product. In effect, a three-tier-rack system provides three separate storage areas at one location. Material stored in racks may or may not be palletized—i.e., stored on platforms for ready handling. Rack and pallet systems usually require the use of a forklift truck or a pallet jack to lift the pallet off the floor by hydraulic or electric power. Palletless systems usually are employed where products are very light and bulky, occupying a disproportionate amount of space for the weight stored. In this case, a special cleanup truck is employed; it is designed to grasp the equivalent of a pallet load of material, but without the need for the pallet itself. Products are stored one on top of the other in the storage area. Soaps and cereals typically employ this system (see STORAGE AND WAREHOUSING).

**Bins and boxes.** Bins and boxes find widest application in the storage of numerous small parts in one container. Nuts, bolts, and fittings are stored in bins and boxes until required. Typically, the entire bin or box is moved to the production line at a specific work station. In some industries, bins and boxes store commodities at the point of sale. Auto dealers, parts suppliers, and hardware merchants use bins and boxes for numerous small parts.

**Monorails and conveyors.** Animal carcasses or parts requiring painting, spraying, or dipping are typically hung on hooks or other devices and moved along on an overhead rail. Conveyors may be powered or gravity run or manually fed on belts, rollers, wheels, or hoppers; they may be fixed or portable and open to the air or closed; and they may carry loose, bulk, or packaged materials.

Conveyors typically find use in production or handling processes requiring more or less continuous operations. Post offices often use conveyors to speed mail sorting. Similarly, manufacturers and distributors find conveyors useful in sorting large numbers of parts destined for customers in different locations. In production facilities, conveyors provide a capability of scheduling work flows across work stations at optimum rates. In this case, the product is moved across a number of different work stations providing maximum employment of effort at production instead of materials handling.

For bulk products, such as sand, gravel, and ores, large-capacity conveyors frequently provide connecting links between processes. Thus, a railcar may intermittently unload coal in large quantities outdoors while a conveyor feeds the coal continuously to a furnace.

Portable conveyors find application where volumes are not large and work stations may move from one point to another. Bagged or bulk merchandise in fairly heavy weights delivered to a number of different stations in a warehouse may require portable conveyors as a loading and unloading aid.

**Containers.** Containers are intended to limit the number of times a product is handled. Constructed of wood, metal, or heavy corrugated paperboard, containers may consist of relatively small boxes or cages to full trailer dimensions. When a trailer is used as a container, it is typically designed for heavy stresses so that it may be lifted with its entire load and placed aboard a flatbed truck trailer, railcar, ship, or airplane. The most recent application of containers of very large size is called LASH, for Lighter Aboard Ship. In this operation, entire barges are lashed to an especially designed oceangoing ship for transfer to distant destinations. Container ships of the traditional type may carry containers that look like ordinary truck trailers. Advantages of containers include substantial increases in production (as much as 40,000 pounds [18,000 kilograms] may be handled in 30 seconds); minimized handling of individual products or packages throughout the system; and less risk of pilferage at transfer points.

LASH  
containers

**Unit loads.** These are similar to containers. A unit load consists of a homogeneous grouping of the same or similar commodities, moved as a unit, while freight in containers may be mixed and heterogeneous. A unit load need not be in a container; flat sheets of plywood, bound together with metal strapping and sheathed in paper, are a case in point.

**Cranes and hoists.** Generally employed for very heavy lifting and moving of machinery and materials, cranes and hoists may be fixed or movable.

Jib cranes, which consist of single arms attached to walls or other structures, have the capability of swinging through an angle of 180° to 360° and therefore are useful for positioning material. Jib cranes are frequently observed in high-rise building construction, where they are set on the topmost floor to move construction materials vertically to the floor that is being worked and horizontally to the place where needed.

Bridge cranes consist of heavy metal beams holding a hoist. The beams, with wheeled ends, traverse a set of guides set at an elevation. The hoist moves vertically in lifting material and horizontally across the bridge in moving it. The entire bridge may move along the girders. Thus, three-dimensional movements over large square or rectangular areas are possible. This type of crane is used in handling large electrical generators and other heavy equipment from one work station to another or in moving heavy parts to a fixed station.

Stacker cranes are used to stack and retrieve materials, usually in close quarters. Typically, they ride along an aisle and lift materials vertically on a platform or other end device up to 30-foot (nine-metre) heights. Stacker cranes have also been employed in automated storage and retrieval systems. Each stack location is given a code number that is placed on a punched card or other control device. When a shipment or order is received, the punched card is inserted to activate the system, and the stacker crane automatically finds the right location.

Gantry cranes have a movable structure similar to bridge cranes. The major difference is that the gantry legs of the crane are wheeled and set in a rail in the ground. The horizontal bar, or bridge, may extend beyond the moving legs of the crane so that clockwise unloading of ores and other materials may be accomplished by the overreach of the crane. Gantries also are used in moving industrial goods from rail cars to plant site and in lifting fully loaded containers or trailers onto a flatbed railcar.

Mobile cranes are wheeled devices with their own motive power, which enables them to move over wide areas. They are generally of the jib type with a single boom attached to the mobile body.

The endpiece of handling equipment on a crane depends upon the product moved and may be tongs, grabs, slings, hooks, magnets, or buckets.

#### TRANSPORTATION

**Evaluating transportation alternatives.** Transportation techniques can be evaluated in terms of time, space, cube, weight carried, and cost.

Time refers to the total number of hours necessary to complete a transfer of goods. An airplane, for example, which provides great transit speeds, may connect with a truck at both pickup and delivery points. Thus, although flight time may be typically 5 hours, the total time needed to complete a delivery may be as much as 24 hours.

Space refers to the coverage of pickup and delivery points that a particular form of transport offers. Most flexible in this respect is the truck, as it can reach any point where a road exists and some locations where one does not. Pipelines are least flexible.

Cube describes the efficiency with which the transport unit is utilized. Optimum utilization of cube results in maximum efficiency of movement, since waste space is held to a minimum. Cube limitations are particularly relevant in transport forms such as truck trailers and airplanes. Railroads do not suffer cube limits in the same way, as freight cars can easily be added to a train.

Cube as a  
limiting  
factor

Weight is particularly important, as the cost of transportation is generally quoted in terms of cost per unit of weight. Weight and cube are interrelated since very light, bulky items will not result in heavy loadings and thus will show a high cost per unit of weight shipped. For this reason many items, such as bicycles, are shipped in partially disassembled form.

Cost of transport is influenced by the four factors mentioned. Generally, the heavier the loading and the higher the density (cube), the lower the cost. Costs increase with speed, however, and with the number of deliveries (space).

The interrelationships of the four factors affecting cost and capacity of various transport types are not always readily apparent. Modern cargo jet airplanes, for example, can carry as much as 125 tons of product. An oceangoing general cargo vessel may carry 10,000 tons in one shipment. The airplane can make one trip a day between Europe and the United States, whereas the cargo vessel can at best make one round trip a week. Thus, over a two-week period, a fully loaded cargo vessel carries 20,000 tons, whereas the airplane carries 3,500 tons in the same period. From this perspective, the cargo capacity of an airplane is about 15 percent as much as a cargo vessel.

**Modes of transport.** The major modes of transportation are highway, rail, pipeline, ocean, inland waterway, and air.

**Highway motor truck.** Trucks and trailers may be of generalized or specialized design. The typical over-the-road trailer is a generalized type of vehicle capable of handling wide ranges of bulk and packaged goods. Specialized trailers, such as refrigerated, liquid-tank, dry-flowable, heavy-duty, and household-goods vans carry limited ranges of commodities.

The main point of contact between trucking and other modes of transportation is in loading and unloading. Ideally, loading and unloading facilities are arranged to keep delays to a minimum. Thus, packaged goods of general merchandise, such as groceries, are expensive to load manually and placing them upon pallets is preferred whenever possible. A higher level of development (with lower cost) is the platform-loaded unitized load, in which a movable floor on wheels is built into the truck. A winch device is used to move the whole floor in and out of the truck. The advantage of this system is that the platform can be preloaded before truck arrival, and unloaded at leisure after truck delivery.

In single-package unloading, the limit of movement is as much as a man can carry. In pallet movement, the limit is set by the forklift truck—usually 2,000 to 4,000 pounds—whereas in unit-platform loading, 20,000 pounds or more can be unloaded in one move.

**Rail.** Through restricted to a single, set rail path, the railroad is the most efficient overland method of transportation for large volumes of bulk materials over relatively long distances.

In the past, railroad freight consisted of coal, petroleum, grain, lumber, automobiles, and similar large volume products. To handle them, the railcar fleet included boxcars, flatcars, hoppers, and other basic types. Competition from larger and more efficient trucks and trailers, inland barges, ships, and pipelines and changes in the outlooks of transport users—who began to choose among alternatives in terms both of service and price—forced the rails to innovate and to design special equipment and cars for specific commodity groups. The boxcar, for example, proved a costly alternative to truck trailers. As the rails lost business, they responded by introducing the trilevel car, capable of carrying a dozen automobiles in place of the boxcar's capacity of four. Loading and unloading operations were also greatly facilitated.

Lumber and a number of other commodities are now handled in similar ways. The all-door boxcar permits side loading of long dimension products such as lumber with modern forklift trucks in bundles at a much faster rate and at lower cost than the conventional boxcar. Flatcars are also employed for unitized materials that do not need enclosed protection in shipping.

Another recent development in materials handling by rail is the unit train, designed to carry a single commodity from point of origin to destination. Coal, grain, and other bulk materials frequently move in unit trainloads of thousands of tons at substantially reduced rates.

Typically, the unit train requires especially designed

cars as well as rather sophisticated materials-handling systems for loading and unloading. Hoppers or large cranes may be employed at the loading point. If a hopper is employed, the railcar moves under the hopper, and gravity feed is employed to load each car in turn. By this method, a single carload of coal may be loaded in less than a minute. Cranes achieve much the same result.

At the receiving end rapid unloading is achieved by gravity, dropping the product onto a storage pile. There is no need to stop the car for unloading of this type, as a simple trip device can be used to open the hopper-car chute and permit the product to fall into the storage area. Cranes and other unloading devices are also used.

Piggyback operations consist of two basic types. One provides a flatcar about 80 feet (24 metres) long that permits loading two over-the-road truck trailers with undercarriage attached. The second type consists of two containers of truck-trailer configuration without undercarriage attached, loaded on flatcars.

The economic advantage of both types lies in the substitution of lower costs of moving railcars, as opposed to trailers, over the road. Rather sophisticated loading and unloading terminal facilities are required at origin and destination. For trailer-on-flatcar operations, an asphalt apron adjacent to the tracks is required. The wheeled trailers are hauled onto the flatcar with an ordinary trailer truck.

In container trains without undercarriage attached overhead gantry cranes, capable of lifting fully loaded trailers off their undercarriage, are required. The truck trailer, in this case, consists of a flatbed truck similar to a rail flatcar.

**Ocean transportation.** Ocean transportation consists of two major types: self-contained vessels of bulk or general-cargo type, and general or special-purpose barges and containers of 3,000 to 5,000 tons capacity moving in especially designed oceangoing vessels.

General-cargo vessels carry a wide range of commodities, typically of the packaged or nonbulk types, and concentrate their activity on major routes where large volumes of potential freight traffic exist. These larger vessels are complemented by smaller itinerant (tramp) steamers or even sailing vessels that chiefly serve the smaller ports. Interisland steamers in the Caribbean and the Pacific and smaller sailing vessels in the Mediterranean fill local needs.

The most important oceangoing general-cargo vessels are conference carriers, which belong to a worldwide association of shipping interests that attempts to control the pricing of oceangoing general freight. Control is accomplished by requiring shippers to agree to ship on conference-member ships or pay a penalty. In return, the shipper generally receives the benefit of higher quality service in the ocean trades, including materials handling of a generally superior type, often with self-unloading devices, access to stevedoring services, customs assistance, agency assistance in ancillary services, and others.

In the bulk trades, the outstanding recent development is the construction of so-called supertankers. These very large tankers, dwarfing all other ships afloat, move large quantities of product, chiefly petroleum, over very long distances at very low unit costs. Despite these advantages, the supertankers have stirred controversy because of their potential for huge oil spills. Other bulk carriers specialize in hauling grain, fluid materials other than oil, and ores.

Combination types of vessels have recently entered the ocean trades. The three major combination types are railcars on ferry ships; container ships, carrying truck-trailer type containers below deck and above; and LASH, for transporting barges aboard a ship. Combination types permit materials handling in containers of relatively large size, which results in greater cargo security and, perhaps more important, increases the speed of port handling and thus reduces the round trip time of the vessel. On the North Atlantic trade, container ships maintain a five-day sailing schedule and a two-week round-trip transit time. A typical general-cargo ship, especially if it is making more than one port of call, takes 30 days or more.

Unitized  
load

Unit trains

**Inland waterways.** On inland waterways, barges of the pushing or pulling type predominate. The push barges common on the inland waterways of the United States employ a power push boat (tug) behind a line of barges. Pull types, common in Europe, attach a tow line to the barge. A single tow may power 10 to 20 barges.

**Air transport.** Though air transport is the fastest method of moving freight over long distances, trucks must be used for local delivery. Because of its high cost, air transport is generally restricted to high-value products.

Air freight moves either in converted passenger aircraft or in freighters. Carrying capacity for the smaller jets and older propeller planes is very restricted, but the larger jets can carry up to 70,000 pounds in all-freight configurations and the "jumbo jets" as much as 250,000 pounds.

Because of the high capital cost of airplanes, it is necessary to limit loading time on the ground. Large freight terminals serving jet aircraft usually use conveyor systems of various types to handle a large assortment of different types of packages. These assortments are typically placed in containers designed to fit smoothly inside the airplane so that cube may be utilized to the maximum. Containers and pallets may be loaded by forklift trucks if the airplane is side loaded, or by winches or forklifts, if tail loaded. Some of the large airplanes now flying can carry upward of 100 automobiles at one time. For specialized products such as cars, special handling systems have been developed.

## Materials Processing

Materials processing is the name generally used to cover those operations that are used to transform industrial materials from a raw-material state into finished parts or products. Industrial materials are defined as those used in the manufacture of "hard" goods, such as more or less durable machines and equipment produced for industry and consumers, as contrasted to disposable "soft" goods such as chemicals, foodstuffs, pharmaceuticals, and apparel.

Detailed treatment of many of these processes will be found in such other articles as METALLURGY; PLASTICS AND RESINS; and STEEL PRODUCTION. The present article provides a summary description of the wide variety of materials-processing techniques in use in modern industry.

Materials processing by hand is as old as civilization; mechanization began with the Industrial Revolution of the 18th century, and in the early 19th century the basic machines for forming, shaping, and cutting were developed, principally in England. Since then, materials-processing methods, techniques, and machinery have grown in great variety and number.

The cycle of manufacturing processes that converts materials into parts and products starts immediately after the raw materials are either extracted from minerals or produced from basic chemicals or natural substances. Metallic raw materials are usually produced in two steps: First the crude ore is processed to increase the concentration of the desired metal; this is called beneficiation. Typical beneficiation processes include crushing, roasting, magnetic separation, flotation, and leaching. Second, additional processes such as smelting and alloying are used to produce the metal that is to be fabricated into parts for assembly in the ultimate product.

In the case of ceramic materials, natural clay is mixed and blended with various silicates to produce the raw material. Plastic resins are produced by chemical methods in powder, pellet, putty, or liquid form. Synthetic rubber is also made by chemical techniques, being produced, as is natural rubber, in such forms as slabs, sheeting, crepe, and foam for fabricating into finished parts.

The processes used to convert raw materials into finished products perform one or both of two major functions: first, they form the material into the desired shape; second, they alter or improve the properties of the material.

### FORMING

Forming and shaping processes can be conveniently classified into two broad types—those performed on the material in a liquid state and those performed on the material in a solid or plastic condition.

**Liquid-state metal processing.** The processing of materials in liquid form is commonly known as casting when it involves metals, glass, and ceramics; it is molding when applied to plastics and some other nonmetallic materials.

Most casting and molding processes involve four major steps: (1) making an accurate pattern of the part; (2) making a mold from the pattern; (3) introducing the liquid into the mold; and (4) removing the hardened part from the mold. A finishing operation is sometimes needed.

**Sand-casting.** This technique employs molds made of sand to which varying amounts of resinous binders have been added. The process is most widely used for iron and steel castings and is applicable for parts ranging from a few pounds to several tons in weight. Sand castings of great complexity are readily produced.

**Permanent-mold casting.** This process makes repeated use of the same molds made in two or more parts hinged and clamped for easy removal of the finished castings. The materials that can be so cast are generally limited to aluminum and magnesium, although some kinds of iron, zinc, and lead are sometimes cast by this process. The average size of permanent-mold castings varies from about half a pound to about 12 pounds (0.2 to five kilograms).

**Plaster-mold casting.** This method of casting utilizes molds made from a slurry (water mixture) of gypsum. The castings have fine finishes, and surface detail is faithfully reproduced. Plaster-mold castings are usually small, up to 20 pounds (nine kilograms). The process is particularly suitable for thin wall parts—down to about  $\frac{1}{16}$  inch (1.5 millimetres) thick. Though most plaster-mold castings are of copper alloys, aluminum and magnesium may also be used.

**Investment casting.** Frequently referred to as the lost-wax (cire perdue) process, investment casting was first used centuries ago in China. Later, such artists as Cellini employed it in the 16th century. A pattern, called an investment, is made of wax, frozen mercury, or plastic in and around a master die. The investment is then covered inside and out with a slurry of ceramic material. After the ceramic mold hardens, the investment is melted out, leaving the cavity into which the molten metal is poured. Investment casting is relatively expensive, but it is suitable for almost any fine configuration and for wall thicknesses as thin as  $\frac{1}{64}$  inch (0.4 millimetre). Castings weighing up to 25 pounds (11 kilograms) and over can be produced in most castable metals.

**Die-casting.** This process, best suited of all the metal-casting processes for high production rates, involves forcing molten metal under pressure into closed metallic

Functions  
of  
processing

dies. Because the dies are solid, the complexity of shapes which may be handled is more restricted than with sand-casting. Most die castings are made of zinc or aluminum but other metals, including copper alloys, lead, and tin can be die-cast. Aluminum parts approaching 100 pounds (45 kilograms) and zinc parts as heavy as 200 pounds (90 kilograms) can be die-cast.

**Electroforming.** This is essentially a plating process. A mandrel or core pattern of the part is placed in a plating bath and metal is deposited to the desired thickness on the surface. Then the part is removed from the bath, and the core separated from the deposited metal. The finished part is a self-supporting structure with inside dimensions matching those of the mandrel, or core.

**Nonmetallics casting and molding.** Molding and casting of plastics is performed with the plastic material either in a hot molten state or as a liquid at or near room temperature.

**Liquid casting.** Liquid or sirupy plastic resins or elastomers (rubbers) to be cast are poured into molds and cured either by heating or chemical reaction. Sheets, rods, and special shapes are produced by casting.

**Low-pressure molding.** Reinforced plastic moldings can be made by mixing liquid resins with mats or fibres of such materials as glass or asbestos and molding at a low pressure.

**Slush and rotational molding.** Combinations of resins, elastomers, plasticizers, and other ingredients in liquid or paste form, called plastisols, and in the form of gels, called plastigels, are used in so-called slush and rotational molding in which the material is placed in a mold and allowed to form a layer on the mold surface. The remaining unsolidified material is then removed.

**Slip casting.** This technique, similar to slush molding, is widely used for making ceramic parts. A stable suspension of a mixture of clay in water is first poured or rotated in a porous mold. The porous mold sucks up the liquid, leaving a solid layer of the material. Ceramics and glass are also cast in the molten state as in metal casting.

**Injection molding.** In injection molding, the plastic resin is melted in a heating chamber and forced under pressure into a closed cold-metal mold, which is then opened and the finished part removed. Injection molding is primarily for thermoplastics, although it is used for molding some thermoset plastics; that is, plastics that cannot be resoftened by heat after setting. Like its die-casting counterpart for metals, this is a relatively fast, high production process and is suitable for parts weighing from around 2 to 300 ounces.

**Compression molding.** In this technique, commonly used for forming thermosetting plastics, resin powders or granules, after being placed in an open mold, are converted into a liquid under heat and pressure when the mold closes. The solid, finished form is produced on cooling in the mold.

**Transfer molding.** A modification of compression molding, this process involves heating the resin in a separate chamber and forcing it into a heated closed-mold cavity.

**Processing solid materials.** Materials in their solid state are formed into desired shapes by the application of a force or pressure. The material to be processed can be in a relatively hard and stable condition and in such forms as bar, sheet, pellet, or powder or it can be in a soft, plastic, or putty-like form. Solid materials can be shaped either hot or cold.

Processing of metals in the solid state can be divided into two major stages: first, the raw material in the form of large ingots or billets is hot-worked, usually by rolling, forging, or extrusion, into smaller shapes and sizes; second, these shapes are processed into final parts and products by one or more smaller scale hot or cold forming processes.

**Rolling.** This is the most common primary metal-forming process. Hot metal ingots or billets are passed through a series of rolls that work the metal in successive stages into the desired cross-sectional shape and size. Plate, sheet, strip, bar, and rod shapes are rolled, as well as such special shapes as I-beams, channels, and angles.

**Extrusion.** In this process, used for producing long lengths of rod, tubing, and other cross-sectional shapes, hot or cold metal is forced through a die of the desired cross section. The process is widely used to produce intricate shapes, chiefly in copper alloys, aluminum, and magnesium.

**Forging.** One of the most widely used metal-forming processes, forging involves the working of either hot or cold metal into the desired shape by impact or pressing. Most metals can be forged. Forging processes are generally more expensive than casting, but they produce parts with greater strength and toughness.

The simplest and oldest method is open-die forging in which the hot metal piece is constantly turned as it is being shaped by a mechanical hammer. The method is limited to such large, heavy shapes as shafts and die and gear blanks.

Drop-forging is a refinement of the open-die process. Hot billets are forged into an open die by the repeated impact of a mechanical hammer. Often, a series of progressive dies are needed to attain the final shape. Drop forgings vary in weight from about one ounce (28 grams) to several tons.

Upset forging is used to make relatively small to medium-size parts from rod stock; that is, a long piece of raw material in the form of a rod. The end of a heated rod stock, while gripped between portions of a die, is struck by another die. The upsetting action reduces the length and increases the diameter of the rod to produce the desired shape.

In cold-heading, similar in principle to upset forging, cold wire stock is fed automatically to the dies and shaped by upsetting. Extremely high production rates are reached in the manufacture of a wide variety of such small parts as nails. Swaging, the opposite of cold-heading, is a cold-working process in which a rotary hammering action reduces the diameter and increases the length of a piece of rod or tubing.

Press-forging employs pressure rather than impact to squeeze hot metal, placed between dies, into the desired shape. As in drop-forging, progressive dies frequently are used. This process is most commonly used for forgings weighing 25 to 30 pounds (11 to 14 kilograms).

Impact extrusion can be considered either as a cold forging or as an extrusion process. A slug of metal placed in a die is subjected to the pressure of a punch, causing the metal to flow into the space between the punch and the die. The process is widely used for making collapsible tubes of soft metals.

**Stamping and pressing.** These two processes make up another large family of metal-forming techniques, all of which are used to cut or form metal plate, sheet, and strip. Almost all metals can be blanked and formed. The steps common to all these operations are the preparation of a flat blank and the shearing or stretching of the metal into a die to attain the desired shape. The forming process is either drawing or stamping. In drawing, the flat stock is either formed in a single operation or progressive drawing steps may be needed to reach the final form. Stamping involves placing the flat stock in a die and striking it with a movable die or punch. Besides shaping the part, the dies can perform perforating, bending, and shearing operations. In general, stampings are limited to metal thicknesses of  $\frac{3}{8}$  inch (10 millimetres) or less. Pressing and drawing operations can be performed on cold metals up to  $\frac{3}{4}$  inch (19 millimetres) thick and on hot metals up to about  $3\frac{1}{2}$  inches (89 millimetres).

In the 1960s many new press forming and drawing techniques were developed, a number of them making use of rubber pads, bags, and diaphragms as part of the die or forming elements. Some involve stretch forming over dies; others combine forming and heat-treating operations. Still other methods, known as high energy rate forming, employ explosives, electrical energy, or magnetic energy to produce shock waves that form the material into the desired shape.

**Powder metallurgy processing.** This involves the production of parts from metals in powder form by compacting the powder in a die to the desired form and heating

Open-die  
forging

New press  
techniques

(sintering) to fuse the powders together. A secondary press operation, known as coining, is sometimes performed on the sintered part. Most metals and many combinations of materials can be formed in this way. Parts ranging in size from less than an inch to around six inches in diameter (20 to 150 millimetres), and up to five or six inches long, can be produced.

Metal strip can also be produced from metal powders. The metal powder, chiefly copper or nickel, is cold-rolled into a continuous strip that passes through a sintering furnace and then through a hot-rolling mill to produce the final thickness and density.

**Nonmetallic forming.** Plastics, ceramics, rubber, and other nonmetallics are formed in the solid or plastic state by processes similar to many of those used for metals. In the sheet forming of thermoplastic materials, the sheet is heated above its softening point, then shaped over a mold by the application of pressure much as in metal-pressing operations. The molding pressure is applied by mechanical or hydraulic force, by preheated compressed air, or by vacuum techniques.

Calendering, widely used for producing plastic-, rubber-, and paper-sheeted products, consists of forming a continuous sheet by squeezing the softened material between two or more rolls.

In extrusion processes, the softened material is forced through a die approximating the desired cross-sectional shape. Most thermoplastics and some thermoset plastics can be extruded as well as rubber, glass, and ceramics.

Powder molding of plastics involves the sintering or fusing of plastic powder to conform to the surface of a mold. Glass and ceramics in powder form are pressed and fused into complex shapes by much the same general techniques used in powder metallurgy. The pressing operation can be done either wet or dry. With certain refractory (high-melting, heat-resistant) ceramic powders, the pressing operation is performed at high temperatures, thus eliminating the sintering step.

Blow molding is a common method for producing hollow plastic objects. Essentially, the process involves using air pressure to force the plastic material to take the shape of the mold. Glassblowing is a somewhat analogous process for forming glass.

#### MATERIAL REMOVAL

In materials processing, a removal process is one that eliminates portions of a piece or body of material to achieve a desired shape. Although removal processes can be and are applied to most types of materials, they are most widely used on metallic materials. Material can be removed from a workpiece by either mechanical or non-mechanical means.

**Mechanical machining (cutting).** There are a number of metal-cutting processes. In almost all of them, machining involves the forcing of a cutting tool against the material to be shaped. The tool, which is harder than the material to be cut, removes the unwanted material in the form of chips. Thus, the elements of machining are a cutting device, a means for holding and positioning the workpiece, and usually a lubricant (or cutting oil). Cutting-tool materials must have a combination of strength, toughness, hardness, and wear resistance at the relatively high temperatures generated by the cutting action.

The oldest and most common machining process is turning, in which the workpiece is simply rotated while a cutting tool moves parallel to its axis, cutting the material away to reduce its diameter.

Shaping and planing are used to cut material from plane surfaces. The cutting tool takes successive cuts straight across the surface of the workpiece in a predetermined pattern to achieve the desired shape. The milling process, in which the cutting is done by rotating multiple-tool cutters, is also used for facing plane surfaces and for cutting grooves and slots. Holes are cut, enlarged, and shaped by drilling, boring, and tapping operations.

Grinding, honing, and lapping remove material with abrasives, which may be bonded in belts or rotating wheels (grinding), or in a fine abrasive stone (honing), or in a soft material with abrasive particles embedded in

it (lapping). In another method, ultrasonic machining, abrasive particles remove material by high-velocity bombardment of the workpiece. A mixture of air or inert gas under pressure can also be used to direct a high-velocity stream of fine abrasive particles against the workpiece.

**Nonmechanical machining (chipless).** There are four basic chipless removal processes: (1) in chemical milling the metal is removed by the etching reaction of chemical solutions on the metal; although usually applied to metals, it can also be used on plastics and glass; (2) electrochemical machining uses the principle of metal plating in reverse, the workpiece, instead of being built up by the plating process, is eaten away in a controlled manner by the action of the electrical current (see also ELECTROPLATING); (3) electrodischarge machining and grinding erodes or cuts the metal by high-energy sparks or electrical discharges; (4) the laser beam has limited application as a chipless cutting tool.

#### JOINING

Joining is the process of permanently, sometimes only temporarily, bonding or attaching materials to each other. The term as used here includes welding, brazing, soldering, and adhesive and chemical bonding.

In most joining processes, a bond between two pieces of material is produced by application of one or a combination of three kinds of energy: thermal, chemical, or mechanical. A bonding or filler material, the same as or different from the materials being joined, may or may not be used.

**Thermal joining.** Three broad groups of processes use heat (thermal energy) to bond materials together: pressure welding, fusion welding, and brazing and soldering (see also WELDING, BRAZING, and SOLDERING).

**Pressure welding.** Sometimes called forge welding, this oldest known welding process involves the heating of the areas to be joined to a plastic condition. The heated surfaces are placed in contact with each other and bonded together by hammering or pressing. In oxyacetylene pressure welding, a gas flame heats the abutting ends of the pieces to be joined. In resistance welding, the joint surfaces are heated by a heavy, localized electric current before mechanical pressure is applied to produce the finished bond.

**Fusion welding.** In fusion welding, the edges of the materials to be joined are heated to the melting point and flow together to achieve localized coalescence. On cooling, a permanent bond is produced. A filler material, the same as or different from the materials being joined, may be melted in the joint area as part of the bonding process.

The heat energy used to bring the metals to the fusion point is provided by any one of a number of sources—electric arc or current, induction heating, atomic hydrogen stream, burning fuels or gases, electron beam, exothermic chemical reaction, and laser beams.

Most metals can be joined by one or more fusion methods. Some thermoplastic-type plastics can also be fusion welded by a gas flame, heated tool, and friction techniques. Heat-sealing, a widely used method for joining plastic films and sheets, involves heating the adjacent surfaces and then fusing them together under pressure.

**Brazing and soldering.** Although this technique is used primarily to join metals, such nonmetallics as ceramics, glass, and graphite are also brazable. Soldering and brazing differ from fusion welding in that the edges or surfaces of the materials being joined are kept below their melting temperature during the bonding process. Only the filler metal, which is always used and which is different from the base metals, is in a molten condition. The part or the joint area of the metals is heated to above the melting temperature of the filler metal, which flows into the joint and coalesces with the base metals to produce the bond. Brazing, by definition, involves the use of filler metals that melt at 800° F (430° C) or higher, and soldering employs filler metals that melt below 800° F. A third method known as braze welding is the same as brazing except that it does not utilize capillary attraction to distribute the filler metal.

Many nonferrous metals, especially copper, nickel, and

Powder  
molding  
of plastics

energy  
used in  
bonding

Turning

Heat  
sealing

the precious metals, are easily brazed or soldered. Aluminum brazing is common and some steels can be brazed. Brazing filler materials most commonly used include alloys of silver, copper, and gold. The commonly used solders include tin alloyed with antimony or silver or lead, leadsilver, cadmium alloyed with silver or zinc, and bismuth alloys. A number of heating methods can be used for brazing and soldering, including torch or flame, furnace or oven, electrical induction, molten metal or salt bath, electrical resistance, hot block or iron, and radiant lamp.

**Adhesive bonding.** Adhesive bonding processes make use of substances capable of holding materials together by surface attachment. Adhesives, which include cement, glue, and paste, are available or can be specially formulated to join almost any two of the same or dissimilar materials (see also ADHESIVES). In adhesive bonding the joint between materials is produced by either of two mechanisms: (1) chemical forces at the interface between an adhesive and the materials being joined, or (2) mechanical adhesion that involves an interlocking action at the molecular level of the adhesive and materials being joined.

The principal steps in adhesive bonding are: (1) preparation of the surface by chemical, mechanical, or electrical treatment; (2) application of the adhesive by spray, roller, extrusion, trowel, knife, brush coating, or film; (3) joining of the materials by application of pressure, sometimes accompanied by heat. Adhesives can be applied in a liquid, paste, powder, film, and tape form.

Solvent bonding, limited to thermoplastic plastics, uses a solvent to soften the bond areas, after which bonding is accomplished by the application of pressure.

The major chemical classes of adhesives are natural, that is, vegetable- and animal-base adhesives and natural gums; thermoplastic, based on thermoplastic resins dissolved in solvent or emulsified in water; thermosetting, based on thermosetting resins; elastomeric, based on natural and synthetic rubbers; and alloys, adhesives compounded of resins from two or more of the other chemical classes. In addition to the above classes, a few inorganic adhesives are available for special applications.

Structural adhesives are those used in load-carrying applications as contrasted to general-purpose adhesives that are used in nonload applications, such as sealing and insulating. Elastomeric and thermoplastic adhesives are most commonly employed for general purpose or nonload-bearing uses. Most structural adhesives are thermosetting.

Adhesives classified by the curing characteristic or method include the following types: solvent release, emulsion, cold setting, hot setting, vulcanization, heat, and pressure.

#### PROPERTY MODIFICATION

The properties of materials can be altered by hot or cold treatments, by mechanical operations, and by exposure to some forms of radiation. The property modification is usually brought about by a change in the microscopic structure of the material.

Both heat-treating, involving temperatures above room temperature, and cold-treating, involving temperatures below room temperature, are included in this category. Thermal treatment is a process in which the temperature of the material is raised or lowered to alter the properties of the original material. Most thermal-treating processes are based on time-temperature cycles that include three steps: heating, holding at temperature, and cooling. Although some thermal treatments are applicable to most families of materials, they are most widely used on metals.

There are three major groups of heat-treating processes: annealing, stress relieving, and hardening.

1. In annealing and normalizing treatments, used to soften materials or improve ductility, the material is heated to the temperature at which the desired microstructural changes take place and then is slowly cooled; *e.g.*, for carbon steels annealing temperatures range from about 1,350° to 1,650° F (730° to 900° C).

2. Stress relieving, used to reduce or eliminate internal

stresses in materials, as applied to metals, is similar to annealing except that lower temperatures are involved; for glass the term annealing is applied to the process of relieving the internal stresses that are built up during the forming and shaping of glass articles.

3. Hardening uses a wide variety of treatments to strengthen materials; the oldest and most widely used processes essentially involving the heating of material to a high temperature and suddenly quenching it with oil, water, or air, after which in some cases, a stress-relieving step follows, referred to as tempering (for glass) or drawing.

A second group of hardening processes, known as precipitation, or age hardening, differ from the first group principally in that sudden changes in temperature are not usually involved and the internal hardening mechanism extends over a period of time.

A number of heat-treating processes may be used only for altering the surface of metals. In induction hardening, currents induced by radio-frequency energy generate heat in the surface of the metal. In flame hardening, the surface is heated by a flame. In both cases the part is subsequently quenched to produce a hardened surface.

Another technique involves heating the material in the presence of a substance that reacts with or diffuses into the surface and alters the surface properties, such as carburizing, in which a carbonaceous material supplies carbon to the metal surface and quenching produces a hardened surface layer. In cyaniding (carbonitriding) the metal is heated in an atmosphere containing carbon and nitrogen and then slowly cooled. A number of other such surface thermal treatments, often referred to as diffusion coating or cementation coating, each using a different diffusion substance, include aluminum (aluminizing), chromium (chromizing), gaseous ammonia (nitriding), zinc (sherardizing), silicon (siliconizing), and nickel-phosphorus.

#### FINISHING PROCESS

Finishing processes are employed to modify the surfaces of materials in order to protect the material against deterioration by corrosion, oxidation, mechanical wear, or deformation; or to provide special surface characteristics such as reflectivity, electrical conductivity or insulation, or bearing properties; or to give the material special decorative effects.

There are two broad groups of finishing processes, those in which a coating, usually of a different material, is applied to the surface and those in which the surface of the material is changed by chemical action, heat, or mechanical force. The first group includes metallic coating, such as electroplating (*q.v.*); organic finishing, such as painting; porcelain enamelling; and others (see PAINTS, VARNISHES, AND ALLIED PRODUCTS). This article is limited to the second broad group in which the original surface of the material is altered in one way or another without the addition of a second material.

**Surface modification by mechanical means.** Under this heading fall such processes as cleaning and mechanical finishing.

**Cleaning.** Cleaning operations are usually an integral part of finishing and are used to remove dirt, grease, chemicals, scale, burrs, and other contaminants. In chemical cleaning the foreign matter is removed by the action of a chemical, which may be an acid, an alkali, an emulsifier, or a solvent. Long-established mechanical cleaning methods involve the blasting of the surface with metal shot or grit or tumbling the objects to be cleaned in barrels containing such materials as sawdust, corncobs, or glass marbles. Other cleaning methods make use of flame, ultrasonic, and electrical techniques.

**Mechanical finishing.** There are two broad groups of mechanical finishing processes. The first includes polishing, buffing, brushing, and barrel finishing, all of which essentially involve wearing down the ridges on the material surface or producing a pattern of fine surface scratches.

Polishing, the oldest of the techniques, involves the use of wheels or belts containing such fine abrasives as pumice, rouge aluminum oxide, or emery. Buffing, which almost always follows another finishing process when a

Hardening processes

Types of adhesives used

Metallic coatings

Polishing

high lustre is desired, essentially involves finer abrasives and more flexible wheels than are used in polishing. Brushing, using either wire or nonmetallic brushes, produces decorative surfaces somewhat duller than those obtained by polishing and buffing.

In barrel finishing, parts are tumbled in a rotating drum in contact with the finishing media. There are two general tumbling methods—abrasive tumbling, and lustring or burnishing, both of which can be performed by either dry or wet techniques.

The second broad group of mechanical finishing processes are blasting, hammering, and embossing, used to produce textured finishes on metals. In blasting, metal shot or grit, sand, or other hard abrasives are directed against the metal surface at high velocity to create a pattern of small indentations. Hammering, done by hand or mechanically, produces surfaces with larger indentations. In embossing, metal sheet is passed between rolls to produce patterned decorative effects.

**Chemical finishing.** Sometimes called conversion coating, chemical finishing processes change the surface layer of the material by a chemical or electrochemical action. Processes involving chemical reactions without the use of an electric current include phosphate, chromate, and oxide coating, the last being applied chiefly to steels and copper and copper alloys. Chromate conversion coatings are widely used on zinc, aluminum, and magnesium. Phosphate coatings are applied to iron, steel, and zinc and to a lesser extent on aluminum and tin. Another group of chemical conversion processes, known as anodizing, produce coatings on aluminum and magnesium by electrolytic processes in which the base metal is made the anode in an electrolyte, such as sulfuric or phosphoric acid.

**Other finishing processes.** Many materials, especially metals, undergo property changes during certain processing operations, particularly the solid-state forming processes. A few mechanical processes are specifically designed to alter material properties; these principally involve the application of impact energy or rolling pressure to plastically deform the metal. This cold-working, as it is called, increases strength and hardness but usually reduces ductility.

Several processes have been developed that involve a combination of mechanical working and thermal, including low-temperature, treatment.

**Radiation processing.** Radiation in the form of light and infrared or radiant heating have long been used for certain processing techniques, but only since the 1960s has radiation been used to alter material properties. Certain plastics, specifically polyethylene, can be irradiated to raise the melting and softening points. Processes have been developed to cure coatings on automobiles by beams of electrons. Although metals can also be hardened and strengthened by radiation, so far the process does not appear to hold much promise in this application.

## Materials Salvage

The word salvage, though its roots are in the Latin *salvare* ("to save"), has in recent years taken on a much broader meaning than merely saving. Its modern usage includes the recovery and re-use, often called "recycling," of almost any material of value. The depletion of the world's natural resources such as oil, gas, coal, mineral

ores, and trees had highlighted the need for new or alternative sources of such materials, to find substitutes for them, or to recycle the spent products. Recognition of the need for recycling is naturally greater in areas of the world in which raw materials are scarce.

Historically, the earliest salvage was probably military in nature. After the battle, the victors claimed the weapons of the vanquished. Almost equally ancient is salvage as the recovery of ships and their cargoes. Ships sunk in shallow harbours or broken up on the rocks of a coast often contained easily salvageable cargoes. Later, the development of the diving bell, diving suits, oxygen tanks, and modern life-support equipment all made deep marine-cargo salvage possible. Lifting equipment and other technology by the 19th century made it possible to raise the hulks themselves from shallow depths, and 20th-century developments have enabled successful operations to be carried out at depths of several hundred feet. At the same time, salvage of raw materials from the waste products of nearly every industry has become commonplace.

### TYPES OF SALVAGE OPERATIONS

There are, then, basically two types of material-salvage operations, one of which may be called internal, the other external. Internal salvage or recycling is the re-use in a manufacturing process of materials that are a waste product of that process. Internal recycle is common, for example, in the metals industry. The manufacture of copper tubing results in a certain amount of waste in the form of tube ends and trimmings; this material is remelted and recast. Another form of internal salvage is seen in the distilling industry, in which, after the distillation, spent grain mash is dried and processed into an edible foodstuff for cattle. External salvage or recycling is the reclaiming of materials from a product that through use has been worn out or rendered obsolete. An example of external recycle is the collection of old newspapers and magazines for the manufacture of newsprint or other paper products.

Whether the recycle or salvage operation is internal or external is of little technological significance but of considerable economic importance. The cost of reprocessing waste or recycled material must be less than the cost of new raw material. In situations of affluence and cheap natural resources there is a tendency to discard used materials. As an economic situation tightens salvage becomes attractive.

Coal has at one time or another been burned as domestic fuel in most of the world. Relatively inefficient domestic coal furnaces never burned all of the coal fed into them; when the ashes were removed, some grains of coal were lost. In times of depression, consumers often picked through the ashes to recover such coal.

More recently, new reasons for material salvage have appeared. First, there has been a widespread realization that the world's resources are not inexhaustible. Second and even more compelling was the discovery that waste materials were beginning to pollute the air, water, and land to a significant extent. Even though the salvage of materials as a pollution-abatement measure cannot always be economically justified, salvage or recycle operations have grown year by year throughout the world.

### TECHNIQUES OF SALVAGING MATERIALS

It would be impossible to consider every recycle or salvage operation currently employed or considered in industry today. A number of representative examples can be cited to acquaint the reader with the general scope of present and future applications.

**Ferrous metals.** Ferrous products can be salvaged by both internal and external methods. Some internal-salvage operations are obvious. Metal cuttings or imperfect products are recycled by remelting, recasting, and re-drawing entirely within the steel mill. The process is much cheaper than producing new metal from the basic ore.

In steelmaking, pig iron is first produced by heating the ore with coke and limestone in a vertical, cylindrical furnace (called a cupola) with tapping spouts at the bottom. Most iron and steel manufacturers produce their

Ship  
recovery

Economics  
of  
salvage

Salvaging  
coke-oven  
by-  
products

own coke in a device known as a coke oven, which burns bituminous coal with too little air to provide complete combustion. By-products from the coke oven include a number of organic compounds, hydrogen sulfide gas, and ammonia. The organic compounds are condensed, distilled, separated, and sold. The ammonia is concentrated and sold in aqueous form or brought into contact with a sulfuric acid solution that reacts with it to form ammonium sulfate, which is subsequently dried and sold as fertilizer. Ammonia that before development of this process was not used is now salvageable and salable.

During its manufacture, steel is pickled (treated with sulfuric or hydrochloric acid) to remove scale formed in the high-temperature drawing and rolling operations. Pickling gives the steel a smooth surface for ease in manufacture of various products. Sulfuric acid pickling solution slowly attacks the scale and removes it, forming iron sulfate in solution. Since the iron sulfate contains a large amount of usable iron, it can be transformed into iron oxide and reprocessed to make more steel. Hydrochloric acid pickling results in the formation of iron chloride, which also can be processed to reclaim iron. Either acid can also be reclaimed for future pickling operations. Blast furnace slag and, to some extent, steel slag are used by the construction industry as all-purpose aggregates for road building and in various types of concrete products. Refuse material from ore preparation from taconite mines has been converted on a research basis into a foamed building material of controlled density; similar potential exists for refuse from copper, lead, and zinc mining.

Steel  
scrap

In the ferrous-metals industry there are also many applications of external salvage or recycle. A significant percentage of the feed to the open-hearth furnace, the Bessemer converter, or the basic oxygen furnace can be in the form of steel scrap, usually in bales supplied by reprocessing companies. The scrap comes from a variety of manufacturing operations that use steel as a basic material. Scrap materials are usually those either too small or of a shape that cannot be re-used in the manufacturing operation.

The second largest salvage operation in the ferrous-metal industries is the reprocessing of old automobile bodies. The average junked automobile contains about 62 percent iron and steel, 28 percent nonferrous metals, and some 10 percent rubber, plastics, and textiles. Salvage operations on automobiles actually begin before they reach the reprocessor. Parts such as carburetors and electrical components can be removed, rebuilt, and resold.

Supercold  
shredding  
of steel

In a process developed in Belgium, liquid nitrogen (at a temperature of  $-320^{\circ}\text{F}$  [ $-196^{\circ}\text{C}$ ]) is sprayed on the auto body before shredding. When steel is subjected to such temperatures, it becomes brittle; nonferrous metals, such as copper and aluminum, do not. Super-chilling the auto body before shredding causes the steel to break in the shredder much as a glass bottle breaks if thrown on a concrete floor. The nonferrous metals tend to agglomerate and are therefore much more easily removed from the ferrous metals after shredding. The same basic procedures apply to washing machines, refrigerators, or other large, bulky steel or iron items.

The engine blocks of most automobiles are either cast iron or aluminum. Since cast iron is usually found in larger pieces and is, therefore, more difficult to compress and shred, it is generally remelted from its original form and recast into pigs (crude castings). Thousands of railroad freight cars are retired from service every year and dismantled for scrap and salvage. About half of these are boxcars and refrigerator cars with sides largely or wholly of wood. Generally, wooden parts are burned away, steel sections are dismantled and sold as scrap, while trucks and wheels are rebuilt.

**Nonferrous metals.** Nonferrous-metals salvage involves many materials, the most important of which are aluminum, copper, lead, and silver. At present, manual sorting seems to be the only practical method of separating pieces of nonferrous scrap from each other. External recycle procedures usually involve such manual sorting

with the return of the basic metal to a reprocessor who melts it down, removes impurities, and recasts it into ingots.

Secondary aluminum reprocessing is a large industry, involving salvage of machine turnings covered with oil and grease, rejected aluminum castings, aluminum siding, and even aluminum covered with decorative plastic. In these mills aluminum in all forms is thrown into a reverberatory furnace (in which heat is radiated from the roof into the material treated) and melted while the impurities are burned off. The resulting material is cast into ingots and resold for drawing or forming operations.

An internal-salvage procedure, used in aluminum mills and in secondary aluminum-recovery operations, removes aluminum from the dross or slag created in a melting process. The slag that forms on the surface of the molten metal is mixed with small amounts of aluminum. By processing this material through a hammer mill (pulverizer), the aluminum, which is malleable, can be separated from the brittle slag. Dross treated in this manner generally contains 20 to 30 percent metallic aluminum.

A salvage operation recently proposed in the copper industry involves reprocessing of the waste from copper mining and smelting operations. This waste, which consists of minute amounts of copper mixed with sand, mica, limestone, and some other minerals, is usually piled in great heaps near the mine. Since copper ore generally exists in the form of copper sulfide, it has been suggested that certain bacteria introduced to the piles of waste will cause oxidation to occur, converting the sulfide to copper sulfate. Copper sulfate is soluble in hot water; by spraying the tailings, the copper sulfate can be dissolved and recovered for processing into metal. Though the proposed method is not yet economic, rising copper prices may someday make it so. Lead recovery is also a secondary smelting operation; the primary source of used lead is discarded electric storage batteries. Lead battery plates may be smelted to produce antimonial lead (a lead-antimony alloy) for manufacture of new batteries, or pure lead and antimony as separate products.

Since photographic paper and X-ray film contain small but valuable quantities of silver, recycle methods utilizing incineration have been developed. Most of the silver salts used in photographic papers are sufficiently volatile that the vent gas from their incineration can be cooled by water sprays and then passed into an electrostatic precipitator where the silver salts are removed at efficiencies up to 99 percent. The silver may then be recycled and used for coating more photographic paper.

Ores of many nonferrous metals, such as copper, zinc, and lead, are found in the form of a sulfide. An atmospheric pollutant, sulfur dioxide, is created when the ore is roasted. The sulfur dioxide can be recovered and sold as a gas, or it can be further oxidized to sulfur trioxide, treated to make sulfuric acid, or reduced to elemental sulfur. Though smelter-gas recovery is still somewhat questionable from an economic standpoint, antipollution legislation will undoubtedly require its adoption.

**Radioactive wastes.** In nuclear power reactors, unwanted fission by-products are formed by the neutron bombardment of the fuel (usually uranium) and other materials within the reactor. When a reactor core (composed substantially of uranium) has reached the end of its useful life, only a small amount of the uranium has been consumed. Even so, the uranium fuel elements must be removed from the reactor and sent for reprocessing. In standard reprocessing techniques, the fuel elements are dissolved in acid and uranium is extracted from the mixture in one of several ways. The resulting acid, however, contains enormous amounts of radioactivity in the form of isotopes that are fission products of the uranium. Though production of radioactive materials in a nuclear reactor is very great, only a small portion can be salvaged and used as radioactive isotopes. The rest is usually stored deep underground.

**Rubber.** Though much used rubber was formerly burned, in most countries this has been greatly curtailed to avoid air pollution. Internal recycle is common in most rubber plants; the reprocessed product can be used wher-

Alumi-  
num  
salvage

Smelter-  
gas  
recovery

ever premium-grade rubber is not needed. External salvage has proved a problem over the years; the ultimate value of old or worn-out tires has been negligible. Recent experimental work, however, has indicated that destructive distillation is a viable means of disposing of scrap rubber products for reclamation of valuable chemicals, including a liquid oil that can be used in manufacturing other chemicals, a combustible gas valuable as a fuel, and a carbonaceous residue useful as a filter char or binder in concrete or asphalt roadways.

**Chemicals and plastics.** The chemical industry produces hundreds of waste products, many of which cannot be recovered economically at present. Because of increasing public concern with air and water pollution, however, recovery has become attractive.

Many plastics-manufacturing processes include a curing or drying operation that converts solvents into a vapour that must be vented. Vinyls, for example, used in chair coverings, automobile seats, and luggage, are usually applied to a natural or synthetic fabric in a coating operation. To cure this vinyl covering, the coated material is passed through a drying oven in which some of the solvents present in the original mixture vaporize or evaporate. Vapour from these ovens may contain valuable solvents such as methyl ethyl ketone and toluene or plasticizers such as dioctyl phthalate. Though some processors burn these noxious gases, others salvage them by passing the air-solvent mixture through a granular bed of activated carbon or charcoal. The bed recovers between 95 and 99 percent of the solvent from the airstream. Once saturated, the bed is ready for desorption or solvent removal, accomplished by flooding it with steam of a temperature higher than the vaporization temperature of the solvent. The steam flushes out almost all the solvent from the activated carbon and is then condensed, forming a mixture of solvent and water. If the solvent is miscible with the water (*i.e.*, mixes with it), then distillation follows. In many cases, however, the solvent is immiscible, separates into a layer, and can be poured off (decanted). This system accomplishes two things: it recycles a valuable solvent, and it prevents air pollution.

Residues  
containing  
chlorine

Manufacture of many insecticides and herbicides as well as polyvinyl chloride plastics results in residues ranging from water-like materials to very thick tars and sludges, all of which contain the element chlorine. Placed in natural water bodies, these by-products have caused large fish kills. Though sometimes they have been dumped far at sea, where their effect is considered to be negligible, such disposal over long periods may eventually damage the marine environment. Since most of these wastes are combustible, they are often burned; hydrogen chloride can be formed in the incinerator as one of the products of combustion. Hydrogen chloride is extremely toxic, cannot be released to the atmosphere, and must be removed from the products of combustion. Since this poisonous substance is soluble in water, it can be separated out by water scrubbing, a process that then presents the manufacturer with the problem of disposing of dilute hydrochloric acid. While the acid may be neutralized with some basic material such as lime, this does not entirely solve the pollution problem because the calcium chloride that results from the reaction of lime and hydrochloric acid is also a water contaminant. Recently, several processes have been developed that involve reclamation of the hydrochloric acid from the incinerator process either as commercial-grade muriatic acid or as anhydrous hydrogen chloride gas. Both of these products can profitably be recycled. At present, only a very large reclamation project involving many tons of residue can be economically justified for hydrogen chloride salvage, but, in the future, the value of such salvage operations may well depend on the reduction of pollution.

Sulfur, another valuable chemical, can cause serious pollution problems when in the form of hydrogen sulfide, sulfur dioxide, or sulfur trioxide. Hydrogen sulfide with its rotten-egg smell is generated in the manufacture of aviation gasoline. Though burning may destroy hydrogen sulfide, the combustion process produces sulfur dioxide, another serious pollutant. If the hydrogen sulfide is

burned in insufficient air, however, a sulfur vapour is created that can be condensed into liquid sulfur, crystallized, and used by the chemical industry.

**Domestic refuse.** One of the biggest and most complex areas of salvage operation is the field of municipal garbage and refuse. Once ferrous and nonferrous metals have been removed from domestic refuse, along with glass and glass products if practical, what remains is essentially organic waste that lends itself to one of several salvage operations. Incineration produces potentially valuable heat energy, along with carbon dioxide and nitrogen, with some residual ash. Composting consists of biological degradation into a pathogenically pure (*i.e.*, no harmful bacteria) disposable waste. Pyrolysis (incineration with a deficiency of air) permits recovery of certain fuel gases and chemicals. Landfill allows the biological action of the earth eventually to rot away the residue and return it to the soil. Incineration appears especially promising in the light of two environmental dilemmas: a worldwide demand for more electric power and the growing mountains of organic wastes and garbage. It is now possible to burn garbage, using the heat produced to create electric power.

The first significant work in this field was done by a Swiss company that developed an incinerator-boiler combination capable of taking 300 tons (270,000 kilograms) of municipal refuse per day, burning it at 99.5 percent combustion efficiency and generating 25,000 pounds (11,000 kilograms) of steam per hour. Another system developed in Germany achieves similar results with slightly different components.

Heat energy can be recovered from a wide variety of industrial wastes. Where it is necessary, for example, to incinerate gas or vapour emanating from an industrial process, it is often quite practical to utilize the heat from the incineration to preheat the fume before incineration. A solvent-air mixture that must be heated to 1,500° F (about 800° C) in the presence of air before it can be incinerated can use some of the heat generated in the incineration process to preheat the solvent-air mixture, thereby cutting fuel costs from 50 to 70 percent.

**Power industry wastes.** The power industry produces a salvageable by-product known as fly ash, which is normally created when a fossil fuel such as bituminous coal is burned. Fly ash, a finely divided powdery material composed of spheres of amorphous silica and alumina, is recovered from flue gases by electrostatic precipitators. It has been utilized in portland cement manufacture, in casting masonry cinder and concrete building blocks, in lightweight aggregate, as a base for highway material, as a filler for bituminous mix, as a filler in material for roofing and putty, as a soil conditioner, as a soil stabilizer, in oil-well grouting, and as a sand substitute in sandblasting or abrasive applications. It has also been used as a filtering medium. Sulfur dioxide is also produced by burning fossil fuels; its salvage has been described above.

**Paper and other cellulose products.** One of the most readily available organic materials for salvage or recycle is cellulose. Trees, vines, grasses, and straws are about one-third cellulose by weight; thus vast quantities accumulate as waste products from food processing, lumbering, papermaking, and grain harvesting. Municipal and industrial wastepaper, rags, boxes, wood, grass, and leaves also contribute to the enormous volume of cellulose waste products. Many of these wastes are currently being recovered; others are under consideration for salvage on an experimental basis. Wallboard, door cores, and mulch have been made from cereal grain straws and bagasse (a waste product of sugarcane). Chemical-grade cellulose has been made from cotton linters, wood, and similar fibres. Animal feed has been made from pea vines and other fibrous vegetable materials. Animal bedding has been made from oat, rice, and wheat straw. Furfuryl alcohol, a component of certain types of plastics, has also been made from bagasse. Chemicals have been produced from corncobs. The cellulose found in urban or municipal wastes differs from its agricultural counterpart in that it has usually been subjected to some type of processing.

In an experimental program, a food protein was de-

veloped by fermenting insoluble cellulose with bacteria. Experimental work on sugarcane bagasse has resulted in a light-brown to yellow powder with a crude protein content from 50 to 60 percent. Such research is particularly significant to the developing countries where food shortages are often severe and where protein is missing from many diets.

In the citrus industry it is possible to salvage almost all parts of the fruit not used as food. Oranges grown mainly for juice have other valuable products to offer. The peels are pressed, leached, drained, and dried as animal food. The material that has been pressed and leached out of the peels is concentrated into a heavy, nutritious molasses.

Bark, wood chips, and lignin (the basic chemical component of wood waste), from sawmills, pulp, and paper mills, constitute one of the largest classes of industrial waste. These wood wastes, a significant source of organic matter, are returned to the soil as fertilizers and soil conditioners.

In papermaking, the process known as kraft pulping produces a variety of undesirable liquid wastes. Several companies have installed devices for the purification of these wastes and recovery of such valuable chemicals as turpentine, methyl alcohol, dimethyl sulfide, ethyl alcohol, and acetone. The first commercial purification unit, developed in Sweden, commenced operation in 1963. Sludges from pulp and paper manufacture and phosphate slime from fertilizer manufacturing can be made into gypsum wallboard that utilizes the calcium sulfate content of the waste.

**Glass.** An easily salvageable material, but one that is difficult to recover economically, is glass. Though enormous numbers of glass containers are used throughout the world, most are not recycled. Even those that are returned by consumers in their original form sooner or later become damaged or broken, causing a disposal problem. The chief problem in recycling glass is separating it from other refuse. Direct re-use of waste glass in the glass-container industry is difficult because separation by colour is necessary before it can be recycled. If colour separation can be accomplished, fairly high percentages of recycled glass can be used in new glass production.

The glass industry now uses about 15 percent cullet (broken or refuse glass) in new glass production, but because the raw materials are so inexpensive no real attempt has been made until recently to see how much recycled glass could be used.

Waste glass has other possibilities also. By melting it and running it into cold water while molten, frit, or finely divided, glass can be formed. Frit is used as landfill, as a soil conditioner, or as a material to be mixed with asphalt for the surfacing of roads. Since glass is essentially silica or sand it may be substituted in a number of building materials that use sand as a basic substance.

**Fish and animal wastes.** Waste from commercial fisheries and processing plants, including parts of fish and shellfish, contains valuable oils and large amounts of protein. Methods have been developed for converting this protein into animal food, and the Food and Agriculture Organization of the United Nations is currently experimenting with the extraction of fish protein from waste materials in the hope that it can be used as a direct food supplement in underdeveloped nations. Work in Chile has indicated that fish stickwater (the water used in large fish-meal processing plants) can be reclaimed through evaporation, producing a high protein concentrate. In the early 1970s the United States Bureau of Mines announced a process for the production of a paraffinic fuel oil from animal wastes. The oil manufactured by this process is reported to have a heating value equal to about 75 percent that of domestic fuel oil and to be low in sulfur.

The large increase in livestock and poultry production in the world has created a problem in several countries of disposing of animal wastes. Processing for use as a component of animal feeds has been under intensive study, along with research on use of the wastes for large-scale composting and on possible dehydration of wastes for use as garden fertilizer.

**Water.** The largest domestic use for water is for human consumption and sanitation. Waste water goes to a sewage treatment plant, where it is purified and recycled to the household. In a good sewage-treatment operation, the only loss of water is evaporation. If the industrial user does not have complete water-treatment facilities, however, the water, along with associated impurities, is funnelled into a river, stream, or ocean for subsequent recycle by nature. Though nature can handle small quantities of certain wastes, temporary or permanent damage has resulted from widespread disposal of this type. In some cases, legislation has prohibited the disposal of harmful wastes, while in others, pretreatment has been required.

A waste-water recycling technique called the Living Filter was developed on an experimental basis in the early 1970s. The experiment was designed to determine if impurities in waste water could be completely filtered out by the soil while simultaneously providing nourishment to crops and developing green cover on barren land. An overwhelming success, the Living Filter has rejuvenated barren and nutrient-scarce soils while purifying waste water. Waste waters from the food and paper industries have been distributed over farm and forest acreage by spray irrigation with beneficial results to the crop and ultimate purification of the water. Experimental studies have also been made in utilization of waste sludge from sewage-treatment plants as a soil conditioner.

(R.D.R.)

## Materials Testing

Materials testing involves measuring the characteristics and behaviour of such substances as steel or wood under various conditions. The data thus obtained can be used in specifying materials and their properties for various applications. A full- or small-scale model of a proposed machine or structure may be tested. Alternatively, investigators may construct mathematical models that utilize known material characteristics and behaviour to predict capabilities of the structure.

Materials testing breaks down into five major catego-

The Living Filter experiment

Glass-recycling problems

ries: mechanical testing; testing for thermal properties; testing for electrical properties; testing for resistance to corrosion, radiation, and biological deterioration; and nondestructive testing. Standard test methods have been established by such national and international bodies as the International Organization for Standardization (ISO), with headquarters in Geneva, and the American Society for Testing and Materials (ASTM), Philadelphia.

#### MECHANICAL TESTING

Structures and machines, or their components, fail because of fracture or excessive deformation. In attempting to prevent such failure, the designer estimates how much stress (load per unit area) can be anticipated, and specifies materials that can withstand expected stresses. A stress analysis, accomplished either experimentally or by means of a mathematical model, indicates expected areas of high stress in a machine or structure. Mechanical property tests, carried out experimentally, indicate which materials may safely be employed.

**Static tension and compression tests.** When subjected to tension (pulling apart), a material elongates and eventually breaks. A simple static tension test determines the breaking point of the material and its elongation, designated as strain (change in length per unit length). If a 100-millimetre steel bar elongates 1 millimetre under a given load, for example, strain is  $(101-100)/100 = 1/100 = 1$  percent.

Elements  
of a  
static  
tension  
test

A static tension test requires (1) a test piece, usually cylindrical, or with a middle section of smaller diameter than the ends; (2) a test machine that applies, measures, and records various loads; and (3) an appropriate set of grips to grasp the test piece. In the static tension test, the test machine uniformly stretches a small part (the test section) of the test piece. The length of the test section (called the gauge length) is measured at different loads with a device called an extensometer; these measurements are used to compute strain.

Conventional testing machines are of the constant load, constant load-rate, and constant displacement-rate types (see Figure 1). Constant load types employ weights directly both to apply load and to measure it. Constant load-rate test machines employ separate load and measurement units; loads are generally applied by means of

a hydraulic ram into which oil is pumped at a constant rate. Constant displacement-rate testing machines are generally driven by gear-screws.

Test machine grips are designed to transfer load smoothly into the test piece without producing local stress concentrations. The ends of the test piece are often slightly enlarged so that if slight concentrations of stress are present these will be directed to the gauge section, and failures will occur only where measurements are being taken. Clamps, pins, threading, or bonding are employed to hold the test piece. Eccentric (nonuniform) loading causes bending of the sample in addition to tension, which means that stress in the sample will not be uniform. To avoid this, most gripping devices incorporate one or two swivel joints in the linkage that carries the load to the test piece. Air bearings help to correct horizontal misalignment, which can be troublesome with such brittle materials as ceramics.

Static compression tests determine a material's response to crushing, or support-type loading (such as in the beams of a house). Testing machines and extensometers for compression tests resemble those used for tension tests. Specimens are generally simpler, however, because gripping is not usually a problem. Furthermore, specimens may have a constant cross-sectional area throughout their full length. The gauge length of a sample in a compression test is its full length. A serious problem in compression testing is the possibility that the sample or load chain may buckle prior to material failure. To prevent this, specimens are kept short and stubby.

**Static shear and bending tests.** Inplane shear tests indicate the deformation response of a material to forces applied tangentially. These tests are applied primarily to thin sheet materials, either metals or composites, such as fibre glass reinforced plastic.

A homogeneous material such as untreated steel casting reacts in a different way under stress than does a grained material such as wood or an adhesively bonded joint. These anisotropic materials are said to have preferential planes of weakness; they resist stress better in some planes than in others, and consequently must undergo a different type of shear test.

Shear strength of rivets and other fasteners also can be measured. Though the state of stress of such items is generally quite complicated, a simple shear test, providing only limited information, is adequate for most purposes.

Tensile testing is difficult to perform directly upon certain brittle materials such as glass and ceramics. In such cases, a measure of the tensile strength of the material may be obtained by performing a bend test, in which tensile (stretching) stresses develop on one side of the bent member and corresponding compressive stresses develop on the opposite side. If the material is substantially stronger in compression than tension, failure initiates on the tensile side of the member and, hence, provides the required information on the material tensile strength. Because it is necessary to know the exact magnitude of the tensile stress at failure to establish the strength of the material, however, the bending test method is applicable only to a very restricted class of materials and conditions.

**Measures of ductility.** Ductility is the capacity of a material to deform permanently in response to stress. Most common steels, for example, are quite ductile and hence can accommodate local stress concentrations. Brittle materials, such as glass, cannot accommodate concentrations of stress because they lack ductility; they, therefore, fracture rather easily.

When a material specimen is stressed, it deforms elastically (*i.e.*, recoverably) at first; thereafter, deformation becomes permanent. A cylinder of steel, for example, may "neck" (assume an hourglass shape) in response to stress. If the material is ductile, this local deformation is permanent, and the test piece does not assume its former shape if the stress is removed. Finally, fracture occurs.

Ductility can be expressed as strain, reduction in area, or toughness. Strain, or change in length per unit length, was explained earlier. Reduction in area (change in area

Tensile  
testing  
of brittle  
materials

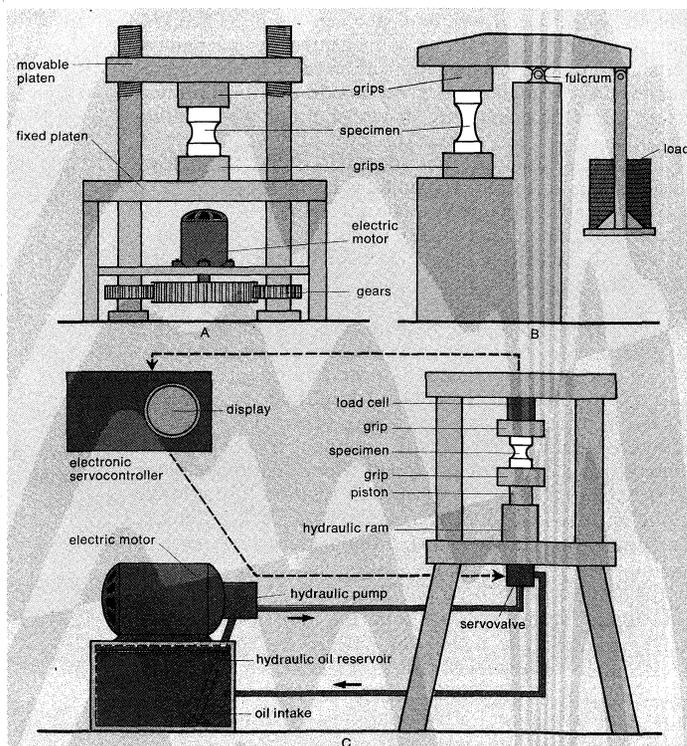

Figure 1: Testing machines: (A) constant displacement-rate type; (B) constant load type; (C) constant load-rate type.

per unit area) may be measured, for example, in the test section of a steel bar that necks when stressed. Toughness measures the amount of energy required to deform a piece of material permanently. Toughness is a desirable material property in that it permits a component to deform plastically, rather than crack, and perhaps fracture.

**Hardness testing.** Based on the idea that a material's response to a load placed at one small point is related to its ability to deform permanently (yield), the hardness test is performed by pressing a hardened steel ball (Brinell test) or a steel or diamond cone (Rockwell test) into the surface of the test piece. Most hardness tests are performed on commercial machines that register arbitrary values in inverse relation to the depth of penetration of the ball or cone. Similar indentation tests are performed on wood. Hardness tests of materials such as rubber or plastic do not have the same connotation as those performed on metals. Penetration is measured, of course, but deformation caused by testing such materials may be entirely temporary.

Some hardness tests, particularly those designed to provide a measure of wear or abrasion, are performed dynamically with a weight of given magnitude that falls from a prescribed height. Sometimes a hammer is used, falling vertically on the test piece or in a pendulum motion.

**Impact test.** Many materials, sensitive to the presence of flaws, cracks, and notches, fail suddenly under impact. The most common impact tests (Charpy and Izod) employ a swinging pendulum to strike a notched bar; heights before and after impact are used to compute the energy required to fracture the bar, and, consequently, the bar's impact strength. In the Charpy test, the test piece is held horizontally between two vertical bars, much like the lintel over a door. In the Izod test, the specimen stands erect, like a fence post. Shape and size of the specimen, mode of support, notch shape and geometry, and velocities at impact are all varied to produce specific test conditions. Nonmetals such as wood may be tested as supported beams, similar to the Charpy test. In nonmetal tests, however, the striking hammer falls vertically in a guide column, and the test is repeated from increasing heights until failure occurs.

Some materials vary in impact strength at different temperatures, becoming very brittle when cold. Tests have shown that the decrease in material strength and elasticity is often quite abrupt at a certain temperature, which is called the transition temperature for that material. Designers always specify a material that possesses a transition temperature well below the range of heat and cold to which the structure or machine is exposed. Thus, even a building in the tropics, which will doubtless never be exposed to freezing weather, employs materials with transition temperatures slightly below freezing.

**Fracture toughness tests.** The stringent materials-reliability requirements of the space programs of the 1960s brought about substantial changes in design philosophy. Designers asked materials engineers to devise quantitative tests capable of measuring the propensity of a material to propagate a crack. Conventional methods of stress analysis and materials-property tests were retained, but interpretation of results changed. The criterion for failure became sudden propagation of a crack rather than fracture (see Figure 2). Tests have shown that cracks occur by opening, when two pieces of material part in vertical plane, one piece going up, the other down; by edge sliding, where the material splits in horizontal plane, one piece moving left, the other right; and by tearing, where the material splits with one piece moving diagonally upward to the left, the other moving diagonally downward to the right.

**Creep test.** Creep is the slow change in the dimensions of a material due to prolonged stress; most common metals exhibit creep behaviour. In the creep test, loads below those necessary to cause instantaneous fracture are applied to the material, and the deformation over a period of time (creep strain) under constant load is measured, usually with an extensometer or strain gauge. In the same

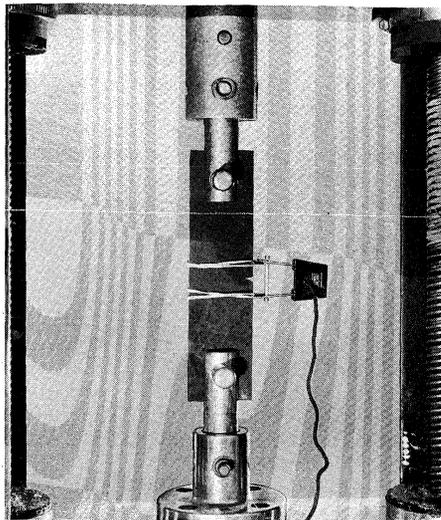

Figure 2: Typical fracture toughness test. The clip-on extensometer output signal is monitored to recognize the stress level at which the crack suddenly propagates because the extensometer will sense a sudden increase in strain without a corresponding increase in load.

By courtesy of K.E. Hofer, IIT Research Institute

test, time to failure is also measured against level of stress; the resulting curve is called stress rupture or creep rupture. Once creep strain versus time is plotted, a variety of mathematical techniques is available for extrapolating creep behaviour of materials beyond the test times so that designers can utilize thousand-hour test data, for example, to predict ten-thousand-hour behaviour.

A material that yields continually under stress and then returns to its original shape when the stress is released is said to be viscoelastic; this type of response is measured by the stress-relaxation test. A prescribed displacement or strain is induced in the specimen and the load drop-off as a function of time is measured. Various viscoelastic theories are available that permit the translation of stress-relaxation test data into predictions about the creep behaviour of the material.

**Fatigue.** Materials that survive a single application of stress frequently fail when stressed repeatedly. This phenomenon, known as fatigue, is measured by mechanical tests that involve repeated application of different stresses varying in a regular cycle from maximum to minimum value. Most fatigue-testing machines employ a rotating eccentric weight to produce this cyclically varying load. A material is generally considered to suffer from low-cycle fatigue if it fails in 10,000 cycles or less.

The stresses acting upon a material in the real world are usually random in nature rather than cyclic. Consequently, several cumulative fatigue-damage theories have been developed to enable investigators to extrapolate from cyclic test data a prediction of material behaviour under random stresses. Because these theories are not applicable to most materials, a relatively new technique, which involves mechanical application of random fatigue stresses, statistically matched to real-life conditions, is now employed in most materials test laboratories.

Material fatigue involves a number of phenomena, among which are atomic slip (in which the upper plane of a metal crystal moves or slips in relation to the lower plane, in response to a shearing stress), crack initiation, and crack propagation. Thus, a fatigue test may measure the number of cycles required to initiate a crack, as well as the number of cycles to failure.

A cautious designer always bears the statistical nature of fatigue in mind, for the lives of material specimens tested at a common stress level always range above and below some average value. Statistical theory tells the designer how many samples of a material must be tested in order to provide adequate data; it is not uncommon to test several hundred specimens before drawing firm conclusions.

Factors in material fatigue

MEASUREMENT OF THERMAL PROPERTIES

*Thermal conductivity.* Heat, which passes through a solid body by physical transfer of free electrons and by vibration of atoms and molecules, stops flowing when the temperature is equal at all points in the solid body and equals the temperature in the surrounding environment. In the process of attaining equilibrium, there is a gross heat flow through the body, which depends upon the temperature difference between different points in the body and upon the magnitudes of the temperatures involved. Thermal conductivity is experimentally measured by determining temperatures as a function of time along the length of a bar or across the surface of flat plates while simultaneously controlling the external input and output of heat from the surfaces of the bar or the edges of the plate.

*Specific heat.* Specific heat of solid materials (defined as heat absorbed per unit mass per degree change in temperature) is generally measured by the drop method, which involves adding a known mass of the material at a known elevated temperature to a known mass of water at a known low temperature and determining the equilibrium temperature of the mixture that results. Specific heat is then computed by measuring the heat absorbed by the water and container, which is equivalent to the heat given up by the hot material.

*Thermal expansion.* Expansion due to heat is usually measured in linear fashion as the change in a unit length of a material caused by a one-degree change in temperature. Because many materials expand only a few millionths of an inch with a one-degree increase in temperature, measurements are made by means of microscopes.

MEASUREMENT OF ELECTRICAL PROPERTIES

Understanding of electrical properties and testing methods requires a brief explanation of the free electron gas theory of electrical conduction. This simple theory is convenient for purposes of exposition, even though solid-state physics has advanced beyond it.

Electrical conductivity involves a flow or current of free electrons through a solid body. Some materials, such as metals, are good conductors of electricity; these possess free or valence electrons that do not remain permanently associated with the atoms of a solid but instead form an electron "cloud" or gas around the peripheries of the atoms and are free to move through the solid at a rapid rate. In other materials, such as plastics, the valence electrons are far more restricted in their movements and do not form a free electron gas. Such materials act as insulators against the flow of electricity.

Variation  
among  
conductors

The effect of heat upon the electrical conductivity of a material varies for good and poor conductors. In good conductors, thermal agitation interferes with the flow of electrons, decreasing conductivity, while as insulators increase in temperature, the number of free electrons grows, and conductivity increases. Normally, good and poor conductors are enormously far apart in basic conductivity, and relatively small changes in temperature do not change these properties significantly.

In certain materials, however, such as silicon, germanium, and carbon, heat produces a large increase in the number of free electrons; such materials are called semiconductors. Acting as insulators at absolute zero, semiconductors possess significant conductivity at room and elevated temperatures. Impurities also can change the conductivity of a semiconductor dramatically by providing more free electrons. Heat-caused conductivity is called intrinsic, while that attributable to extra electrons from impurity atoms is called extrinsic.

Conductivity of a material is generally measured by passing a known current at constant voltage through a known volume of the material and determining resistance in ohms. Total conductivity is simply the reciprocal of total resistivity.

TESTING FOR CORROSION, RADIATION,  
AND BIOLOGICAL DETERIORATION

Testing for breakdown or deterioration of materials under exposure to a particular type of environment has

greatly increased in recent years. Mechanical, thermal, or electrical property tests often are performed on a material before, during, and after its exposure to some controlled environment. Property changes are then recorded as a function of exposure time. Environments may include heat, moisture, chemicals, radiation, electricity, biological substances, or some combination thereof. Thus, the tensile strength of a material may fall after exposure to heat, moisture, or salt spray, or may be increased by radiation or electrical current. Strength of organic materials may be lessened by certain classes of fungus and mold.

*Corrosion.* Corrosion testing is generally performed to evaluate materials for a specific environment or to evaluate means for protecting a material from environmental attack. A chemical reaction, corrosion involves removal of metallic electrons from metals and formation of more stable compounds such as iron oxide (rust) in which the free electrons are usually less numerous. In nature, only rather chemically inactive metals such as gold and platinum are found in pure form; most others are mined as ores that must be refined to metal. Corrosion simply reverses the refining process, returning the metal to its natural state. Corrosion compounds form on the surface of a solid material. If the compounds are hard and impenetrable, and if they adhere well to the parent material, the progress of corrosion is arrested. If the compound is loose and porous, however, corrosion may proceed swiftly and continuously.

If two different metals are placed together in a solution (electrolyte), one metal will give up ions (electrically charged particles) to the solution more readily than the other; this difference in behaviour will bring about a difference in electrical voltage between the two metals. If the metals are in electrical contact with each other, electricity will flow between them and they will corrode; this is the principle of the galvanic cell or battery. Though useful in a battery, this reaction causes problems in a structure; for example, steel bolts in an aluminum framework may, in the presence of rain or fog, form multiple galvanic cells at the point of contact between the two metals, corroding the aluminum.

Analogy  
of the  
galvanic  
cell  
battery

Corrosion testing is performed to ascertain the performance of metals and other materials in the presence of various electrolytes. Testing may involve total immersion, as would be encountered in seawater; or salt fog, as is encountered in chemical-industry processing operations or near the oceans where seawater may occur in fogs. Materials are generally immersed in a 5 percent or 20 percent solution of sodium chloride or calcium chloride in water, or the solution may be sprayed into a chamber where the specimens are freely suspended. In suspension testing, care is taken to prevent condensate from dripping from one specimen onto another. The specimens are exposed to the hostile environment for some time, then removed and examined for visible evidences of corrosion. In many cases, mechanical tests after corrosion exposure are performed quantitatively to ascertain mechanical degradation of the material. In other tests, materials are stressed while in the corrosive environment. Still other test procedures have been developed to measure corrosion of metals by flue or stack gases.

*Radiation.* Materials may be tested for their reactions to such electromagnetic radiation as X-rays, gamma rays, and radio-frequency waves, or atomic radiation, which might include the neutrons given off by uranium or some other radioactive substance. Most affected by these forms of radiation are polymers, such organic compounds as plastic or synthetic rubber, with long, repeated chains of similar chemical units.

Radiation tests are performed by exposing the materials to a known source of radiation for a specific period of time. Test materials may be exposed by robot control to nuclear fuels in a remote chamber, then tested by conventional methods to ascertain changes in their properties as a function of exposure time. In the field, paint samples may be exposed to electromagnetic radiation (such as sunlight) for prolonged periods, then checked for fading or cracking.

Exposure to radiation is usually, but not always, detrimental to strength; for example, exposure of polyethylene plastic for short periods of time increases its tensile strength. Longer exposures, however, decrease tensile strength. Tensile and yield strength of a type of carbon-silicon steel increase with exposure to neutron radiation, although elongation, reduction in area, and probably fracture toughness apparently decrease with exposure. Certain new wood/polymeric composite materials are even prepared by a process that employs radiation. The wood is first impregnated with liquid organic resin by high pressure. Next, the wood and resin combination is exposed to radiation, causing a chemical change in the form of the resin, producing a strengthened material.

**Biological deterioration.** In recent years there has been considerable activity in the new field of formulating tests to ascertain the resistance of organic materials to fungi, bacteria, and algae. Paints, wrappers, and coatings of buried pipelines, structures, and storage tanks are typical materials exposed to biological deterioration.

When biological composition of the soil in a given area is unknown, colonies or cultures of its various fungi, bacteria, or algae are isolated and incubated by standard laboratory techniques. These are then used to test materials for biological degradation, or to test the effectiveness of a fungicide or bactericide. In testing for algae resistance, for example, treated and untreated strips of vinyl film, such as might be used to line a swimming pool, are immersed in growing tanks along with seed cultures of algae plants. Within three days, luxuriant algae growths appear on untreated samples.

#### NONDESTRUCTIVE TESTING

The tensile-strength test is inherently destructive; in the process of gathering data, the sample is destroyed. Though this is acceptable when a plentiful supply of the material exists, nondestructive tests are desirable for materials that are costly or difficult to fabricate, or that have been formed into finished or semifinished products.

**Liquids.** One common nondestructive technique, used to locate surface cracks and flaws in metals, employs a penetrating liquid, either brightly dyed or fluorescent. After being smeared on the surface of the material and allowed to soak into any tiny cracks, the liquid is wiped off, leaving readily visible cracks and flaws. An analogous technique, applicable to nonmetals, employs an electrically charged liquid smeared on the material surface. After excess liquid is removed, a dry powder of opposite charge is sprayed on the material and attracted to the cracks. Neither of these methods, however, can detect internal flaws.

**Radiation.** Internal as well as external flaws can be detected by X-ray or gamma-ray techniques in which the radiation passes through the material and impinges on a suitable photographic film. Under some circumstances, it is possible to focus the X-rays to a particular plane within the material, permitting a three-dimensional description of the flaw geometry as well as its location.

**Sound.** Ultrasonic inspection of parts involves transmission of sound waves above human hearing range through the material. In the reflection technique, a sound wave is transmitted from one side of the sample, reflected off the far side, and returned to a receiver located at the starting point. Upon impinging on a flaw or crack in the material, the signal is reflected and its travelling time altered. The actual delay becomes a measure of the flaw's location; a map of the material can be generated to illustrate the location and geometry of the flaws. In the through-transmission method, the transmitter and receiver are located on opposite sides of the material; interruptions in the passage of sound waves are used to locate and measure flaws. Usually a water medium is employed in which transmitter, sample, and receiver are immersed.

**Magnetism.** As the magnetic characteristics of a material are strongly influenced by its overall structure, magnetic techniques can be used to characterize the location and relative size of voids and cracks. For magnetic testing, an apparatus is used that contains a large coil of wire through which flows a steady alternating current (prima-

ry coil). Nested inside this primary coil is a shorter coil (the secondary coil) to which is attached an electrical measuring device. The steady current in the primary coil causes current to flow in the secondary coil through the process of induction. If an iron bar is inserted into the secondary coil, sharp changes in the secondary current can indicate defects in the bar. This method only detects differences between zones along the length of a bar and cannot detect long or continuous defects very readily. An analogous technique, employing eddy currents induced by a primary coil, also can be used to detect flaws and cracks. A steady current is induced in the test material. Flaws that lie across the path of the current alter resistance of the test material; this change may be measured by suitable equipment.

**Infrared.** Infrared techniques also have been employed to detect material continuity in complex structural situations. In testing the quality of adhesive bonds between the sandwich core and facing sheets in a typical sandwich construction material such as plywood, for example, heat is applied to the surface of the sandwich skin material. Where bond lines are continuous, the core materials provide a heat sink for the surface material, and the local temperatures of the skin will fall evenly along these bond lines. Where the bond line is inadequate, missing, or faulty, however, temperature will not fall. Infrared photography of the surface will then indicate the location and shape of the defective adhesive. A variation of this method employs thermal coatings that change colour upon reaching a specific temperature.

Finally, nondestructive test methods also are being sought to permit a total determination of the mechanical properties of a test material. Ultrasonics and thermal methods appear most promising in this regard.

**BIBLIOGRAPHY.** J. MARIN, *Engineering Materials: Their Mechanical Properties and Applications* (1952), a classic work describing the qualitative mechanical behaviour of materials, and *Mechanical Behaviour of Engineering Materials* (1962), a comprehensive treatment of the determination and utilization of mechanical properties of materials in design; Z.D. JASTRZEBSKI, *Nature and Properties of Engineering Materials* (1959), similar to Marin's earlier work, but updated to the end of the decade; H.R. CLAUSEN *et al.* (eds.), *Encyclopedia of Engineering Materials and Processes* (1963); and J.M. ALEXANDER and R.C. BREWER, *Manufacturing Properties of Materials* (1963); two comprehensive and easily read texts on material properties.

Other general works include: C.W. RICHARDS, *Engineering Materials Science* (1961), a highly readable and up-to-date book; F.A. MCCLINTOCK and A.S. ARGON (eds.), *Mechanical Behavior of Materials* (1966), an excellent description of both sophisticated and conventional techniques for acquiring and utilizing modern material property data; and O.J. HORGEV (ed.), *ASME Handbook*, vol. 1, *Metal Engineering: Design*, 2nd ed. (1965), the official Mechanical Engineering Society position on the utilization of advanced material properties in design; I.E. CAMPBELL, *High-Temperature Technology* (1956); and W.D. KINGERY, *Introduction to Ceramics* (1960); books illustrating the utilization of ceramic materials and emphasizing high temperature applications; J.E. DORN (ed.), *Mechanical Behavior of Materials at Elevated Temperatures* (1961), a thorough treatment of advanced material properties, particularly of metals, as influenced by high temperature; and H.E. DAVIS, G.E. TROXELL, and C.T. WISKOCIL, *The Testing and Inspection of Engineering Materials*, 3rd ed. (1964), a highly comprehensive and easily understood work offering sufficiently detailed information on the various testing methods for use in the training of materials testing personnel.

(K.E.H.)

## Mathematics, Foundations of

The study of the foundations of mathematics has dealt with the concepts and the assumptions about those concepts with which mathematics starts. Especially since 1900, foundational investigations have come to include also an inquiry into the nature of mathematical theories and the scope of mathematical methods.

#### THE AXIOMATIC METHOD

**Geometry according to Euclid.** Euclid's *Elements*, a treatise written about 330 BC on the foundations of math-

Euclid's use of the deductive method

ematics as well as on geometry, is said to have had a greater circulation than any book in history except the Bible. Euclid employs the deductive method, which had come down from Pythagoras two centuries earlier and which is outlined in the following three stages.

First, Euclid introduces fundamental concepts such as point, line, plane, and angle. He relates these to physical space by such definitions as "A line is length without breadth"; but, since their definitions play no further role in his system, they constitute primitive or undefined terms.

Second, Euclid asserts certain primitive propositions or postulates about these primitive terms. These are propositions that the reader is asked to accept as true immediately on the basis of the definitions of the primitive terms relative to the physical world.

Third, Euclid deduces from the postulates further propositions, called theorems, such as the theorem of Pythagoras, "The sum of the squares constructed on the arms of a right triangle is equal to the square constructed on the hypotenuse." That is, he shows that their truth follows logically from the truth of the primitive propositions. While doing so, he also introduces defined terms, such as triangle, right triangle, and hypotenuse, which are single words that can take the place of phrases using besides ordinary language only the undefined terms.

The net result is that the reader, starting with postulates of which he is supposed to be immediately convinced, is led, by a long series of simple steps each intended to be convincing, to accept the truth of other propositions, of which he would be far from convinced had they been asserted at the outset.

**Non-Euclidean geometry.** Euclid's parallel postulate, on which depends the theorem "Through a point  $P$  not on a line  $L$  there can be drawn exactly one line parallel to  $L$ ," had long seemed less evident than his other postulates. Attempts to prove it as a theorem from the other postulates culminated in the 19th century in the independent discoveries by the Russian and Hungarian mathematicians Nikolay Ivanovich Lobachevsky and János Bolyai that a different parallel postulate can be substituted to give a non-Euclidean geometry in which instead: "For some plane, some line  $L$  in the plane, and some point  $P$  in the plane and not on  $L$ , there exist at least two distinct lines in the plane passing through point  $P$  and not intersecting line  $L$ ." Bolyai was aware of the noncontradictory character of the new geometry in 1825 and Lobachevsky possibly in 1826, though the publications of both men were delayed.

Insofar as Euclidean geometry fits physical space, it is impossible to say that the geometry of Lobachevsky and Bolyai does not also fit. It is only necessary that the discrepancies between the two be too small to show up in any measurements that can be made. So, while Euclid thought of his geometry as a true description of physical space, it is necessary to regard it as one of a number of different possible mathematical models of that space.

That a theorem of Euclidean geometry be exactly true can only be a property of the geometry as a logical structure. A person who accepts Euclidean geometry as a valid logical structure is equally obliged to accept the geometry of Lobachevsky and Bolyai. For example, as the leader in German mathematics Felix Klein observed in 1871 (and an Italian, Eugenio Beltrami, in somewhat different terms in 1868), the postulates of Lobachevsky and Bolyai's plane geometry are true in Euclidean plane geometry when in those postulates the plane is interpreted to be the interior of a circle, the lines to be the chords of that circle, and congruence, distance, and angle are defined by a method given in England by Arthur Cayley in 1859.

**Formal axiomatic method.** Here the meaning of the undefined terms of a postulational theory has been varied while holding the deductive structure fixed, a procedure that is characteristically modern. One can deduce a theory from its postulates without saying at all what the undefined terms are to mean. The theory applies to any system of objects that when taken as supplying the meanings of the undefined terms make the postulates true.

Indeed, in a postulational theory, one should be able to

perform the deductions treating the undefined terms as meaningless. For, if their meanings had to be used, whatever had to be taken from their meanings should instead be provided by additional postulates. In Euclid's *Elements* some properties of the undefined terms did in fact enter from their meanings via the figures. These hidden assumptions were brought to light and stated as postulates by the German mathematicians Moritz Pasch in 1882 and David Hilbert, the latter in his *Grundlagen der Geometrie* (1899; *The Foundations of Geometry*, 1902). Thus, Hilbert states as a postulate, "If a line  $L$  cuts the side  $AB$  of a triangle  $ABC$  and does not pass through  $A$ ,  $B$  or  $C$ , then it must also cut  $AC$  or  $BC$ ."

The postulational method when the undefined terms are treated as meaningless is called the formal postulational method, or formal axiomatic method. In this connection, "axiom" and "postulate" are often used synonymously, in contrast with the material axiomatic method of Euclid.

It might be thought that meaninglessness of the undefined terms would rob a theory of its interest, but the opposite can be the case. Thus, for some theories many different interpretations of their undefined terms each make the postulates true (e.g., Euclidean geometry without the parallel postulate or in algebra abstract groups). The deduction of such a theory independently of any interpretation makes it a mathematical tool prepared in advance for diverse applications. If in essential respects only one such interpretation exists, the postulates are categorical; that is, admitting of no further qualifications. If there is no such interpretation, the theory is without value, and one of the problems for foundations is to exclude such theories.

**THE GENETIC METHOD**

**Arithmetic, analysis.** Systems of numbers are more often introduced by the genetic method, so called by Hilbert. In this the objects are generated or constructed in a certain orderly manner, and the theorems express properties of the system of the objects assured by this mode of generation, the term genetic being taken from biology. Of course, deductive reasoning is used, just as in the axiomatic method, to obtain unobvious properties from obvious or immediate ones, and the immediate properties can be listed as postulates. Thus, the natural numbers 0, 1, 2, . . . , used in counting discrete objects, are describable genetically as the objects that are generated by starting with a first object, 0, and by proceeding from any object,  $n$ , already generated to the next object,  $n + 1$ , objects differently generated being distinct. A suitable selection of immediate properties constitutes the five postulates of Giuseppe Peano, an Italian mathematician and logician, expressed in 1889, which are categorical for the arithmetic of the natural numbers. By starting from these postulates, rather than from the generation, that arithmetic can then be considered as a formal axiomatic theory. But the genetic method will be used here in describing some other mathematical systems of objects.

Arithmetic has several senses; but one of them is the theory of the natural numbers and of similar systems of numbers, such as the integers (an extension of the natural numbers, by way of including negatives of natural numbers) . . . ,  $-2, -1, 0, 1, 2, \dots$ , or the rational numbers such as  $\frac{1}{2}, \frac{2}{3}, \frac{4}{5}$ , which are the numbers expressible as fractions  $p/q$  in which  $p$  and  $q$  are integers with  $q$  not 0.

Analysis deals with such systems of objects as the real numbers, used in the measurement of continuously variable magnitudes. A theory of real numbers not resting on vague geometrical imagery was only achieved in the latter part of the 19th century, in Germany and France, by Karl Weierstrass, Richard Dedekind, Charles Méray, and Georg Cantor. A version using infinite decimals will suffice here. For example,  $\frac{9}{4} = 2.25 = 2.24999 \dots$ ,  $-\frac{9}{4} = -2.25 = -3 + 0.75 = -3 + 0.74999 \dots$ ,  $1 = 0.99999 \dots$ ,  $\sqrt{2} = 1.41421 \dots$ ,  $\pi = 3.14159 \dots$ . In each example, a real number  $x$  is expressed as a sum  $X + 0.x_0x_1x_2x_3x_4 \dots$  of an integer  $X$  and a non-terminating decimal fraction  $0.x_0x_1x_2x_3x_4 \dots$  (i.e., one without all digits 0 after some place). The real numbers

Manipulation of undefined terms

are given genetically, each number uniquely, as all possible such sums.

**Cardinal number, the theory of sets.** If, in a tribe of aborigines unable to count above 20, whose chief is by custom the member with the most numerous herd, there were two contenders for the chieftaincy, the tribe could decide the winner (or that the two contenders are tied) by passing their herds, no matter how large, through a gate, a pair of animals, one from each herd, at a time.

Cantor's  
contribution

Cantor was the first who applied this idea systematically to the comparison of infinite collections. A one-to-one correspondence between two collections, or sets, of objects  $S$  and  $T$  is a collection of ordered pairs in which the first member of each pair belongs to  $S$ , the second member to  $T$ , and each member of  $S$  occurs as first member, each member of  $T$  as second member, of just one pair. Two sets have the same cardinal number if there is a one-to-one correspondence between them.

The natural numbers  $0, 1, 2, \dots$ , the positive integers  $1, 2, 3, \dots$ , the squares of the positive integers  $1, 4, 9, \dots$  (an example used by Galileo in 1638), and the integers  $0, 1, -1, 2, -2, \dots$  have the same cardinal number. Infinite sets with this cardinal are countable (or countably infinite, to distinguish them from finite sets, which are also countable), because they can be counted off or listed by using the natural numbers. A fifth example of a countably infinite set is the rational numbers; for each rational can be written as a positive or negative ratio of integers,  $(-1)^n p/q$ , with the least possible natural numbers  $n, p, q$ , and then the rationals can be enumerated by various techniques in order to make it explicit that they are countable. One such technique is to enumerate  $(-1)^n p/q$  in the order of magnitude of the positive integers  $2^n 3^p 5^q$ .

A part, or subset, of a set  $S$  is a set each member of which is a member of  $S$ . As Galileo had noted, a part not the whole of an infinite set can be in one-to-one correspondence with the whole. (Dedekind in 1888 used this property to distinguish infinite sets from finite sets.) A set  $T$  is of greater cardinal number than another set  $S$  if there is a one-to-one correspondence between  $S$  and a subset of  $T$  but not vice versa.

Cantor showed in 1874 by a method now called the diagonal method that there are sets of greater cardinal number than the natural numbers (see Box, 1-4).

Thus, infinity is not simple, but indeed there are a whole host of infinite or transfinite cardinal numbers. This result is only one of many in Cantor's theory of sets, which greatly extended the mathematical horizon, besides seeming to provide the ideas for a general foundation of mathematics.

#### THE CRISIS IN FOUNDATIONS FOLLOWING 1900

**The paradoxes.** In the last decade of his scientific life Cantor became aware that his theory of sets pushed too far leads to contradictions; two may be described.

If  $S$  be the set of all sets and  $T$  the set of the subsets of  $S$ , then, since  $T$  corresponds one-to-one to itself as a subset of  $S$ , it cannot have a greater cardinal than  $S$ . Yet by Cantor's theorem it must; this is Cantor's paradox, stated in 1899.

The phrases in the English language are countable. After listing all the phrases, strike out those that do not define number-theoretic functions. Application of Cantor's diagonal method to the list remaining enables one to define in the English language a function that differs from every function definable in the English language. This paradox was found by J.A. Richard in 1905.

These modern paradoxes have a counterpart in the ancient paradox of the liar, which in one form appears in a paradoxical statement attributed to Epimenides (6th century BC) and in another is attributed to Eubulides (4th century BC), who has a person say, "What I am now saying is a lie." The quoted sentence if true must by what it says be false, and if false be true.

No one has succeeded in disposing of the paradoxes by simply pointing out a fallacy upon which all can agree.

Cantor's paradox is evidently connected with the use of too-large sets. It is difficult, however, to determine which

- (1) A (single-valued) number-theoretic function  $f$  of one variable  $x$  is a correspondence by which, to each natural number  $x$ , there corresponds a unique natural number  $f(x)$ , called the value of  $f$  for  $x$  as argument. The set of these functions is uncountable, as can be shown by the following reasoning. For any infinite list  $f_0, f_1, f_2, \dots$  of such functions, the function  $f$  defined by  $f(x) = f_x(x) + 1$  (so the values of  $f$  come by altering every value in the diagonal, if the values of  $f_0, f_1, f_2, \dots$  have been written in successive rows) is not in the list; for if  $f$  were  $f_q$ , the contradictory equation  $f_q(q) = f_q(q) + 1$  would be obtained upon taking the value for  $q$  as argument. The set of these functions is of greater cardinal number than the natural numbers; for on the other hand, the natural numbers  $n$  are in one-to-one correspondence with the constant functions  $f(x) = n$ .
- (2) In the generation of the real numbers using infinite decimals, the nonterminating decimals can be construed as number-theoretic functions taking values  $\leq 9$ ; so the reals are uncountable, by reasoning the same as above except taking  $f(x) = 8$  when  $f_x(x) = 9$ .
- (3) A given set of natural numbers is represented by a function which takes 0 or 1 as value according as the argument is in the set or not; so the sets of natural numbers are uncountable, by reasoning the same as above except taking  $f(x) = 0$  when  $f_x(x) = 1$ .
- (4) It is not hard to show that these three uncountable sets have the same cardinal. The third illustrates Cantor's theorem, "The cardinal number of the set of the subsets of a set  $S$  is greater than the cardinal number of  $S$ ."

sets are too large and to replace Cantor's definition "any collection of definite well-distinguished objects of our perception or our thought into a whole."

In fact, it is possible to reformulate set theory to exclude too-large sets. In doing so, axioms are listed to govern just what sets shall be allowed; and set theory becomes a formal axiomatic theory instead of a genetic one. The first system of axiomatic set theory was given in Italy by Ernst Zermelo in 1908 and improved in Germany and Scandinavia by Abraham Adolf Fraenkel and Thoralf Skolem in 1922-23. Axiomatic set theory provides probably the simplest system in which most existing mathematics, but not the paradoxes as far as is known, can be deduced. The Austrian logician Kurt Gödel in 1938 showed that Cantor's continuum hypothesis, "The cardinal number of the real numbers is the least cardinal number greater than that of the natural numbers," can be added as a new axiom to set theory without introducing contradiction, and Paul J. Cohen of the United States in 1963 showed the like for its negation (see SET THEORY).

That the paradoxes arose shows there is some defect in the methods, which hitherto had been trusted, of constructing and reasoning about mathematical objects. Transforming the theory of sets from a genetic into a formal axiomatic theory leaves over the problem of whether there is an interpretation of the undefined terms that makes the axioms in some sense true. To ignore these issues is to adopt a mathematical nihilism. Formally axiomatized mathematics cannot be all of mathematics. To draw upon another formal axiomatic theory for such an interpretation is a regress. At some level there must be a meaningful mathematics. At the very least it must be believed that the theorems of a formal axiomatic theory really do follow from the axioms. As a further example, when mathematicians say that by a certain method it can be determined in a finite number of steps whether an equation  $ax + by + c = 0$  with given integral coefficients,  $a, b, c$  has a solution for  $x, y$  in integers, they certainly do not mean merely that this proposition can be deduced from certain axioms.

The great French mathematician and philosopher of

Explanation of the paradoxes

science Henri Poincaré and the outstanding English mathematician and philosopher Bertrand Russell about 1905 concluded that the explanation of the paradoxes lies in a certain circularity of definition. When a set  $M$  and an object  $m$  are so defined that  $m$  is a member of  $M$  but is defined only by reference to  $M$ , the definition of  $M$  or of  $m$  is called impredicative. An impredicative definition can be found in each of the paradoxes. Thus, the sickness of mathematics could be cured by banning impredicative definitions, if it did not inconveniently turn out that the cure would kill the patient; for, as was especially emphasized in the German-born U.S. mathematician and physicist Hermann Weyl's *Das Kontinuum* (1918; "The Continuum"), there are impredicative definitions also in analysis.

(S.C.K.)

**Intuitionism.** In the first quarter of the 20th century three main schools of thought, called Logicism, Formalism, and Intuitionism, arose to account for and resolve the crisis in the foundations of mathematics. Each of these is a version of a more or less traditional view of the nature of mathematics. The first is a form of Platonic Realism, according to which mathematics investigates a realm of abstract objects (such as points, numbers, sets, and the like) that "exist" external to and independent of the investigator. In Logicism it was argued that all mathematical notions are reducible to the idea of abstract property and that mathematics is derived from basic logical principles concerning properties; this is discussed in more detail below. The attempted reduction in Logicism to evident principles was not completely successful, but the work on this led to an axiomatization of Cantor's notion of set (or class) as a basis for current mathematics (see SET THEORY). Formalism holds that mathematics consists simply of the manipulation of finite configurations of symbols according to prescribed rules. Some of these configurations may have concrete meaning; others are considered as meaningless. In the Formalist view, the choice of rules is dictated by pragmatic considerations or, even better, by theoretical justification of their use in deriving concretely meaningful statements; this is also discussed below. Finally, Intuitionism is a version of the conception of mathematics as a self-sustained intellectual activity that deals with mental constructions governed by self-evident laws. These three schools of thought were principally led, respectively, by Russell, Hilbert, and the Dutch mathematician and philosopher L.E.J. Brouwer.

Mathematical logic was considerably developed in order to make these positions precise and study them more deeply. Set theory was allied with the increasingly general and nonconstructive tendency in mathematics. On the other hand, Intuitionism led to a considerable redevelopment of portions of mathematics in constructive terms, to eliminate what were regarded as philosophically untenable features. It and Formalism together bordered on the development of the important notion of mechanically computable function.

*Historical background of Intuitionism.* Immanuel Kant, an 18th-century philosopher who was the founder of critical philosophy, is often cited as a progenitor of Intuitionism in mathematics, inasmuch as he viewed space and time as forms that the mind imposes upon human sensibility or perception and, thus, as a priori and Idealistic. Leopold Kronecker, a 19th-century mathematician specializing in number theory and algebra, is also viewed as a progenitor because of his attitude to existence proofs. These typically give information about possible solutions to an equation or condition, such as the existence of at least one function that solves a differential equation or the existence of some point at which a continuous function achieves its maximum value in an interval. Kronecker doubted the significance of proofs, of a sort increasingly used in mathematics, that established the existence of such solutions by indirect arguments without necessarily being able to construct any one of them explicitly or even provide a finite procedure for finding one. In the beginning of the 20th century there was a French semi-Intuitionistic school of mathematics led by Émile Borel, which concentrated on explicit construc-

Kronecker's views

tions in mathematical analysis. During the same period, Poincaré was very influential through his informal writings, where he stressed the basic intuition of the sequence of integers and questioned the use of certain definitions selecting members from assumed completed infinite totalities (the so-called impredicative definitions mentioned above).

*Basic features of Intuitionism.* The basic concepts and results of Intuitionism in its full modern development were laid out, however, by Brouwer, who is, therefore, now considered to be the founder of the school. He regarded the starting point for mathematics to be the intuitive understanding of the generation of the sequence of (positive) integers, that is, of the repeated duplication,  $|, ||, |||, \dots$  of a single entity considered abstractly.

Brouwer believed that this was derived from a more basic inner awareness of time, whose unity is separated into a "two-ity" by the present moment; this is related to Kant's views as to the a priori status of time. Brouwer also took this idea of repeated division to be the intuitive source of the generation of sequences of rationals which make up the real number system. Thus, in contrast to the Platonic Realist position, the infinite collections considered were conceived of as potential rather than completed infinite totalities. On the Platonist view it is true to say, e.g., that either the sequence 0123456789 occurs at some position in the decimal expansion  $3.14159 \dots$  of  $\pi$  or there exists no such position; one can further proceed to define a number  $n$  as the least position where the first case holds, if indeed it holds, and as 0 otherwise. In opposition to the Platonist conception, Brouwer restricted mathematical knowledge to that which can be known about mental constructions and proofs. For him, to know a proposition  $P$  one must have a proof of it; to know its negation not- $P$  one must have a disproof of it; that is, a proof that  $P$  leads to a contradiction. For the proposition  $P$  that expresses that 0123456789 occurs at some position in the decimal expansion of  $\pi$ , there is at present neither a proof of  $P$  nor a disproof of  $P$ ; for this reason there is not an explicit construction of the number  $n$  above.

More generally, on the Platonist position, one accepts for any proposition  $P$  (even ones which refer to infinite totalities) the law of the excluded middle,  $P$  or not- $P$ ; in other words, that  $P$  is true or  $P$  is false. This cannot be accepted in general by the Intuitionist in his interpretation since he cannot be sure that for every  $P$  one shall be able to find either a proof of it or a disproof of it. From this point of view, some of the most fundamental arguments and definitions in mathematical analysis and other branches of mathematics become unsupported, and these subjects require a complete re-examination.

Brouwer's work on Intuitionism falls into several distinct periods: the first, beginning with his thesis in 1907, was primarily negative, with vigorous criticisms of the Realist (Cantorian and Logicist) as well as Formalist viewpoints; and the second, in the 1920s, was positive, being occupied with the reconstruction of mathematics according to the Intuitionistic tenets. After a long period of silence, Brouwer returned to the scene in the late 1940s with his "theory of the creative subject," which was even more radically subjectivist than his previous ideas.

*The criticisms of Realism and Formalism.* Brouwer's criticism of the Realist position concentrated on the application therein of the so-called classical logic of propositions and predicates referring to infinite totalities. In particular, by the law of the excluded middle in classical logic, if  $n$  is used to symbolize any member of the infinite set of integers 1, 2, 3,  $\dots$  and  $P(n)$  denotes a property or predicate  $P$  of  $n$ , one must admit:

(A) "Either there exists an  $n$  such that  $P(n)$  holds, or, for all  $n$ ,  $P(n)$  fails."

One example of this has already been considered in the preceding section.

For another example, each real number that is between 0 and 1 (possibly equalling 0 or 1) has some representation  $r = 0.a_1a_2a_3 \dots$  where each  $a_n = 0, 1, \dots, 9$ . If  $P(n)$  is the property " $a_n$  is less than 9," then because

Intuition of the integers

$r = 1$  just in case each  $a_n$  is equal to 9 ( $1 = 0.999 \dots$ ), the general logical law (A) reduces to the statement in this case that  $r \neq 1$  or  $r = 1$ . Similarly, one may use (A) to justify " $r$  is less than  $s$  or  $r$  is greater than or equal to  $s$ " for any real numbers  $r$  and  $s$ , which is basic to the classical treatment of mathematical analysis. One may then go on to define discontinuous functions  $f$  of real numbers  $r$ , such as the so-called step function  $f$  that has the value 0 if  $r$  is less than 1 and 1 if  $r$  is greater than or equal to 1.

Of course the law (A) can be checked directly when  $n$  ranges over a given finite set of integers and  $P(n)$  is a decidable property; i.e., there is available a method that will tell for each  $n$  whether or not  $P(n)$  holds. Brouwer argued that the assumption of (A) is based on an unjustified extrapolation of the experience with finite sets to the infinite.

Brouwer's criticism of Formalism was principally directed at Hilbert's formulation of that position, described in more detail below. Briefly, Hilbert's idea was to justify all of mathematics on the basis of the most elementary and concrete methods of finite combinatorial reasoning. The vehicle for this was to be the representation of mathematical statements as strings of symbols in formal logical systems.

The justification was to consist in giving Finitist proofs of consistency of such formal systems and, thence, of their correctness for deriving finitistically meaningful statements. Brouwer did not object to the use of Finitist reasoning, because this is just a part of what is Intuitionistically acceptable. The difference is that Finitism uses constructions only on concretely conceived objects such as the integers, whereas Intuitionism uses them also on abstractly conceived objects, such as proofs and constructions. Brouwer saw no special reason for the proposed restriction to Finitist methods. But his main objection to Hilbert's program was that in his view mere consistency of formal systems of mathematics could not justify them; only a prior understanding of the symbols of these systems and direct intuitive verification of the axioms and rules could do that. Moreover, one could not expect to pin down, once and for all, in any formal system the nature of the ongoing creative process of concept formation and discovery in mathematics. Brouwer's criticisms of Hilbert's program were in a way subsequently borne out by the famous work of Kurt Gödel in 1931, showing the inherent limitations of that program (see below *Logicism, Formalism, and the metamathematical method*).

*Redevelopment of mathematics.* The system of real numbers forms the basis of the calculus and more generally of mathematical analysis; this, in turn, is essential for the solution of the equations employed in scientific applications such as the differential equations of mathematical physics. It seemed to many that the Intuitionistic abandonment of classical logic would undermine a vast body of knowledge. Nevertheless, Brouwer set out to re-create mathematics in accordance with his tenets. His positive contributions to this reconstruction included a new theory of real numbers and of real functions (real-valued operations on real numbers), a theory of sets (called species), and a theory of ordinals (finite and transfinite construction stages). The groundwork was thus laid for a redevelopment of substantial portions of classical algebra, analysis, geometry, and topology. Even so, Brouwer attracted few converts to the Intuitionistic position thereby. Some of the reasons for this lie in the character of his expositions, which in the first period were polemical and in the second (technical) period were rather frequently obscure, involving unfamiliar or even "suspect" notions and familiar terminology with new meanings. This may be illustrated with Brouwer's assertion:

(B) Every real function is continuous.

This assertion is patently contradictory with the classical interpretation since, for example, the step function described above is not continuous. To understand the Intuitionistic interpretation of (B), one must first explain how real numbers are to be considered. In the classical

interpretation, every real number  $r$  is the limit of a convergent sequence  $s$  of rational numbers  $s_1, s_2, s_3, \dots$ ; this is indicated by the symbolism  $s = \{s_n\}$ . There are many possible such  $s$  for each real  $r$ ; one, for example, is given by the sequence  $s_n = a_0 + a_1/10^1 + \dots + a_n/10^n$  when  $r = a_0.a_1a_2a_3 \dots$  is written in decimal form. Intuitionistically, one can operate directly only with the sequences  $s = \{s_n\}$ , which are called real-number generators. Two such sequences  $s = \{s_n\}$  and  $s' = \{s'_n\}$  are said to be equivalent, and one writes  $s = s'$  if the difference  $s_n - s'_n$  approaches 0 as  $n$  increases without bound. (This relation is to be distinguished from that of strict identity, where, for each  $n$ ,  $s_n = s'_n$ .) A real function  $f$  can only be given by a construction  $F$  that associates with each generator  $s$  another generator  $t = F(s)$  such that if  $s = s'$  (in the sense just explained) then  $F(s) = F(s')$ .

Now each specific real-number generator  $s = \{s_n\}$  must also be given by a construction that determines  $s_n$ , given  $n$ . In practice, however, one does not make use of a rule for  $s$  when determining the terms of the generator  $F(s)$ , rather only the successive values  $s_1, s_2, s_3, \dots$ , so to speak, as they appear. Brouwer introduced the new concept of infinitely proceeding sequence (ips); roughly speaking, this is any sequence of which one can determine as many values as desired, although at any stage not more than an initial segment need be known. Every constructively defined  $s$  is an ips, but one may also think of  $s$  that are generated by some random processes or free acts of choice. Any construction that assigns to each ips  $s$  a rational number can only make use of some finite amount of information  $s_1, s_2, \dots, s_n$  about  $s$ . Brouwer's assertion (B) easily follows from this general continuity principle. Of course there is no constructive  $F$  that determines a step function  $f$ ; for otherwise it would follow that one could determine for any ips  $s$  whether or not  $s$  is less than 1 simply on the basis of some finite initial segment of  $s$ . This, of course, is absurd, because the remaining terms  $s_{n+1}, s_{n+2}, \dots$  could radically alter the situation.

With the new meanings given to the basic notions of analysis in this way, each classical theorem must be re-examined to see whether it has a correct Intuitionistic version. For example, a classical result often used is that if  $f$  is a continuous real function defined on a closed interval, then  $f(r_0)$  has a maximum possible value for some  $r_0$  in that interval (and similarly for a minimum). This is not Intuitionistically demonstrable, because one can constructively define a function  $f$  such that there is no constructive way to determine an  $r_0$  at which  $f$  attains its maximum value. If  $f$  satisfies stronger conditions (such as differentiability) that are frequently met in applications, however, it is possible to obtain the existence of such  $r_0$  constructively as well. When a classical result has a correct Intuitionistic version it usually requires a sharpening of the hypotheses, but for existential results one then also gets a sharpening of the conclusion.

*Intuitionistic logic.* The assertions that are made in Intuitionistic mathematics are supposed to be reports of completed proofs that have been carried out by a series of steps that are evident for the objects conceived when combined by suitable (mental) constructions. It is of interest to compare in general terms the type of reasoning that is admitted under this conception with that which makes use of classical logic. For this one needs an explanation of the conditions under which one has a constructive proof (or grounds) for a compound assertion; the following is based on the explanation provided by Heyting. Here  $P, Q$  denote any propositions,  $S$  is any given set, the variable  $x$  ranges over the objects of  $S$ , and  $P(x)$  is a predicate of  $x$ .

#### Conditions for Compound Assertions

FORM OF ASSERTION	GROUNDINGS FOR THE ASSERTION
(a) $P$ or $Q$	(a) At least one of $P, Q$ has already been proved.
(b) $P$ and $Q$	(b) Both $P$ and $Q$ have been proved.
(c) $P$ implies $Q$	(c) One has a construction $C$ of which it has been proved that whenever $C$ is applied to any possible proof of $P$ then the result is a proof of $Q$ .

Brouwer's objection to Hilbert's program

Continuity of a real function

- (d) *not P* (d) The same as for "P implies  $1 \neq 1$ "; that is, every possible proof of *P* is shown to be transformed into a contradiction.
- (e) *there exists an x such that P(x)* (e) One has constructed an *s* in *S* and proved *P(s)*.
- (f) *for all x, P(x)* (f) One has a proof which is shown to specialize to a proof of *P(s)* for each *s* in *S*.

It should be understood that these do not constitute an explanation of the logical connectives in terms of prior, logic-free notions. They do show, however, the circumstances under which the connectives are used in practice, and they indicate the form of such an explanation in the strict sense of the word.

The conditions given do not justify the law of excluded middle *P* or *not-P*, because, as already discussed, there is no reason to expect that for any proposition *P* it is possible either to find a proof of it or to show how to derive a contradiction from it. If one accepts Brouwer's notion of ips, however, and the general continuity principle for these, one can actually disprove this classical law. This is true because, as has been pointed out, this implies the general law (A) above, of which the following is then a special case:

(C) For every ips  $s = \{s_n\}$ , either there exists an *m* such that  $s_m = 0$  or for all *m*,  $s_m \neq 0$ .

A consequence is the following:

(D) For every ips  $s = \{s_n\}$ , there exists an *m* such that either  $s_m = 0$  or for all *p*,  $s_p \neq 0$ .

By the general continuity principle, one should be able to associate with any *s*, two numbers *n* and *m* such that for any *s'* with  $s'_1 = s_1, \dots, s'_n = s_n$ , either  $s'_m = 0$  or for all *p*,  $s'_p \neq 0$ ; one can also assume that *m* is less than or equal to *n*. If one starts with a sequence *s* of nonzero terms, however, one can always define *s'*, which agrees with *s* on the initial segment  $1, \dots, n$  but is such that  $s'_{n+1} = 0$ . Thus (D), and hence also the law of excluded middle, leads to a contradiction. In other words, the following has been shown:

(E) It is not the case that (C) holds.

By a similar argument the following can be shown:

(F) Not for all ips *s* and *t*, either *s* is less than *t* or *t* is less than or equal to *s*. (S.Fe.)

**Logicism, Formalism, and the metamathematical method.** While the philosophical debate at the foundations of mathematics was identified for many years with the debate among the three schools of thought, Logicism, Formalism, and the Intuitionism considered above, a broadened basis for reasoning followed from the work of Gödel, Church, and Turing in the 1930s. Thus, a contemporary presentation of the problems at the foundations of mathematics is coloured by the automata-based reasoning that is identified with Turing's name. Whereas Intuitionism yielded somewhat to Formalism at the hands of Heyting, the techniques made available to Logicism and Formalism were enormously broadened with the introduction of Turing's machine (see below *Turing's computing machine and formal systems*). While the lines separating the traditional three schools of thought have become less distinct since mid-20th century, it now seems natural to present the points of view with Intuitionism on the one hand and Logicism and Formalism, as transformed by the metamathematical method (in which the object of a mathematical study is a mathematical system), on the other. Such a division should not be interpreted to mean that metamathematical methods have not been fruitfully applied in studies of systematizations arising from the Intuitionistic schools.

**Logicism.** The Logicistic thesis is that mathematics is a branch of logic. A German logician and mathematician, Gottfried Wilhelm Leibniz, in 1666 had conceived of logic as a universal science embracing the principles underlying all others. Richard Dedekind in 1888 and, especially, Gottlob Frege in 1884 and 1893, both of Germany, derived arithmetic from logic. The thesis that all of mathematics is reducible to logic alone is due to Russell.

Russell, after rediscovering results of Frege, had to make provision against the paradoxes. This provision took the form of a ramified theory of types. Roughly described, the primary objects not being subjected to logical analysis he took to be of one type—say, type 0—properties of objects of type 0 to be of type 1, properties of properties of type 1 to be of type 2, etc.; and he excluded from use any properties not belonging to one of these types. Then, to exclude impredicative definitions within a type, he separated the types above type 0 into orders, the properties defined using the totality of properties of a given order being placed in the next higher order. Finally, to overcome the obstacle that exclusion of impredicative definitions opposes to analysis, he postulated his axiom of reducibility, which asserts that to any property belonging to an order above the lowest there is a property of order 0 possessed by exactly the same objects.

On this basis, mathematics was deduced from logic, in a symbolic language, in the monumental *Principia Mathematica*, by the English mathematician Alfred North Whitehead and Bertrand Russell, in 1910–13.

The use of the axiom of reducibility weakens the case for the Logicistic thesis. For, if the axiom be true, should not the reductions to order 0 be constructed instead of being merely postulated as existing? Weyl hence remarked in 1946 that in *Principia Mathematica* "mathematics is no longer founded on logic, but on a sort of logician's paradise."

Leon Chwistek in 1921 and F.P. Ramsey in 1926 introduced a simple theory of types in which the separation into orders is suppressed. This theory still allows the deduction of mathematics from logic, with the paradoxes apparently excluded, but it does not improve the philosophical position.

A fundamental objection to the Logicistic thesis is posed by the Intuitionists, who find an essential mathematical kernel in the idea of iteration, which already has to be used in establishing the hierarchy of types and even in listing the propositions in a proof.

The logician Willard Van Orman Quine of the United States in 1937 weakened the type restriction to one of stratification. The resulting system is a form of axiomatic set theory rather than of type theory. Indeed, though the Logicistic thesis did not so develop historically, it could be based as well on a set theory as on a type theory.

**Formalism.** Hilbert accepted that the parts of classical mathematics employing the completed infinite go beyond intuitive evidence. But, instead of rejecting those parts, he proposed in 1905 and, more specifically, after 1918 roughly to formulate classical mathematics up to a suitable point as a formal axiomatic theory and to prove this theory consistent—i.e., free from contradiction.

Previous to this proposal of Hilbert, proofs of consistency had been given for axiomatic theories by interpreting their undefined terms in another theory so that the axioms become true or briefly by giving a model. Thus, the plane Lobachevskyan geometry was interpreted in Euclidean geometry by Beltrami. The consistency of geometries generally is reduced to that of analysis by René Descartes's analytic geometry of 1637, which employs real numbers as coordinates of points, so that geometrical propositions become propositions in the algebra of real numbers. For proving the consistency of analysis itself, the method of models offers no hope, because no theory is available in which analysis could be interpreted that appears safer than analysis.

Hilbert's proposal called for proving consistency by a new method, based directly on the meaning of consistency as freedom from contradiction. Not only should all the mathematical assumptions of a theory be listed but also all of the principles of logic, both the primitive propositions and the rules for drawing inferences, to be used in deducing theorems from the mathematical postulates. This listing done, it is possible to undertake to show that no two proofs in the theory terminate in theorems one of which is the negation of the other. Hilbert would thus make the proofs of the formal theory the object of an intuitive theory, called proof theory, or metamathematics. The latter should use only intuitively convincing

methods, called by him finitary methods. These methods in practice are Intuitionistic methods on the level of number theory. The formal theory provides a sort of stereotyped model of the previously existing informal theory, which is called the interpretation of the formal theory. This interpretation should play no role in the metamathematics, though it motivates the choice of the particular formal theory that is the object of the metamathematics.

To guarantee that all the principles of logic used in deducing theorems have been listed as axioms and rules of inference, the meanings of all the words should be left out of account in deducing theorems, just as in a formal axiomatic theory it should be possible to leave out of account the meanings of the undefined mathematical terms. Because of the irregularities and ambiguities of the existing word languages, it is feasible to do this only by reconstructing the informal theory as a symbolic language, which can be done by combining symbolic logic with the symbolization common in modern mathematics. The resulting formal theory is called a formal system, or logistic system, a statement in it a formula (or by some writers a well-formed formula, to emphasize that it must be formed from the symbols by listed formation rules) and the method the logistic method. The description of a formal system must be given from outside in an informal theory. The method was already available, but Hilbert added the proposal to make the formal system the object of mathematical investigations in this informal theory or metamathematics.

Brouwer–  
Hilbert  
contro-  
versy

There ensued a controversy in which Brouwer questioned how a metamathematical proof of consistency of classical mathematics would meet the objection that the propositions of classical mathematics beyond a certain elementary level lack a clear intuitive meaning. The upshot was that the Intuitionists would accept Hilbert's program as unobjectionable if the Formalists refrained from construing a consistency proof as in some manner vindicating classical mathematics intuitively. Hilbert drew an analogy with the stratagem in mathematics of adjoining ideal elements to a previously constituted system to achieve some theoretical end (e.g., the irrational numbers were added to the rationals so that all convergent sequences should have limits, the imaginary numbers to the reals so that all algebraic equations should have solutions; see ANALYSIS, REAL). He called the statements of classical mathematics with an intuitive meaning real, the others ideal. The statements involving the completed infinite are ideal. So, he said, in classical mathematics the ideal statements are adjoined to the real to give the theory as a whole a simpler logical structure, and it is no more reasonable to require that each separate statement should be interpretable taken by itself than that in theoretical physics each separate statement should be verifiable by experiment. The possibility appeared that classical mathematics reinforced by a proof of consistency might even serve as a tool for the Intuitionistic proof of real statements via shortcuts through the ideal statements.

Hilbert's program was undertaken after 1920 by him and his collaborators, the German Wilhelm Ackermann and the Frenchman Paul Bernays, and by others, including the Hungarian-born U.S. mathematician John von Neumann and the Frenchman Jacques Herbrand. The start was made by investigating a formal system of classical arithmetic (with several variants), obtained by adding Peano's postulates and definitions of sum and product to the first-order functional calculus as developed by Peano and as described in Hilbert and Bernays' *Grundlagen der Mathematik* ("The Foundation of Mathematics") in 1934 and 1939. A proof by Ackermann in 1924–25 of consistency of a subsystem did not lead at once to a proof of consistency of the whole system. Then in 1931 results of Gödel appeared that clarified the situation. These results are presented below from a standpoint that was reached after 1935.

The metamathematical method proved valuable for a variety of purposes in studying formal systems generally, as well as the ones Hilbert considered. Thus, a formal system of intuitionistic logic and mathematics was described by Heyting in 1930.

*Turing's computing machine and formal systems.* For certain classes of questions in mathematics, a method is known that can be applied to answer by "yes" or "no" any given question of the class. For example, for any positive integers  $a$  and  $b$ , the question "Is  $a$  a multiple of  $b$ ?" can be answered by dividing  $a$  by  $b$  and seeing whether the remainder is 0 or not. As a less obvious example, there is a method for deciding, for any given integers  $a, b, c$ , whether  $ax + by + c = 0$  has solutions for  $x, y$  in integers. Such a method is called an algorithm, or decision procedure; and the problem of finding such a method for a class of questions is called the decision problem for that class. Similarly, for a class of questions that require for their answers not "yes" or "no" but the exhibiting of some object, one speaks of an algorithm, or computation procedure, and a computation problem.

In the logistic method, the description of a formal system must enable one to decide whether any given formula is an axiom and whether any given formula comes by a permitted inference from one or two others; so there is a decision procedure for whether a given finite list of formulas is a proof in the system. But a decision procedure is not thereby provided for whether a given formula is provable; i.e., for whether there is a proof of it. The problem of finding a decision procedure for the latter is often called the decision problem for the formal system and was recognized in Germany as a problem of logic by Ernst Schröder in 1895, Leopold Löwenheim in 1915 and Hilbert in 1918. In the United States Emil L. Post gave in 1921 a decision procedure for the classical propositional calculus.

The  
decision  
problem

A decision procedure for a formal system embracing a given portion of mathematics would make automatic the solution of any problem in that portion statable as a "yes" or "no" question. It is therefore implausible that there should be a decision procedure for a formal system embracing the usual arithmetic, in view of the experience of mathematicians in trying to solve the one particular problem whether Fermat's last theorem is true; and many other similarly refractory problems are known. (The French mathematician Pierre Fermat around 1637 claimed to have proved that the equation  $x^n + y^n = z^n$  has no solution in positive integers  $x, y, z$  for any positive integer  $n > 2$ ; but no one since then has been able to confirm or disprove this so-called "last theorem" of his.) For there to be a decision procedure would mean, so to speak, that the infinitely many arithmetical problems involve only a finite number of difficulties such that once those are overcome no further ingenuity will be required. But it might have seemed equally farfetched in 1918 to hope that mathematics could get a hold on the problem of finding a decision procedure for arithmetic, which would enable this problem to be solved by showing that there cannot be one. Exactly this latter was done in 1936 by Alonzo Church.

The consideration of the computation problems for number-theoretic functions can lead to the question of what functions can be computed or effectively calculated, in the sense that, for a given argument, the value can be found by use only of preassigned rules, applicable without ingenuity on the part of the computer. Instead of a human, it can be proposed to have a machine to do the computation, according to rules built into its structure.

As this description is somewhat vague, what is needed is an exact mathematical formulation that comes to the same end. Such a formulation was given briefly by Post in 1936 and independently in detail by Turing in 1936–37. What Turing did was to describe a kind of theoretical computing machine, not limited in use by a fixed maximum amount of storage of information nor liable to malfunctioning, as are actual computing machines. A Turing machine operates in the following manner. At discrete moments the machine assumes one of a finite list of states (fixed for a given machine), the first of which is called the passive state, the other active, of which there are  $k$  in number, in which  $k$  is 1 or a greater integer. A linear tape, potentially infinite to the right, is ruled in squares, each of which is either blank or has printed upon it one of a finite number  $j$  (one or more) of symbols

Computation of number-theoretic functions

(fixed for a given machine), including, say, the tally |; but only a finite number of squares are printed. The tape passes through the machine so that one of its squares is scanned. If at the given moment the machine is in an active state, then it can alter the condition of the scanned square (by erasing, printing, or both), and/or move the tape so that the scanned square becomes the one next right or left, and/or change to another state between the given moment and the next or any combination of the preceding; this act is determined (for a given Turing machine) by the state of the machine and the condition of the scanned square at the given moment.

Turing used his machines primarily to compute in succession the digits of decimal expansions of real numbers, but they can be adapted to compute number-theoretic functions. Let an argument  $x$  be supplied to the machine by placing a blank followed by  $x + 1$  tallies on successive squares of the tape starting with the leftmost square, leaving the tape otherwise blank, and placing the tape in the machine with the rightmost tally scanned and the machine in its first active state. The machine is said to compute a value  $y$  for  $x$  as argument, if then it eventually reaches the passive state with the  $x + 1$  tallies followed immediately to the right by a blank and  $y + 1$  tallies, the rightmost being scanned, and the tape being otherwise blank. If, for each natural number  $x$ , the machine computes the correct value  $y = f(x)$  of a function  $f$ , when supplied the argument  $x$ , it computes the function  $f$ , which is then said to be Turing-computable.

Turing advocated the thesis that any function that can be effectively calculated is Turing-computable. His arguments include showing that various operations that a human computer can perform can be analyzed into successions of the simple operations his machines perform. Church had already in 1936 proposed the thesis that every effectively calculable function is  $\lambda$ -definable in a sense due to himself and S.C. Kleene of the United States or, equivalently, general recursive in a sense due to Gödel, who built on a suggestion of Jacques Herbrand of France; and this thesis was subsequently proved equivalent to Turing's, so the  $\lambda$ -definable functions, the general recursive functions, and the Turing-computable functions are the same.

*Church's theorem, logical systems without decision procedures.* The pattern of behaviour of a Turing machine is completely described by a  $k \times (j + 1)$  table showing the act to be performed for each of the  $k$  active states with each of the  $j + 1$  conditions of the scanned square. A system for encoding such tables can be established that, to each table, gives a natural number  $t$  as code number so that a person who knows the system can from  $t$  find the table and thence the behaviour of a machine  $M_t$  with this table. If  $t$  is the code number of a machine,  $M_t$ , that computes a value for  $x$  as argument, let  $f_t(x)$  be this value; and let  $f_t(x)$  be undefined otherwise.

The function  $f$  may be defined by letting  $f(x) = f_x(x) + 1$  if  $f_x(x)$  is defined, and  $f(x) = 0$  otherwise. This function  $f$  is not computable. For, if machine  $M_q$  with code number  $q$  computes a value for  $q$  as argument, that value is  $f_q(q)$ , not  $f_q(q) + 1$ , as it would have to be if  $M_q$  computes  $f$ . It follows that the property " $f_x(x)$  is defined" is undecidable. For otherwise  $f(x)$  could be computed, given  $x$ , thus: first decide whether  $f_x(x)$  is defined; then, if it is, imitate the behaviour of  $M_x$  to compute it and add 1; if it is not, write 0.

Thus, from Turing's thesis one has proved that there is a class of quite elementary arithmetical questions for which there is no decision procedure. This essentially is Church's theorem (1936), which he proved from his thesis using a corresponding class of questions in terms of  $\lambda$ -definability. For each  $x$ , the proposition " $f_x(x)$  is defined" is expressible in any formal system  $S$  that includes the usual vocabulary of arithmetic, by a formula  $A_x$  effectively determinable given  $x$ . If the quoted proposition is true, it is demonstrable intuitively by exhibiting the sequence of the acts of machine  $M_x$  in computing  $f_x(x)$ . If  $S$  includes ordinary arithmetical reasoning, then that demonstration can be translated into a proof in  $S$  of  $A_x$ ; i.e.,  $A_x$  is provable in  $S$  whenever (the proposition ex-

pressed by it is) true. Finally, if it be supposed about  $S$  that  $A_x$  is provable in  $S$  only when true, then there can be no decision procedure for provability in  $S$ ; for, if there were, by answering whether  $A_x$  is provable in  $S$ , one would have a decision procedure for " $f_x(x)$  is defined."

Moreover, there is no decision procedure for the important logical system  $F$  of first-order functional (or predicate) calculus, as Church in 1936 and Turing in 1936-37 showed. For a proof of  $A_x$  in  $S$  can be arranged as a deduction by  $F$  of  $A_x$  from a suitable finite set of arithmetical axioms independent of  $x$ , the conjunction of which can be written as one formula  $C$ . If the symbolism has been suitably chosen, then  $A_x$  is provable in  $S$ , if and only if the implication  $C \supset A_x$  is provable in  $F$  (the symbols  $C \supset A_x$  are read "if  $C$ , then  $A_x$ "). From these beginnings, a considerable theory has grown about "unsolvable decision problems," with further contributions in the United States, Russia, England, and Poland by Post, A.A. Markov (the younger), Turing, Alfred Tarski, Andrzej Mostowski, P.S. Novikov, and others.

*The effect of Gödel's theorems on Formalism.* A formal system such as  $S$  is consistent if for no formula  $B$  are both  $B$  and its negation  $\sim B$  provable in  $S$ ; complete if for each formula  $B$  without free variables (otherwise  $\sim B$  may not express the opposite of  $B$ ) either  $B$  or  $\sim B$  is provable in  $S$ .

It may be further supposed that  $\sim A_x$  is provable in  $S$  only when true. It is absurd that  $S$  be complete (and that  $\sim A_x$  be provable in  $S$  whenever true). For,  $A_x$  is provable in  $S$  (when and) only when true. So if, for each  $x$ , either  $A_x$  or  $\sim A_x$  were provable, it could be decided whether  $f_x(x)$  is defined or not, by searching through all the proofs in  $S$  until one is found of  $A_x$  or of  $\sim A_x$ . This is Gödel's theorem of 1931 in a negative form.

To obtain the positive form, the process can be considered, for a given  $x$ , of searching through all the proofs in  $S$  for one of  $\sim A_x$  and writing 0 if one is found. A Turing machine, say machine  $M_q$  with code number  $q$ , carries out this process, when supplied with  $x$ . Now by the choice of the formulas  $A_x$ ,  $\sim A_q$  is true if and only if  $f_q(q)$  is undefined, which by the choice of  $M_q$  is the case if and only if  $\sim A_q$  is unprovable in  $S$ . In brief,  $\sim A_q$  expresses its own unprovability (compare the paradox of the liar). So, were  $\sim A_q$  provable, it would be false, contradicting the supposition that  $\sim A_x$  is provable only when true. So  $\sim A_q$  is unprovable but true, and  $A_q$  is also unprovable (since false).

Hilbert's program called for embodying classical mathematics, including arithmetic, analysis, and set theory short of the paradoxes, in a formal system and proving that system consistent by finitary methods. The part of Gödel's theorem that  $\sim A_q$  is unprovable but true shows that not even the first step can be carried out fully. Despite the great value of the logistic method as a way of defining exactly the presuppositions of a given portion of mathematics, this very process of definition restricts that portion to include less of arithmetic than free use of intuitive reasoning would give, at least if what is already incorporated in the formal system is intuitively correct.

The part of the theorem that neither  $\sim A_q$  nor  $A_q$  is provable in  $S$  shows the inadequacy of  $S$  to decide by proof or disproof, irrespective of the interpretation, all the statements expressible in it. Thus,  $A_q$  is said to be formally undecidable in  $S$ .

In showing  $\sim A_q$  unprovable (and true), the assumption was used (for  $x = q$ ) that  $\sim A_x$  is provable in  $S$  only when true. This can be replaced by the metamathematical assumption (not ostensibly using the interpretation) that  $S$  is consistent. For, if  $\sim A_q$  were provable,  $f_q(q)$  would be defined, and hence, as noted above,  $A_q$  would be provable, which would contradict the consistency.

The assumption that  $A_x$  is provable only when true, used in showing  $A_q$  unprovable, can be replaced by the assumption that  $S$  is  $\omega$ -consistent, in the sense that for no formula  $B(x)$  are  $B(0), B(1), B(2), \dots$  and  $\sim(x) B(x)$  all provable in  $S$ , when " $x$ " expresses "for all  $x$ ." In verifying this,  $B(x)$  will express "at the  $x$ th moment  $M_q$  has not yet computed  $f_q(q)$ ." Adjoining  $A_q$  to  $S$  as a new axiom produces a formal system that is consistent but

Gödel's theorem

not  $\omega$ -consistent, if  $S$  is consistent. J. Barkley Rosser of the United States in 1936 modified Gödel's formally undecidable formula so that consistency sufficed; in fact, letting  $M_t$  carry out the process of searching through all the proofs in  $S$  for one of  $\sim A_x$  and writing 0 if one is found before one of  $A_x$  is found,  $\sim A_x$  is unprovable but true, and  $A_x$  is unprovable, if  $S$  is consistent.

As Gödel observed in proving his theorem, the objects employed in a formal system, say  $S$ , are countable; and after correlating natural numbers (called now Gödel numbers) effectively to them, by talking about those numbers instead of the formal objects, the metamathematics of  $S$  becomes a part of arithmetic and so expressible in  $S$ . Now the implication "If  $S$  is consistent, then  $\sim A_q$  is true," was obtained above as part of Gödel's theorem. If Consis was the formula of  $S$  that expresses " $S$  is consistent" in  $S$  via the Gödel numbering, then the quoted implication translated into  $S$  becomes Consis  $\supset \sim A_q$ . Gödel claimed that, by imitating formally in  $S$  the intuitive proof of his theorem, it should be possible to prove this formula in  $S$ . (This was done in detail by Hilbert and Bernays in 1939 in their formal system of arithmetic.) But then, if Consis were also provable,  $\sim A_q$  would be, which is contrary to Gödel's (first) theorem if  $S$  is consistent. Thus Gödel obtained his second theorem: if  $S$  is consistent, then the formula Consis, which says in  $S$  via the Gödel numbering that  $S$  is consistent, is unprovable in  $S$ .

Gödel's second theorem raises an obstacle to the second part of Hilbert's program. One might have supposed that the finitary methods to be used in proving consistency would be part of the methods formalized in the system, which amounts to saying that a finitary proof of consistency of  $S$  should be formalizable as a proof in  $S$  of Consis. Only such methods appear to have been used in attempts before 1931. Gödel's second theorem shows that not even all the methods incorporated in  $S$ , including the nonfinitary ones, would suffice.

Some mathematicians felt that this ended once and for all Hilbert's plan to make classical mathematics more secure by a consistency proof. Others thought it possible that methods might be found for proving consistency that, though not formalizable within  $S$ , could be construed as finitary and thus as safer than some of the methods incorporated in  $S$ . Thus, Gerhard Gentzen in 1936 gave a proof of the consistency of a system  $S$  of classical arithmetic, in which the nonelementary method (not formalizable in  $S$ ) is an extension of mathematical induction from the natural number sequence to a certain segment of the transfinite ordinal numbers that Cantor had introduced for extending the counting process beyond that provided by the natural numbers.

Gödel's (first) theorem provided confirmation for the view advanced earlier by the Intuitionists on philosophical grounds that the possibilities for intuitive mathematical thinking cannot be circumscribed in advance. Taking Brouwer's interpretation of a statement "a  $y$  exists such that  $P(y)$ " as meaning such a  $y$  can be found and applying Church's thesis to the case the  $y$  depends on  $x$ , Kleene in 1943 proposed the further thesis that a statement "for each  $x$ , a  $y$  exists such that  $P(x, y)$ " is provable Intuitionistically only if such a  $y$  can be given as a computable function of  $x$ . Using this thesis, there are theorems of classical arithmetic, by Kleene in 1943, and of classical analysis, by Ernst Specker in 1949, that are unprovable Intuitionistically (not merely in some formal system but absolutely); so classical mathematics reinforced by a consistency proof cannot serve as a tool of Intuitionistic proof, except of a very restricted class of statements. Kleene in 1945 and David Nelson in 1946 together showed that the Intuitionistic formal arithmetic based on Heyting's Intuitionistic formal logic does conform to the thesis. Gödel in 1932-33 (partially anticipated by A.N. Kolmogorov in 1924-25) correlated to each arithmetical formula  $B$  a classically equivalent formula  $B'$  that is provable in the Intuitionistic formal arithmetic if (and of course only if)  $B$  is provable in the classical formal arithmetic. In particular, the correlation proves very simply that the classical formal arithmetic is consistent if the

- (5) Church's theorem exhibits an undecidable property of a very simple form. In this treatment the undecidable property is " $f_x(x)$  is defined." If " $T(t, x, y)$ " abbreviates " $t$  is the code number of a Turing machine  $M_t$  that, when supplied with  $x$  as argument, completes the computation of a value at moment  $y$  (but not earlier)," and if " $(Ey)$ " abbreviates "there exists a  $y$  such that" or briefly "exists  $y$ " or "for some  $y$ ," then  $[f_x(x) \text{ is defined}] \equiv (Ey)T(x, x, y)$  (for all  $x$ ), the symbol  $\equiv$  representing "is identical to." But  $T(t, x, y)$  and hence  $T(x, x, y)$  is a decidable relation. So the undecidable property is of the form  $(Ey)R(x, y)$  where  $R(x, y)$  is a decidable relation. Using  $\sim(Ey)T(x, x, y) \equiv (y)\sim T(x, x, y)$ , there is also an undecidable property of the form  $(y)R(x, y)$  with  $R(x, y)$  decidable [where " $(y)$ " means "for all  $y$ "]. Any decidable property  $R(x)$  is expressible in both the forms  $(Ey)R(x, y)$  and  $(y)R(x, y)$ , by taking  $R(x, y) \equiv R(x) \ \& \ y=y$ , but neither  $(Ey)T(x, x, y)$  nor  $(y)\sim T(x, x, y)$  is expressible in the form the other has. For, given any decidable relation  $R(x, y)$ ,  $(Ey)R(x, y) \equiv (Ey)T(p, x, y)$  where  $p$  is the code number of a Turing machine  $M_p$  that, when supplied with  $x$  as argument, searches for the least  $y$  such that  $R(x, y)$ . So, if  $(y)\sim T(x, x, y) \equiv (Ey)R(x, y)$  held for some decidable  $R$ , we would have  $(y)\sim T(p, p, y) \equiv (Ey)R(p, y) \equiv (Ey)T(p, p, y) \equiv \sim(y)\sim T(p, p, y)$ , which is absurd. By similar reasoning, to each of the two forms  $(y)(Ez)R(x, y, z)$  and  $(Ey)(z)R(x, y, z)$  with decidable  $R$ , there is a property,  $(y)(Ez)T(x, x, y, z)$  or  $(Ey)(z)\sim T(x, x, y, z)$ , respectively, of that form that is not expressible in the other form and hence not in any of the simpler forms  $R(x)$ ,  $(Ey)R(x, y)$ , or  $(y)R(x, y)$ ; and likewise with three, four, . . . alternating exist-operations and all-operations. This is the (arithmetical) hierarchy theorem of Kleene.

Intuitionistic is. However, the Intuitionistic arithmetic distinguishes differing degrees of indirectness among statements classically equivalent.

Using the classical law of excluded middle, Gödel in 1930 proved a completeness theorem for the first-order functional calculus  $F$ . In one form, this says that, if a formal system obtained by adjoining mathematical axioms to  $F$  is consistent, it has a model; i.e., there is an interpretation that makes the axioms true. Indeed, the model can be constructed using the natural numbers as the objects. In another form, the theorem says that in such a system every formula is provable that is true under all the interpretations of the undefined terms that make the axioms true. In view of this, when  $S$  is based on first-order functional calculus, the unprovability in  $S$  of  $\sim A_q$  implies that, while  $\sim A_q$  is true under the intended interpretation of the undefined terms, there is some other interpretation that makes the axioms true (a nonstandard model) under which  $\sim A_q$  is false. This illustrates the theorem of Skolem in 1933 that no list of axioms in the symbolism of the first-order functional calculus can characterize the natural numbers categorically. If higher functional calculus is used, the deductive apparatus will be incomplete. It thus appears that the logistic method is inadequate to characterize the natural numbers categorically. Peano's axioms characterize them categorically but only through an interpretation that cannot be rendered fully through the deductive possibilities. Also one sees the Gödel formal undecidability of  $A_q$  as similar to the undecidability of Euclid's parallel postulate from the other postulates of Euclidean geometry.

*Degrees of decidability in arithmetic according to Kleene and Mostowski.* By Church's thesis, the decidable properties of a natural number are countable; for each decidable property  $P$  is decided by a Turing machine that computes 0 or 1 for  $x$  as argument according as  $x$  has the property  $P$  or not, and each Turing machine's behaviour is described by a code number. Thence the existence of undecidable properties follows simply by Cantor's theorem, by which the sets of natural numbers are uncountable; for each property  $P$  corresponds to the set  $S$  of the natural numbers that have the property.

Gödel's  
second  
theorem

Skolem's  
theorem

Church's theorem, however, goes beyond this: it exhibits an undecidable property of a very simple form (see 5). It can also be found that the properties in arithmetic are arranged in a hierarchy, with decidable properties at the bottom and above each level another level containing new properties defined by more uses of "exist" or "all" (see 5). This is a consequence of the (arithmetical) hierarchy theorem of Kleene in 1943, abstracted in 1940, found independently in another version by Andrzej Mostowski in 1947.

Further content is lent to this theory by the notion due to Turing in 1939 of a machine that is like a computing machine except that it has access to an "oracle"; e.g., such a machine may be designed to answer questions whether numbers have property  $P$  with the help of an oracle that answers questions whether numbers have property  $Q$ . This means that, in the process of answering a given question "Does  $x$  have property  $P$ ?" the machine (besides performing mechanical operations) may ask and receive from the oracle answers to questions "Does  $y$  have property  $Q$ ?" If such a machine exists, then it may be said that  $P$  is decidable from  $Q$ . In fact,  $(\exists y)T(x, x, y)$ , though undecidable absolutely, is decidable from  $(y)(\exists z)T(x, x, y, z)$ , but not vice versa; so it may be said that  $(y)(\exists z)T(x, x, y, z)$  is "more undecidable" than  $(\exists y)T(x, x, y)$ .

The hierarchy has been extended upward and also applied to properties of sets. (S.C.K.)

#### CURRENT DIRECTIONS

**Intuitionistic foundations of mathematics.** Brouwer's program for the constructive redevelopment of mathematics was continued by Heyting and others. In the 1960s, the U.S. mathematician Errett Bishop carried out a substantial extension of this program. At the same time his treatment differed from Brouwer's in that he avoided the use of notions, such as ips, that classical mathematicians had viewed with suspicion. This and other work showed that Intuitionism can provide a coherent and viable alternative to the other positions for the foundations of mathematics insofar as they apply to practice.

The logical study of formal systems has also revealed the potentialities of Intuitionistic reasoning. First, proceeding from the conditions for asserting compound statements described above, Heyting set up an Intuitionistically justified formal system of logic. This was formulated in such a way that the system of classical logic can be obtained simply by adjoining the laws of excluded middle. The same was done for a system of elementary number theory. In 1932, Gödel found a translation of the systems based on classical logic into the corresponding Intuitionistic ones. This was the first step in providing a theoretical explanation for the possibility of an Intuitionistic account of significant portions of mathematics.

Much work has been done since the midcentury in setting up formal systems for Intuitionistic theories of functions, ips, species, etc., and studying their relations with classical systems. This has also served to clarify the more distinctive Intuitionistic notions and principles, especially that of ips and the associated continuity principles. The theory of Turing computable functions has also turned out to be an important tool in the study of these systems. To the classical mathematician they provide a precise substitute for the informal idea of constructive function. To the Intuitionist, however, there is no reason to believe that the mechanically computable functions exhaust the conceivable (potential) totality of constructive functions. (S.Fe.)

Recursion,  
proof,  
model,  
and set  
theory

**Non-Intuitionistic studies on the foundations of mathematics.** From around 1960, work on the foundations of mathematics outside the Intuitionistic school has been described as falling mainly into four areas: recursion theory, proof theory, model theory, and set theory.

Recursion theory is another name for the theory of computability and decidability. This name came into use from treatments based on the general recursive functions.

Proof theory is another name for metamathematics. One of the newer developments in proof theory is the singling out of portions of analysis formalized so as to

use only properties of sets up to a given level in the recursion-theoretic hierarchy.

Model theory deals with the interpretations, or models, that satisfy the axioms of a given formal system. For example, by Gödel's completeness theorem of 1930, if a formal system based on the first-order functional calculus  $F$  is consistent, there is a model in which the objects are the natural numbers. But the axioms might be those of an axiomatic set theory, which purport to describe an uncountably infinite totality! The model is then a "non-standard model" of set theory (first observed to exist by Skolem in 1922–23). The opposition of Gödel's completeness and incompleteness theorems reveals that there is a nonstandard model of arithmetic.

Set theory, as a branch of foundational investigations, received great impetus from the construction in 1963 by Cohen of models that falsify the continuum hypothesis of Cantor. Cohen's and related methods are being used to show that various conjectures in set theory, analysis, and topology cannot be settled on the basis of the usual axioms of Zermelo and Fraenkel, sometimes augmented by new axioms. (S.C.K.)

**BIBLIOGRAPHY.** Some general references on the foundations of mathematics are HERMANN WEYL, *Philosophy of Mathematics and Natural Science* (1949 and 1963); PAUL BENACERRAF and HILARY PUTNAM (eds.), *Philosophy of Mathematics: Selected Readings* (1964); and RAYMOND L. WILDER, *Introduction to the Foundations of Mathematics*, 2nd ed. (1965). Advanced books, generally without emphasis on Intuitionism, include S.C. KLEENE, *Introduction to Metamathematics* (1952, reprinted 1971) and *Mathematical Logic* (1967); EVERT W. BETH, *The Foundations of Mathematics*, 2nd ed. rev. (1965); ALFRED TARSKI, ANDRZEJ MOSTOWSKI, and RAPHAEL M. ROBINSON, *Undecidable Theories* (1953, reprinted 1969); JOHN B. ROSSER, *Simplified Independence Proofs* (1969); and ANDRZEJ MOSTOWSKI, *Constructible Sets with Applications* (1969). An excellent source book for all the schools of thought and developments in the foundations of mathematics in the period 1879–1931 is JEAN VAN HELJENOORT (ed.), *From Frege to Gödel: A Source Book in Mathematical Logic, 1879–1931* (1967). For the area of Intuitionism, see AREND HEYTING, *Intuitionism: An Introduction* (1956); and A.S. TROELSTRA, *Principles of Intuitionism* (1969), two general expositions. (S.C.K./S.Fe.)

## Mathematics, History of

Studies of the languages of primitive peoples and related investigations of extinct languages indicate that a process apparently as simple as counting passed through many stages before it reached a level that permitted the systematization that is essential for any mathematical procedure. Similar observations have been made in the study of early writing. Only tortuous processes led from symbols for sets of concrete objects to a general notation that can be justly called a system of numerals. Mathematics originated only in a very few areas within the framework of highly developed urban civilizations and well-organized economic conditions.

### The development of mathematics

Of the great civilizations of antiquity—Babylon, Egypt, Greece, and Rome—two contributed little to the development of mathematics: neither Egypt nor Rome advanced beyond the level of elementary practical arithmetic and mensuration. Priority in the development of mathematics belongs to Babylonia, where ancient land numerical, algebraic, and geometrical methods existed at least from

the Hammurabi dynasty, around 1700 BC. Little is known of the earlier or later period, until Persian times, the 6th century BC. Nevertheless, that the tradition had been kept alive is established by texts of the last three centuries BC, when Babylonia had come under Greek and then Parthian domination. By that time Babylonian astronomy, which was to become the main carrier of Babylonian arithmetical methods, but already begun developing rapidly. How widespread these arithmetical methods were is evidenced in the persistence of the division of hours and degrees using 60 as the base number.

Simple categories are no longer applicable to the modern development of mathematics, though the earliest phase followed closely the examples of antiquity. The development of analysis in the 17th century by the mathematicians Pierre de Fermat, René Descartes (both French), and Isaac Newton (English) soon left behind classical methods and problems, and an enormous wealth of new discoveries revealed an interaction between theoretical mathematics and all branches of physics and astronomy. This period of brilliant and somewhat haphazard discovery culminated in the work of the Swiss mathematician Leonhard Euler in the middle of the 18th century. Soon afterward the need for increasing rigour and abstraction became the dominant motif, and these qualities have remained characteristic for mathematics. This tendency not only profoundly influenced each of the traditional branches of mathematics; it all but obliterated the boundaries between individual fields by revealing their common logical and operational background. By the second half of the 20th century the enormous importance of mathematical physics, accompanied by the development of computing machines, furnished a new incentive to mathematical research similar to the situation at the threshold of the 19th century.

#### ANCIENT AND MEDIEVAL

**Mesopotamia.** The superiority of Babylonian mathematics is based on the place-value notation (see below) of its number system, which was equally well adapted to the expression of numbers, however large, and of fractions. The system was not an intentional invention but emerged slowly during the 3rd millennium BC. In the highly developed economic life of the period a notation evolved for recording monetary transactions in which larger and smaller units of weights of silver were expressed by simple juxtaposition of numbers, denoting units of different values, similar to the notation \$5.20 as distinguished because of order of digits from \$20.5. Thus the arrangement of the numbers determined their relative value. In the United States, the ratio of dollars to cents is 1 to 100; in the Babylonian monetary system it was 1 to 60. This notation was then extended to numbers in general, creating what is called a sexagesimal place-value system. In the United States, then, 5.20 means  $5 + \frac{20}{100} = 5 + \frac{1}{5}$  (dollars) or  $500 + 20 = 520$  (cents). Similarly 2.30 in the sexagesimal system means  $2 + \frac{30}{60} = 2 + \frac{1}{2}$  or  $2 \times 60 + 30 = 150$ . All other arithmetical rules familiar from the decimal system have their exact counterpart in the sexagesimal place-value system. Tutoring in the decimal system produced knowledge of all products of integers up to 10 times 10; the Babylonians (and later the Greek and Islāmic astronomers) tabulated corresponding products up to 60 times 60. In this fashion all arithmetical operations—addition, subtraction, multiplication, division, squaring, cubing, and extracting roots—were carried out in Babylonian mathematics from the 2nd millennium BC on and then—beginning around the 5th century BC—by the astronomers of Mesopotamia, of Greece and Alexandria, of India, of the Islāmic world and the Byzantine world and their Western pupils to the 15th century and later.

A number system based on a place-value notation encounters the problem of the occurrence of empty places; in the sexagesimal system, the problem arises when in addition some digits total exactly 60 and are carried as 1 to the next higher place. In the earlier period of Babylonian mathematics no special symbol existed for such cases; only the relative order of the digits, which was easy to

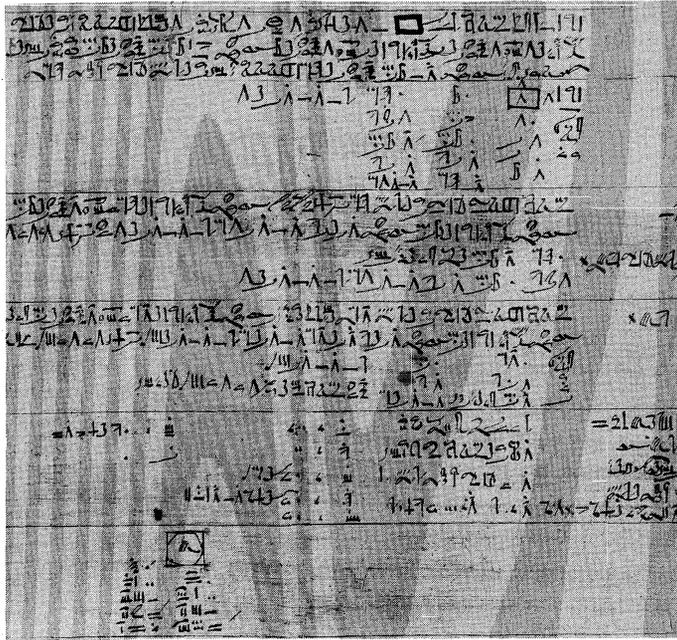

mistake, indicated it. In the late period, however, a special sign was written for every empty place. This zero symbol was in common use in all astronomical computations and reached Hellenistic mathematicians, along with the sexagesimal place-value notation. Thus in all Greek trigonometric tables (for instance, in Ptolemy's *Almagest* of about 140 AD) a zero sign is used exactly as it is today. This condition holds for Islāmic and Byzantine tables as well; in late Greek manuscripts the form  $\bar{o}$  for zero is the most common one. When Hindu astronomy was developed under Western influence, beginning about the 5th century, the zero symbol was transferred to a decimal place-value notation. The decimal system was well-known to Islāmic scholars, although astronomical practice remained sexagesimal in most cases. In western Europe, the decimal notation gained ground very slowly, and not until the 17th century was a consistent place-value notation developed by François Viète in France and by Simon Stevin in Holland.

The facility of numerical computations, as a result of the place-value notation, is everywhere visible in Babylonian mathematics. An old Babylonian text (c. 1700 BC) investigates triples of Pythagorean numbers; that is, numbers satisfying the relationship  $a^2 + b^2 = c^2$  (an example is 3, 4, and 5).

Many problems were of the type that requires determination of two numbers with a given sum when their difference is known. For example, if  $(a + b) = 5$  and  $(a - b) = 1$ , then  $a$  is 3 and  $b$  is 2. This type of problem involves linear equations, in which the unknowns are not raised to higher powers than 1. Quadratic equations involve squares of unknown quantities and were involved in the problem of determining two numbers of known sum and product. For instance, if  $(a + b) = 6$  and  $ab = 8$ , the determination of  $a$  and  $b$  requires a solution of the equation  $a + 8/a = 6$ . This is the quadratic equation  $a^2 - 6a + 8 = 0$ . Equations of fourth order (involving  $a^4$ ) were obtained by squaring equations of the second order (involving  $a^2$ ). A numerical algebra was developed from this insight. Similar problems in geometric formulation were handled involving concepts of similarity, the basic area relations, and volumes. The Pythagorean theorem for right triangles, the fact that a triangle inscribed in a semicircle contains a right angle, and relations in regular polygons were all known, leading to good approximations for the square roots of 2, 3, and other integers. The crude value of 3 was often used for  $\pi$ , the ratio of the circumference of a circle to its diameter, but  $3\frac{1}{2}$  was also known.

**Egypt.** The main source of present knowledge of Egyptian mathematics is two papyri, the so-called Rhind (or Ahmes, after the scribe who prepared it) papyrus of the British Museum, written sometime before 1700 BC, and the Golenishev papyrus in Moscow, dating from about 1900 BC. Several smaller fragments confirm impressions gathered from the two larger texts. Arithmetical operations were developed additively, repeated duplication for multiplication, with corresponding rules for division and fractions, derived from successive halvings. These often long-winded procedures were used to solve very elementary practical problems; e.g., distributing bread and beer in given quotas. Also determined in the same fashion were areas of triangular or polygonal fields and volumes of solids, in particular of a truncated pyramid (probably in the special shape of a corner block of two sloping walls). The area of a circle was found by squaring  $1 - \frac{1}{9}$ , or  $\frac{8}{9}$ , of the diameter (corresponding to a value of about 3.16 for  $\pi$ ).

**Greek and Hellenistic mathematics.** Late antiquity attempted to supplement the dim records of the past by associating the origin of mathematical knowledge with the early philosophical school of the 7th and 6th centuries BC in Ionia, identified with Pythagoras. These claims are not confirmed by modern research. The basic facts of elementary geometry and arithmetic had been known in Mesopotamia for many centuries. On the other hand, Greek astronomical and cosmogonic concepts in the 5th century BC were still so primitive that only a very narrow margin is left for earlier discoveries. Indeed, it seems

Section of the Rhind mathematical papyrus copied by the scribe Ahmes, c. 1650 BC. In the British Museum. By courtesy of the trustees of the British Museum

more plausible to assume that the independent development of Greek mathematics began in the second half of the 5th century and the first half of the 4th century as evidenced in the earliest reliable records, namely, the determination of certain areas bounded by circular arcs by Hippocrates of Chios and the investigation of curves in space in connection with the problem of the duplication of the volume of a cube by Archytas of Tarentum. Whether this rapid development of scientific mathematical theory had anything to do with increasing contact with the Near East is unknown; it seems unlikely. Clear influence of the Oriental tradition appears much later, in the 1st- and 3rd-century-AD writings of Heron of Alexandria and Diophantus of Alexandria, although the numerical methods used in astronomy reveal Babylonian influence at least from about 150 BC and the work of Hipparchus.

Although Plato lived during the most important formative period of Greek mathematics, it seems unlikely that he played any active role in its development. Nevertheless, philosophy was of great importance for the origin of scientific mathematics, if only for the necessity of removing mathematical argumentation from the unsafe ground of philosophical discussion. The paradoxes about the infinite divisibility of space and time attributed to Zeno of Elea, 5th century BC, and the related attempts of avoiding them through the assumption of atomistic structures attributed to Democritus, c. 400 BC, led to the necessity of defining exactly the postulates to be made for the objects of mathematical discussion. These investigations soon resulted in the discovery that the rational numbers do not suffice for the measurement of geometrical quantities; thus, an independent foundation of geometry was required. As a result the mathematicians of the early 4th century BC, foremost among whom were Theaetetus and Eudoxus of Cnidus, developed a geometric theory of what are now called irrational numbers. (Rational numbers are numbers that can be expressed as quotients of integers such as  $6$ ,  $\frac{1}{6}$ ,  $\frac{3}{7}$ , etc.) The concept of area gave rise to a near rigorous theory of integration even in ancient times.

The strictly geometric formulation of these problems directed Greek mathematics away from algebraic procedures although a purely algebraic notation had been used by Aristotle in his investigation of formal logic in spite of the continuation of the Oriental tradition within elementary mathematics.

Theoretical mathematics perhaps received its original impetus from such philosophical problems as the mean-

ing of infinite divisibility of lines, the meaning of area and volume, or the mutual relationship between geometrical and arithmetical ratios connected with the theory of harmonics. Two other relatively early lines of interest, however, are also discernible: namely, curves traceable by mechanical means, and conic sections (curves that are produced by taking a section of a cone). In the first group are the problems of spherical geometry as suggested by the apparent motion of the celestial bodies. The second group probably also has an astronomical origin in the theory of sundials. By the end of the 4th century BC all these areas of investigation had reached a level at which a certain codification became possible, even necessary. Eudemus of Rhodes, a pupil of Aristotle, wrote a history of mathematics, unfortunately known only in some short excerpts. Somewhat later appeared Euclid's *Elements*, concerning the most refined part of theoretical mathematics, culminating in Book X, the classification of irrationals. A work on conic sections by Euclid is lost, but some smaller writings have survived, notably a spherical astronomy that shows how far in the future a spherical geometry lay.

The theory of conic sections, however, had reached a high degree of perfection, and its significance for the solution of algebraic problems had been understood. This relation was amply attested by the use of conic sections made by Archimedes and, above all, by Apollonius of Perga, whose great work includes a systematic discussion of elementary properties of conic sections. Many theorems are also proved, but the significance of this operation was recognized only with the 19th-century development of the subject known as projective geometry. In these early sources there are theorems of duality, transformation of coordinates, a discussion of evolutes, and theorems that are related to the projective generation of conic sections from pencils of lines.

With Archimedes and Apollonius, theoretical mathematics had reached its climax in antiquity. From then on, astronomical problems determined the direction of further progress. Apollonius showed that the anomalies in the motion of the Sun, Moon, and planets can be explained. It is easy to see that the apparent position of a body moving on an eccentric circle can be predicted by trigonometric relations, which in turn are always reducible to the solution of right angles. The new element brought to the problem by its astronomical application consists in the need for repetitiveness in order to describe the motion of a body by its consecutive positions. This need leads to the construction of numerical tables or to graphical or mechanical devices. In the 3rd century BC, Babylonian mathematical astronomy had reached full maturity. With Hypsicles of Alexandria and Hipparchus the Babylonian, numerical methods, with difference sequences as the main tool, appeared in Greek astronomy. Hipparchus is credited with the computation of a table of chords of circles. In the same period must belong the invention of stereographic projection, which transfers problems of spherical geometry to plane geometry under preservation of circles. Similarly, methods of descriptive geometry were invented, the so-called analemma, again with the purpose of treating spherical problems in the plane. This phase of the development was completed by the middle of the 1st or the end of the 2nd century BC.

The progress of spherical trigonometry as a method was much slower, for obvious reasons. Plane trigonometry involves no new principle beyond the Pythagorean theorem and the fact that two chords over a diameter form a right angle, both known since Old Babylonian times. Spherical trigonometry required new insight, in particular the restriction to great circle arcs (such as meridians on the surface of the Earth). The discovery of the latter fact seemed to be due to Menelaus (c. AD 100). The contrast between the work of Menelaus and the earlier *Sphaerica* of Theodosius of Bithynia in the 1st century BC shows clearly the progress made. Inequalities and qualitative considerations were replaced by accurate solutions of spherical triangles, based on the Menelaus theorem. With Ptolemy in the 2nd century AD this method became the standard procedure for spherical astronomy.

The work of Archimedes and Apollonius

Development of postulates

In the 4th century AD, the sciences became an object of teaching and commentaries. Pappus of Alexandria, Theon of Alexandria, and Hypatia paraphrased, commented on, and edited the great classics. Much is owed to their industry, and a work such as the *Mathematical Collection* of Pappus had great influence on the revival of mathematics in the 17th century, particularly on Descartes. The 5th-century philosopher Proclus wrote an introduction to the *Almagest* and commented on Book I of Euclid's *Elements*. Eutocius of Ascalon in the 6th century competently discussed Archimedean treatises. Unfortunately, what was left of Greek mathematical literature in Byzantium had sunk to the level of elementary summaries.

**The Middle Ages.** Very few details are known about the survival of ancient science during the period from the final victory of Christianity to the beginning of Islāmic science in the 9th century. Persia undoubtedly played a role in this process, not only as a refuge for exiles—non-Christian as well as Christian—from orthodox persecution, but also as an intermediary with India. In the 6th century, under Sāsānian rule, Gondēshāpūr in southwestern Iran, Khūzestān province, was a centre of learning, particularly in medicine. Under the influence of the 'Abbasid caliph al-Manṣūr a project of systematic translating was begun, centred at the House of Wisdom in Baghdad and based on a widespread search for Greek scientific literature. In the same period, Indian astronomy had reached Baghdad, thus creating the first school of Islāmic astronomy, the best known representative of which is al-Khwārizmī, who died about 850. His name still lives in the term algorithm (to designate a rule of procedure) as well as in the term algebra, which was derived from the title of one of his works, *Kitāb al-jabr wa al-maqābalah*, famous although of little originality because it closely follows the tradition of elementary mathematics traceable from Mesopotamia through the works of Heron of Alexandria and others. Yet for the revival of mathematics and astronomy, al-Khwārizmī's work was of great importance.

The most significant contribution of India to medieval mathematics was in trigonometry. For a circle of unit radius the length of an arc is a measure of the angle it subtends at the centre of the circle. The Greeks, to facilitate calculations in geometry, tabulated values of the chord of arcs. This method was replaced by Hindu mathematicians with the half chord of an arc, known as the sine of the angle. The use of the decimal system, however, remained of much lesser importance, though it occurred occasionally in Islāmic, and then also in Byzantine, works. No influence on the West was exerted by the development in India in the 6th century of a theory of Diophantine equations; *i.e.*, equations with two or more variables for which the solutions are required to be integers. The origin for these investigations in all probability lay in questions related to the periodicity of planetary phenomena. Thus methods had been known in India that were not rediscovered until 1624 by the French mathematician Claude-Gaspar Bachet, sieur de Méziriac. The Hellenistic theory of numbers culminated in, among other things, the proof of the existence of an infinity of prime numbers by Euclid. What remained of Greek theory of numbers—for example, in Iamblichus or Diophantus—did not form a connected theory and had little influence during the Middle Ages.

The progress due to Islāmic mathematicians and astronomers probably lay mostly in the perfection of computational devices. Accurate tables for the sine and tangent function were computed, and methods were devised to modify the sine function in order to tabulate the equation of centre for planetary orbits. Spherical trigonometry was developed far beyond the level reached in antiquity. The use of the Menelaus theorem was replaced by more elegant methods; for example, the sine theorem, known since about AD 1000 and attributed to the Muslim mathematician Abū al-Wafā. At the same time the ancient tradition of descriptive geometry and graphical procedures was developed in the theory of sundials.

Abū al-Wafā and his contemporary Kūshyār ibn Labbān wrote treatises on sexagesimal computation. From

them proceeds a continuous tradition to al-Kāshī, the first director of Ulūgh Beg's observatory in Samarkand in about 1400. Among these scholars, a method was developed for the determination of the  $n$ th root by means of an iteration process, one in which some standard simple procedure is repeated several times to achieve the result, such as in long division. Al-Kāshī wrote a treatise on the computation of  $\pi$  in which he gives approximations both in sexagesimal and decimal fractions to 9 and 16 places, respectively, based on the comparison of an inscribed and a circumscribed regular polygon of more than 8,000,000,000 sides.

Al-Bīrūnī's 11th-century work on India or Ibn Khaldūn's 14th-century sociological studies, both masterpieces of scientific analysis, exemplify the depth of Islāmic culture that Westerners rightly regarded with the greatest of admiration. Measuring Islāmic science by its new discoveries and independent achievements, however, it is clear that the five centuries from AD 900 to 1400 cannot compete with the most creative period of Hellenistic science from 300 BC to AD 200.

The process of transmission of Islāmic science to Europe began in the 11th century with such men as the English philosopher Adelard of Bath, who visited Syria, and in the 12th century with the Italian mathematician Leonardo Pisano in north Africa and Italy at the time of Frederick II, whose court in Palermo became a centre of learning. Gerard of Cremona, working in Toledo in the 12th century, was perhaps the most prolific translator of Arabic versions of such Greek works as those of Euclid, Archimedes, and Theodosius of Bithynia. Many European scholars worked in Spain during the 12th and 13th centuries, often helped by Jewish scholars, committing to Latin an Arabic text. Their works formed the foundation on which the science of the Renaissance was built.

#### MODERN PERIOD

In 1545, only two years after the Polish astronomer Nicolaus Copernicus had published his *De revolutionibus orbium coelestium* ("Concerning the Revolutions of Heavenly Bodies"), which upset the Ptolemaic conception of the universe, and after the anatomist Andreas Vesalius had corrected the physiology of the 2nd-century-AD physician Galen, the Italian mathematician Gerolamo Cardano published the *Artis magna sive de regulis algebraicis* ("The Great Art, or the Rules of Algebra"), a book that opened a new era in mathematics. Linear and quadratic equations had been solved for thousands of years, but the cubic—involving the cube of a variable—had resisted all efforts, until suddenly several Italian algebraists discovered a solution. First to succeed seems to have been Scipione del Ferro about 1510; but the formula often is named after Niccolò Tartaglia, a rediscoverer, or after Cardano, who first published it in the *Artis magna*, together with Lodovico Ferrari's solution of the quartic. This unexpected success gave a fillip to the theory of equations, and enthusiasm for algebra, "the great art," spread to other lands. Simon Stevin of Bruges gave rules for locating roots of equations and established the systematic use of decimal fractions in 1585. In France, at the court of Henry IV, François Viète gave algebra a new name, the "analytic art," and a more general form. His use of vowels for unknown quantities and consonants for known paved the way later for the important concepts of variable (an entity standing for many possible constant values) and parameter (a variable that holds a fixed value within a given context), as well as for the rapid rise of a truly symbolic algebra. He is remembered also for his part, in 1579, in continuing the efforts of Johann Müller, whose work was published to establish trigonometry as more than a stepchild of astronomy.

**17th century.** Viète died in 1603, just over the threshold of the "century of genius." Brilliant discoveries were about to crowd close upon one another. In 1614 John Napier of Scotland published his discovery of logarithms (see MATHEMATICS AS A CALCULATORY SCIENCE and below *Calculatory science*). In the following year Johannes

Indian work in trigonometry

Islāmic mathematics

Cardano's "Rules of Algebra"

Kepler devised infinitesimal methods, which Bonaventura Cavalieri in 1635 fashioned into a geometry of indivisibles. An example of his method is the determination of the area of an ellipse (see GEOMETRY, ANALYTIC AND TRIGONOMETRIC). It is supposed that the ellipse has a major axis of length  $2a$  and a minor axis of length  $2b$ . A circle is drawn around the ellipse with a radius  $a$  and the same centre. Now it is supposed that a system of parallel lines is taken parallel to the minor axis. These parallel lines are intercepted to form chords of the ellipse and of the circle, and it is a property of the configuration that the ratio of the length of a circle chord to the length of an ellipse chord is  $a/b$ . Cavalieri conceived that the whole plane was divided into parallels. Each chord can then be thought of as a small rectangle of infinitesimal thickness, called an indivisible element by Cavalieri. The area of a given figure is the sum of these elements, and it follows that the ratio of the area of a circle to that of an ellipse is  $a/b$ . Hence an ellipse has an area of  $\pi ab$ . This is the basic principle used in integration, the idea of the addition of an infinite number of infinitesimal parts.

Descartes's  
discovery  
of  
analytic  
geometry

In 1637 the French philosopher-mathematician René Descartes published, along with his *Discours de la méthode*, his greatest discovery, analytic geometry, in which a point can be represented by a pair of numbers giving its distances from two lines called axes. The numbers are known as the coordinates of the point. A function of a variable  $x$  is a mathematical expression involving  $x$ , such as  $x^2$ . Neither coordinates nor the graphical representation of functions was new at the time of Descartes, but he, with his contemporary and fellow countryman Pierre de Fermat, correlated these in the basic principle that an equation in two unknown quantities represents a curve and vice versa. For example, a general point has coordinates  $(x, y)$ . The equation  $y = x$  describes all points whose  $x$  coordinate equals their  $y$  coordinate. These lie on a straight line bisecting the angle between the axes.

Except for a few isolated cases (such as projective geometry), "Cartesian geometry" overshadowed "pure geometry" for almost two centuries. One of the immediate results of the new geometry was a tremendous increase in the variety of curves that came to be studied. So few curves had previously been known that no need had been felt for a general definition of tangent line; a tangent had been, with certain obvious exceptions, a line that touches the curve at one and only one point. It was Fermat, primarily, who introduced the modern idea of the tangent to a curve at any given point  $P$ . In essence, he took a second point  $Q$  on the curve, found the slope of the secant line  $PQ$ , and from this, by permitting  $Q$  to tend toward coincidence with  $P$ , he calculated the slope of the tangent. This method rightly earned for him the title of inventor of the differential calculus, in which the rate of change of a function is found. When one notes also his share, in 1654, together with the French scientist Blaise Pascal, in the founding of the theory of probability, his work on the quadrature of curves, his use of mathematical induction, and his achievements in the theory of numbers, one appreciates why Fermat, for whom mathematics was but an avocation, has been hailed as the greatest of amateurs. Fermat found the length of the semicubical parabola in 1658, the year in which the Dutch mathematician and astronomer Christiaan Huygens determined the length of the cycloid, although rectifications had been anticipated by Evangelista Torricelli, a student of Galileo, who had found the length of the logarithmic spiral in about 1640.

Pascal and the English mathematician John Wallis also studied the cycloid, the curve traced out by a fixed point on a circle as the circle rolls along a line. Its beautiful properties led to many disputes over priority and it has been called the "Helen of Geometry." Huygens showed that the evolute (see GEOMETRY, ANALYTIC AND TRIGONOMETRIC) of a cycloid is an equal cycloid, a property that led to the concept of curvature and that was applied to the making of pendulum clocks.

*Development of the calculus—Newton and Leibniz.* Of all the 17-century mathematicians, none compared in

power and original contributions with Sir Isaac Newton. One of his earliest discoveries was that of the binomial theorem for rational fractional exponents. The binomial theorem is the expansion of the expression  $(x + y)^n$ , in which  $n$  is an integer. When  $n$  is not a whole number the expression expands into an infinite number of terms. This discovery introduced Newton to the study of infinite series, which are sums of an infinite number of terms of some sequence. An example is  $1 + \frac{1}{2} + \frac{1}{2}^2 + \frac{1}{2}^3 + \dots$ , with an infinite number of terms. The value of a series is obtained by the limit of partial sums. The first term here has a value of 1; the sum of the first two terms is  $1\frac{1}{2}$ ; the sum of the first three is  $1\frac{3}{4}$ . As the number of terms increases, the partial sum approaches a limit of 2, this being the value of the series. Such a series is said to be convergent, as opposed to a divergent series, which does not have a limit. The ideas involved in infinite series loomed large in Newton's work on the calculus at about the same time. Areas had been found by summations by earlier mathematicians from Archimedes to Wallis; differentiations had been carried out by Fermat. Newton and the German mathematician and philosopher Gottfried Wilhelm Leibniz discovered the fundamental principle of the calculus that integrations can be performed far more easily by inverting the process of differentiation. This discovery was made possible, in the case of Newton, by his study of the methods of his teacher, Isaac Barrow, as well as by works of Fermat and Wallis; Leibniz seems to have been led to the calculus independently during the period between 1673 and 1676 by reading the works of Barrow and Pascal. Neither inventor was able to establish the calculus on a sound logical basis. Newton at first adopted a crude explanation in terms of infinitely small "moments."

Later Newton based his theory on rates of change. Briefly he used two concepts: fluents, which were changing quantities, and fluxions, which were rates of change of magnitudes. A quantity  $x$  may be considered to change uniformly with time and the rate of change of  $x^2$ , say, can be found. If  $x$  changes to  $(x + h)$ ,  $x^2$  changes to  $(x + h)^2$  in the same time; that is, it changes to  $x^2 + 2hx + h^2$ ,  $x$  increasing by  $h$  and  $x^2$  increasing by  $2hx + h^2$ . Newton used the idea of prime and ultimate ratios. The ratio of the increments is  $h : 2hx + h^2$ , or  $1 : 2x + h$ . If  $h$  is disappearingly small, the ultimate ratio is  $1 : 2x$ ,  $2x$  being the fluxion of  $x^2$  giving the rate at which  $x^2$  changes when  $x$  changes. The general case of finding the fluxion of  $x^n$  involved the use of the binomial theorem for  $(x + h)^n$ . Newton's notation  $\dot{x}$  for the fluxion of  $x$  is still used.

Leibniz used the idea of infinitesimally small differentials, denoted by  $dx$  and  $dy$ , and tried (unsuccessfully) to explain his method in terms of sums and quotients of these. The notation has been used ever since.

Newton's first publication of the calculus was in 1687 in a short offhand explanation in the *Philosophiæ Naturalis Principia Mathematica* (*The Mathematical Principles of Natural Philosophy*, 1729), conceded to be the greatest of all scientific treatises. The *Principia* is written in Latin, the synthetic language of the ancients, even though the discoveries in the book were made through the new analytic devices that the author helped to develop. Newton is best known for his demonstration, in the *Principia*, of one of the greatest of scientific generalizations, the law of gravitation. Newton's discovery of the composite nature of white light was published in the *Opticks* of 1704, a treatise containing also Newton's *Quadrature of Curves* and his *Enumeration of Cubic Curves*. Whereas Newton's aim was to understand nature, the motive of Leibniz was to find a general pathway to knowledge. The Leibnizian search for a universal characteristic, which resulted in the first steps toward a symbolic logic, failed to attract a following until the publication of the English mathematician George Boole's *Investigation into the Laws of Thought* in 1854; but the method of differentials, the formal algorithmic nature of which was in accord with the aims of its inventor, became the mainspring of mathematical development during the course of the 18th and 19th centuries.

The  
binomial  
theorem

The work of Leonhard Euler

**18th century.** The mathematical contributions of the versatile Leibniz were more modest than those of Newton, but Leibniz' influence on the continent was far greater. The Bernoulli family in particular, great admirers of Leibniz, were fired with enthusiasm for the differential calculus; and the greatest and most influential pupil of Johann Bernoulli was Leonhard Euler, the most prolific mathematical author of all time. The 18th century saw few spectacular discoveries; yet this prosy age generated more new mathematics than had any earlier period, and most of this centred on the work of Euler. One of his treatises, the *Introductio in analysin infinitorum* ("Introduction to Infinitesimal Analysis") of 1748, may be called the foremost mathematical textbook of modern times, for it was this work that fashioned the function concept and infinite processes into the third member of the mathematical triumvirate comprising geometry, algebra, and analysis.

Euler contributed to all analytic aspects of mathematics. His treatises on the differential and integral calculus are the source from which modern authors have drawn material. He was one of the founders of two branches of mathematics: the calculus of variations and differential geometry. The former is an extension of calculus applied to cases in which a function depends on another function or a curve. Differential geometry is the application of differential calculus to studies of the general properties of curves and surfaces. Euler was also the greatest figure in the theory of numbers since Fermat; and he contributed much to mathematical physics. The vast scope of his interests accounted perhaps for a lack of soundness in his logical foundations. He based the calculus on quotients of "qualitative zeros," and he had no qualms about operating with the "sums" of series that did not converge and thus could not be used to represent numbers.

Mathematicians of the 18th century generally were connected with a university or a royal court, and Euler, no exception, found patrons at Berlin and St. Petersburg. When in 1766 Euler resigned from the Prussian academy to return to Russia, Frederick II the Great chose as his successor Joseph-Louis Lagrange of France, reputed the greatest mathematician of the century. The interests of Lagrange (algebra, analysis, the theory of numbers, and mechanics) were much like those of Euler, but his disposition was different. Lagrange published far less, but his contributions were beautifully finished products with a sound foundation. His *Théorie des fonctions analytiques* ("Theory of Analytic Functions") of 1797 made mathematicians more keenly aware of the need for rigour; but the book that earned him greatest fame was the *Mécanique analytique* (1788), which established mechanics as a branch of mathematical analysis. Beginning with a small number of postulates, the author built up the principles of the subject without recourse to anything beyond deductive logic. The Age of Reason, typified by the French mathematician and encyclopaedist Jean Le Rond d'Alembert, may be thought of as culminating in the *Mécanique analytique*. The greatest legacy left to mathematics by the French Revolutionary period was the establishment in 1794 of the École Polytechnique, a school that boasted among its teachers the greatest mathematicians of France, including Lagrange, Pierre-Simon Laplace, and Gaspard Monge. Laplace established celestial mechanics as a branch of analysis, and it was through his work that such tools as potential theory (see ANALYSIS, COMPLEX), the Laplace transform (see ANALYSIS, FOURIER), the Laplace equation (see DIFFERENTIAL EQUATIONS), and orthogonal functions (see ANALYSIS, FUNCTIONAL) became the stock-in-trade of the analyst. His masterpiece, the *Mécanique Céleste* ("Celestial Mechanics") published in five volumes between 1799 and 1825, purported to prove the stability of the solar system, for the origin of which the author proposed a nebular hypothesis. The students of the École Polytechnique esteemed as their greatest teacher Gaspard Monge, who began an era in mathematics characterized by a resurgence of geometry. His *Géométrie descriptive* published in 1799, originally devised for military purposes, was the first significant contribution to synthetic geometry after

Lagrange's *Mécanique analytique*

1639; but the author was not a single-minded synthesist, and the emphasis at the École Polytechnique upon analytic and differential geometry was in large measure the result of the successful textbook of Monge published in 1795. The key idea in his work was that each step in an analytic calculation corresponds to some geometrical construction. Lazare Carnot, the "organizer of victory" for the French Revolutionary armies, likewise made valuable contributions both to analytic and synthetic geometry, his greatest treatise being the *Géométrie de position* of 1803.

**19th and 20th centuries.** Carnot had sought to avert the despotism of Napoleon, but Monge and Jean-Baptiste-Joseph Fourier were friends and ardent admirers of the Emperor. Fourier's chief contribution to mathematics is typical of the originality (but not the rigour) of the new century. His classic *Théorie analytique de la chaleur* (*The Analytical Theory of Heat*) of 1822 showed that an arbitrary function can be expanded in a Fourier series of sines and cosines. In the very same year, Fourier's boldness in analysis was paralleled in projective geometry by the *Traité des propriétés projectives des figures* ("Treatise on the Projective Properties of Figures") of Jean-Victor Poncelet, a student of Monge. Poncelet became a centre of controversy over the principle of continuity and other concepts. His reckless charges of plagiarism antagonized a young German geometer, Julius Plücker, who became the greatest of analytic geometers.

In his many treatises, Plücker developed basic ideas. In Germany his work was not well received, for Jakob Steiner by 1832 had built up a strong following in synthetic geometry. Steiner hated analysis as thoroughly as Lagrange disliked geometry, arguing that calculation replaces thinking, whereas pure geometry stimulates it. His ideas were carried on by Karl G.C. von Staudt, also of Germany, who, with still sharper logic, examined the structure of pure geometry.

*Non-Euclidean geometry.* Probably no earlier period in the history of mathematics rivalled the 19th century either in critical spirit or originality of development, both of which are seen in the rise of non-Euclidean geometry. The parallel postulate of Euclid is that, if a point lies outside a line, then only one line can be drawn through the point parallel to the first line. This postulate seemed less fundamental than the others, but numerous attempts were made to prove it.

Between 1826 and 1832 the Russian mathematician Nikolay Ivanovich Lobachevsky and János Bolyai of Hungary showed that self-consistent geometries can be built without this principle. In 1854 Bernhard Riemann of Germany proposed the characterization of a new geometry by the quadratic differential form for arc length (see PHYSICAL THEORIES, MATHEMATICAL ASPECTS OF), involving an idea essential later in general relativity. Carl Friedrich Gauss of Germany, still another independent discoverer of non-Euclidean geometry, failed to publish his thoughts on the subject. The informed consensus is that Archimedes, Newton, and Gauss were the greatest mathematicians of all time. When he was not yet 19, Gauss discovered in 1796 that a regular polygon of 17 sides can be constructed in the Euclidean sense. Other results were entered in his diary and went unpublished until rediscovered by others. His *Disquisitiones Arithmeticae* ("Inquiries into Arithmetic") of 1801, containing the law of quadratic reciprocity and the theory of congruences (see NUMBER THEORY), is a classic in the theory of numbers; and the *Disquisitiones Generales Circa Superficies Curvas* ("General Inquiries Concerning Curved Surfaces"), of 1828, marked a new epoch in differential geometry through the exploitation of the parametric representation of surfaces and their Gaussian curvature (see GEOMETRY, DIFFERENTIAL). These books show a modern tinge in a meticulous attention to proofs. Gauss was also a prolific contributor to statistics and to applied mathematics, especially in the fields of astronomy, geodesy, and magnetism.

*Theories of groups, functions, and complex variables.* That the square of a positive or a negative number is a positive number and that the square root of a negative

The work of C.F. Gauss

number cannot be a real number (see ANALYSIS, REAL) and is said to be imaginary were recognized by Cardano, who said that the square root of  $-9$  is not  $+3$  or  $-3$  but is of hidden nature. The usual notation is to write, say,  $\sqrt{-9}$  as  $3i$ , in which  $i$  is  $\sqrt{-1}$ . A complex number is a combination of a real number and an imaginary one ( $a + ib$ ).

Gauss proved in 1799 that every equation of the form  $a_0x^n + a_1x^{n-1} + \dots + a_n = 0$  has at least one root. Two contemporaries, the Norwegian mathematician Niels Henrik Abel and the French mathematician Évariste Galois, demonstrated independently that in most cases the root cannot be expressed as radicals. Abel proved in 1824 that the quintic equation cannot be solved by an explicit algebraic formula. Galois observed that every algebraic equation is associated with a certain group of substitutions and that solvability is determined by the properties of this group, thus establishing Galois theory, part of the theory of groups. Many of his findings were written down on the night before he died, in a duel in 1832 at the age of 20.

In 1872 the German mathematician Felix Klein, in his famous *Erlangen Programm*, pointed out the unifying role of the group concept (see ALGEBRAIC STRUCTURES) in geometry; and Sophus Lie of Norway, through the theory of continuous groups (see TOPOLOGICAL GROUPS AND DIFFERENTIAL TOPOLOGY) in about 1873, made it a part of analysis.

Both Gauss and his French contemporary Augustin-Louis Cauchy, the foremost mathematicians of their day, are typical exponents of 19th-century mathematics in their rigour and inventiveness. The prolific Cauchy was the successor of Lagrange in the theory of functions, to which subject he added the theory of a complex variable (see ANALYSIS, COMPLEX). The graphical representation of complex numbers by the Swiss-born mathematician Jean-Robert Argand published in 1813-14 and the discovery by Abel in 1824 of the imaginary period of elliptic functions had led up to this; but the complex variable really came into its own in 1825 with the Cauchy integral theorem. This work later was continued in two directions: Karl Weierstrass of Germany emphasized the pure analytic aspect through the analytic continuation of functions defined by power series; Riemann made greater use of geometric intuition through a study of conformal representation and Riemann surfaces (see ANALYSIS, COMPLEX).

*Algebraic geometry.* British mathematics had been handicapped throughout the 18th century by excessive deference to synthetic methods and the notations of Newton. In 1816, however, the Cambridge Analytical Society was formed to promote the Leibnizian methods of the calculus. Moreover, the first half of the 19th century was characterized by the rise of mathematical journals (mathematical societies being chiefly a product of the latter half of the same century), and these facilitated publication and dissemination of knowledge. Hence it was not long before England, through the voluminous work of Arthur Cayley, became the stronghold of algebraic geometry. The geometry of  $n$  dimensions (dimension higher than three) had been hinted at by the Irish mathematician and physicist William Rowan Hamilton in 1843 and by the German mathematician Hermann Günther Grassmann in 1844, but Cayley is regarded as the true founder of this branch of geometry with his publication of 1869, as well as of the theory of matrices and algebraic invariants (see ALGEBRA, LINEAR AND MULTILINEAR). Algebra, overshadowed by analysis for two centuries, again was assuming a decisive role, with the application of determinants in algebra and analysis becoming one of the most fruitful lines of development. The critical spirit of the 19th century found clearest expression in the ever-greater arithmetization of mathematics. In Italy Bernard Bolzano already had taken a step in this direction in 1817; but development of the foundations of arithmetic dates especially from 1872 when definitions of irrational number were given in Germany by Weierstrass, Richard Dedekind, and Georg Cantor. These definitions, based on the notion of in-

finite classes (see SET THEORY), led Cantor in his *Beiträge zur Begründung der transfiniten Mengenlehre* (1895-97; *Contributions to the Founding of the Theory of Transfinite Numbers*, 1915) to one of the most strikingly original contributions of all time—the theory of transfinite numbers (see CANTOR, GEORG). After showing that the class of algebraic numbers is denumerable, Cantor was led to the startling conclusion that the number of points in space of  $n$  dimensions is not greater than that in a single dimension, a paradox confirmed by the space-filling curve of the Italian mathematician Giuseppe Peano.

*Influence of science on analysis.* Perhaps the most powerful impetus on the development of analysis came from mathematical physics and astronomy. The common role of extremal principles for the laws of optics as well as dynamics became clear through the work of Hamilton and his German contemporary Karl Gustav Jacobi. The geometric interpretation of the  $2n$  canon variables of the differential equations of dynamics led Sophus Lie in about 1873 to the concept of contact transformations and continuous groups that, in its abstract form, gained an important place in modern topology (see TOPOLOGICAL GROUPS AND DIFFERENTIAL TOPOLOGY). The deep interaction between analysis and mathematical physics is also visible in the work of the virtually self-taught Scottish genius James Clerk Maxwell, which ranged from the investigation of the stability of Saturn's rings to thermodynamics and his celebrated field theory of electrodynamics of 1873. The theory of statistical mechanics as developed by Maxwell, Ludwig Boltzmann of Germany, and J. Willard Gibbs of the United States opened the road to the investigation of the so-called ergodic theorems (see ANALYSIS, FUNCTIONAL), a general version of which was given in 1932 in the United States by George David Birkhoff. Through the theory of probability of Norbert Wiener of the United States, first published as a study of Brownian motion (see PROBABILITY, THEORY OF) in 1923, and the axiomatic approach to probability of A.N. Kolmogorov of the U.S.S.R. (published 1932), it had become clear that problems of statistical mechanics are essentially problems of the theory of measure, and in this form the ergodic theory has again developed into a branch of abstract mathematics. A similar development can be observed in the theory of integral equations that slowly emerged during the second half of the 19th century from problems of electrostatics and the theory of potentials (see ANALYSIS, COMPLEX: *Potential theory*). The essential turn toward a solution originated from the investigation of determinants of infinitely many rows and columns, begun by George William Hill in 1877 in connection with the perturbation theory of the lunar motion. This new type of approach led the Swedish mathematician Ivar Fredholm in 1900 to the discovery of the algebraic analogue of the theory of integral equations (equations in which a function to be determined appears as the integrand of some integral), which was crowned by the theory of eigenvalues of David Hilbert of Germany in 1906 and the related theory of spaces of infinitely many dimensions (Hilbert space and its modern generalizations; see ANALYSIS, FUNCTIONAL).

*Fundamental questions.* Hilbert in 1900 prophetically proposed to the second International Congress of Mathematics at Paris a series of fundamental problems that should challenge the efforts of the new century. The first problems concerned the continuum: the question of whether or not there is a transfinite number between that of a denumerable set and that of the continuum remained unanswered. Questions inquiring about the transcendence of certain numbers were partially solved in Germany by Carl Ludwig Siegel about 1930 and by Aleksandr Osipovich Gelfond of the U.S.S.R., and completed by Gelfond and Schneider (Germany) in 1934.

The problems that stimulated the most spectacular development were those in the relatively novel field of analysis situs, or topology. Certain puzzle problems of Euler were suggestive of topology, and Gauss prophesied the rise of the new subject; but the origins are more clearly apparent in the results at the beginning of the 20th

Hilbert's  
problems  
of 1900

The  
geometry  
of  $n$   
dimensions

century of Henri Poincaré of France. By the middle of the 20th century the infant prodigy had burgeoned into a major branch of mathematics. Originally an offshoot of geometry, topology became closely related also to algebra and analysis.

One of Hilbert's favourite questions concerned the compatibility of the axioms of arithmetic. The German logician and mathematician Gottlob Frege in 1879 had given a critical definition of the word "number," and just a decade later the Peano postulates for arithmetic were proposed; but by far the most ambitious effort to establish the foundations of mathematics appeared in the *Principia Mathematica*, published in three volumes between 1910 and 1913, of Bertrand Russell and Alfred North Whitehead. This *Principia*, like that of Newton, set the fashion for decades to come, so that research in symbolic logic at mid-20th century constituted a major branch of mathematics. In fact, the greatly expanded role of the axiomatic approach became possibly the most conspicuous aspect of 20th-century mathematics. Such studies in the foundations of mathematics engendered lively controversy in which varying orthodoxies are distinguishable—from the Formalists, who assert, as did Hilbert, that mathematics is a meaningless game played with meaningless symbols, to the Intuitionists, who, with the Dutch mathematician L.E.J. Brouwer, hold to a more Kantian view of the subject's "inner meaning." One factor contributing to the dilemma was the persistence of deep-rooted paradoxes. By rejecting the use of impredicative definition, Poincaré, Hermann Weyl (German-born U.S. mathematician and physicist), and Brouwer eliminated the antinomies; but this drastic solution, to which Brouwer (and later Weyl) added also the rejection of the law of the excluded middle, cut the ground out from under much of classical mathematics. Hilbert sought to save the mathematical fortunes by rejecting the idea of mathematics as necessarily true, clinging only to the criterion of self-consistency; but such efforts were dealt a shattering blow by the 1931 theorem of the Czech-born mathematician Kurt Gödel, which showed that if mathematics actually is consistent, the fact of this consistency cannot be proved within the rules of mathematics itself (see MATHEMATICS, FOUNDATIONS OF). The conclusion necessarily following from such a devastating discovery is that the ultimate foundations of mathematics must remain a mystery—at least to mathematicians. One should expect the result of this to be a deep pessimism. On the contrary, everywhere in the modern period the faith that mathematics was entering a golden age surpassing even the brightest periods of the past could be found. Theories of integration, revolutionized by the French mathematician Henri-Léon Lebesgue through his concept of measure appearing in 1902, had carried the subject far beyond Archimedes, Cauchy, and Riemann into the realm of abstract spaces; and the unification of analytic methods had led to the general analyses of E.H. Moore in 1906 and Maurice-René Fréchet of France in 1928.

Twentieth-century algebra, with its concern for such abstract axiomatic concepts as field, ring, and ideal, is far more general than in any previous age. Geometry—now encompassing spaces of infinitely many dimensions—undertakes a critical examination of its postulational basis.

**Historical development of representative non-probabilistic areas of mathematics**

Just as the first attempts at writing came long after the development of speech, so the first efforts at the graphical representation of numbers came long after people had learned to count. Probably the earliest way of keeping record of a count was by some tally system involving physical objects such as pebbles or sticks. Judging by the habits of primitive tribes of the present as well as by the oldest trace remaining of written or sculptured records, the earliest numerals were simple notches in a stick, scratches on a stone, marks on a piece of pottery, or the like. Having no fixed units of measure, no coins, no commerce beyond the rudest barter, no system of taxation and no needs beyond those to sustain life, people had no necessity for written numerals until about the beginning

of what are called historical times. Vocal sounds were probably used to designate the number of objects in a small group long before there were separate symbols for the small numbers, and it seems likely that the sounds differed according to the kind of object being counted. The abstract notion of two, signified orally by a sound independent of any particular object, probably appeared very late.

It appears that the primitive numerals were |, ||, |||, and so on, as found in Egypt and the Grecian lands, or —, =, ≡, and so on, as found in early records in the Far East, each going as far as the simple needs of the people required. As life became more complicated, the need for group numbers became apparent, and it was only a small step from the simple system with names only for one and ten to the further naming of other special numbers. Sometimes this happened in a very unsystematic fashion. In the 20th century, for example, the Yukaghirs of Siberia counted, "one, two, three, three and one, five, two threes, two threes and one, two fours, ten with one missing, ten." Usually, however, a more regular system resulted, and most of these more regular systems can be classified, at least roughly, according to the logical principles underlying them.

**Table 1: Comparison of Selected Systems of Numerals**

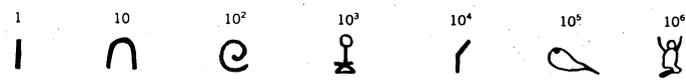

European	1	2	3	4	5	6	7	8	9	0
Arabic	١	٢	٣	٤	٥	٦	٧	٨	٩	٠
Devanagari	१	२	३	४	५	६	७	८	९	०
Tibetan	༡	༢	༣	༤	༥	༦	༧	༨	༩	༠
Kashmir	३	३	३	३	५	२	५	३	६	•
Bengalese	১	২	৩	৪	৫	৬	৭	৮	৯	০
Siamese	๑	๒	๓	๔	๕	๖	๗	๘	๙	๐

**NUMERALS AND NUMERAL SYSTEMS**

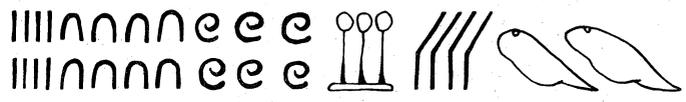

**Simple grouping systems.** The earliest example of a simple grouping system is that encountered in hieroglyphs that the Egyptians used for writing on stone. (Two later Egyptian systems, the hieratic and the demotic, which were used for writing on papyrus, are considered later; they are not simple grouping systems.) The hieroglyphic symbol for one was | and more than one was

The Egyptian system

represented by aggregates of these; thus four was ||||. An aggregate of 10 was then represented by a new symbol, ∩, and aggregates of these were written in a similar way. Ten of these—i.e., a total of 10 × 10, or 10<sup>2</sup>, units—were written ⊙, and so on. Here 10 is the base of the system. The hieroglyphic symbols were

Thus, since the Egyptians customarily wrote from right to left, they would have used for 243,688 = 2(10<sup>5</sup>) + 4(10<sup>4</sup>) + 3(10<sup>3</sup>) + 6(10<sup>2</sup>) + 8(10) + 8 the symbol

Numbers of this size occur in records concerning royal estates and must have been commonplace in the logistics and engineering of the great pyramids.

In general, a simple grouping system is an assignment of special names to the small numbers, the base *b*, and powers of the base *b*<sup>2</sup>, *b*<sup>3</sup>, etc. Intermediate numbers are then formed by addition, each symbol being repeated the required number of times. An example of this method of formation is the Roman numeral for 23, which is written XXIII.

**Cuneiform numerals.** Around Babylon, clay was abundant, and the people impressed their symbols in the damp clay tablets and then baked the tablets in the sun or in a kiln, thus forming documents practically as perma-

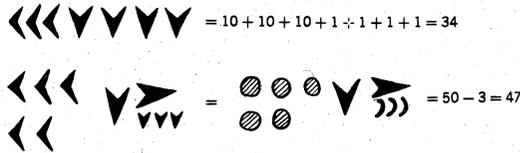

Diverse views concerning the nature of mathematics

Primitive representations of numbers

ment as stone. Since the pressure of the stylus gave a wedge-shaped symbol, the writings are known as cuneiform (Latin *cuneus*, "a wedge," and *forma*, "a shape") inscriptions. The symbols could be made either with the pointed or the circular end of the stylus as follows:

For numbers up to 60 these symbols were used in the same way as the hieroglyphs, except that a subtractive symbol was also used:

The cuneiform and the curvilinear numerals occur together in some documents from about 3000 BC. There seem to have been some conventions regarding their use; the cuneiform type was always used for the number of the year or the age of an animal, while wages already paid were written in curvilinear and wages due in cuneiform. For numbers larger than 60 the Babylonians used a mixed system, described in ARITHMETIC.

*Greek numerals.* The Greeks had two important systems of numerals besides the primitive plan of repeating single strokes, as in ||||| for six, one of which was again a simple grouping system. Their predecessors in culture—the Babylonians, Egyptians, and Phoenicians—had generally repeated the units up to nine, with a special symbol for 10, and so on. The early Greeks also repeated the units to nine and probably had various symbols for 10. In Crete, where the early civilization was so much influenced by Phoenicia and Egypt, the symbol for 10 was —, a circle was used for 100, and a rhombus for 1,000. But the precise forms are of less importance than the fact that grouping by 10s, with special symbols for certain powers of 10, was characteristic of the early systems of the Near East.

Greek notation

The Greeks, entering the field much later, and influenced in their alphabet by the Phoenicians, based their first elaborate system chiefly on the initial letters of the numeral names. This was a natural thing for all early civilizations, because the custom of writing out the names for large numbers was at first quite general, and the use of an initial by way of abbreviation of a word is universal. These initial numerals, in modern characters, were

- II or Γ, pi, for ΠΕΝΤΕ (pente), 5;
- Δ, delta, for ΔΕΚΑ (deka), 10;
- Η, an old Attic breathing, like the letter h, later represented by a special symbol like <sup>ε</sup>, for ΗΕΚΑΤΟΝ (hekaton), 100;
- Χ, chi, for ΧΙΛΙΑΙ (chilioi), 1,000;
- Μ, mu, for ΜΥΡΙΑΙ (myrioi, murioi), 10,000

These numerals were frequently combined with the symbol for 5; thus

- Γ<sup>π</sup> OR Γ<sup>δ</sup>, ΠΕΝΤΕ-ΔΕΚΑ, FOR 5 x 10, OR 50;
- Γ<sup>ε</sup>, ΠΕΝΤΕ-ΗΕΚΑΤΟΝ, FOR 5 x 100, OR 500;
- Γ<sup>ε</sup>, ΠΕΝΤΕ-ΜΥΡΙΑΙ, FOR 5 x 10,000 OR 50,000

Therefore, in this notation

$$36,756 = \text{MMM} \Gamma^{\text{X}} \Gamma^{\text{HH}} \Gamma^{\text{II}}$$

This system appears in records of the 3rd century BC but was probably used much earlier. Because in the 2nd century AD it was described by the grammarian Herodianus, these characters are often spoken of as Herodianic numerals, more properly called Attic numerals, being the ones always found in the Attic inscriptions.

*Roman numerals.* The direct influence of Rome for such a long period, the superiority of its numeral system

over any other simple one that had been known in Europe before about the 10th century, and the compelling force of tradition explain the strong position that the system maintained for nearly 2,000 years in commerce, in scientific and theological literature, and in belles-lettres. It had the great advantage that the mass of users needed to memorize the values of only five letters—I, V, X, L, and C. Moreover, it was easier to see three in III than in 3, and to see nine in VIII than in 9, and correspondingly easier to add numbers—the simplest of all the operations.

As in all such matters, the origin of these numerals is obscure, although the changes in their forms since the 3rd century BC are well-known. Of the various theories, that of Theodor Mommsen, advanced in 1850, has had the widest acceptance. This was that the use of V for 5 is due to the fact that it is a kind of hieroglyph representing the open hand with its five fingers. Two of these gave the X for 10. Three of the other symbols, he asserted, were modifications of Greek letters not needed in the Etruscan and early Latin alphabet. These were *chi*, which appears in inscriptions not only as X but also in such forms as L, J, and which later became the I that was arbitrarily chosen for 50; *theta* θ, which was selected for 100, being finally changed to C under the influence of the word *centum* (hundred); and *phi* φ, to which was assigned the value 1,000, and which finally took the forms I and M, the last being chosen because of the word *mille* (thousand).

Mommsen's theory of Roman notation

The earliest noteworthy inscription containing numerals representing very large numbers is on the Columna Rostrata, a monument erected in the Roman Forum to commemorate the victory of 260 BC over the Carthaginians. In this a symbol for 100,000, which was an early form of ((I)), was repeated 23 times, making 2,300,000. This illustrates not only the early Roman use of repeated symbols but also a custom which extended to modern times—that of using (I) for 1,000, ((I)) for 10,000, (((I))) for 100,000, and ((((I)))) for 1,000,000. The symbol (I) for 1,000 frequently appears in various other forms, including the cursive ∞. All these symbols persisted until long after printing became common. In the Middle Ages a bar (*vinculum*, *titulus*) was placed over a number to multiply it by 1,000, but this use is not found in the Roman inscriptions. When the bar appears in early manuscripts it was merely for the purpose of distinguishing numerals from nouns, as in the case IIIVIR for *duumviri*. In the Middle Ages such forms as |X| or |X| for 1,000,000 and |M| for one thousand hundred thousand were also used.

Of the later use of the numerals, a few of the special types are as follows:

1. c · lxxij · ccc · l · i, for 164,351, Adelard of Bath (c. 1120)
2. II. DCCC.XIII, for 2,814, Jordanus Nemorarius (c. 1125)
3. MCCLVI, for 1,656, in San Marco, Venice
4. cIo . Io . Ic, for 1,599, Leiden ed. of Capella, 1599
5. IIIxet huit, for 88, a Paris treaty of 1388
6. four Cl.M, for 451,000, Baker's arithmetic (1568)
7. vj.C for 600 and CCC.M for 300,000, Recorde (c. 1542)

The first represents the use of the bar; (2) represents the place value as it occasionally appears in Roman numerals; (3) illustrates the not infrequent use of C [like D, originally half of (I), the symbol for 1,000]; (4) illustrates the persistence of the old Roman form for 1,000 and 500, and the subtractive principle so rarely used by the Romans for a number like 99; (5) shows the use of *quatre-vingts* ("four twenties") for 80, commonly found in French manuscripts until the 17th century, and occasionally later, the numbers often being written like *iiij<sup>xx</sup>*, *vij<sup>xx</sup>*, and so on; (6) represents the coefficient method, "four C" meaning 400, a method often leading to forms like *ijM* or *IIM* for 2,000, as shown in (7).

The subtractive principle is seen in Hebrew number names, and in the occasional use of IV for 4 and IX for 9 by the Romans. They also used *unus de viginti* ("one from twenty") for 19 and *duo de viginti* ("two from twenty") for 18, occasionally writing these numbers as XIX (or IXX) and IIXX, respectively. The subtractive principle, however, was little used in the classical period.

**Multiplicative grouping systems.** In multiplicative systems special names are given not only to 1,  $b$ ,  $b^2$ , but also to the numbers 2, 3, . . . ,  $b - 1$ ; the symbols of this second set are then used in place of repetitions of the first set. Thus if 1, 2, 3, . . . , 9 are designated in the usual way, but 10, 100, and 1,000 are replaced by X, C, and M, respectively, then in a multiplicative grouping system 7,392 is written as 7M3C9X2. The principal example of this kind of notation is the Chinese numerical system, three variants of which are shown in Table 2. In the traditional notation, 2,605 would appear as 二千六百五 (here written from left to right rather than vertically downward, as is customary). The modern national and the mercantile systems are positional systems and use the circle  $\bigcirc$  for zero.

Table 2: Chinese Numeral Systems

Traditional national system										
一	二	三	四	五	六	七	八	九	十	百千
Modern national system										
一	二	三	四	五	六	七	八	九	百	千
Mercantile system										
1	11	111	1111	11111	111111	1111111	11111111	111111111	1111111111	11111111111

**Ciphered numeral systems.** In the ciphered systems, names are given not only to 1 and the powers of the base  $b$  but also to the multiples of these powers. Thus, starting from the artificial example given above for a multiplicative grouping system, a ciphered system is obtained if unrelated names are given to the numbers 1, 2, . . . , 9; X, 2X, . . . , 9X; C, 2C, . . . , 9C; M, 2M, . . . , 9M. This requires the memorization of many different symbols, but it results in a very compact notation.

The first ciphered system seems to have been the Egyptian hieratic (literally, priestly) numerals, so called because the priests were presumably the ones who had the time and learning required to develop this shorthand outgrowth of the earlier hieroglyphic numerals. An Egyptian arithmetical work on papyrus, employing hieratic numerals, was found in Egypt about 1855; known after the name of its finder as the Rhind papyrus, it provides the chief source of information about this numeral system. With the symbols as indicated in Table 3, which is exemplary of the kind of information to be found in the Rhind papyrus, the number 3,052 would be written (from left to right) as 𐀓𐀔𐀕𐀖 (the customary way of writing was from top to bottom). There was a still later Egyptian system, the demotic, which was also a ciphered system.

Table 3: Egyptian Hieratic Numerals (mathematical papyrus, about 1600 BC)

	1	2	3	4	5	6	7	8	9

Tens of thousands	𐀤								
Hundreds of thousands	𐀥								

Egyptian hieratic numerals

As early as the 3rd century BC a second system came into use in Greece, paralleling the initial-letter system but better adapted to the theory of numbers and more difficult of comprehension by the trading classes. These Ionic, or alphabetical, numerals were simply a ciphered system in which nine Greek letters were assigned to the numbers of units 1–9, nine more to the numbers of tens 10, . . . , 90, and nine more to the numbers of hundreds 100, . . . , 900. Since, however, there were only 24 letters in the Greek alphabet, three were added: the Phoenician *vau* (shaped like the letter F); *koph*, *qoph*, or *koppa* (shaped somewhat like Q, and indeed derived from the same source); and a character known in modern times as *sampi* (then shaped somewhat like the Greek  $\pi$ , but tipped about 45° to the right, and represented here by S). Only capital letters were used; lower-case letters are a relatively modern invention. The numerical values of the

Table 4: Ionic Greek Ciphered Numeral System

	1	2	3	4	5	6	7	8	9
Units	A	B	Γ	Δ	E	[F]	Z	H	θ
Tens	I	K	Λ	M	N	Ξ	O	Π	[Q]
Hundreds	P	Σ	T	Τ	Φ	X	Ψ	Ω	[S]

letters are shown in Table 4. The thousands were often indicated by placing a bar at the left of the numeral, thus:

$\bar{A} = 1,000; \bar{B} = 2,000; \bar{I} = 10,000; \bar{T} = 300,000.$

Such numeral forms were not particularly difficult for computing purposes once the operator was able automatically to recall the meaning of each. To be able to express 10,407 by  $\bar{I}T\bar{Z}$  would have seemed to a Greek considerably simpler than the system now in use.

Other ciphered numeral systems include Coptic, Hindu, Brāhmī, Hebrew, Syrian, and early Arabic. The last three systems, like the Ionic, above, are alphabetic ciphered numeral systems. The Hebrew system is shown in Table 5.

Table 5: Hebrew Ciphered Numeral System

Units	א	ב	ג	ד	ה	ו	ז	ח	ט
Tens	י	כ	ל	מ	נ	ס	ע	פ	צ
Hundreds	ק	ר	ש	ת	ך	ם	ן	ף	ץ
	100	200	300	400	500	600	700	800	900

**Positional number systems.** The modern number system is an example of a positional system in which a certain number of digits are given special names and groupings of these are represented by the position of a digit in a sequence. Thus, in the system using a base of 10, digits 1, 2, 3, 4, 5, 6, 7, 8, and 9 are used and ten is represented by 10, in which the digit 1 is displaced to the left and the symbol 0 is used for zero. In positional notation, with a base  $b$ , special symbols are not used for powers of the base  $b^2$ ,  $b^3$ , etc. Instead, the information is supplied by the position of a digit, so that the example 7M3C9X2 given above (see *Multiplicative grouping systems*) is written more simply as 7,392. (Characteristics of modern numeral systems are discussed under ARITHMETIC.) (W.J.LeV./D.E.S.)

**MATHEMATICAL SYMBOLS**

Mathematical symbols constitute a language in which quantities, operations with them, and their relations to each other are represented in abstract terms, clearly and concisely. As records, symbols eliminate much needless remembering, and the statements themselves frequently suggest the various procedures to be followed in mathematical thinking.

The symbols used in the earliest printed works in arithmetic and algebra were abbreviations and initial letters

such as the hand copyists of earlier days had used. These shortcuts were later supplemented by signs devised for specific purposes. This was the case in the first known use of the equality sign (=) which the English mathematician Robert Recorde introduced in his algebra (1557) with the explanation: ". . . to auoide the tedious repetition of these woordes: is equalle to: I will sette as I doe often in woorke vse, a paire of paraleles, or Gemowe [i.e., twin] lines of one lengthe, thus: ————, because noe .2. thynges, can be moare equalle."

From the 15th to the 17th century there was great activity in representing unknown quantities and their powers and in indicating operations with numbers. For relationships among numbers, the symbols <, =, and > (meaning less than, equal to, and greater than) sufficed. Various symbols were proposed for the same idea; in the hands of several authors, a single symbol might have as many different meanings. Some symbols seem to have survived because of the importance of the people who introduced them; others apparently persisted because they were adapted to new developments in subject matter. The result is that the symbols of elementary mathematics have been aptly described by the Italian-U.S. mathematician Florian Cajori as "a mosaic of individual signs of rejected systems."

Among 16th-17th-century mathematicians who gave serious study to the subject of mathematical symbols were François Viète, William Oughtred (English), René Descartes, and Gottfried Wilhelm Leibniz. Viète used vowels for unknown quantities and consonants for known quantities. This made possible the representation of an equation in general terms. Descartes followed this pattern but used the letters from the beginning of the alphabet as known quantities and those from the end of the alphabet as unknown quantities. Oughtred experimented with more than 150 symbols, of which only a few survive. Toward the close of the 17th century, Leibniz made a careful study of the symbols that were in use at that time, paying particular attention to their clarity and to the ease with which they could be printed. It was in the course of this work that Recorde's equality sign came to be preferred to its competitors.

The use of symbols had its detractors in this period; according to the 17th-century English philosopher Thomas Hobbes, "Symbols are poor unhandsome though necessary scaffolds of demonstration." In reference to Wallis' work, Hobbes wrote, "And for . . . your Conic Sections, it is so covered over with the scab of symbols, that I had not the patience to examine whether it be well or ill demonstrated."

The differing approaches to calculus held by Newton and Leibniz produced different notations. For more than a century, British mathematicians clung to Newton's symbols, mathematicians on the continent to those of Leibniz.

In the 18th century, Euler contributed an unusual number of symbols that lasted in mathematics; few men have been responsible for more than one. Among Euler's symbols are  $f(x)$ , meaning a function of  $x$ ;  $e$ , the base of the natural logarithms;  $\Sigma$ , indicating summation; and  $i$ , standing for  $\sqrt{-1}$ .

As a young man Leibniz had a dream of devising a method of representing ideas in a symbolic language. He failed to implement this and the project lay dormant until the 19th century. Then, following the publication of the English mathematician George Boole's *Analysis of Logic* in 1847, the attention of mathematicians began to be directed toward the matter of symbolic logic. And in the first half of the 20th century, the study of the structure of these mathematics became of prime importance. Each of these activities was accompanied by specific symbolism. Thus the modern symbolism used in the newer algebra and the symbols for symbolic logic exhibit a variety similar to that which accompanied the development of algebra and of calculus. (V.S.)

**CALCULATORY SCIENCE**

**The history of tables.** Mathematical tables appear in the earliest records of history. Thus, certain elementary

numerical values connected with the combination of fractions are found in the Egyptian Rhind mathematical papyrus, the copy of a scribe named Ahmes, written some time before 1700 BC. More extensive than these are the records of the Babylonians, dated perhaps as early as 2000 BC, which contain multiplication tables and tables of reciprocal values; i.e., values of  $1/n$  for certain values of  $n$ .

Renewed interest in the mystery of the computation of Ahmes' table was stimulated by references to it in *Historical Topics* (edited by A.E. Hallerberg) issued in the United States in 1969 by the National Council of Teachers of Mathematics. Among both the Egyptians and the Greeks it was the custom to use fractions with unit numerators. Thus Heron of Alexandria expanded the fraction  $31/51$  as the sum of the unit fractions  $1/2$ ,  $1/17$ ,  $1/4$ , and  $1/51$ . To aid in such representations Ahmes provided a table of fractions of the form  $2/(2n + 1)$ , in which  $n$  designates successively all the numbers up to and including 49, expressed as the sum of two, three, or four fractions with unit numerators, such as, for example,  $2/3 = 1/2 + 1/6$ ,  $2/13 = 1/8 + 1/52 + 1/104$ . Florian Cajori in his *History of Mathematics* observed that if  $2/x = 1/a + 1/b$ , and if  $x$  is expressed as the product of  $p$  and  $q$ , that is,  $x = pq$ , then  $a = 1/2p(p + q)$  and  $b = 1/2q(p + q)$  will furnish a solution. Unfortunately these formulas will produce only the values in Ahmes' table when  $x$  is a prime, not, for example, the expansion of  $2/6$  as given above. If  $x^2 = PQ$ , instead of  $x = pq$ , then  $a = 1/2(P + x)$  and  $b = 1/2(Q + x)$  will give all the values in Ahmes' table for sums of two fractions. This solution also provides a clue to the Ahmes mystery. The Egyptians were fully aware of the use of Pythagorean triplets such as 3, 4, 5 in the sum  $3^2 + 4^2 = 5^2$ , which their so-called rope-stretchers employed in orienting their temples. It is thus significant to note that the sum  $2/x = 1/a + 1/b$  can be written in the form of such a triplet sum, namely,  $x^2 + (a - b)^2 = (a + b - x)^2$ . The solution to the Ahmes mystery follows as an immediate consequence of this formulation.

The first mathematical table in the modern sense of the word is the table of chords found in the *Syntaxis Mathematica*, or, as it is more commonly called, the *Almagest*, of Ptolemy. This remarkable table, dating from the middle of the 2nd century AD, gives the values of the chords of a circle at intervals of one-half degree to six-place approximation. In the computation of this table, Greek mathematical ingenuity reaches one of its highest points. It is probable that the table is derived from an earlier work by Hipparchus, which is mentioned by Theon of Alexandria. Three lines of this table as it appears in a Greek edition of the *Almagest* published in Basel in 1538 are given in Table 6.

Early use of fractions

kanonion		translation of the canon			
$\kappa\gamma$	$\kappa\gamma \nu\epsilon \kappa\zeta$	$\circ \alpha \alpha \lambda\gamma$	23	23 55 27	0 1 1 33
$\kappa\gamma\delta''$	$\kappa\delta \kappa\varsigma \iota\gamma$	$\circ \alpha \alpha \lambda$	23 1/2	24 26 13	0 1 1 30
$\kappa\delta$	$\kappa\delta \nu\varsigma \nu\eta$	$\circ \alpha \alpha \kappa\varsigma$	24	24 56 58	0 1 1 26

For the translation into Hindu-Arabic numerals the following table of equivalent symbols is necessary:

$\alpha$	$\beta$	$\gamma$	$\delta$	$\epsilon$	$\varsigma$	$\zeta$	$\eta$	$\theta$	$\iota$
1	2	3	4	5	6	7	8	9	10
$\kappa$	$\lambda$	$\mu$	$\nu$	$\xi$	$\omicron$	$\pi$	$\rho$		
20	30	40	50	60	70	80	90	100	

Fractions were customarily written with one accent on the numerator and two on the denominator, which was written twice. Thus  $\iota\gamma' \kappa\theta'' \kappa\theta'' = 13\frac{55}{29}$ . For fractions of unit numerator the denominator only was written. Thus it is possible to interpret that  $\mu\delta'' = 1/44$ ,  $\gamma'' = 1/3$ , and so on. Although the usual way of writing  $1/2$  was  $\beta''$ , the symbol  $\varsigma''$  was also in common use for  $1/2$ , as in the table of Ptolemy.

The modern character of this table is seen from the fact that it contains first the values of the argument, then the

tabular entries, and finally a table of differences. To interpret the table it is necessary to know only that Ptolemy used the sexagesimal system of numbers. He divided the radius into 60 parts, each of these units into 60 parts, and so on. Hence, in terms of the radius, the following is obtained:

$$\text{chord } 24^\circ = 2\frac{2}{60} + 5\frac{5}{60} + 5\frac{5}{60} = 0.415824.$$

This value is equivalent to  $\sin 12^\circ = \frac{1}{2} \text{ chord } 24^\circ = 0.207912$ , which is correct to the last place.

Develop-  
ment of  
mathemat-  
ical tables

Although mathematical tables were prepared and used both by Hindu and Arab mathematicians, it was not until the 15th century that modern development of this art began. Great tables of the natural trigonometric functions were started in the middle of the 15th century under the direction of Georg von Peurbach, who divided the radius into 600,000 parts; and his pupil Johann Müller, more generally called Regiomontanus, who computed a table of sines to every minute of arc with a radius of 1,000,000 and a table of tangents. In the first book of his *De revolutionibus orbium coelestium* ("Concerning the Revolutions of Heavenly Bodies") published in 1534, Nicolaus Copernicus gave a five-place table of sines. An improved table of tangents appeared in the *Canon foecundus* of Erasmus Reinhold in 1553 and the first table of secants in the contemporary *Tabula benefica* of Francisus Maurolycus.

Among the greatest labours ever undertaken in table-making were those of Rhäticus, Otho, and Pitiscus. Georg Joachim von Lauchen, generally known as Rhäticus, a student of Copernicus, began the task of computing a table of the trigonometric functions to 15 decimal places for every 10 seconds of arc and for every second in the first and last degrees of the quadrant. He completed the tables of sines and began the construction of tables of tangents and secants, but died before he was able to complete them. It is said that Rhäticus kept several men in his employ as calculators for 12 years.

The great task was finished by his pupil Valentin Otho, who produced the celebrated ten-place canon *Opus Palatinum de triangulis* ("The Palatine Work on Triangles") in 1596. The 15-place table of sines was published in 1613 under the title *Thesaurus Mathematicus* by Bartholomäus Pitiscus. These works formed the basis of modern tables.

*The introduction of logarithms.* A logarithm is a number  $y$  appearing in the equation  $x = b^y$ . Here  $y$  is said to be the logarithm of  $x$  to the base  $b$  and  $x$  is the antilogarithm of  $y$ . For example, since  $100 = 10^2$ , 2 is the logarithm of 100 to the base 10. Similarly, since  $81 = 3^4$ , 4 is the logarithm of 81 to the base 3. Logarithms are useful aids to computation because two numbers can be multiplied by adding their logarithms. For example, 81 is  $3^4$  and 27 is  $3^3$ . Then  $81 \times 27$  is  $3^4 \times 3^3$ , which is  $3 \times 3 \times 3 \times 3 \times 3 \times 3 \times 3$ —or  $3^7$ . Thus the logarithm of  $81 \times 27$  is 7, a value obtained by addition of the logarithms of 81 and 27. In this way multiplication can be facilitated by use of a table giving the logarithms of numbers. In order to multiply numbers together their logarithms are obtained from the table and added to give the logarithm of the product. The answer is also obtained from the table by looking up the number that corresponds to this logarithm; *i.e.*, by finding its antilogarithm. This property is a consequence of the relationship  $b^y \times b^z = b^{(y+z)}$ .

Division and the extraction of square roots can be performed by procedures based on  $b^y \div b^z = b^{(y-z)}$  and  $(b^y)^z = b^{yz}$ . Here  $y$  and  $z$  are powers of  $b$  and are called exponents.

The germ of the idea of logarithms goes back at least as far as a work of the German mathematician Michael Stifel that was published in 1544. Stifel, as well as Simon Stevin of the Netherlands, denoted powers (that is, repeated products) by indices, but their notation was probably not known to the originators of tables of logarithms.

With the independent publication of a table of logarithms by John Napier in Edinburgh in 1614 and a brief table of antilogarithms by the Swiss mathematician Joost Bürgi in Prague in 1620, numerical computation took a

fresh start. These men were motivated by the hope of simplifying such computations as those required in astronomy, and their invention arose from comparing arithmetic and geometric progressions. An arithmetic progression is one in which each term is derived from the preceding one by addition of a constant factor. A simple example is the progression: 0, 1, 2, 3, 4, 5, . . . . A geometric series is one in which each term is derived by multiplying the preceding one by a constant factor; for example, 1, 2, 4, 8, 16, 32. The terms in the arithmetic series are logarithms of corresponding terms in the geometric series. Since the theory of exponents had not been worked out, the simpler modern approach was not available to them; this makes their discovery all the more remarkable.

Napier's table of logarithms extended to eight places, but his base was essentially  $1/e$ ,  $e = 2.7183 \dots$ . Although it is common to refer to tables of logarithms to the base  $e$ , namely of  $\log_e x$ , as tables of Napierian logarithms, they are more correctly called natural or hyperbolic logarithms. Napier's logarithms (Nap. log), given by Nap.  $\log y = 10^y$  ( $\ln 10^y = \ln y$ ), were awkward for computations. For one thing, the logarithm decreased as the number increased.

The first table of logarithms to the base 10 was computed by the English mathematician Henry Briggs and published under the title *Arithmetica Logarithmica* in 1624. The computations were made to 14 decimal places, but included only the logarithms of numbers from 1 to 20,000 and 90,000 to 101,000.

Although Briggs had intended to complete his monumental computations, he was anticipated in this by the Dutch mathematician E. de Decker in his *Tweede Deel der Nieuwe Telkonst* of 1627 and the Dutch bookdealer, publisher, and mathematician Adriaan Vlacq in his so-called *Editio Secunda* of Briggs's *Arithmetica* in 1628. These men, who were essentially partners in the undertaking, gave ten-place logarithms together with differences over the integers 1 to 100,000.

Extensive tables of common logarithms were thus generally available before 1630. They were calculated by tedious repeated multiplications and the extraction of square roots. A clear construction of the theory came more slowly. As calculus developed, the logarithmic function appeared inevitably as the function that has a derivative of  $1/x$ . In 1668 the German-born astronomer Nicolaus Mercator stated a special case of the series for  $\ln(1+x)$ , which could have saved much of the work of preparing tables. Wallis followed with the first general expression for the Mercator logarithmic series. The logarithmic function attracted attention, quite apart from the use of logarithms in calculation, because it is inevitably involved in applied mathematics. The differential equation  $dy = ydx$ , with a solution that is the exponential function (the inverse of the logarithmic function), states that the rate of change of  $y$  is proportional to  $y$  itself. Because this law of change is common to the growth of biological populations, the decay of radioactive substances, and the accumulation of money at continuous compound interest, as well as to many other phenomena, the logarithmic function has numerous applications. Moreover, the exponential function is essential in the solution of various differential equations, including all linear equations with constant coefficients.

Attempts to extend logarithms to negative numbers in the early 18th century led to considerable controversy among Leibniz, Johann Bernoulli I, and Euler. In 1742 the English mathematician William Jones gave the first systematic treatment of logarithms as exponents, and about 1747 Euler extended the theory to negative and complex numbers.

The work of de Decker and Vlacq was reprinted by George von Vega in 1794 under the title *Thesaurus Logarithmorum Completus*. Vega also included Vlacq's table of log sines and log tangents, described below, and a table of natural logarithms to 48 places computed by J. Wolfram, a lieutenant of artillery in the Netherlands. Wolfram's tables, which extended over all the numbers up to 2,200 and all the primes, together with a few num-

Base 10  
logarithms

## Logarithmic trigonometric functions

bers the least factor of which is a large prime, to 10,000, was printed for the first time in the *Sammlung* by J.C. Schulze in 1778.

Tables of the logarithmic trigonometric functions followed shortly the publication of the logarithmic tables of integers. The fundamental contributions were made by Vlacq in his *Trigonometria Artificialis* of 1633, which gave ten-place values of log sines and log tangents to every 10 seconds of the quadrant with differences, and by Briggs in his *Trigonometria Britannica* of 1633, which gave the natural sines to 15 places, tangents and secants to 10 places, log sines to 14 places, and log tangents to 10 places at intervals of  $0.01^\circ$  from  $0^\circ$  to  $45^\circ$ . It is interesting to observe that mathematicians have followed Vlacq's division of the degree rather than Briggs's. A new turn to this question was given at the time of the French Revolution, when weights and measures were being reduced to the metric system.

Gaspard Riche, baron de Prony, was placed in charge of a project to produce the values of trigonometric functions in centesimal units, namely divisions of the quadrant into 100 parts called grades, each grade divided into 100 minutes and each minute into 100 seconds. This vast undertaking, called the *Tables du Cadastre* from the fact that Prony was the director of the Bureau du Cadastre, was carried out on a scale that involved the calculation of the natural sine to 22 decimal places and log sine and log tangent to 14 decimal places. Although the original work was never published, tables based upon it have appeared.

With the now rapidly growing demands of science on the one hand and commerce (as shown by extensive manuals of navigation) on the other, the number of tables increased rapidly. The 18th century produced more tables than the 17th; and the 19th, by greatly expanding the number of functions tabulated, increased both the volume of tables and their variety. The first half of the 19th century, for example, originated tables of elliptic integrals, elliptic functions, hyperbolic functions, gamma functions, probability functions, Bessel functions, and many others (see ANALYSIS, COMPLEX: *Elliptic functions*; DIFFERENTIAL EQUATIONS: *Special Functions*; and PROBABILITY, THEORY OF).

With the widespread use of calculating devices, the 20th century had by 1970 increased by manyfold the total number of tables produced in all the preceding centuries. Hence the history of tables is becoming rather a history of the tables of special functions.

*The bibliography of tables.* In the early 19th century some systematic account of the origin, size, and accuracy of tables became necessary, and a number of excellent historical and bibliographical surveys were produced. By 1943 the need for current information became so great that the National Research Council of the United States established a special quarterly journal to review recent tables, record manuscript tables, list errata in standard tables, publish bibliographies of tables in special fields of research and of particular functions, and describe calculating machines.

With the rapid proliferation of tables it became evident that a more comprehensive and general bibliography was urgently needed. Such a work appeared in 1946: *An Index of Mathematical Tables*, by Alan Fletcher, J.C.P. Miller, and L. Rosenhead, recording the origin, range, and extent of something in excess of 2,000 tables, a monumental undertaking.

Three years later *A Bibliography and Index of Mathematical Tables*, by Harold Thayer Davis and Vera Fisher, recorded not only the titles and categories of 3,410 tables but also the production of mathematical tables by centuries from 1500—one index of the growth of scientific productivity. Thus the 16th century produced 9 tables; the 17th, 70; the 18th, 84; the 19th, 986, the 20th to 1947, 2,262, which at its mid-point had increased to something in excess of 2,800. Other bibliographies appeared in Germany and the U.S.S.R.

Since the production of mathematical tables continued to increase at a rate in excess of 100 tables per year, these bibliographies and indexes were soon found to be inadequate; Fletcher, Miller, and Rosenhead, with the assis-

tance of L.J. Comrie, produced a second edition of their *Index* in 1962 in two volumes, more than double the original edition.

With the great increase in tables a new dimension was added to the problem, that of producing a general work that would provide, somewhat like a dictionary, a comprehensive compilation of the available values of the tabulated functions and a description of their properties. The first work of this kind had been prepared by Eugen Jahnke and F. Emde in 1909, *Funktionentafeln mit Formeln und Kurven*, which proved so useful that it reached a fifth edition in 1952. A more comprehensive work was published by the National Bureau of Standards in 1964, *Handbook of Mathematical Functions with Formulas, Graphs, and Mathematical Tables*, under the editorship of Milton Abramowitz and Irene A. Stegun. This massive work provides tables covering 29 classes of functions. The difficulty of this task is readily seen from the fact that the work is essentially an abridgment of numerous other works, some multivolumed and many devoted to the tables and properties of single functions.

A word should be said about table-makers themselves. Peter Barlow, in the preface to his classical *Tables* (1814), somewhat disparages the art of the mathematician as a computer with these words:

Little is to be expected of mathematical reputation; nothing more being requisite for the execution of such an undertaking than a moderate skill in computation and a persevering industry and attention; which is not precisely the qualifications a mathematician is most anxious to be thought to possess.

But Barlow is wrong, because often the problems involved in computation are among the deepest and most intricate found in analysis, as is shown by the roster of table-makers including many of the greatest mathematicians: Kepler, Legendre, Euler, Gauss, Laplace, Cayley, Lord Kelvin, Lord Rayleigh, and many distinguished mathematicians of the 19th and 20th centuries.

**The evolution of analogue devices.** In the extraordinary expansion of the physical sciences and technology beginning in the 18th century, mathematical formulations were essential. Questions in understanding and on the design and operation of devices could be expressed in terms of analytic concepts.

Any mathematical problem may require a lengthy computation, or it may be impractical or impossible to solve directly as a mathematical problem. The scientific analysis that produced the mathematical problem, however, may also indicate methods of handling it. One method is to obtain analogous physical systems, the behaviour of which can be quantitatively observed. Examples of this are models of ships, waterways, and wind tunnel experiments on aircraft wings or fuselage shapes. To make the numerical measurements applicable, one needs dimensional theory (see PHYSICAL THEORIES, MATHEMATICAL ASPECTS OF) to indicate the significant relations.

An analogue computing device is a physical apparatus that depends on interrelated measurable quantities to deduce numbers that can serve as solutions to mathematical problems. The science of constructing analogue computers is as old as Western science itself, dating to the machines of Heron of Alexandria and of Archimedes (q.v.). Certain specialized analogue devices that have become important in modern times are mentioned in some detail here; most analogue devices, however, are of historical interest only since their work has been taken over by digital computers.

*Harmonic analyzer.* Simple harmonic motion is the motion of a body with an acceleration that is directed toward a fixed point and is proportional to its displacement from the point. An example is the swinging of a pendulum. Such motion is periodic; that is, it goes through a number of identical cycles and can be represented by an equation of the form  $y = A \sin Bt$ , in which  $y$  is the displacement of the body at time  $t$  and  $A$  and  $B$  are constants. The motion of bodies emitting musical sounds is the combination of many simple periodic motions of this form, hence the name harmonic motion. More complicated periodic motions, represented by some

The  
role of  
mysticism  
in  
harmonic  
analysis

function  $f(x)$ , can be shown to be formed from a number of simple harmonic motions and  $f(x)$  can be analyzed into a sum of simple harmonic functions. This is harmonic analysis, and a device for performing it is a harmonic analyzer.

Much of the history of harmonic analysis is the story of the strange marriage of mysticism and mathematics. In the 6th century BC, Pythagoras taught that the essence of harmony was inherent in the miraculous power of numbers; but his mysticism was allied with keen observation and deduction. For example, he knew that the musical note produced by a string of fixed tension was converted into its octave (vibrated at higher frequency) when the length was reduced one-half, and its fifth when reduced two-thirds. The great astronomer Johannes Kepler in the 16th and 17th centuries was imbued with the mysticism of Pythagoras, which was enjoying a revival in centres of learning, particularly in Italian universities. Kepler, while not accepting in a physical sense the "music of the spheres" of Pythagoras, believed it was possible to represent the motion of every planet in terms of musical notation. Stimulated by the quest for a basic harmony in arithmetic, geometry, and music, Kepler opened a new era of mathematics with his discovery of the laws of planetary motion. Even in his lyrical moods, Kepler maintained the mathematician's quest for precision. For example, his staff notation of the tune appropriate to Mercury indicated, in strongly accented arpeggios, that its orbit is more elliptical than that of the other planets.

Another scientist who drew his inspiration from mysticism and his technique from mathematics was Isaac Newton. Newton, who was a disciple of the mystic Jakob Böhme, wrote in the *Principia*, 1687: "Nature is pleased with simplicity, and affects not the pomp of superfluous causes."

But it was Newton, the hardheaded mathematician who said in a letter that "the best and safest method of philosophizing seems to be, first diligently to investigate the properties of things, and establish them by experiment, and then to seek hypotheses to explain them," who gave the first mathematical treatment of wave motion in the *Principia*. His calculations gave the ellipticity of the earth as  $1/230$ ; the figure accepted today is  $1/297$ .

In connection with the study of the vibration of musical strings the Swiss Daniel Bernoulli and Leonhard Euler laid the groundwork for Fourier's elaborate mathematical structure. The equations known as the Fourier series were first published by Bernoulli in 1728.

In keeping with the ancient traditions of harmonic analysis, James Clerk Maxwell in the 19th century pronounced Fourier's *Analytical Theory of Heat* "a great mathematical poem."

In *Science and the Modern World* (1925), Alfred North Whitehead notes that

we have in the end come back to a version of the doctrine of old Pythagoras, from whom mathematics, and mathematical physics, took their rise. He . . . directed attention to numbers as characterizing the periodicity of notes of music . . . . And now in the 20th century we find physicists largely engaged in analyzing the periodicities of atoms.

Fourier, in his study of the transmission and diffusion of heat, first made use of the simplification that often occurs when a complicated function or curve is represented as the sum of a number of simple harmonic or sinusoidal components. The importance of such a representation has increased with the years, and the measurement of the harmonic components in empirically given data is of importance to the study of communication lines, of electrical power machinery, and in the theory of prediction of statistical data.

While much of the analysis in these fields is carried out by numerical processes, some is done by harmonic analyzers. Under suitable restrictions on the function analyzed, a periodic regularly recurring function  $f(x)$  can be represented by  $f(x) = \sum (A_n \sin nx + B_n \cos nx)$ , in which the amplitudes  $A_n$ ,  $B_n$  are determined by integral expressions (see ANALYSIS, FOURIER). (Ed.)

A harmonic analyzer is a device for determining the coefficients  $A_n$  and  $B_n$ . The English physicist Lord Kel-

vin in 1876 was the first to invent such an instrument by an adaptation of a device invented by his brother, James Thomson, in the same year. The first completed instrument designed by Kelvin and used for the harmonic analysis of tidal observations embodies 11 sets of a disk-sphere-cylinder mechanism, one for each harmonic to be measured. The curve to be analyzed is wound on a central cylinder, and the simple harmonic motions of the proper periods are communicated to the disks by suitable gearing. The bar to which the tracer is attached has a series of forks that embrace the spheres. In actual use, the tracer is made to follow the curve, and the readings on the different integrating cylinders give the required coefficients. The English scientists Olaus Henrici and Abraham Sharp invented an improved form of the analyzer in 1894.

A different type of harmonic analyzer, based on the English mathematician William Kingdom Clifford's graphic method, was invented by O. Mader in 1909. Essentially Mader's instrument consists of a gear and linkage that, as a pointer traces a given curve, cause a point on the gear to describe a transformed curve; the area enclosed by the transformed curve is measured by an ordinary polar planimeter (a mechanical device that integrates), and is proportional to the required harmonic coefficient. In using the Mader instrument, a guide ruler that forms part of the machine is placed parallel to the base line of the curve to be analyzed, and the tracer of the planimeter is placed in one of two holes in the gear. For each harmonic to be found there is an appropriate gear with two indentations in its face. To find the sine coefficient, the tracer of the planimeter is placed in one of the indentations while the analyzer traces the given curve, and to find the cosine coefficient, the tracer of the planimeter is placed in the other. The Mader instrument measures only one harmonic at a time, as contrasted with the Henrici analyzer, which measures several simultaneously.

Several analyzers have been devised to use optical and photoelectric means. One such device was designed by H. C. Montgomery in 1939. To use Montgomery's analyzer, the curve to be analyzed is drawn or photographed on a transparent film, and the area of the film on one side of the curve is blacked out to make it opaque. A set of standard films is available in which the density varies along the length of the film. Thus when light falls on any part of the film, the fraction of the light transmitted is proportional to the function  $C + D \sin nx$ ;  $C$  and  $D$  are constants and  $x$  is the distance from a reference mark to that part of the film where the light falls. If the film carrying the curve to be analyzed is superposed on the standard film, then the quantity of light transmitted through any transverse strip of the two superposed films is proportional to the width of the clear part of the one film multiplied by the transmission ratio of that strip of the standard film. Except for the appearance of the additive constants in the factors, this product is the integrand in the definition of the required harmonic coefficient, and the total light transmitted by the entire length of the films is the integral of the product. The total light is measured by photocells, and from this quantity the harmonic component can be deduced. The operation of the instrument is largely automatic, and 30 harmonics can be measured in about a minute and a half.

*Differential analyzer.* The most frequently encountered mathematical problems of engineering and physics are expressed in terms of differential equations, either ordinary or partial. The methods and theory of the solution of ordinary differential equations have received treatment at the hands of many of the masters of mathematics, but comparatively few differential equations arising in practice have solutions expressible in terms of a finite number of the elementary functions: sines, cosines, Bessel functions. In the applications of differential equations to physical systems, formal solutions may not be necessary or desirable if a numerical or graphic solution is obtainable. To calculate a graphic solution a number of differential analyzers have been constructed in the United States, Great Britain, and other countries. These have been used to solve numerous problems in design of electrical machinery, study of the scattering of electrons by

analyzer

atoms and determination of the paths of electrons in the field of magnetic dipoles, performance of automatic industrial control systems and of transients in electric lines, determination of the energy exchanges between gases and solids, and study of the boundary layer motion of viscous fluids; the analyzers also found extensive use in World War II in the computation of thousands of ballistic trajectories.

The development of the differential analyzer is largely due to the U.S. electrical engineer Vannevar Bush and his associates at the Massachusetts Institute of Technology in Cambridge. In 1927 Bush and others completed and described a product integrator or continuous integrator that was a forerunner to the analyzer. This device solved differential equations of the form  $d^2y/dx^2 = f_a(f_1 + f_2)$  in which the  $f$ 's are functions of  $x$  ordinarily given in the form of graphs.

In 1928 Bush published a description of the first differential analyzer capable of solving a broad class of differential equations. Many minor modifications have been made in the detailed mechanisms of this machine, and more or less exact copies have been produced for use at educational institutions and industrial laboratories throughout the United States, Great Britain, and Europe.

The Rockefeller differential analyzer, dedicated in 1945, represented a considerable advance over the original model partly in refinement of elements but principally in the speed and convenience of means for setting up and controlling the operation of the analyzer.

The basic elementary device in the differential analyzer is the disk and wheel integrator, which appeared first in the early planimeters. Its function is to perform the integration  $z = \int y dx$  in which, in the integrator,  $x$  is the angular displacement of the disk,  $y$  is the distance of the integrating wheel from the centre of the disk, and  $z$  is the resulting angular displacement of the integrating wheel. The addition of two quantities,  $x$  and  $y$ , each represented by the angular displacement of a shaft, is performed by a mechanical differential or adder, so arranged that a third shaft is rotated through an angle equal to the sum,  $z$ , of the first-mentioned displacements:  $z = x + y$ . Multiplication by a constant is accomplished in the analyzer by appropriate gearing; thus, if  $k$  is the gear-ratio between a shaft representing a variable  $x$  and another shaft representing a variable  $y$ , then  $y = kx$ . Arbitrary or empirical functions are introduced by means of input tables, on which are plotted the necessary functions in graphic form.

The solutions resulting from the operation of the differential analyzer appear in graphs drawn by the analyzer on output tables, or in numerical values printed by the machine at predetermined intervals.

The original differential analyzer was entirely mechanical in construction, all connections between the computing elements being made by means of shafts and gears that are mounted on a bedplate approximately 4 ft wide by 18 ft long. In using the differential analyzer, the equations to be solved are first written as a set of equations, each of which may contain an integration, an addition, a multiplication by a constant, or a functional relation like  $y = f(x)$ . From the equations, a working diagram is made in which symbolic representations of shafts, integrators, adders, and gears appear. The variables of the equations are equated to the rotations of corresponding shafts with suitable proportionality factors, and the performance of each mathematical operation in the equations is assigned to a particular one of the elementary mechanisms. The shafts, gears, integrators, and other elements of the analyzer are set up in accordance with their symbolic representation on the working diagram.

In the Rockefeller analyzer, shaft rotations are converted by means of rotating electrical condensers into electrical signals which control motors in such a way that the shafts driven by the motors follow very closely the positions of the controlling shafts. Electrically operated switches steer the control signals as required from place to place, thus dispensing with the necessity of connecting shafts by mechanical means. All the information needed to set up the analyzer for a given problem is coded and

punched in paper tapes which automatically arrange the electrically operated switches as required, in a few minutes.

(G.R.St.)

*Slide rule.* One of the most successful of the analogue devices, one of old origin, is the slide rule, a rule consisting of graduated scales, each movable, and by means of which simple calculations may be carried out mechanically. In ordinary slide rules these operations include multiplication, division, and extraction of square roots, as well as, in some cases, calculation of trigonometrical functions and logarithms. The slide rule has become an essential tool in the mathematics of science and engineering and is widely used in business and industry as well.

The logarithmic slide rule is a compact device for rapidly performing calculations with limited accuracy (see above *The introduction of logarithms*). Napier's early conception of the importance of simplifying mathematical calculations resulted in his invention of logarithms, and this invention made possible the modern slide rule. In 1620 an English mathematician, Edmund Gunter, plotted logarithms on a two-foot straight line. With such scales, multiplication and division were performed by addition and subtraction of lengths by a pair of dividers.

Another English mathematician, William Oughtred, according to his own statement of 1633, constructed and used as early as 1621 two of these Gunter's lines together, so as to do away with the need for dividers. The lines were used in both the straight and circular forms. In the former the scales were held against one another by the hands; in the latter, dividers were replaced by an opening index—really a pair of dividers fixed centrally on the circular scale. Oughtred's two scales were the forerunners of the C and D scales, the basic scales on nearly all slide rules from then on.

The first known slide rule in which the slide worked between parts of a fixed stock was made by Robert Bissaker of Great Britain in 1654. Others were due to the enterprise of the English surveyor and mathematical writer Seth Partridge in 1657, the English mathematician Henry Coggeshall in 1677—a slide in a two-foot folding rule adapted to timber measure—and Thomas Everard in 1683, whose rule was adapted for gauging. The usefulness of the slide rule for rapid calculation became increasingly recognized, especially in England, during the 18th century, and the instrument was made in considerable numbers, with slight modifications.

Improvements in the direction of increased accuracy in graduation were initiated by the English engineers Matthew Boulton and James Watt from about 1779 in connection with calculations in the design of steam engines.

In 1815 the English physician Peter Mark Roget invented his "log-log" slide rule for performing the involution and evolution of numbers. The fixed scale, instead of being divided logarithmically, is divided into lengths that are proportional to the logarithm of the logarithm of the numbers indicated on the scale; the sliding scale is divided logarithmically.

Amédée Mannheim, an officer of the French artillery, invented in 1859 what may be considered the first of the modern slide rules, having scales on one face only, and although quite simple is basically a type still made and designated by his name. The disposition of the scales in the Mannheim rule is the arrangement still adopted in the great majority of rules made in the 20th century. This rule, which also brought into general use a cursor, or indicator, was much used in France, and after about 1880 was imported in large numbers into other countries.

A great improvement was introduced in 1886 by Denbert & Pape in Germany by dividing the scales on white Celluloid, instead of on wood, brass, or ivory as before, which, giving a much greater distinctness in reading, was later almost universally adopted.

Before 1890 slide rules were made only in England, France, and Germany, but at that time an invention by William Cox led to the manufacture of rules in the United States. This invention introduced a revolutionary construction providing for scales on both front and back of the slide rule. An indicator with glass on both sides made

wheel  
integrator

The first  
modern  
slide rule

it possible to refer to all the scales on both sides of the rule simultaneously.

Many refinements in both scale arrangements and mechanical constructions have been made since that time. The decade from 1940 to 1950 saw further developments of slide rules with scales on both faces. Most important of these improvements was the arrangement of the scales, trigonometric and log-log, so that they operate together and at the same time maintain consistent relationship to the basic C and D scales. This arrangement gave added speed and flexibility to the solving of many problems, simple and complex alike, since it produced solutions by continuous operations, without the need of intermediate readings. Electronic calculators became widely available in the 1960s and 1970s; these fulfill many of the functions of the slide rule (see further MATHEMATICS AS A CALCULATORY SCIENCE). (A.W.Ke.)

#### GEOMETRY

**Egyptian, Babylonian, and Greek geometry.** Geometry is encountered in the first written records of mankind. Fundamental formulas for measurement were known in ancient Egypt and Babylonia, and knowledge of the so-called Pythagorean theorem, which identifies the square of the hypotenuse of a right triangle with the sum of the squares of the two sides, is shown in clay tablets dating from the end of the 3rd millennium BC.

In Babylonia, geometry provided much of the language of algebra. Ancient Babylonians would state an algebraic problem like this: "Length, width. I have multiplied length and width to get the surface. I have added the excess of the length over the width to the surface: 183. I have added the length and the width: 27. Asked length, width, surface."

Today the symbols  $x$  and  $y$  are used in place of the words length and width, and the problem reads as follows:  $xy + x - y = 183$ , and  $x + y = 27$ .

Problems of truly geometrical character can also be found in cuneiform literature, and were stated in this way: "A beam, long 30, leans against a wall. The top has been lowered by 6. How far has the bottom gone away?"

More abstractly, this problem asks for the third side of a plane right triangle, given the hypotenuse (30) and another side ( $30 - 6 = 24$ ). From the Pythagorean theorem the third side equals  $\sqrt{30^2 - 24^2}$ .

The right triangle with sides ratio 3:4:5 occurs most frequently in Babylonian mathematics, which also provides an extensive table of other Pythagorean triangles. Good approximations of the ratio of diagonal and side of the square ( $\sqrt{2}$ ) are also found in Babylonian texts. Though theoretical texts on geometry from this period have not been unearthed, some theory probably existed. Empirical methods alone do not lead to ideas like the Pythagorean theorem; some kind of genuine geometrical reasoning is needed.

According to the pre-300-BC Greek philosopher Eudemos of Rhodes the first geometrician was Thales, who is said to have predicted the solar eclipse of 585 BC, and to have proved a number of geometrical theorems. Eudemos' report has often been questioned because it seems improbable that the first geometrician could have proved theorems that presuppose deep insight, and that are not even mentioned by Euclid (flourished 300 BC). It is clear from Babylonian excavations that Thales of Miletus was not the first geometrician. Strong Babylonian influences have been shown in Greek algebra and astronomy, and doubtless reached Thales himself.

Pythagoras, who died about 490 BC, was known to his contemporaries and even later to Aristotle as the founder of a religious brotherhood in southern Italy, where the Pythagoreans played a political role in the 5th century BC (see PYTHAGOREANISM). The linking of his name to the Pythagorean theorem is rather recent and spurious. Pythagorean mathematicians developed number theory, music theory, and number mystics, and Euclid's arithmetical books (vii and viii) presumably come from a Pythagorean source. An important discovery ascribed to Pythagoras, and in any case due to his school, is that of the incommensurability of side and diagonal of the square;

that is, the ratio of diagonal and side of the square is not equal to the ratio of two integers.

The proof (in Euclid's tenth book) runs as follows in modern notation: If  $a$  be the side and  $d$  the diagonal of the square, then, according to the Pythagorean theorem,  $d^2 = a^2 + a^2 = 2a^2$ . Given integers  $m$  and  $n$  such that  $d:a = m:n$ , then,  $d^2:a^2 = m^2:n^2$ , and hence  $m^2 = 2n^2$ . The integers  $m$  and  $n$  may be supposed without common divisor. From  $m^2 = 2n^2$  it follows that  $m^2$  is even. This is only possible if  $m$  itself is even. If  $l$  be half of  $m$ , then  $4l^2 = m^2 = 2n^2$ , hence  $n^2 = 2l^2$ . Thus,  $n^2$  is even and  $n$  is even; however, then  $m$  and  $n$  would have a common divisor. Thus, there are no integers  $m$  and  $n$  such that  $d:a = m:n$ . This discovery of irrationality fundamentally influenced the development of Greek geometry.

In Pythagorean mathematics quadratic equations were formulated and solved by a geometrical procedure, the application of areas with excess (hyperbole) or with defect, or falling short (ellipsis). The quadratic equation  $(a + x)x = P$  was interpreted as a problem of finding a rectangle of area  $P$  and with sides of length  $x$  and  $(a + x)$ , that is, a rectangle whose area is the sum of  $ax$  and the excess  $x^2$ . The equation  $(a - x)x = P$  was interpreted in a similar way.

The Pythagorean discovery of incommensurability remodelled Greek geometry in the following way.

To prove for rectangles with the same altitude the proportionality of areas and bases, or to prove that proportional segments are cut off by parallel lines upon two fixed lines, a simple procedure may be applied as long as it is believed that two line segments always possess a common measure of which they are integral multiples. By suitable subdivisions similitude is reduced to congruency. Through the discovery of incommensurable pairs of line segments, Greek geometricians were faced with the problem of developing a satisfactory theory of proportionality. In their efforts to fill this gap, they realized that, in addition to proving theorems, inventing definitions might be a mathematical problem, especially when some field of empirical experience is to be organized mathematically. It was obvious how to define ratio and proportionality as long as the magnitudes under consideration were commensurable. It was recognized that a suitable definition of ratio and proportionality in the general case would be the clue to proving theorems.

The ultimate procedure for handling ratio, proportionality, and incommensurability in Greek mathematics is explained in Euclid's fifth and sixth books. Probably it is attributable to Eudoxus of Cnidus, a 4th-century-BC mathematician. Earlier, Aristotle had mentioned *antanaresis* or *antaphairesis* ("taking away from each other"), a procedure similar to continued fractions: If  $a_0$  and  $a_1$  are two magnitudes to be compared, subtract the second from the first as many times as possible, say  $m_1$  times: if this procedure does not exhaust  $a_0$ , a remainder  $a_2$  will be left. Continue by subtracting  $a_2$  from  $a_1$ ,  $m_2$  times, with a remainder  $a_3$ . Generally,  $a_i = m_{i+1}a_{i+1} + a_{i+2}$ ,  $i = 0, 1, \dots$ , with positive integers  $m_i$  and  $0 \leq a_{i+2} < a_{i+1}$ . If this procedure stops with some  $a_{p+1} = 0$ , then  $a_p$  is a common measure, the largest common measure of  $a_0$  and  $a_1$ . In this case the procedure is known as the Euclidean algorithm (first expressed in Euclid's *Elements* VII, 2 and X, 2-3). In the general case it generates an infinite number of integers  $m_i$  that in modern notations are the denominators of the expansion of  $a_0:a_1$  into a continued fraction. If this development is broken off by neglecting the  $p$ th remainder, it yields an approximation of the given ratio by a ratio of integers. For instance, if  $a_0$  is the diagonal and  $a_1$  the side of a square, then  $m_0 = 1$ , and  $m_1 = m_2 = \dots = 2$ , which leads to approximations for the ratio of diagonal and side ( $\sqrt{2}$ ) by fractions  $\frac{1}{1}$ ,  $\frac{3}{2}$ ,  $\frac{7}{5}$ ,  $\frac{17}{12}$ ,  $\frac{41}{29}$ ,  $\dots$ , when any fraction  $s_i/t_i$  is computed from the preceding one by the rule  $s_{i+1} = s_i + 2t_i$ , and  $t_{i+1} = s_i + t_i$ . In his *Republic* Plato alludes to these "side-and-diagonal-numbers." By Euclid's codification, however, this Pythagorean discovery was eliminated from official mathematics.

The last pre-Eudoxian theory of proportionality must have consisted in defining two ratios to be equal if they

Discovery of incommensurability

have the same *antanaireis*; that is, if the numbers  $m$ , appearing in the above procedure are correspondingly equal. From this definition theorems can be derived.

Eudoxus' theory of proportionality

Eudoxus' solution (shown in Euclid's books V and VI) was more elegant. Eudoxus did not define ratio. He only said that it is a relation with respect to magnitude. Then he continued: Magnitudes are said to have a ratio if, when multiplied (by integers), they can surpass each other. This means, if  $a$  and  $b$  are magnitudes, Eudoxus' definition urged the existence of integers  $m$  and  $n$  such that  $ma > b$ , and  $nb > a$ . This property if postulated for a system of magnitudes is usually called the Archimedean axiom, though Eudoxian would be more apt. By this definition a line segment and an area have no ratio. Eudoxus' definition of equality of ratio reads in modern terminology as  $a:b = a':b'$  if and only if for any pair of positive integers  $m$  and  $n$ ,  $ma > nb$  and  $ma' > nb'$  go together as well as  $ma = nb$  and  $ma' = nb'$  and as well as do  $ma < nb$  and  $ma' < nb'$ . Ratios are compared with each other by the definition:  $a:b > a':b'$  if and only if there is a pair of positive integers  $m$  and  $n$  such that  $ma > nb$ , but  $ma' < nb'$ . After these three definitions the question arises whether  $a < b$  implies that  $a:a > a:b$ . This means that positive integers  $m$  and  $n$  must be sought such that  $ma > na$ , but  $ma < nb$ . If  $m = n + 1$  is tried, then  $(n + 1)a < nb$ . In other words,  $a < n(b - a)$ , which can be fulfilled if  $a$  and  $b - a$  both have a ratio in the sense of Eudoxus' definition.

This axiom is the foundation of Eudoxus' theory of ratio, proportionality, and similitude. His method of combining all essential tools into a few definitions foreshadowed the most modern mathematical procedures. His approach was more elegant than that of *antanaireis*, in which an incommensurable ratio is located by comparing it with a special sequence of approximating commensurable ratios. In Eudoxus' approach it is compared with all commensurable ratios. In a certain sense *antanaireis* corresponds to defining real numbers by decimal fractions; Eudoxus' method foreshadowed modern theories in which a real number is determined by its order relation to any rational number, not only to finite decimal fractions.

Through the problem of incommensurability the Greek mathematicians learned logical analysis and mathematical rigour. These virtues, when exaggerated, finally hampered the progress of Greek mathematics. The view that the existence of incommensurable ratios cannot be granted algebraically, but only by geometry, led them to disregard algebra as developed by the Babylonians. By translating algebraic relations into geometry they created geometric algebra, a tool that could be handled by geniuses only. Genuine algebra had to be rediscovered when modern mathematics started.

Parallel lines

Another theory that must have been highly problematic before Euclid is that of parallel lines. The uniqueness of the line through a given point and parallel to a given line is required as a postulate in Euclid's first book (whereas the existence of the parallel line is proved). Though enunciated in advance, the application of this postulate is postponed in Euclid's first book as long as possible. This delay indicates that rather than being spontaneous, the adoption of this postulate as such by Greek mathematics was probably preceded by a thorough exploration of the possibilities. It is probable that at some time before Euclid the need of adopting this postulate was under discussion and, in a comment of Aristotle's, evidence can be found for a competing theory of parallels, using points at infinity.

Euclid's activity was mainly that of a compiler. There were pre-Euclidean *Elements*, which, aside from a few fragments or vague indications, are lost. Euclid compiled pieces of different characters and qualities, and did not succeed in avoiding inconsistencies in terminology and structure. Thanks to these defects the single pieces can be isolated.

Euclid's Elements

Euclid's *Elements* start with definitions, postulates, and axioms. The definitions are a strange collection of explanatory statements, loosely connected with the bulk of the work. The famous postulate of parallels is an example of his postulates; the axioms are of the type: "The whole is

greater than the part." The *Elements* have become famous as the outstanding example of a deductive theory. The claim, however, that all theorems are derived logically from the definitions, postulates, and axioms is unfounded. Modern criticism has shown essential gaps. Order notions, such as the division of the plane by its straight lines, are never mentioned, though they are implicitly used when proving the existence of parallel lines (eventually the proposition 16 stating that in a triangle an exterior angle is greater than any opposite interior angle). Even the proof of his first theorem concerning the construction of equilateral triangles is invalid, because the circles used are tacitly assumed to intersect. Postulates of congruency are lacking. The proof of the fundamental congruency theorem actually relies heavily on intuition.

It is not justifiable, however, to apply modern standards and notions of rigorous deductivity to Euclid's work. The Greek philosophy of mathematics has little in common with the modern ideal of deriving all conclusions from a few fundamental propositions (postulates or axioms). According to Plato and Aristotle, geometrical subjects are real and knowable; their properties are settled anyhow, whether they are explicitly stated or not; fundamental facts need not be announced explicitly unless they are controversial.

Nevertheless, as a deductive systematization of a field of knowledge, Greek geometry is much superior to Babylonian and Egyptian geometry. During more than 2,000 years Euclid's *Elements* were a model of deductive approach, often imitated, but never surpassed.

It should be added that after the climax of Greek mathematics the *Elements* were not adequately appreciated. The *Elements* teach geometry with a definitive approach, ignoring prior and alternative approaches, and without motivating highly sophisticated turns. Older works, which could have filled this gap, were completely lost through Euclid's authority. Thus, the problem Eudoxus solved in the theory of proportionality was not understood until Dedekind in 1871 solved the same problems independently of Eudoxus, but by the same idea. Euclid's sophisticated theory of parallels was not understood until after the invention of non-Euclidean geometry. Algebra suffered under geometrical influence, because the theoretical background of the geometrization and the subject matter could be uncovered only by modern historical research.

Euclid's unnatural and artificial methods have been taken over by many textbook writers. Geometrical transformations are changes in figures according to certain rules. A simple example is a rotation or translation of the figure in space. Other transformations involve expansion or diminution of the size of a figure or projection of it from one plane to another. Transformations do not occur in Euclid's work although they were known and used by his predecessors, especially symmetry, which played an important part in Thales' geometry (6th century BC). Possibly geometrical transformations were eliminated by Euclid because they seemed to belong to mechanics. Instead, Euclid used artificial auxiliary lines and subdivisions into congruent triangles. In elementary-school geometry his unfortunate method prevailed as late as the mid-20th century.

From Archimedes' *The Method* (a palimpsest discovered in 1906), it is known that Archimedes in the 3rd century BC did not repudiate infinitesimal and mechanical methods. Probably his finest discoveries were made in this way, but in the final editing the improved tools were eliminated in order to meet the requirements of Euclidean rigour. There are different levels of mathematical rigour that have their own functions in teaching, learning, and exploring. As long as there were written records or oral traditions of unofficial mathematics, Greek geometry could progress. After a sudden break, as by political events, the tradition could not be resumed. The level of sophistication in the surviving literature was too high for it to be used in self-instruction.

Geometric algebra was just sufficient to solve second-degree problems, corresponding geometrically to construc-

tions with ruler and compass. When studying famous higher-degree problems, such as the duplication of the cube and the trisection of the angle, Greek geometers had to solve the application problems of proportionality with a variable  $P = y^2$  (in which  $y$  was again subjected to a quadratic relation, in order to raise the degree of the whole system). The application problem then runs  $(a + x)x = y^2$ , or  $x^2 - y^2 + ax = 0$ , which in modern terms describes an orthogonal hyperbola. After a slight generalization of the application problem, general hyperbolas appear. Other cases of the application problem provide ellipses and parabolas. (The names of these curves are simply those of the different cases of the application problem.) Greek passion for geometrization led Menaechmus, a student of Eudoxus, to the discovery that these curves are plane intersections of a cone. Menaechmus' work was continued by Archimedes and finished by Apollonius of Perga at the end of the 3rd century BC. In his formidable work he studied conics extensively, using different kinds of coordinates, though always in the clumsy language of geometric algebra.

**The algebraic approach.** In the period coming after the break of the tradition, genuine algebra was resumed and redeveloped by people who were unaware of Greek scruples. Following the Arabian and "rule of cross" period in the late Middle Ages, it got its final shape in the 16th and 17th centuries by the French mathematicians François Viète's and René Descartes's work. Descartes's *Geometrie* (1637) is the converse of Euclid's, the algebraization of geometry. Descartes progressed from the point where Apollonius had failed. He did not attach a coordinate system to a conic but to the plane, and he studied different figures in their mutual relations. By his method the points in the plane can be described by pairs of numbers (called coordinates) that are the distances of the point from two intersecting axes. The figures in the plane are represented by equations between these coordinates. Straight lines are represented by linear equations,  $ax + by + c = 0$ , and the conics by quadratic equations,  $ax^2 + 2bxy + cy^2 + dx + ey + f = 0$ . Problems of higher degree, and even nonalgebraic problems, can be studied with the same ease. With three coordinates the same can be done in space.

Descartes's discovery seemed to eliminate geometry theoretically. Practically, it was eliminated by the growing importance of calculus. In the 19th century, when geometry revived, a step taken that had been due during Descartes's lifetime was the invention of higher-dimensional space; it found its codification in the German mathematician Hermann Günther Grassmann's works of 1844 and 1861, in which a system of  $n$  numbers is considered as a point of  $n$ -space; the  $n$  numbers are its coordinates. Linear subspaces (corresponding to the straight lines and planes of 3-space) are defined by systems of linear equations between coordinates. Just as the distance between two points in a plane is given by Pythagoras' theorem, distance in  $n$ -dimensional space is defined by a higher-dimensional use of the theorem.

At the same time, by a slight though fundamental shift of stress, vector algebra changed the intuitive background of geometry in the work of the Italian mathematician Giusto Bellavitis and the Irish mathematician Sir William Rowan Hamilton. In mechanics many physical quantities are only completely specified by both their magnitude and their direction. The resultant of two forces, for example, depends not only on their size but on the directions in which they act. Such quantities are called vector quantities; they can be represented by arrows. Under the general name of vector, arrows (used before in mechanics to represent forces, velocities, and accelerations) were introduced in geometry. Formally, addition of points in  $n$ -space may be defined by  $(\xi_1, \dots, \xi_n) + (\eta_1, \dots, \eta_n) = (\xi_1 + \eta_1, \dots, \xi_n + \eta_n)$ . Only if the point  $x$  is intuitively replaced by the arrow pointing from the origin to the point  $x$  does this vector addition get the intuitively significant meaning of the addition of forces, velocities, and accelerations in mechanics. The notion of inner product of two vectors,  $(x, y) = \xi_1\eta_1 + \dots + \xi_n\eta_n$  if  $x = (\xi_1, \dots, \xi_n)$  and  $y = (\eta_1, \dots, \eta_n)$ , was also bor-

rowed from mechanics. The inner product  $(x, y)$  of the force vector  $x$  and the path vector  $y$  just equals the work done by  $x$  through  $y$ . Vector inspiration vivified such bloodless algebraic notions as the determinants, a formal tool for solving linear equations. For example, the volume of the parallelepiped spanned by  $n$  vectors was found to be equal to the determinant carrying the given vectors as rows or columns.

In the early 20th century the geometrical spirit of vector algebra was still enforced under the impact of the abstract algebraic school represented by the German mathematicians Ernst Steinitz and Emmy Noether and the Hungarian mathematician Frigyes Riesz. Vectors are not to be introduced by their coordinates (which have no direct geometrical meaning) but axiomatically by their intrinsic properties. This procedure leads to the definition: The set  $R$  is called an abstract vector space over the field  $F$  of numbers (scalars) and its elements are called vectors, if two operations are defined in  $R$ : adding elements  $x, y, z, \dots$  to each other, and multiplying elements  $x, y, z, \dots$  with scalars  $\alpha, \beta, \gamma, \dots$  such that certain laws are fulfilled (see ALGEBRA, LINEAR AND MULTILINEAR). The underlying field  $F$  may be that of the real numbers or complex numbers, or any other algebraic system, which are endowed with an addition and a multiplication with the usual properties.

In the (intuitive) plane two vectors  $e_1, e_2$  can be found from which all vectors  $x$  may be combined in the form  $x = \xi_1 e_1 + \xi_2 e_2$ ; the numbers  $\xi_1$  and  $\xi_2$  are called the coordinates of  $x$  with respect to this special basis  $e_1, e_2$ . In the case of ordinary space a basis of three vectors is required.  $R$  is called  $n$ -dimensional if a basis of  $R$  consists of  $n$  elements, and infinite-dimensional if no such basis is available. Infinite-dimensional spaces are important in modern analysis, which has fundamentally been influenced by this geometric terminology.

The notion of vector space is refined by requiring the existence of an inner product of vectors. When  $F$  is the field of real numbers, the laws of inner product can be quite succinctly expressed (see ALGEBRA, LINEAR AND MULTILINEAR). By one of the laws a vector length  $|x| = \sqrt{(x, x)}$  can be defined with the (provable) properties  $|ax| = |a| \cdot |x|$  and  $|x + y| \leq |x| + |y|$ .

**Projective geometry.** From the Greek period to the end of the 18th century two momentous geometric discoveries were made, by Desargues in 1639 and Pascal in 1640.

Briefly Desargues' theorem is concerned with perspective triangles, that is, two triangles placed so that three lines joining their corresponding vertices all intersect at a point. The theorem states that the points of intersection of pairs of corresponding sides of such triangles are collinear. Pascal's theorem is that if a hexagon is inscribed in a conic, the three pairs of opposite sides intersect in collinear points. It is sometimes named after the 3rd-century-AD Greek geometer Pappus of Alexandria who formulated a special case of the theorem, namely the case when the conic is a pair of intersecting straight lines. (A pair of lines can be regarded as a special case of a hyperbola in which the section of the cone is taken through the vertex. It is called a degenerate conic.)

Desargues' and Pascal's theorems were like erratic blocks in Euclidean geometry. The only relation that matters in their statements is that of incidence of points and straight lines. No part is played by distance, angle, congruency, or similitude (except for the definition of conic). On the other hand, in spite of the simplicity, an unusual amount of care is required in their proof—and even in their formulation—as soon as due regard is paid to the case when two or more lines are parallel. For example, if two corresponding sides are parallel Desargues' theorem states that the intersections of the other two pairs of corresponding sides both lie on a line parallel to the first sides; or that each side of one triangle is parallel to its corresponding side.

These problems were overcome by postulating points at infinity, such that every straight line is enriched with a point at infinity, and every plane with a line at infinity, this new point (line) being the same for all parallel lines

(planes). All infinite elements of space were supposed to lie on the infinite plane of space.

This postulate defined projective plane and "projective space" genetically. Parallelism disappeared as a relation: the only one still left from the variety of Euclid's is that of incidence (lying on). It is puzzling why this step, due to Jean-Victor Poncelet, a mathematician and general in Napoleon's army, which indicated a 19th-century revival of geometry, was not made earlier. If simplicity signifies truth, then the new geometry was much more true than Euclid's. A host of new notions and new truth, never dreamed of before, were discovered.

If a plane is considered and a point taken outside this plane, then any figure on the plane has a central projection on another plane (the plane of projection). Lines from the point (the centre of projection) through points on the figure make intersections with the projection. A conic has a central projection that is another conic, but some properties are not preserved under projection. Projective geometry can be defined as the study of those properties that are invariant under projection.

In ordinary space an intuitively important tool like central projection of one line (plane) upon another was of little use, because of the fact that at a certain point (line) the image vanished into infinity. In projective geometry, however, the central projection could be considered as a mapping of full lines (planes). The mappings resulting from repeated central projections became important under the name of projectivities. They are dealt with in the following theorems:

*Fundamental Theorem of projective geometry:* A projectivity of a straight line leaving three points invariant leaves invariant every point of that line. New light spread over large parts of traditional geometry thanks to the notion of harmonicity; quadruples of points on a line constructed in a certain way are called harmonic.

*Theorem of Harmonicity:* Three points of a harmonic quadruple determine the fourth uniquely, that is, independently of the choice of the auxiliary points of the construction.

*Steiner's Theorem:* The two pencils by which a conic is projected from two of its points are projectively related in the earlier defined sense of projectivity. By a converse of this theorem a purely projective definition of conics could be given, independent of their generation as plane sections of a cone. The relation of orthogonality in a pencil appeared to be a special kind of projectivity. Inverting this phenomenon, Euclidean geometry was successfully incorporated into projective geometry; assigning one line of the projective plane (to be called the line "at" infinity), and a certain projective relation in the pencil (to be called orthogonality), could produce Euclidean out of projective geometry.

A major problem was to free projective geometry from its Euclidean substrate and to found it independently. This problem seemed to be solved when the German mathematician Karl Georg Christian von Staudt in 1847 started with such incidence axioms as: two points determine one straight line; three points, not on a straight line, determine a plane; two planes intersect in a straight line, and so on. He then defined projectivity as a mapping preserving harmonicity. Taking three points on a line and constructing successively fourth harmonics, the line can be covered by a net that intuitively penetrates into any interval of the line. A projectivity leaving the given triple invariant leaves invariant every point of the net, hence, according to von Staudt, any point of the line. This condition, von Staudt said, proves the fundamental theorem of projective geometry, especially the theory of conics. Finally, von Staudt showed how to algebraize this projective geometry by geometric means.

Though von Staudt's performance was admirable, he still took the intuitive order relations in line and plane for granted without feeling the need for explicit formulations. Even worse, his process of fourth harmonics in succession was essentially the same as that of building up commensurable ratios. His transition from the net to the whole line essentially meant that things proved for commensurable ratios were believed to be valid for all

ratios. In 1847 von Staudt had not yet confronted the problems with which Greek geometry had wrestled before Euclid. In 1873 another German mathematician, Felix Klein, discovered the gap in von Staudt's reasoning. Though convinced of the possibility of founding projective geometry independently, he did not succeed in filling the gap.

A final solution for founding projective geometry independently postulates: (1) the incidence axioms; (2) cyclical order on the projective line and its preservation under projective mappings; and (3) some kind of Archimedean axiom, which permits the conclusion that a harmonic net penetrates every interval on the line (as the classical Archimedean axiom grants the possibility of fencing in incommensurable ratios by commensurable ratios).

This solution was possible under the German mathematicians Georg Cantor's and Richard Dedekind's re-examination in 1871 and 1872 of the ancient problematic. About 1880 two other German mathematicians, Moritz Pasch and Otto Stolz, a pupil of Weierstrass, recognized the import of the Archimedean axiom. In 1882 Pasch published the first rigorously deductive system of geometry in history. Through the Italian school of geometry, the formulation of the Archimedean axiom (still too Euclidean in Pasch's system) was better adapted to projective geometry.

A model of the projective plane in ordinary space is obtained by accepting a point  $O$  outside the plane and converting a point  $P$  of the plane into the line  $OP$  and a line  $l$  of the plane into the plane through  $O$  and  $l$ . The system of lines and planes through  $O$ , with its relations of incidence, then represents the system of points and lines of the projective plane. Analogously, projective  $n$ -space may be defined as the system of vector subspaces of an  $(n+1)$ -dimensional vector space, every  $(k+1)$ -dimensional vector subspace corresponding to a  $k$ -dimensional projective subspace. By this particular artifice the algebraization of Euclidean geometry immediately applies to projective geometry. The points of projective  $n$ -space can be described by the  $n+1$  coordinates  $\xi_0, \xi_1, \dots, \xi_n$ , when two  $(n+1)$ -tuples represent the same point if they are proportional.

**Non-Euclidean geometry.** Projective geometry toward the end of the 19th century had turned to fundamental research. Yet interest in the foundations of geometry had had an earlier modern awakening. It then centred on the celebrated parallel postulate of Euclid: that only one line can be drawn through a given point parallel to a given line. After a great many attempts to prove this postulate Gerolamo Sacheri, a Jesuit father of Milan, shifted the standpoint in 1733 by deliberately weighing alternative hypotheses and their consequences. Apparently, he was the first to do so, though possibly important work on parallel lines before Euclid may have been lost. Yet he was still strongly biased in favour of the Euclidean postulate. The title of his major work was *Euclides ab omni naevo vindicatus* ("Euclid Vindicated from Every Flaw"). Gauss, who had very early seized upon the idea of non-Euclidean geometry (perhaps before the end of the 18th century), never published his discovery (fearing, he said in personal letters, the clamour it would arouse). His fear was unfounded. When, in the early 1830s, the Russian mathematician Nikolay Ivanovich Lobachevsky and the Hungarian mathematician János Bolyai independently made and published the same discovery, nobody was disturbed. After Gauss's death it was said that he had pursued non-Euclidean geometry. But even Gauss's name was not a strong enough incentive to invite interest in non-Euclidean geometry.

If a line  $l$  is given and a point  $P$  is outside  $l$ , then in plane Euclidean geometry a line  $m$  through  $P$  turning around fails to meet  $l$  just once. In non-Euclidean geometry as presented by Gauss, Lobachevsky, and Bolyai, it is assumed that there is an infinity of nonintersecting lines, and among them a first one and a last one. Pursuing the consequences of this assumption, they found no trouble in developing a geometry, and they did not hit upon contradictions. Gauss even considered testing the non-Euclidean hypothesis experimentally by surveying large

triangles. In non-Euclidean space the sum of the angles of a triangle is not necessarily equal to  $180^\circ$ .

Non-Euclidean geometry was reapproached about 1868 by the mathematicians Bernhard Riemann, Hermann Ludwig von Helmholtz (both German), and Eugenio Beltrami (Italian) in another context. In 1870 Klein discovered a model of non-Euclidean geometry in Arthur Cayley's work. By this model the abstractness of non-Euclidean geometry was mitigated, and non-Euclidean geometry became familiar to mathematicians. However, the discipline was likely to be considered as a strange aberration, often confused with four-dimensional space and projective geometry.

The  
Cayley-  
Klein  
model

The Cayley-Klein model of non-Euclidean geometry stems from the fact that projective geometry embraces both non-Euclidean and Euclidean geometry. Instead of postulating a line at infinity, a conic  $K$  is assigned in the projective plane. Inside  $K$  the projectivities of the plane look like the rigid motions in the Euclidean plane. They preserve straightness, and if some point inside  $K$  is fixed, they carry the other points around on circlelike curves. They allow a transfer of line segments and angles that obeys the classical Euclidean congruency theorems. By the restriction to the interior of  $K$ , however, there is an infinity of lines through  $P$  that do not intersect the given line  $l$ . (Distance and angle measure have to be redefined in this geometry; the line  $l$  has an infinite length, though in the model its Euclidean length is finite.)

Into the same frame Klein fitted another non-Euclidean plane geometry, overlooked by Gauss, Lobachevsky, and Bolyai, but discovered by Riemann in 1854, published 1867. It arises if the real conic is replaced by an imaginary one. Another model of this geometry is still easier: The model of the projective plane mentioned above is taken in ordinary space as having lines through a point  $O$  considered as points and planes through  $O$  as lines of a projective plane. Intersect this model with a spherical surface  $S$  ( $O$  being its centre). It follows that to projective points correspond pairs of antipodal points of  $S$ , to projective lines correspond great circles of  $S$ . In order to avoid ambiguities, antipodal points are to be considered as one single point. Consequently, on  $S$  through two different points there is one straight line (great circle), and two straight lines (great circles) always intersect in one point. Again the rigid motions in  $S$  preserve straightness (as conceived on  $S$ ) and allow the transfer of line segments (great circle arcs) and of angles under the same congruency laws as in the Euclidean plane. Now the straight lines are closed and finite.

Apart from the identification of antipodes, this system is just spherical geometry as pursued on the terrestrial or celestial sphere. The analogous model of the first non-Euclidean geometry would use a sphere with imaginary radii.

The two non-Euclidean geometries are distinguished as hyperbolic (the first) and elliptic (the second). In hyperbolic geometry the sum of the angles of a triangle falls short of  $180^\circ$ ; in elliptic geometry it exceeds  $180^\circ$ , the excess or defect appearing to be proportional to the area of the triangle.

In this exposition non-Euclidean geometry has been restricted to two dimensions. Spatial elliptic geometry requires a 3-dimensional sphere in 4-dimensional Euclidean space as a model. This requirement has been and still is a difficulty if the intuitive function of a model is not really understood. A model and the thing it represents need not be alike in all aspects. The model of non-Euclidean 3-dimensional space in 4-dimensional space does not imply that a non-Euclidean universe actually needs a fourth dimension to be realized. It may be embedded in a higher-dimensional space, but its shape does not depend on that embedding.

Mathematicians themselves felt uneasy because they did not fully grasp the logical status of a model. Klein's model of non-Euclidean geometry, they said, proved nothing. It was constructed in the frame of projective geometry, which in turn depended on Euclidean geometry, the mother of all geometries. Klein replied that he had founded projective geometry independently of Eu-

clidean geometry, though his claim was not much better established than von Staudt's had been. People believed that the gap could be filled only in Euclidean geometry; though even in Euclidean geometry it remained unfilled as long as Eudoxus' solution was ignored. But the arguments in this discussion were not to the point. It does not matter whether projective geometry depends on Euclidean geometry (though in itself this is an important question). By constructing a model of non-Euclidean geometry in projective geometry (and hence by means of Euclidean geometry) it had been proved that non-Euclidean geometry was as consistent as the Euclidean version. Non-Euclidean geometry had been shown to be noncontradictory unless there were a contradiction in Euclidean geometry. This fact had been exactly proved, and no more could be done by mathematics. But this was a secret to be unveiled later when the logical status of geometry became clear.

**Philosophical aspects.** The philosophical view on geometry had not essentially changed since antiquity. In the realm of knowledge geometry was a peculiar problem. It was reasoned that all knowledge of the physical universe is mere opinion; it enters through the senses, which are liable to error and are to be watched by reason. Geometry was held the only exception. Geometrical truth, though dealing with the concrete world and not mere abstractions, can be proved mathematically, and was seen as beyond any doubt. Euclid's long-lasting influence is witnessed by a host of philosophers, theologians, historians, lawyers, and physicians who, imitating Euclid's method, attempted to prove their theories *more geometrico* ("in geometric fashion"). Kant, wondering how it is possible to construct *more geometrico*, with closed eyes as it were, things that prove true with one look into real space, asked the question: How are synthetic judgments a priori possible? He did not doubt that there were synthetic judgments a priori. Geometric judgments are synthetic according to Kant; they bring together notions that do not depend on each other by mere analysis. And, he said, they are a priori (prior to sensual experience) because otherwise they would not be sure.

It does not matter here how Kant answered his question. Philosophical discussions on space and geometry in the 19th century were heavily influenced by Kant's problem and solution. His starting point was never seriously questioned.

Pasch's first rigorous deductive system of (projective) geometry undertook to avoid any surreptitious use of intuition and he scrupulously fulfilled his program:

Whenever geometry has to be really deductive, the process of inferring must be independent of the *meaning* of the geometrical notions as well as of the figures. The only things that matter are the *relations* between the geometrical notions, such as (have been) established in the used theorems and definitions.

Since antiquity an axiom had been considered an evident truth that neither could nor should be proved. Mostly this meant even that axioms need not be formulated. Most people spoke of axioms and never mentioned any one explicitly. If someone pointed out a gap in a geometrical proof, he was likely to be told that this was just an axiom. This was one of the usual contexts of the word "axiom." From Pasch mathematicians learned how to formulate postulates or axioms. They also learned that a complete axiomatic system of geometry must be much more involved than Euclid's, and that there were more axioms than the postulate of parallel lines worthy of special attention. In the Italian school projective planes were discovered in which the axioms of order and the Archimedean axiom cannot be satisfied.

The final solution of the philosophical dilemma on geometry was given by the German mathematician David Hilbert in his *Grundlagen der Geometrie* (1899; *The Foundations of Geometry*, 1902). He starts this work, after a short introduction, with the words: "Wir denken uns . . ."—"we imagine three kinds of things . . . called points . . . called lines . . . called planes . . . we imagine points, lines, and planes in some relations . . . called lying on, between, parallel, congruent . . ." and then he enu-

Hilbert's  
resolution

merates the "axioms" to be fulfilled by things and relations imagined.

With "Wir denken uns" the bond with reality is cut. Geometry has become pure mathematics. The question of whether and how to apply it to reality is the same in geometry as it is in other branches of mathematics. Axioms are not evident truth. They are no truth at all in the usual sense.

Hilbert does not define what points, lines, planes are, or what "lying on," "between," "parallel," and "congruent" mean. These undefined notions are presented implicitly through the set of axioms in which they occur, as it were by rules that tell how to play the game with the things and the relations. In introducing the axioms of order Hilbert says, "The following axioms define the notion of order." When stating the axioms of congruency he states, "The following axioms define the notion of congruency or motion."

The idea that fundamental notions are defined implicitly by the axioms was the background of Pasch's work, too, though he did not say so. Whereas Pasch still believed that geometry deals with real space and anxiously stuck to what analysis may derive from sense data, in Hilbert's approach geometry was removed from sensory space. This modern idea on the logical status of geometry occurred a few years earlier to the Italian mathematician Gino Fano, and it was pronounced with even more emphasis by two of his countrymen, Mario Pieri and Alessandro Padoa, one year after Hilbert.

The clean cut between mathematics and phenomenalist sciences became the paradigm of a new methodology. Through Albert Einstein's booklet of 1916, *Über die spezielle und die allgemeine Relativitätstheorie* ("Concerning Special and General Relativity Theory"), this doctrine made its way in the lobbies of science and philosophy. A few sentences written by Einstein in his 1921 lecture "Geometrie und Erfahrung" have grown classical:

As far as the mathematical theorems refer to reality, they are not sure, and as far as they are sure, they do not refer to reality. . . . The progress entailed by axiomatics consists in the clean-cut separation of the logical form and the realistic and intuitive contents. . . . The axioms are voluntary creations of human mind. . . . To this interpretation of geometry I attach great importance for should I not have been acquainted with it, I would never have been able to develop the theory of relativity.

**The axiomatic method.** The idea on the logical status of geometry is not the only result of Hilbert's *Grundlagen*, and it is not its most important one. For the axiomatic method, which has pervaded mathematics in the 20th century, Hilbert's work was the first specimen, and a manual, in which the method is not explained in so many words but is shown instead by splendid examples.

Whoever proposes an axiomatic system has to show that it is consistent, that is, does not involve contradictions. In most cases consistency cannot be proved directly. It is done by exhibiting a so-called model that fulfills the axioms. A model of the axiomatic system of points, lines, circles and so on cannot be sought in physical nature or a pre-existent realm of Platonic ideas, which are no longer acceptable. Hilbert found his models of geometry in algebra, using Descartes's procedure. Since antiquity the relation between geometry and algebra had been inverted. Greek mathematicians were endeavouring to justify algebra by geometrization; in modern mathematics geometry is justified by algebraization.

Another concern in axiomatics is to know whether the different axioms are logically independent of each other, and what is the exact scope of any one of them. Hilbert showed how to drop axioms or to replace them by alternatives, and how to look for the consequences these changes might cause in suitable models.

In this course of thought he resumed the ancient problem of the theory of ratio and proportionality. He succeeded in getting rid of such notions and assumptions of topological character (to use modern terminology) as order and Archimedean axiom. He simply defined proportionality by means of the fundamental theorem, which was Eudoxus' first goal.

Instead of the Archimedean axiom, Desargues' and Pappus' theorems can be used as foundations of the theory of ratio and proportionality. (Actually Desargues' can still be derived from Pappus'.) This idea has surprising simplicity, and it may have occurred to Greek mathematicians. In fact, that it never arose in Greek thinking cannot be asserted. But, if it arose, it was apparently rejected, and a remark of Aristotle's reveals why.

Greek geometers probably would not have been satisfied with this theory of ratio and proportionality that applies only to line elements instead of to all kinds of magnitudes. Hilbert, on the other hand, was allowed to stop at line elements, for meanwhile the rest of the problem had been solved by Descartes. Indeed, if some line segment OE is assigned as a unit, the product OC of two line segments OA and OB can be defined by means of the proportion  $OC:OA = OB:OE$  and by this geometry can be algebraized (the sum of line segments being unproblematic). But in algebraization all other geometrical magnitudes, such as areas and volumes, are comprehended, and no new theory of ratio is required to deal with them.

Looking to the proportion that defines the product, it can be found that Pappus' theorem actually enforces the commutativity of multiplication, that is, the law  $ab = ba$ . Dropping Pappus' theorem as an axiom, geometry can still be algebraized, though over a noncommutative field. Non-Pappian geometries with their algebraic matches, the noncommutative fields, have been extensively studied in modern geometry and algebra.

The algebraic equivalent of Desargues' theorem is the associativity of multiplication, the law  $(ab)c = a(bc)$ . The existence of non-Desarguean geometries has been shown by an example of Hilbert's. But there is a still weaker geometrical theorem than Desargues', the theorem of harmonicity. In 1933 Ruth Moufang discovered that its algebraic equivalent is a kind of weak associativity, called alternativity,  $a(ab) = (aa)b$ ,  $(ab)a = a(ba)$ ,  $a(bb) = (ab)b$ . By this discovery geometry gave algebra a new notion of major importance.

The fundamental geometric properties (harmonic, Desarguean, and Pappian) are matched by the fundamental algebraic properties of multiplication (alternative, associative, and commutative). It is remarkable that these properties are realized by the most important algebraical systems, the Hurwitz algebras, which generalize complex numbers, yet preserving the law  $|ab| = |a| \cdot |b|$ , in which

$$|a| = \sqrt{a_1^2 + a_2^2}$$

is the norm of the complex number  $a = a_1 + ia_2$ . It appears that the only Hurwitz algebras are those of the real numbers, the complex numbers, the quaternions (discovered by Hamilton in 1845), and the octaves (discovered by the English mathematician and jurist John Thomas Graves in 1829 and somewhat later by Arthur Cayley) with 1, 2, 4, and 8 basis units respectively. Real and complex numbers are commutative; quaternions are associative; octaves are alternative. The outstanding examples of Pappian, Desarguean and harmonic geometries are constructed over these algebras.

**Geometrical transformations.** Geometrical transformations, though a quite natural tool, were rejected by official Greek mathematics, perhaps because they were reckoned to belong to mechanics. Though this argument was refuted long ago, it is still used to oppose teaching geometrical transformations at the secondary level. Geometrical transformations belong to mechanics as little as functions do. Of course functions are used in mechanics and can be interpreted in a mechanical sense, and so can transformations.

The most perspicuous geometrical transformation (or mapping) is symmetry. Stone Age decorations witness that it was known to early mankind. Symmetry with respect to a plane maps any point of space upon its mirror image. Symmetry with respect to a straight line turns it around this line as an axis over an angle of  $180^\circ$ . Symmetry with respect to a point A maps every point X into the point X' with the property that A is the midpoint of XX'.

In the plane, if first the symmetry with respect to l and then that with respect to  $m(\parallel l)$  is applied, any point X

Symmetry

is first mapped upon its mirror image  $X'$  with respect to  $l$ , and then  $X'$  upon its mirror image  $X''$  with respect to  $m$ . All the line segments  $XX''$  are equal and parallel. The resulting mapping is a translation. If, however,  $l$  and  $m$  intersect in  $O$ , then the resulting mapping is a rotation around  $O$ . Another translation or rotation is obtained if the two symmetries are interchanged.

If two translations are applied successively, the result is a translation. Two rotations generally produce a rotation unless the rotation angles are opposite; then a translation results. Symmetries, translations, and rotations all are mappings of the plane that preserve distance, hence the rigid structure of the plane.

There are mappings of the plane that multiply all distances by the same factor; for example, the similitude mapping  $X$  upon  $X'$  such that all lines  $XX'$  go through a fixed point  $O$  and  $X$  divides  $OX'$  in a fixed ratio. These mappings still preserve angles. Parallel projections of one plane upon another preserve parallelism, but generally change angles. Projectivities of projective planes preserve linearity, but not parallelism.

When two mappings are performed, first  $f$  and then  $g$ , the resulting mapping is indicated by  $gf$ . To any mapping  $f$  of the examples given, the inverse mapping (called  $f^{-1}$ ) can be constructed with the property that (for every  $X, Y$ ) if  $f$  maps  $X$  upon  $Y$ , then  $f^{-1}$  exactly maps  $Y$  upon  $X$ . A trivial case is the identity mapping  $i$  that carries every point into itself. Both  $ff^{-1}$  and  $f^{-1}f$  are identity mappings, but generally  $fg$  and  $gf$  differ from each other.

Groups of mappings

Examples like these lead to the notion of group (of mappings). A set  $G$  is said to form a group if a product  $fg$  is specified for any couple of elements of  $G$  such that: for any  $f, g, h$  of  $G$ ,  $fg$  belongs to  $G$  and  $(fg)h = f(gh)$ ; there is an (identity)  $i$  in  $G$  such that for any  $f$  in  $G$ ,  $fi = if = f$ , and for any  $f$  in  $G$  there is one  $f^{-1}$  in  $G$  such that  $ff^{-1} = f^{-1}f = i$ .

The mappings of the plane preserving distance form such a group, as do the mappings preserving the ratios of distances, the mappings preserving parallelism, the mappings of the projective plane preserving linearity (the projectivities), and the projectivities leaving invariant the non-Euclidean distance.

Lie and Klein were the first to stress the import of the notion of group in geometry. A geometry is a relational system (for example, a system of points and lines with the relation of incidence). The mappings of the system that preserve these relations form a group, the group of this geometry. In order to know whether some relation depends on some other, it is useful to determine if the mappings preserving the first one also preserve the other one. Thus, through group theory it can be decided to which kinds of geometry some notion belongs, and how different geometries are related to each other. The relationship between the non-Euclidean geometries and projective geometry was settled in this way, and a good many other geometries, discovered in the 19th century, were better understood when they were fitted into projective geometry by group-theory methods. This is, in a few words, the purport of Klein's *Erlangen Programm*, so called for the university at which he taught.

In the 20th century the French mathematician Élie-Joseph Cartan stressed the group-theory aspect even more. If  $G$  is the group of some classical geometry and  $H$  the subgroup leaving invariant a point  $X_0$ , then any point  $X$  can be characterized by the mappings of  $G$  carrying  $X_0$  into  $X$ . They form what is called in group theory a coset of  $H$  in  $G$ , and  $G$  is the union of all these cosets. By this device the study of this given geometry reduces to a study of the set of cosets of  $H$  in  $G$ , which can be performed by group-theory methods alone. A significant part of geometrical research has since been devoted to such homogeneous spaces; that is, spaces having an associated group such that any point is carried into any other point by a suitable mapping belonging to that group.

The German mathematician Friedrich Bachmann expressed in 1959 a group-theory approach to foundations of geometry that can be sketched by the example of plane geometry: If  $P$  and  $l$  mean not only a point and a line, but also the symmetries with respect to them, then,

in the sense of group theory,  $PP = i$  and  $ll = i$ . Then clearly  $Pl = lP$  means the belonging of  $P$  to  $l$ , and  $l_1l_2 = l_2l_1$  means the orthogonality of the lines  $l_1$  and  $l_2$ , and so forth. In this language of group theory, it is possible to formulate involved relations and, especially, fundamental axioms.

**The concept of space.** Throughout the 19th century, the foundations of geometry were identified with the German philosopher Helmholtz' approach of 1868 (finally overshadowed by Hilbert's). Helmholtz renounced the conventional attitude toward geometry. Rather than being a logical analysis of some existing geometry, his philosophically minded attempt aims at a quest into the nature of space. To a certain degree Helmholtz was Kantian, but the a priori in space he would grant was no more than a vague topological substratum that is organized a posteriori by the knowledge of some experimental fact. This fact, he pointed out, was the existence of freely movable rigid bodies.

Helmholtz' view of space

Indeed, all traditional approaches to space up to that time bore this feature, though Helmholtz was the first to recognize and analyze it mathematically. His analysis is not free from tacit assumptions and arbitrary statements. It is as rigorous as it could have been at that time, though his style, compared with today's, is vague and often admits of alternative interpretations.

Actually, to Helmholtz the whole of space was a rigid body. In modern terminology this means that it is a metric space, a space in which distance is numerically defined for pairs of points, and that the distance-preserving mappings of space on itself are considered as what should be called motions. These motions form a group. Though Helmholtz did not mention (presumably did not know) the notion of group, he extensively used group-theory notions and methods, anticipating Klein and Lie.

The free mobility of rigid bodies, or rather of space itself, according to Helmholtz, means: Any point is carried into any other by some motion. If, however, one point  $P_0$  is fixed, then two points at the same distance from  $P_0$  can still be carried into each other by some motion. If two points  $P_0$  and  $P_1$  are fixed, then the same is true of any pair of points at the same distance from both  $P_0$  and  $P_1$ . Finally, if three points in a general situation are fixed, no continuous motion is possible. (The last assumption, which means confined rather than free mobility, probably aimed at a restriction of the dimension of space; it is redundant, because this restriction was urged before by topology.)

For  $n$ -dimensional space, free mobility, according to Helmholtz, goes as far as fixing  $n - 1$  points, whereas immobility is reached after an  $n$ th point has been fixed. Helmholtz claimed that the only spaces with this property are essentially the classical Euclidean and non-Euclidean spaces, but in 1890 Lie showed that Helmholtz' methods were mathematically unsatisfactory. He improved Helmholtz' proofs, but did not remove differentiability assumptions, which are unnatural to modern taste, and represent a major obstacle. The final formulation and solution of Helmholtz' problem was not found until 1953. It is the solution of the German mathematician Jacques Tits, which after a few topological assumptions only asserts: If some triple of points can by motion be carried into any other triple with the same distances from each other, then space is Euclidean or non-Euclidean or spherical  $n$ -space.

**Differential geometry.** The classical concept of space interpreted as if it were a freely movable rigid body had been renounced by Riemann in 1854 (published in 1867) even before it was disclosed by Helmholtz. Riemann, espousing the philosophy of the German Johann Friedrich Herbart rather than Kant, did not accept a general fact such as that of rigid bodies to organize the topological substratum into space. Instead he displayed a hypothesis, the metric structure of space, not subjected to Helmholtz' restrictions, but as general as could be imagined in that time. The metric was supposed to be Euclidean up to the first approximation, with higher-order deviations from Euclidicity, which might vary from point to point.

Riemann's view of space

This idea had been Gauss's earlier when he studied the differential geometry of curved surfaces. Riemann ventured to extend it to space. In order to make things clear, here it will be provisionally restricted to the two-dimensional case. Any curved surface is flat in first approximation, that is, if replaced by its tangent plane in the neighbourhood of any one of its points. In the next approximation it shows deviations from flatness, slight deviations if curvature is small and more significant deviations if curvature is stronger. To discover curvature, however, the outside view is not compulsory. A two-dimensional being (a hypothetical thinking being confined to two dimensions) confined to the surface can discover its curvature and determine it numerically while performing measurements upon the surface. Interpreting the shortest curves between any pair of points as straight, and surveying triangles, a two-dimensional being will state deviations from the Euclidean structure, such as excessive or defective totals of angles, and defective or excessive hypotenuses (as compared with those calculated according to the Pythagorean theorem). He will explain these deviations, which might vary from point to point, as caused by a positive or negative curvature of the surface he is on, and he will be able to calculate the curvature numerically.

The same train of thought applies in three dimensions. As three-dimensional beings inhabiting a three-dimensional universe, men can get information on its curvature by surveying their neighbourhood in the universe, as has been done by 20th-century astronomers. With regard to the terrestrial surface men are happier than two-dimensional beings living on it. They can learn about its curvature also from outside; they can see ships vanish behind the horizon's edge. But they cannot put their heads out of the universe to see its curvature. Men are committed to measurements within the universe. This inside view of space, though the quintessence of Riemann's theory, was barely considered in the confused discussions of the 19th century, but in the theory of relativity it has been justified in the most splendid way. The disregard paid to Riemann's theory in the 19th century resulted partly from Helmholtz' erroneous criticism. Helmholtz argued that surveying a Riemannian space requires freely movable rigid bodies as measuring tools. If this were true, Riemann would have derived no more than Helmholtz' theory yields in a more satisfactory way. Riemann's procedure, however, requires freely movable rigid rods only; as it were, one-dimensional rigid bodies. Unless two-dimensional disks are admitted as tools, Riemann's spaces are much more general than Helmholtz'.

In the 20th century Riemann's theory was supplemented by the notion of parallel transport of vectors in a curved space. The notion of parallel transport was developed by the Italian mathematician Tullio Levi-Civita in 1917 and Jan G. Schouten in 1918. What this means will again be explained here on a surface, particularly on the terrestrial surface.

A freely suspended pendulum changes its oscillation plane after a while. This is the famous experiment of the French physicist Jean-Bernard-Léon Foucault performed in 1851 that verifies the rotation of the earth. Actually the pendulum tends to preserve its oscillation plane in space. Thus, if the earth did not turn, no such change would occur. To explain this phenomenon, replace the Foucault pendulum by a point oscillating in a tangential plane of the earth. As long as this plane rests, the velocity vector of the oscillation does not change. As soon as the plane is turned around, this vector is forced to change. What happens is that it loses its component orthogonal on the plane. In the same way a being living on a curved surface is transporting his vectors over the surface by having them lose their components orthogonally on the surface. This vector transport is an inner feature of the surface, independent of its embedding, and so it can be defined in curved space too.

In the Foucault case, if a vector is moved around with the moving sphere along a parallel circle of the underlying fixed sphere, what happens can be shown quantitatively by constructing the tangential cone of the sphere along

the parallel circle and spreading it upon a plane (along the two straight lines the cone was cut up; in space they are to be identified). Parallel transport along the parallel circle brings the vector back to the beginning point, but then it has undergone a turn equal to the angle of the spread cone.

This is a general feature of parallel vector transport in curved spaces. A vector moved along a closed path may appear to have changed, and the numerical value of this change depends on the value of curvature of the space.

**Topology.** Topology is the youngest branch of geometry but, nevertheless, its most sophisticated. In spite of important but isolated earlier results, its continuous development did not start until about 1911, when the Dutch mathematician L.E.J. Brouwer contributed general methods to topology. Since then it has developed vigorously, closely connected to modern algebra. A few very elementary examples can be used to show what topology means.

Rigidity is the main characteristic of the shapes of elementary geometry. All that Euclid could tell about straight lines, circles, spheres, cones, conics, and so on is lost under the slightest deformation of such figures. More arbitrary curves and surfaces are studied in differential geometry. If a curve is smooth enough, its curvature at any point is an important notion to differential geometry. The completely arbitrary curve, however, is an object of topology and is studied with respect to its most basic intuitive properties. In topology the circumference of a circle is not distinguished from that of an ellipse, of a square, or of the leaf of a plant. All of them, however, are topologically different from the curve suggested by the symbol 8. The capital letters *D* and *O* are topologically equivalent (closed simple curves); *C*, *I*, *J*, *L*, *M*, *N*, *S*, *U*, *V*, *W*, and *Z* are topologically in the same class (simple arcs); *E*, *F*, and *T* do not differ essentially from each other, and among the remaining capital letters there are a few other types.

The simple arc does not cut the plane. A simple closed curve cuts the plane into exactly two parts. These theorems, though intuitively evident, require sophisticated methods for their proof, first achieved by the French mathematician Camille Jordan in 1887.

Spheres and potatoes are topologically equivalent. But they are different from a tire, or ring, called a torus in topology. Indeed, a spherelike surface is cut into two pieces by any simple closed curve on it. On a ringlike surface, however, simple closed curves that do not cut the surface can be drawn easily. The surface of a ladder is still more involved, becoming more involved with each additional rung. This kind of surface also cuts space, as was first proved by Brouwer in 1912.

A key theorem of Brouwer's runs in intuitive terms as follows: If a wooden sphere is clothed in thin rubber, then it is impossible to uncover any point of the wooden sphere by deforming the rubber sphere, even if folding is allowed. (Tearing the rubber is forbidden; deformations should preserve the connection of the parts.)

Two closed curves in space can be located free from each other, or they can be interlaced as the links of a chain. These are topological differences. A simple closed curve can be knotted or not. It is difficult to prove that the clover knot is topologically different from its mirror image. There are infinitely many topologically different knots, but to know whether two of them are equivalent or not is difficult.

The classifying tool of topology is so-called topological mapping, which, by definition, is univalent and continuous in both directions. Topology studies those properties that are preserved under these mappings. (Ed.)

#### ALGEBRA

Algebra is the expression of relationships between numbers by use of general symbols. For instance, the fact that  $4 \times (2 + 1) = 8 + 4$  is an example of a general law that any numbers, denoted by  $x$ ,  $y$ , and  $z$ , are related by  $x \times (y + z) = x \times y + x \times z$ . [This is usually written  $x(y + z) = xy + xz$ .] Here are  $x$ ,  $y$ , and  $z$  are called variables; they are used to represent any three numbers.

Foucault's  
pendulum  
experiment

In arithmetic the law could not be stated; its consequence could be demonstrated by a number of specific examples like that above. The law can also be stated in words: the product of a number and the sum of two other numbers is the sum of the products of the number with each of the other two numbers. The algebraic formulation is clearly more compact and allows the easy manipulation of such equations to give other relationships. Algebra can be defined as a generalization of arithmetic.

**Babylonian, Egyptian, and Greek contributions.** Algebra separated from arithmetic early in the development of mathematics, probably in Babylonia when equations and methods for reducing them were introduced. A considerable number of cuneiform mathematical tables from the period of the Hammurabi dynasty (1800–1600 BC) deal with problems now classified as algebra. The calculations of the examples from this period are presented in a way that makes clear that the general methods, and not the numerical results, are the main goal. A mastery of quadratic equations is evident; often they were presented in the standard form  $x + x^{-1} = a$ , which could be solved by means of tables or by reduction to a square root extraction as at present. Another normal form for quadratic problems in two unknowns was  $x \pm y = a$ ,  $x \cdot y = b$ . More complicated problems were reduced to these. Closely related to these questions are studies of the integral solutions of Pythagorean triangles, that is, determination of integers satisfying  $x^2 + y^2 = z^2$ . There occur instances of fourth-degree equations (involving a variable raised to the fourth power) reducible to quadratic equations and also special cases of cubic equations, presumably solved by tables. Summation of arithmetical progressions and of the sums of squares of integers also was known.

The Egyptian knowledge of algebra seems to have been much more limited than that of Babylonia and may have developed under Babylonian influence. The problems as are known from the Rhind mathematical papyrus are in the main limited to linear equations. A first approach to formal algebra is the use of a standard symbol  $h$  (*aha, hau*), meaning quantity, to denote the unknown to be determined.

The cultures of Asia Minor and Babylonia influenced Greece strongly, and the Greeks undoubtedly received much of their basic knowledge of algebra from these sources. Within Greek mathematics, however, algebra took on a geometric aspect, primarily, it is believed, because of the logical difficulties created by irrational numbers. In the geometric language, for instance, of Euclid's *Elements* (c. 300 BC) the quantities were represented by lengths of lines, products of two quantities by the area of rectangles, and products of three factors by volumes of rectangular solids. In this manner all problems appear in the form of homogeneous relations between quantities of the same dimension. Thus the quadratic equation can be written  $b^2 = x(x \pm a)$ , and the solution consists in finding a rectangle with sides  $x$  and  $x \pm a$  the area of which is equal to that of a given square  $b^2$ . The actual construction can be made by right triangles or mean proportionals. In line with this geometric view of algebra is the development of the theory of conic sections, which reached its zenith in the *Conica* by Apollonius of Perga in 220 BC. The solution of such problems as the duplication of the cube and the trisection of the angle also were given in terms of the intersection of special curves.

The later Alexandrian period of Greek mathematics seems to have been closer to Babylonian sources. From the point of view of algebra the most noteworthy work is the *Arithmetica* of Diophantus of about AD 200. His problems are mostly of the so-called Diophantine type, the solutions of which are positive fractions or integers; usually the equations are linear or quadratic in several unknowns, but these are systematically reduced to a single unknown. Remarkable are the beginnings of algebraic notation or shorthand. The unknown is denoted by  $s$  (perhaps from the final letter in the Greek *arithmos*, "number") with special terms for the first powers. Terms

to be added are simply written together; a special sign is used for minus.

**Contributions from the Orient, India, and the Islāmic world.** Concerning the development of algebra in the Orient: in India, China, and Japan there is still a good deal of dispute, some of it having a nationalistic flavour. The beginnings of algebra in these countries seem to have been influenced by the Babylonian and Greek schools. Among Hindu algebraists, Brahmagupta, whose work on indeterminate equations in about 630 in many ways goes beyond Diophantus, deserves special notice. Somewhat later, about AD 1150, are the outstanding works of Bhāskara, the *Līlāvātī* ("Arithmetic") and the *Vīja-gāṇita* ("Algebra"). These works give rules for dealing with negative quantities: a dot over a number was used to indicate minus. It was realized that positive numbers have two square roots, and Bhāskara also mentions that there are no roots of negative numbers. Unknowns were denoted by the names of various colours. Powers and roots were indicated by the initial letters or first syllables in the corresponding words, giving a close approach to algebraic symbolism.

With the ascendancy of Mohammedanism the Islāmic world became the centre for mathematical studies. A number of Islāmic mathematicians wrote commentaries upon Greek works in the geometric tradition, but there also were notable original algebraic contributions. The cubic equation was a favourite topic for such writers as al-Mahani and Tabit ibn Korra in the middle of the 9th century, Alhazen a hundred and fifty years later, and particularly the poet and mathematician 'Omar Khayyam in the beginning of the 12th century, who dealt with it extensively in his algebra; the solutions were obtained by intersections of conics.

The most influential algebraic work from this period was the *Kitāb al-jabr wa al-muqābalah* ("The Science of Restoration and Reduction") of al-Khwārizmī composed in Baghdad about 825. The influence of the book on Europe was so great that its name became synonymous with equation theory. The unknown was called *shai*, "the thing"; otherwise al-Khwārizmī shows little tendency to algebraic symbolism.

Islāmic algebra was introduced to Europe, especially to Italy, in the 13th and 14th centuries. Most important in this process was Leonardo of Pisa's *Liber abaci* ("Book of the Abacus") of 1202 from which later Italian algebra books borrowed freely. Under the influence of Islāmic usage the unknown was called *res* in Latin, *cosa* ("the thing") in Italian, while algebra itself became known as *l'arte della cosa*, cossic art or the rule of coss. Occasionally algebra was termed the *ars magna*, "the great art" in contradistinction to the lesser art of arithmetic.

**Medieval and modern European developments.** Italian algebraists, for instance Lucas Pacioli in 1494, had expressed the belief that the general cubic equation could not be solved algebraically by means of radical expressions. Thus it was a remarkable achievement when around 1515 Scipione del Ferro, professor at the University of Bologna, succeeded in solving the cubic equation in the special form  $x^3 + ax = b$ . Del Ferro did not reveal his formula, but after his death it passed to his pupils. In a mathematical tournament with one of them, Niccolò Tartaglia from Brescia rediscovered the method and confided it to Gerolamo Cardano, a physician in Milan, under promise of secrecy. In 1545 Cardano published his *Artis magna* ("The Great Art"), the most important algebraic work of the Renaissance. It contained the solution of the cubic equation, still erroneously called Cardano's formula, and also the method for solving fourth-degree equations discovered by Cardano's former servant and protégé, Lodovico Ferrari. The *Artis magna* contained novel ideas concerning the relations between roots and the coefficients of equations; Cardano even calculated formally with imaginary numbers. Publication of this work had a considerable influence on the rapid growth of algebra in Europe.

The presentation in the *Artis magna* is partly geometric in the Greek tradition and partly verbal, with scant use of symbols. For problems as complicated as these, such a

Cardano

form became very cumbersome, and evidently a stage had been reached at which effective simplification was required. Some standard notations had already become common in arithmetic; for instance,  $\bar{p}$  and  $\bar{m}$  were used for plus and minus. The latter symbol was reduced to the bar to denote minus; the plus sign  $+$  is a condensed form for the Latin *et* ("and"). The  $\times$  sign for multiplication appeared in England around 1600; the radical sign  $\sqrt{\quad}$  may originally have been the letter *r* as an abbreviation for *radix*.

Cardano's compatriot Raphael Bombelli about 1560 had made some attempts at simplified writing of algebraic formulas, but the credit for a first systematic effort to introduce an algebraic sign language must go to François Viète. In his *Isagoge in artem analyticam* ("Introduction to the Analytical Art") of 1591 the quantities are denoted by letters, often vowels for the unknowns and consonants for given numbers. The powers of a number *A* were written *Aq* (*quadraticus*), *Ac* (*cubus*), *Aqq* (*biquadraticus*), and so on. The present usage of denoting unknowns by the last letters (*x*, *y*, *z*) of the alphabet and known quantities by the first letters (*a*, *b*, *c*) is attributed to Descartes; he was the first to write powers with exponents in the modern form, although this notation had been used sporadically by earlier writers. John Wallis and Isaac Newton introduced fractional exponents for roots in the second half of the 17th century. The equality sign is attributed to Robert Recorde in 1557. From the middle of the 17th century the algebraic notations were close to the modern ones. Once initiated, the advantage of symbolic writing was obvious, and the development of an effective and logical mathematical sign language has since been a continuous process.

The rapid use of algebraic technique in the 16th and 17th centuries rendered obsolete some of the medieval algebraic methods, particularly the popular rule of false position inherited from Islām. This rule was used to solve linear problems by trying out one or two particular values and adjusting them to satisfy the given conditions. As Recorde states in his *Ground of Artes* of 1542:

Suche falsehode is so good a grounde  
that truth by it will soone be founde.

Use of  
determi-  
nants

The idea of solving systems of linear equations by determinants seems to have been originated by Leibniz, although Chinese and Japanese sources contain some indications of similar methods. The first systematic treatments of determinant theory were given by the French mathematicians Alexandre-Théophile Vandermonde in 1771 and Pierre-Simon Laplace in 1772, but they were not commonly used until further phases of the theory had been developed in 1812 by the French mathematician Augustin-Louis Cauchy and Karl Jacobi of Germany. A standard tool of algebra, the binomial theorem, is ancient and was quite well known by the middle of the 16th century. The more general multinomial theorem is usually ascribed to Leibniz. Interest in equation theory stimulated study of symmetric functions of roots. Fundamental facts about them were developed particularly by Newton, Wallis, Edward Waring, and other members of the English school of mathematicians studying combinatorial analysis.

The introduction of such new fields of mathematics as analytic geometry by Descartes and the calculus by Newton and Leibniz also contributed greatly to the development of algebra. The Greek idea of a geometric algebra was now reversed into an algebraic geometry. The study of algebraic curves advanced the field of algebra itself by introducing methods of reduction and elimination for general algebraic equations in several unknowns, together with various concomitant concepts such as resultants and discriminants as developed in 1764 by Étienne Bézout, a French textbook writer and mathematician.

The properties of algebraic equations indicated the desirability of recognizing complex numbers as roots on a par with real roots. Only then would the fundamental theorem of algebra be valid. The theorem states that an equation of *n*th degree always has *n* roots. This was realized as early as Cardano for third- and fourth-degree equations. It was expressed by the French mathematician

Albert Girard in 1629 and by Descartes. A fully rigorous proof was given first by Gauss in 1799 in his doctoral thesis. The representation of complex numbers graphically by coordinates in the plane is also sometimes ascribed to him, but the credit for this idea first expressed in 1795 must be awarded to the Norwegian-born Danish surveyor and mathematician Caspar Wessel.

Methods for numerical resolution of equations, in particular for extracting square and higher roots, were devised by all the ancient schools of mathematics. Leonardo of Pisa gives a numerical solution of a cubic equation with the root accurate to more than six sexagesimal places. The calculus facilitated the development of a large number of such methods; among them are those proposed by Viète in 1600, Newton, and William George Horner, an English mathematician whose method published in 1819 is still in use (see below *Computation of roots*). Various criteria were devised to determine the general locations of the roots, for instance, the number of positive roots or roots in an interval. Theorems of this kind were proved by Newton, Fourier, Jacobi, and others; most complete is a criterion by the French mathematician Charles-François Sturm that was published in 1835.

The Renaissance discovery of methods for the solution of equations of third and fourth degree left open the puzzling question of whether similar radical expressions could be found for roots of fifth- and higher-degree equations. This was a central problem in algebra in the 17th and 18th centuries, and many excellent mathematicians, notably Joseph-Louis Lagrange, expended much effort on it. A feeling that the problem was insoluble became widespread. A first proof was published by Paolo Ruffini in 1803 and 1805, but the proof by Niels Henrik Abel in 1824, 1826, is generally regarded as the first rigorous one for what has come to be known as the Abel-Ruffini theorem (see below *Evolution of the theory of algebraic equations of one variable*), which states: the general algebraic equation of degree higher than four cannot be solved by radical expressions. Abel attacked the general problem when an algebraic equation of higher degree can be solved by radicals.

Evariste Galois in 1831, independently of Abel, based his remarkable theory of equations upon the new and fundamental concept of group theory (see below *The Galois theory*). Although the importance of Galois's work was not realized until long after his death, group theory now permeates all fields of mathematics and has become one of the most important branches of algebra.

The 19th century saw a great surge in algebraic research and the creation of several new branches of algebra. Introduced were such topics as invariant theory, originally inspired by the desire to determine those algebraic quantities of a curve that are independent of the choice of the coordinate systems; the theory of algebraic functions; the theory of algebraic numbers created by the German mathematicians Ernst Kummer and Richard Dedekind, including the theory of ideals, one of the most fertile concepts of modern algebra; further extensions of the number concepts, first through the quaternions of William Hamilton and later through general hypercomplex numbers, which in turn are closely related to the theory of matrices, which is an all-pervading part of recent mathematics.

The algebraists of the 20th century have continued the work in these and many other domains. With increased knowledge in so many branches of algebra has come the realization that the various theories are related through certain general principles underlying them all, which has led to the development of a so-called abstract algebra with two chief aims: (1) A deduction problem consisting of the derivation of the properties of a system with given axioms. These axioms are of algebraic nature, and the operations on the elements correspond in some way to addition, subtraction, multiplication, and division. (2) A completeness problem consisting of the construction and classification of all systems that can exist for a given family of axioms. A typical example of an analysis of the latter kind is a work by Ernst Steinitz published in 1910 deriving all types of fields; that is, an algebraic system in

Abstract  
algebra

which all the ordinary axioms for the four basic operations are satisfied. The theory of rings has become equally fundamental, uniting the principles of many domains of algebra; this theory deals mainly with operations corresponding to the first three fundamental ones. Finally, intense efforts have been made in the study of groups and grouplike systems with only one operation, sometimes called an addition but more often a multiplication.

(O.Or.)

**Evolution of the theory of algebraic equations of one variable.** The theory of equations is concerned with determining the solvability of algebraic equations and with the development of techniques for the solution of equations that are theoretically solvable.

An equality that holds for all values of the unknowns is an identity. Thus  $3x + 2 = 5$ , true only for  $x = 1$ , is an equation;  $x^2 - y^2 = (x + y)(x - y)$ , holding for all values of  $x$  and  $y$ , is an identity. To distinguish identities from equations the symbol  $\equiv$  is sometimes used, as in  $x^2 - y^2 \equiv (x + y)(x - y)$ .

The theory of equations is concerned chiefly with the properties of a single algebraic equation of the type (see Box, equation 1) in which  $c_0$  does not have the value zero,  $n$  is a positive whole number called the degree of the equation, and the  $c_0, c_1, \dots, c_n$ 's are either given numbers or numbers that are not specified but are assumed known, called the coefficients of the equation. Roughly speaking, the theory of equations discusses this

$$(1) \quad c_0 x^n + c_1 x^{n-1} + \dots + c_n = 0, \quad (c_0 \neq 0)$$

problem: the coefficients being specified, find all values of  $x$  that make the equation true. Such values are called roots of the equation, and finding them is called solving the equation. More generally, there are often sets of simultaneous equations in several variables  $x, y, z, \dots$  to be solved, but the solution of these may be reduced (by eliminating variables) to solving a number of equations of the above type.

The earliest known equivalents of algebraic equations occur in the Rhind papyrus, evidently compiled from earlier works by the Egyptian Ahmes sometime before 1700 B.C. For example, he proposes this problem: "A quantity and its seventh added together become 19. What is the quantity?" The problem, therefore, is to solve the equation  $x + x/7 = 19$ , as mathematicians would now express it. Lacking a convenient algebraic notation, he proceeded by a cumbersome method later known as that of false position.

Although the Greeks are sometimes credited with solving equations of the second degree, in general neither the Egyptians nor the Greeks made any progress that is significant from a modern point of view, and neither people rose to the abstract conception of a theory of equations as a fruitful field of mathematical science. Indian and Islāmic mathematicians achieved more, but it was not until the Renaissance, when the Italian mathematicians of the 15th and 16th centuries succeeded in solving by radicals general equations of the third and fourth degree, that any work of lasting interest was done. Similar attempts to solve equations of higher degree led nowhere, however; deeper insight into the nature of the roots of an algebraic equation was required, and this did not come until the work of Lagrange in 1770–71 and, more decisively, that of two young mathematicians half a century later, Abel and Galois.

Niels Henrik Abel at the age of 22 almost proved that equations of degree greater than 4 could not be solved by radicals. His attempt contained two oversights, however, and the definitive proof of this important fact must be credited to Evariste Galois. Killed in a duel at the age of 20, Galois spent the night before his death outlining a comprehensive theory of the roots of equations in a hastily scrawled letter to a friend. This theory, which now goes by the name of Galois theory, is a prime source of information about algebraic equations and has served as

an inspiration to much modern work in algebra and number theory.

In general, the theory of equations dates from the early part of the 19th century. The approximate solution methods developed then have remained largely unchanged, and although modern algebra has enormously simplified the theory of Galois, the basic ideas are the same.

*Statement of the problem.* The theory of algebraic equations discusses what is essentially a two-fold problem. In addition to ordinary real numbers, there are also complex numbers, those of the form  $a + bi$ , in which  $a$  and  $b$  are real and  $i = \sqrt{-1}$ ; the real numbers are, then, those complex numbers for which  $b = 0$ . The algebraic equation given above can be written as  $f(x) = 0$ , and its coefficients can be taken to be either real or complex numbers; if all the coefficients are real, the equation is called real. This is the important case, since otherwise, multiplying  $f(x)$  by  $\bar{f}(x)$ , in which the coefficients have been changed into their complex conjugates ( $a - bi$ ), gives a new equation  $F(x) = 0$ , which is real, of twice the degree and such that all the roots of the original equation are also roots of this new equation. The term root in this case means a complex number  $\alpha$  such that  $f(\alpha) = 0$ . Even if the equation is real, it may well have complex roots.

The central problems of the theory are these:

A. The coefficients being given as definite numbers, find the roots of the equation—exactly, if possible; if not, determine how to calculate them to as many decimal places as desired.

B. Find general formulas that express the roots in terms of the coefficients. If possible the formulas should require only the operations of addition, multiplication, subtraction, division, and extractions of roots, this being called a solution by radicals. If such formulas are not possible, find the simplest functions of the coefficients that do satisfy the equation.

After the above-mentioned work of Abel and Galois, the French mathematician Charles Hermite in 1858 succeeded in solving the general equation of degree 5 by means of elliptic functions (see ANALYSIS, COMPLEX). Modern work in this direction, originating with Henri Poincaré about 1880, solves the general Fuchsian equation of degree  $n$  in terms of what are called Fuchsian functions. For a time, problem (A) was considered exhausted, but new methods have been developed that are especially suited to computers. Problem (B) now involves group theory and algebraic number theory, as well as special functions of a complex variable.

*The fundamental theorem of algebra.* A basic result applicable to both of the central problems of the theory of equations is the so-called fundamental theorem of algebra, which states that every algebraic equation has a root. It is proved either from this, or from an application of a formula of Augustin-Louis Cauchy, that an equation of degree  $n$  has precisely  $n$  roots. The remarkable feature of this theorem is that it always allows any algebraic equation to be solved without going beyond the domain of complex numbers. Although the theorem is thus so useful that the seasoned mathematician sees in it a species of fortunate miracle, the sophisticated critic views it with suspicion. The first allegedly satisfactory proof was given in 1799 by Gauss, who subsequently added three more proofs.

The first useful consequence of the theorem is the following. If  $x_1, x_2, \dots, x_n$  are the  $n$  roots of  $f(x) = 0$ , then  $f$  can be factored into a product of  $n$  terms, each involving a distinct root (see 2, 3). Conversely, if  $f(k) = 0$ , then  $x - k$  is a factor of  $f(x)$ . More generally, if  $t$  is any complex number,  $f(t)$  is equal to the remainder obtained on dividing  $f(x)$  by  $x - t$ , and hence  $f(t)$  can be calculated by division, a result of importance in the numerical solution of equations. This is called the remainder theorem.

Since  $c_0, c_1, \dots, c_n$  are any complex numbers independent of  $x$ , and  $c_0 \neq 0$ , the equation  $f(x) = 0$  may be divided throughout by  $c_0$ . It then becomes  $x^n + a_1 x^{n-1} + \dots + a_n = 0$ , in which  $a_1, \dots, a_n$  are complex numbers. This form is precisely as general as the original and

$$(2) \quad f(x) \equiv c_0 x^n + c_1 x^{n-1} + \dots + c_n$$

$$(3) \quad f(x) = c_0 (x - x_1)(x - x_2) \cdots (x - x_n)$$

$$(4) \quad x^n + a_1 x^{n-1} + \dots + a_n$$

$$(5) \quad (x - \alpha_1)(x - \alpha_2) \cdots (x - \alpha_n)$$

is convenient to use. If the roots are  $\alpha_1, \alpha_2, \dots, \alpha_n$ , the linear (first degree in  $x$ ) factors of the polynomial (see 4) involve a distinct root  $\alpha_k$  (where  $k$  is some number 1 and  $n$ ) in each factor (see 5). Hence, on comparing coefficients of like powers of  $x$ , it is seen that  $a_1 = (-1)$  times the sum of the roots and  $a_n = (-1)^n$  times the product of all the roots. This result frequently is useful in testing for rational roots an equation whose coefficients are rational numbers; by this means all the rational roots may be found.

*Approximate location of roots.* The problem of finding the roots of an equation, in particular calculation of the roots by an approximative method, can be confined to a discussion of the real roots of real equations; this is the significant case, because the determination of the complex roots may be reduced to locating the real roots of an auxiliary real equation. In fact, attention may even be confined to locating just the positive real roots, because the negative real roots of  $f(x) = 0$  are the positive roots of  $f(-x) = 0$ , which is obtained from  $f(x) = 0$  by changing the signs of all the terms of odd degree.

The problem divides naturally into two steps. First comes the approximate location of the real roots, which includes both determining their total number and isolating them. (A real root is said to be isolated if two real numbers  $\alpha$  and  $\beta$  are known such that the equation has exactly one real root between  $\alpha$  and  $\beta$ .) Once the root is known approximately, a method of calculating it to any desired degree of accuracy must be determined.

If it is assumed that  $f(x)$  is real, then the most straightforward way to locate the roots approximately is to graph the equation  $y = f(x)$  and to locate the points  $\alpha_i$  where the graph crosses the  $x$ -axis. At these points  $f(\alpha_i) = 0$ . The problem is that because only part of the graph can be drawn, one has to decide in advance in what interval of the axis the roots will appear, and this may not be easy. Once a root is located approximately, by enlarging the scale and redrawing the graph, it can be located with any desired degree of accuracy.

A fundamental principle used in isolating the roots is this: if  $f(a)$  and  $f(b)$  have opposite signs, then  $f(x)$  will have a root between  $a$  and  $b$ ; that is, on the interval  $[a, b]$  of the axis. Geometrically, if the graph of  $f(x)$  is below the axis at  $x = a$  and above it at  $x = b$ , then the graph must cross the axis somewhere in between. Mathematically, this is a consequence of the fact that the polynomial  $f(x)$  is a continuous function and therefore has a graph that is unbroken.

A difficulty is that  $f(x)$  may have not just one root on  $[a, b]$  but three, five, or some other odd number. (A repeated root is to be counted with its multiplicity, as explained earlier.) To be sure there is only one root, it is useful to determine that the first derivative  $f'(x)$  does not change sign on  $[a, b]$ . Geometrically, this guarantees that the graph will always be rising or falling on the interval, so that it can cross the  $x$ -axis only once within the interval.

More powerful tools, however, must usually be applied. Conclusive isolation of the roots is given by a method discovered in 1829 by the French mathematician Charles-François Sturm. For an equation of degree  $n$ ,  $n$  auxiliary polynomials called the Sturm functions must be computed (a rather laborious task); the number of real roots (counted with multiplicities) of  $f(x) = 0$  between  $\alpha$  and  $\beta$  is then ascertained by inspection from the signs of the Sturm functions evaluated at  $\alpha$  and  $\beta$ . Budan's theorem, named after the French physician Ferdinand-François-Désiré Budan de Boislaurent, who published it

in 1807, derives a different set of auxiliary polynomials, which are used in the same way; although they are easier to compute, they give less precise information.

*Computation of roots.* When a real root of a real equation  $f(x) = 0$  has been isolated by any of the methods suggested, it may be calculated, digit by digit, by any one of several arithmetical processes, the most common of which are those named after William George Horner (1819), although they were known to the Chinese mathematicians of the 13th century, and Newton's method of about 1675.

Newton's method has the great advantage of being applicable to equations other than algebraic. It can be explained by using his own example,  $x^3 - 2x - 5 = 0$ , which has only one root between 2 and 3. To find this root, replace  $x$  by  $2 + h$ , in which  $h$  is necessarily between 0 and 1. The terms in  $h^2$  and  $h^3$  being negligible in comparison with  $h$ , in the new equation (see 6)  $h = 0.1$  is clearly a first approximation to  $h$ , and hence the root is roughly 2.1. Replace  $h$  by  $0.1 + k$  in the  $h$ -equation, and obtain the next approximation (see 7). Omit the  $k^3$  and  $k^2$  terms, which are small in comparison with  $k$ ; then  $k$  is approximately  $-0.0054$ . From  $h = 0.1 + k$  the result  $h = 0.0946$  is obtained, giving 2.0946 as an approximate value of the required root. By repeating this process a sufficient number of times, any desired degree of accuracy is attainable.

In Horner's method a set of equations, one for each digit of the required root, is obtained successively from the given equation. The process is a refinement of the crude graphical method, and amounts to successive shifts of the origin and magnifications of the scale. The method for positive real roots involves the successive diminution of the roots of the given equation by the smaller member in successive pairs of positive approximations; that is, a gradual approach to the root from behind. For example: a real root of  $f(x) = 0$  has been isolated between 200 and 300. If an equation  $f_1(x) = 0$  whose roots are those of  $f(x) = 0$  each diminished by 200 is constructed, then  $f_1(x) = 0$  will have one and only one root between 0 and 100. By one of the proposed methods this root is located between 60 and 70. Then  $f(x) = 0$  has a root between 260 and 270. Construct an equation  $f_2(x) = 0$ , whose roots are those of  $f_1(x) = 0$  diminished by 60, and repeat the argument. It follows that  $f_2(x) = 0$  has a root between 0 and 10, which may be located as before; say it is between 5 and 6. Thus 5 is the third digit of the required root of  $f(x) = 0$ . Next, construct  $f_3(x) = 0$ , whose roots are those of  $f_2(x) = 0$  diminished by 5;  $f_3(x) = 0$  then has a root between 0 and 1, say 0.2. The required root so far is 265.2, and the process can be continued to any prescribed number of digits. (E.T.B./A.P.Ma.)

*Formulas for solving equations of low degree.* On the problem of the solution of equations by means of exact formulas for the roots in terms of the coefficients: The three equations of low degree for which such formulas exist are the quadratic (of degree 2), cubic (degree 3), and biquadratic (degree 4). Thus, the quadratic equation (see 8) has paired solutions (see 9), and so a single square-root extraction is needed to solve it. In a sense this formula, the famous quadratic formula, is only an approximate solution, since the square root can be only approximately calculated; the significant thing, however, is that the formula is universal: one formula takes care of all possible choices for the coefficients.

$$(6) \quad h^3 + 6h^2 + 10h - 1 = 0$$

$$(7) \quad k^3 + 6.3k^2 + 11.23k + 0.061 = 0$$

$$(8) \quad ax^2 + bx + c = 0$$

$$(9) \quad x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

Sturm  
functions

Horner's  
method

Similar formulas for the roots of the cubic equation were first published in the *Artis magna* in 1545 by Cardano, who obtained them from Tartaglia by questionable means; they are rather complicated, and Horner's method is in general preferable. In particular, if all three roots are real, the formulas give them in terms of complex numbers, a fact which makes the formulas quite impracticable; alternative formulas give the roots as trigonometric functions of the coefficients. Even more impracticable is the general solution to the quartic equation, found by Lodovico Ferrari at about the same time.

*The Galois theory.* The general theory of the roots of equations can now be discussed. The Galois theory proves the impossibility of such general formulas as the above whenever the equation is of degree greater than four.

A rational number (or common fraction) is a real number which is the quotient of two integers, so that, in particular, the sum, product, difference, and quotient of rational numbers are also rational numbers. If it be assumed that the equation  $f(x) = 0$  has rational numbers for coefficients, that  $f(x)$  cannot be factored as a product of polynomials of lower degree with rational coefficients, and further that  $x_1, x_2, \dots, x_n$  are the roots of this equation, then these roots are complex (or perhaps real) numbers, and all different, since  $f(x)$  cannot be factored. The crucial notion is that of an admissible permutation (or substitution) of these roots. A permutation  $(x_1, \dots, x_n) \rightarrow (x_{i_1}, \dots, x_{i_n})$  of the roots—i.e., a scrambling of them—is said to be admissible if every algebraic relation holding among the roots continues to be valid after the permutation is made. Only those relations expressible in terms of sums of products of the roots, with rational numbers as coefficients, are considered here; for example, in the equation  $x^4 - 2 = 0$ . If  $x_1$  is the real positive fourth root of 2, the other roots are  $x_2 = ix_1$ ,  $x_3 = -x_1$  and  $x_4 = -ix_1$ . The permutation  $(x_1, x_2, x_3, x_4) \rightarrow (x_2, x_1, x_3, x_4)$  is not admissible, because the valid algebraic relation  $x_1x_3 + x_2x_4 = 0$  goes by the permutation into  $x_2x_3 + x_1x_4 = 0$ , which is false. But the permutation  $(x_1, x_2, x_3, x_4) \rightarrow (x_2, x_1, x_4, x_3)$  is admissible. That it does preserve the validity of the given relation is easily checked, though this check in itself would not be sufficient to prove the permutation admissible. In this case, of the 24 possible permutations, exactly 8 are admissible. If permutations are multiplied in the usual way by performing one after the other, the admissible permutations form a group.

The Galois group

The set of admissible permutations is called the Galois group of the equation. Since there are  $n$  roots, the total number of all permutations is  $n!$ ; thus the Galois group can be no larger than  $n!$  and it may in fact be much smaller. Here  $n!$  denotes the product  $n(n-1)(n-2) \dots 2 \cdot 1$ . If it is of this maximal size, however (i.e., if every permutation is admissible), then the equation is said to have the symmetric group. Loosely speaking, if an equation is written down at random, the chances are that it will have the symmetric group; the ones with smaller Galois groups are rare.

This group measures what might be called the algebraic symmetries that the roots possess, much as the group of the six possible rigid motions carrying an equilateral triangle onto itself (three rotations and three reflections) measures its sixfold geometric symmetries.

In general a finite group  $G$  is called solvable if it has subgroups  $G = G_1, G_2, \dots, G_r = \{1\}$  such that each  $G_{i+1}$  is a normal subgroup of  $G_i$  and such that  $G_i$  has  $p_i$  times as many elements as  $G_{i+1}$ , when  $p_i$  is a prime number. Such groups are very special kinds of groups. The heart of Galois's theory is the theorem that an algebraic equation is solvable by radicals if and only if its Galois group is a solvable group.

Roughly speaking, the  $p_i$  entering above into the structure of  $G$  corresponds to the solution of the equation by extraction of  $p_1$ th,  $p_2$ th,  $\dots$ ,  $p_r$ th roots; the possibility of solving the equation by simple root extractions is the reflection of the possibility of elucidating the structure of its Galois group by finding a sequence of subgroups of the sort indicated. Now, since it can be shown that the group of all permutations on  $n$  symbols (there are  $n!$  of them)

is not solvable when  $n \geq 5$ , and since there are equations with rational coefficients which have these groups as Galois groups, it follows that these equations cannot be solved by radicals. Thus there cannot be any general formula for the roots in terms of the coefficients when  $n \geq 5$ , because such a formula would have to work regardless of what the coefficients were, and in particular would have to work for the special unsolvable equations as well. (A.P.Ma.)

### Historical development of probabilistic areas of mathematics

Of the precise meaning of probability there are conflicting views among experts (philosophers, mathematicians, statisticians). The reasons for this may be partly grasped from a survey of the various channels through which a scientific concept of probability has emerged.

Commercial insurance against risks was developed in the Italian cities of the early Renaissance. The theoretical foundations of life insurance were laid in the 17th century. The English statistician John Graunt in 1662 drew attention to the stability of statistical series obtained from registers of deaths. Soon after, the English astronomer Edmund Halley showed how to calculate annuities from mortality tables.

Another early reason for interest in probability was in connection with the weight of evidence in legal procedure. The theory of judicial evidence occupies a prominent place in probability mathematics up to the mid-19th century.

### VARIOUS MATHEMATICALLY BASED PROBABILITIES

Mathematical problems relating to games of chance had been considered, though with minor success, by Luca di Paciolo, Gerolamo Cardano, Niccolò Tartaglia, and other mathematicians of the Renaissance. The subject was developed into a "geometry of the die" (*aleae geometria*) by Blaise Pascal, Pierre de Fermat, and Christiaan Huygens in the 17th century. Fermat treated the problems within a general theory of combinations, which was further developed by the Swiss mathematician Jakob Bernoulli. The latter can be regarded as the founder of probability theory as a branch of mathematics: his posthumously published *Ars Conjectandi* of 1713 can be said to aim at a fusion of the a priori methods of combinatorial probability and the a posteriori methods of early statistical theory. The research in probability done by 18th-century mathematicians culminated in the immense work of Pierre-Simon Laplace, the founder of a tradition that dominated the subject throughout the 19th century.

Laplace advocated a strictly deterministic view of the universe: an omniscient intelligence ("Laplace's demon") would be able to predict the course of nature in minutest detail with infallible accuracy. On this view, probability enters into a science of nature only as a theory of errors; that is, as a systematic study of the deviations from a mean that appear in repeated measurements of a quantity. This study was developed by Laplace, by Legendre, and by Gauss. The mathematical calculus of probability soon provided tools for handling statistical material in connection with public finance, health administration, the conduct of elections, and other social matters besides insurance. The Marquis de Condorcet and later the astronomer Adolphe Quetelet were champions of a social science based on probabilistic statistics.

From the middle of the 19th century, probability gradually gained ground as a part of physical theory. It first appeared in the theory of heat. James Clerk Maxwell in 1860 deduced gas laws from underlying probabilities for the distribution of positions and velocities over the molecules. The German physicist Ludwig Boltzmann in 1877 interpreted the irreversibility of thermal processes as a tendency toward a most probable distribution of the energies of the molecules. The rise of quantum mechanics saw the theory of radiation put on a probability basis by another German physicist, Max Planck, in the first year of the 20th century. With the further development of quantum physics, probability invaded atomic theory. By the middle of the 20th century the deterministic view of

nature was thought in some quarters to be in process of being replaced by a probabilistic view. The concept of probability had become one of the fundamental notions of a modern science and philosophy of nature. This gave a new urgency to the need for clarifying the structure and meaning of the idea.

**The abstract calculus of probability.** In the course of the development already outlined, several definitions of probability were suggested. Accordingly, alternative methods were devised for basing the edifice of probability mathematics on those definitions. These alternative calculi take different views of the meaning of their fundamental notion, but they agree, by and large, in having a common logical structure.

These observations offer a starting point for attempts to create an abstract calculus of probability. It abstracts from various interpreted calculi their common structure, the formal properties of which it studies independently of any definition of probability.

In the abstract calculus developed by the Soviet mathematician A.N. Kolmogorov in 1933, probability figures as a function of sets. This theory, which has found much favour among mathematicians, incorporates probability mathematics within the general theory of measurable sets of points.

Abstract calculi of a type that might be called logistic were constructed by the English economist J.M. Keynes in 1921, Harold Jeffreys in 1939, the German-American philosopher Hans Reichenbach and other authors. In these systems probability figures as an undefined logical relation between propositions or attributes.

The symbol  $a/h$  can be read as "the probability of  $a$  given  $h$ ." It is often convenient to speak of  $a$  as an "event" and of  $h$  as some "conditions" or "data" or "evidence." It is not necessary to assume that any pair of propositions (or attributes) determines a numerical value of the functor. If there is a numerical probability, it should, for noncontradictory data, satisfy the following four postulates: (1)  $a/h \geq 0$ ; (2)  $h/h = 1$ ; (3)  $a/h + (\text{not-}a)/h = 1$ , the principle of complementarity; and (4)  $(a \text{ and } b)/h = a/h \times b/(h \text{ and } a)$ , the general multiplication principle. These four postulates suffice, with the aid of a few principles of a subordinate character, for the erection of the whole fabric of probability mathematics.

From the first, second, and third postulates it follows that all probability values are in the interval from 0 to 1 inclusive.

From the third with the aid of the fourth can be proved the general addition principle:  $(a \text{ or } b)/h = a/h + b/h - (a \text{ and } b)/h$ .

If  $a$  and  $b$  are mutually exclusive alternatives, the probability of their joint occurrence is 0. Thus the equality for exclusive  $a$  and  $b$  holds:  $(a \text{ or } b)/h = a/h + b/h$ . This is called the special addition principle.

If  $a/h = a/(h \text{ and } b)$ , then it is said that  $a$  is independent (for probability) of  $b$  (in  $h$ ). The notion of independence is of great importance to the further development of the calculus. It follows from the fourth postulate and the definition of independence that for independent  $a$  and  $b$  there is the equality  $(a \text{ and } b)/h = a/h \times b/h$ . This is called the special multiplication principle.

**The frequency theory of probability.** This is the view that, popularly speaking, the probability of  $a$  given  $h$  means the relative frequency with which the event  $a$  takes place when the conditions  $h$  are fulfilled. The probability of  $a$  given  $h$ , in other words, is the proportion of  $h$  situations that lead to  $a$  events.

The frequency view of probability has a long history. Aristotle defines "a probability" as being "what men know to happen or not to happen, to be or not to be, for the most part thus and thus." A similar opinion was entertained by writers of the 17th and 18th centuries, who were interested in statistics or in a "theory of evidence."

The history of probability mathematics from Jakob Bernoulli to Laplace and his followers is allied to a different view of the meaning of probability, the range theory, discussed below. The rebirth of the frequency theory followed a criticism of the foundations of the Laplacean

calculus, particularly of the use of the principle of indifference for the determination of probability values (see below *The principle of indifference*). The attack was launched by the British philosophers and economists R. Leslie Ellis, John Stuart Mill, and French economist and mathematician Antoine-Augustin Cournot in 1843. The frequency conception of probability was first worked out in a mathematical theory by John Venn in 1866.

Early proponents of the frequency theory spoke of probability as a relative frequency "in the long run." This loose way of speaking is not very satisfactory. Venn was the first to define an event's probability as the limiting value which its relative frequency approaches as the number of occasions is indefinitely increased. An improved version of this frequency-limit theory was presented by the German-American physicist and mathematician Richard von Mises in 1919; another later well-known adherent of the theory is Reichenbach.

Von Mises also thought that a probability cannot be simply the limiting value of a relative frequency, and he added the qualification that the event ought to be irregularly or randomly distributed in the series of occasions in which its probability is measured. This demand of randomness he called the principle of excluded gambling systems.

It is a great merit of von Mises to have stressed the importance of the idea of random distribution to a frequency theory of probability. With this idea, however, he introduced a considerable difficulty into the theory, the problem of defining random distribution. The definition proposed by von Mises has been challenged as inconsistent, but it is doubtful whether any of the proposed alternative definitions can be regarded as satisfactory.

The demand of randomness is relevant to the question of the adequacy of the frequency view as a proposed analysis of the meaning of probability. But randomness is not relevant to the question of the mathematical correctness of interpreting abstract probability in terms of frequencies. A frequency definition does satisfy the four postulates of the abstract calculus.

Many other objections can be raised against the frequency view. Nevertheless, some form of frequency theory is thought by many writers to offer the best account, for a large category of cases, of the relation between abstract probability and empirical reality.

**The range theory of probability.** Another definition of probability is given in terms of range. In its simplest form, this theory runs as follows: Analyze  $h$  into a number  $n$  of alternative conditions. That  $h$  is fulfilled means that either  $h_1$  or  $\dots$  or  $h_n$  is fulfilled. Some of these alternatives, say  $m$ , entail the occurrence of  $a$ ; the remaining ones entail the occurrence of not- $a$ . Using a traditional terminology, the first group of alternatives is known as favourable to  $a$  and the second unfavourable to  $a$ . The probability of  $a$  given  $h$  is the ratio  $m:n$  of the number of favourable alternatives and the number of all alternatives.

Omitting an important qualification discussed below, this is substantially the definition of probability that emerged from the mathematical treatment of games of chance and was canonized in the theory of Laplace; it is the classical form of the range definition.

The mutually exclusive alternatives covered by a proposition or an attribute are what is called its range. The classical definition can be generalized as follows: The probability of  $a$  given  $h$  is the ratio of the measure of the range of  $h$ -and- $a$  and the measure of the range of  $h$  alone.

The notion of range (in German, *Spielraum*) was introduced into probability theory by Johannes von Kries in 1886. It was used to define probability as a logical relation between propositions by Ludwig Wittgenstein (1922). Substantially the same definition had been given by the Czech mathematician Bernard Bolzano as early as 1837. A generalized form of the Bolzano-Wittgenstein definition was suggested by Friedrich Waismann in 1929 and was further developed and extensively studied by Rudolf Carnap in 1950. The Waismann-Carnap definition is independent of any specific way of measuring ranges.

Early  
work  
on range

The range definition, both in its classical and in its generalized form, satisfies the postulates of abstract probability. The definition, no doubt, is mathematically correct. Whether it gives an adequate account of the meaning of probability is another matter.

**The principle of indifference.** The main difficulty confronting a range theory of probability concerns measurement of the ranges. This difficulty is allied to the question of how to analyze propositions or attributes into alternatives. Usually there are several possibilities for the choice of a measure and the analysis of the data into alternatives.

The classic workers in probability theory were aware of these difficulties; the first to discuss the matter fully was Jakob Bernoulli. He stressed that the alternatives into which  $h$  is analyzed ought to be equally possible; *i.e.*, "each case ought to have the same facility as any other case of coming about." This condition of equipossibility in the cases was usually added to the classical range definition of probability. The condition, it will be noted, is tantamount to a principle of measuring ranges. Jakob Bernoulli laid down a rule for the conditions in which cases can rightly be pronounced equally possible; the rule is known as the principle of insufficient reason, the principle of equal distribution of ignorance, or in Keynes's phrase the principle of indifference. In its classical version this principle states that two cases are equally possible if no reason is known why the one case rather than the other should come about.

Reliance on a principle of indifference for measuring ranges (probabilities) has a certain *prima facie* plausibility in games of chance, where there usually is complete agreement among experts as regards the right analysis of the situation into alternatives of equal possibility. In cases which present no obvious analogy to games of chance, reliance on the principle becomes dubious. It was the use of it made by Laplace and his followers, particularly for the notorious doctrine of inverse probability, that, in the middle of the 19th century, provoked criticism of the foundations of the entire classical fabric of probability theory. Among the notable earlier critics of the principle of indifference were R. Leslie Ellis, George Boole, Charles Sanders Peirce, and Johannes von Kries.

J.M. Keynes further discussed the principle acutely and in detail. Severely criticizing its unguarded uses, he also attempted to refashion it and to make clear its relevance to any philosophy of probability. Warranted use of the principle is tied to the question of symmetry in the unit alternatives under consideration; and the problem of symmetry in its turn is tied to the problem of an ultimate analysis of propositions or attributes into alternatives. Any judgment of symmetry or ultimacy, as it presupposes that all relevant information about the cases has been taken into account, is, negatively, a judgment of irrelevance or independence for probability among propositions or attributes. Any pronouncement on irrelevance involves, so Keynes thought, an "element of direct judgment or intuition."

The principle of indifference has usually been discussed in connection with the classical range definition, to which it was traditionally regarded as a necessary supplementation. However, the problems connected with this principle recur within any theory which defines probability in terms of the relative magnitudes of ranges.

**The belief theory of probability.** Many philosophers and mathematicians have spoken of probability as a degree of belief or of certainty. Frank Plumpton Ramsey in 1926 and, somewhat later, B. de Finetti in 1937 made a systematic attempt to base the mathematical theory of probability on the notion of partial belief. Both take as their point of departure an old idea, measuring a person's belief by proposing a bet and observing the lowest odds that he will accept. A person who distributes his partial beliefs (his subjective assignments of probabilities) contrary to the laws of calculus could have a so-called Dutch book made against him and would then stand to lose in any event. Because of this, the laws of probability may be called rules for consistent (coherent) sets of degrees of belief.

Ramsey, moreover, made an ingenious effort to generalize the procedure of measuring beliefs. A bet can be regarded as an option between goods, and accepting lowest odds as a reflection of an attitude of indifference in any option. A distribution of partial beliefs contrary to the laws of probability, Ramsey says, "would be inconsistent in the sense that it violated the laws of preference between options, such as that preferability is a transitive asymmetrical relation."

The ideas of Ramsey and de Finetti were later taken up by Leonard J. Savage in 1954, who became the founder of a subjectivist or personalist school in probability and statistics. The combination of probabilistic ideas with the value-theory notions of preference and utility has had fruitful applications to the mathematical study of economic and related forms of human behaviour. Acknowledgment of this fact does not exclude taking a somewhat critical view of the epistemological and logical basis of the belief theory of probability.

**Probability: subjective or objective.** The subjectivist conception of probability as a degree of belief is often contrasted with the objectivist conception of the notion as either a relative frequency or a ratio of measures of ranges. It is questionable, however, whether a sharp contrast can be maintained between objectivism and subjectivism in the philosophy, particularly the epistemology, of probability.

Supporters of the frequency view have found that an adequate analysis of probability requires them to combine their definition of the concept with the idea of a random distribution of events on a series of occasions. Supporters of a range theory have had recourse to some form of a principle of indifference for the determination of equipossibility in certain unit alternatives. The question may be raised whether randomness and equipossibility can be satisfactorily accounted for without reference to states of knowledge or ignorance. If the answer is negative, it shall have to be admitted that an adequate account of the meaning of probability cannot be given in purely objectivist terms.

On the other hand, the belief theory does not necessarily entail an identification of probability with belief as a psychological phenomenon. The attitudes in options between goods may be said to reveal subjective estimations of probability. But the derivation of the laws of probability within the belief theory does not confer on them the status of psychological laws of believing. It rather makes them standards of rationality (consistency) in the distribution of beliefs or in preferences. It would therefore be an oversimplification to regard the belief theory as an account of probability in purely subjectivist (that is, psychological) terms.

**Bernoulli's theorem.** If it is assumed that the probability for the occurrence of an event  $a$  on a certain occasion of  $h$  is not affected by its occurrence or nonoccurrence on previous occasions of  $h$  (that the occurrences of  $a$ , in other words, are independent for probability of one another), and if this probability is  $p$ , then the special multiplication and addition principles can be used to calculate the probability that the event  $a$  will, on  $n$  occasions of  $h$ , be realized with a relative frequency in the interval  $p \pm \epsilon$ . From considerations about this second-order probability it can be proved that:

1. The most probable value of the event's relative frequency on  $n$  occasions is that value which comes nearest to its probability  $p$ .

2. In the long run the event will almost certainly be realized with a relative frequency corresponding to its probability; that is, the probability that the event's relative frequency on  $n$  occasions will deviate from its probability  $p$  by less than a given amount  $\epsilon$ , however small, approaches 1 as a limit when  $n$  is indefinitely increased.

For example: The probability of head and tail in tossing with a normal coin is  $\frac{1}{2}$ . The results are independent for probability: no combination of head and tail in previous tosses will influence the probability of getting head or of getting tail in the next toss. A simple calculation shows that the probability of getting 49, 50, or 51 heads in 100 tosses is approximately 0.16; the probability of getting

between 490 and 510 heads in 1,000 tosses is 0.47; and the probability of getting between 4,900 and 5,100 heads in 10,000 tosses is 0.95. In other words: in 10,000 tosses it is almost certain that the proportion of heads will deviate by less than 0.01 from its probability  $\frac{1}{2}$ .

This remarkable theorem is known as Bernoulli's theorem. It is chronologically the first of a class of propositions called the laws of large numbers, a name introduced by Siméon-Denis Poisson in 1837.

**Inverse probability.** In 1763 Thomas Bayes proved that, if  $m:n$  is the relative frequency of an event on  $n$  independent occasions, then  $m:n$  is also the most probable value of the event's probability, provided that any value of this probability is initially (a priori) as probable as any other value. The same theorem was proved independently by Laplace in 1774. Laplace also proved that, on the assumptions mentioned, it will in the long run become almost certain that the probability of the event coincides with its relative frequency.

The Bayes-Laplace theorem is the inversion of Bernoulli's theorem and the cornerstone of the classical doctrine of inverse probability for the estimation of probabilities on the basis of frequencies. The doctrine was developed and put to extensive use by Laplace and his followers. It was thought to be of great relevance to the problem of induction.

The Achilles' heel of inverse probability is its dependence on initial or a priori probabilities. These were in the classical doctrine often established by deplorably uncritical use of the principle of indifference. The doctrine was challenged in the 19th century, particularly by early proponents of the frequency view. The use of inverse probability is still a matter of debate. Some researchers, among them the British statistician Sir Ronald Fisher, have altogether rejected it.

**Asymptotic probabilities and the principle of moral certitude.** It was often thought in the past that, by virtue of Bernoulli's theorem, "events will, in the long run, happen in numbers proportional to probabilities" as expressed by Augustus De Morgan in 1838. But this is a serious mistake. The theorem only says that it becomes increasingly probable that the frequency coincides with the probability. And this, by itself, does not warrant any conclusion about actual frequencies, not even in the long run. The error latent in the idea that Bernoulli's theorem provides a bridge from a subjectivist conception of probability as a degree of certainty to an objectivist conception in terms of frequencies was first clearly seen and conclusively criticized by R. Leslie Ellis in 1843. There were many lapses into the error afterward, but today the correctness of the criticism is universally admitted.

There is, however, another way of using Bernoulli's theorem and other asymptotic principles of probability (laws of large numbers) as a bridge from (uninterpreted) probabilities to statistical frequencies without committing a logical error. It may be briefly indicated as follows:

Either from observations about frequencies or from considerations about ranges or from some other source, a hypothesis is framed about the probability of a given  $h$ . From this hypothesis it is calculated as "almost" or, in Bernoulli's term, "morally" certain (say probable to degree 0.95) that in a series of  $n$  trials the relative frequency of the event will deviate from its probability by less than a small fraction (say 0.01). In other words, it is "most unlikely" ("morally impossible") that the frequency will fall short of the hypothetical probability by more than this fraction. Adopting the maxim that very improbable events are "practically excluded" and that "moral certainty" should be treated as equal to full certainty, then, if the event's frequency nevertheless deviates from the hypothetical value by more than the fraction in question, it ought to be said, not that something very improbable has happened, but that the probability hypothesis has to be rejected.

The proposed maxim was in fact suggested by Bernoulli. It might be called Bernoulli's principle of moral certitude. Its adoption seems to accord with the actual use of probability calculations for scientific and other purposes.

It partially explains why, without detriment to the applications of probability, judgment can be suspended on the meaning of this controversial notion. The calculus permits transition from hypothetical probabilities to predicted frequencies. If the observed frequencies conflict with the principle of moral certitude, the hypotheses are modified or rejected. The boundaries of moral certitude are, of course, elastic; and whether they are provisionally fixed at one value rather than at another will depend upon a multitude of circumstances peculiar to each case: the amount of statistical evidence at hand, the possibilities of repeated trials, the facility with which dependencies between occurrences can be controlled, and ethical considerations relating to gains and losses from choosing one probability hypothesis over another as a basis of action.

**"Probability": one or many meanings.** The word "probability" can be put to many uses, as in these statements: (1) "the probability of a normal six-sided die turning up 'six' is  $\frac{1}{6}$ "; (2) "the probability that Shakespeare wrote the plays commonly attributed to him is overwhelming"; (3) "Fresnel's experiment increased the probability of the undulatory theory of light."

According to Hans Reichenbach, one of the chief proponents of the frequency theory in modern times, there is only one scientific meaning of probability. A statement of the second type, which concerns the probability of an individual event, is literally meaningless, but may be reinterpreted as a statement about that which usually is the case under similar circumstances. Statements of the third type, which attribute probability to general propositions (laws of nature, theories, hypotheses) may, according to Reichenbach, be given a frequency interpretation as referring either to a proportion of successful predictions, or to a proportion of true theories within a class.

A unitary view of probability was also taken by J.M. Keynes, though on quite different grounds. According to Keynes, the difficulties presented by cases such as the second and third types exemplified above would indicate that probability is a wider notion than the concept that figures in a frequency theory or even in any theory that requires probability to be a measurable quantity. In its wide sense, probability is a degree of rational belief, not necessarily measurable.

Those who have advocated a dualistic view of probability have usually wished to contrast cases of the third type, or the probability of laws of nature, with other types of probability. Jakob Friedrich Fries called the probability of laws "philosophical probability" and contrasted it with "mathematical probability." This distinction was adopted by many logicians and philosophers of the 19th century such as Ernest Friedrich Apelt, Antoine-Augustine Cournot, and M.W. Drobisch. Philosophical probability was thought to be nonnumerical in principle. A similar position has found favour with many 20th-century authors: Bertrand Russell in 1948 contrasted "credibility" and "mathematical probability"; William Calvert Kneale in 1949, "acceptability" and "chance"; R.B. Braithwaite in 1953, "reasonableness" and "probability."

A dualistic view of a somewhat different nature was developed by Rudolf Carnap in his *Logical Foundations of Probability*. Of the two concepts of probability that he distinguishes, the first (which he also calls "degree of confirmation") is probability in the sense of a range theory; the second is probability in the sense of a frequency theory. Carnap tries to reconcile the rival claims of the two theories by assigning to each concept of probability its proper field of application. In view of the difficulties, however, which both theories encounter as proposed analyses of probability, it cannot be taken for granted that this reconciliation is altogether satisfactory. (G.H.von W.)

#### DEVELOPMENT OF MATHEMATICAL STATISTICS

Development of the conceptual content of mathematical statistics was gradual, extending over a century and a half. As noted earlier the behavioristic approach to problems of estimation is found in the work of Laplace and Gauss. Laplace seems one of the first to test statistical hypotheses; but at that time there was no question of mathe-

J.M.  
Keynes's  
view

mathematical statistics as an independent discipline. Laplace's criteria for testing statistical hypotheses were intuitive rather than mathematical and in no way similar to his approach to the problem of point estimators. The behavioristic approach to estimation was soon forgotten.

Mathematical statistics as an independent discipline seems to have appeared in the latter part of the 19th century in the work of the English, French, and German mathematicians Adolphe Quetelet, Gustav Theodor Fechner, Karl Pearson, George Udny Yule, and the Czech mathematician Emanuel Czuber. The then existing branches of applied mathematics (*e.g.*, analytical mechanics) were, so to speak, individualistic. Many scientific problems required a new mathematical discipline concerned with aggregates of objects, all of which satisfy a specific definition but differ in individual characteristics. Such an aggregate (population) might be all men of military age in a country; these men differ in height. Another population would be the set of gas molecules in a container; each molecule has a unique velocity as its individual characteristic.

Any population, however, has its own characteristics, conditioned by those of the individual members, but essentially different. Gas pressure is a characteristic of the population of molecules conditioned by their velocities; temperature is another such characteristic. These are examples of what Fechner called *Kollektivmass*. The average height of recruits is also a *Kollektivmass*, as is the frequency with which they are found with height between 5 ft 10 in. and 5 ft 11 in. The set of such frequencies (the frequency distribution) is also a *Kollektivmass*.

In the late 19th and early 20th centuries mathematical statistics emphasized the *Kollektivmasslehre*, a mathematical discipline concerned with collective characteristics of populations. The term descriptive statistics was introduced to mean the use of a variety of methods (including graphical and tabular methods) for describing such characteristics of populations. An important method of descriptive statistics is to consider a family of flexible curves or surfaces (depending on a moderate number of parameters) that can be used to approximate the empirical frequency distribution. A number of such families were developed, all representing interpolation formulas. The most successful system seems to be that due to Karl Pearson.

A conceptual problem studied by the German mathematician Wilhelm Lexis developed to deprive *Kollektivmasslehre* of its independent status. Lexis was concerned with the year-to-year fluctuation of sex ratio among children born in a city, and similar ratios arising in the study of vital statistics. The question was whether an empirical index of dispersion is consistent with the assumption that determination of sex is governed by a simple chance mechanism such as a toss of a coin. This renewed a continuing effort concerned with chance mechanisms acting on individuals to produce the observed collective characteristics.

Interest in flexible formulas specifically developed to fit empirical distributions gradually decreased, except for those that could be deduced from clearly defined chance mechanisms. In the 1920s the Hungarian-U.S. mathematician George Polyá constructed a system of chance mechanisms that can generate almost all the distributions of Karl Pearson's system. Thus mathematical statistics shifted from *Kollektivmasslehre* to the construction of chance mechanisms or (as they are called) stochastic models of phenomena. This idea was explicitly stated by Émile Borel of France:

The basic problem of mathematical statistics is to invent a system of simple chance mechanisms, such as throws of a coin, so that the probabilities determined by this system agree with the observed relative frequencies of the various details of the phenomena studied.

Although Borel's definition was appealing, developments following its formulation indicated that it leaves mathematical statistics without a field of its own. Depending on the attitudes of given research workers, stochastic models belong to the relevant substantive fields or to the theory of probability. Thus stochastic models of

hereditary phenomena are an integral part of genetics; stochastic models of epidemics are an integral part of epidemiology; and so on. However, considerable literature on stochastic processes developing in time (*e.g.*, birth and death stochastic process constructed to represent the growth of biological populations) is one of the most active sections of the theory of probability. Each problem of the theory of stochastic processes is reducible to that of determining probabilities (*e.g.*, that a biological population will eventually die out). While the field indicated in Borel's definition continued to grow in importance, it was claimed by other disciplines, leaving nothing to mathematical statistics.

While these ideas were in the process of dissolution, increasing effort was given to problems of estimation and of testing hypotheses. In connection with his system of curves, Karl Pearson developed a method of point estimation known as the method of moments; in 1900 he published his famous  $\chi^2$  (chi-square) test for goodness of fit. In 1908 F.Y. Edgeworth of England found that consistent use of the method of moments must yield an excessive frequency of large errors of estimation (a distinctly behavioristic approach) and proposed a new method of estimation, conjectured to be much better. Fourteen years later, Sir Ronald Fisher discussed the same ground more rigorously and intensively. He introduced the term method of maximum likelihood. The English mathematician Student (pseudonym of William Scaly Gosset) and Fisher developed a number of tests of particular hypotheses. However, studies of this kind were not yet connected by any unifying idea and were limited to particular decision functions. Problems of testing hypotheses and of estimation remained unrecognized as an independent field for systematic study.

Such recognition came when Fisher in 1922 gave a new definition of statistics. Stating that the object of statistical methods is the reduction of bulky data, Fisher distinguished three basic problems: those of specification of the kind of population from which the data come (*i.e.*, of the *Kollektivmass*), of estimation, and of distribution (probabilistic problems connected with point estimation). This was followed by a paper concerned specifically with the theory of estimation; the underlying ideas are distinct precursors of the behavioristic approach to mathematical statistics described earlier. ## Mathematics as a Calculatory Science

Mathematics as a logical body of knowledge can be used as a guide for arriving at precise results. If the precise results are expressible in terms of numbers or are arrived at with the use of numbers, the calculatory nature of mathematics becomes evident. Mathematics as a calculatory science includes the use of computers, as is obvious, but it includes many other things as well. In fact, a historical view of the entire mathematical literature reveals that the inclination of mathematical thought to build upon repetitious steps that submit to automation, or its inclination to reduce abstract reasoning to physical models, is not unrelated to mathematics as an abstract discipline in which it is possible to begin with unproved statements called axioms and deduce consequences. Significantly, one of the evident turning points that has affected the foundational thinking of mathematics occurred when the English mathematician Alan Turing characterized in succinct language in the 1930s precisely what is meant by an algorithm, with the use of which mathematical proofs can be constructed. Turing's work led to the modern concept of the computer, itself, and not inconsistently to a fuller understanding of mathematics as a whole (see AUTOMATA THEORY; MATHEMATICS, FOUNDATIONS OF).

Mathematics as a calculatory science is then concerned with the ingredients of mathematics that characterize the automated form of the reasoning process and the methods of thought that rely upon such things as

physical models and number storage and manipulation. The end results of a mathematical calculation may be a statement, a decision, a number, a geometrical drawing, a plan, or other recorded conclusion. The calculatory ingredients of mathematics are thus varied. The outline, as given below, is a guide to what is meant by the subject.

### NUMERICAL NOTATIONS

**Aggregations.** A numerical notation is usually directly associated with counting. The usefulness of the notation is dependent on the ease and effectiveness with which such other operations as addition, subtraction, multiplication, and division can be accomplished.

In its most elementary form, counting is based on a memorized sequence of the names of numbers. An obvious analogy is with counting by the fingers, and the advantage of aggregating the given units into larger units is clear. The Romans, for instance, grouped objects into fives, and the Roman numeral V for five is supposed to represent the hand. Aggregation by tens is the most com-

$$(1) \quad \left\{ \begin{array}{l} \rightarrow 1 \times 132 = 132 \\ \quad 2 \times 132 = 264 \\ \rightarrow 4 \times 132 = 528 \end{array} \right.$$

mon form, but this may also appear in the so-called biquinary form in which there is an alternate aggregation by fives and by twos. Both primitive societies and advanced electronic computers aggregate by twos and threes.

Practical situations suggest a further development of aggregation. For example, retail sales in the case of certain items may be by units or dozens, but wholesale dealings may be in grosses—*i.e.*, dozens of dozens—or great grosses. Aggregation by twenties was once popular as evidenced by the term score. The Mayan culture of Central America used a system of aggregation that was basically in twenties. Aggregation by sixties apparently arose from a certain method of dividing the arc of a circle.

The aggregations that arose in the British marketplace, however, tended to be extremely *ad hoc*; for example, 16 drams equal one ounce, 16 ounces equal one pound, 14 pounds equal one stone; 12 pence equal one shilling, 20 shillings equal one pound. For such a system, only addition and multiplication by small natural numbers is at all practical. From the operational point of view, uniform aggregation by a constant factor, which may explain the British change to a decimal coinage and the metric system, both base 10, in the 1970s, is much more desirable.

**Multiplication and division by doubling: Egyptian notations.** An example of aggregation by a constant factor is given by the Egyptian system described in the Rhind papyrus, written by a priest, Ahmes, sometime before 1700 BC and based on sources that are believed to be much older. It is a collection of tables and problems that were used for instruction. The Ahmes notation for a number is based on assigning a symbol for each unit aggregate. These were a vertical bar, |, for one, an arch,  $\cap$ , for ten, and a C for one hundred. Symbols were assigned to these unit aggregates up to 10,000,000. A number was represented by writing down a symbol for each aggregate involved; for example, 231 was written CC $\cap$ nn|. This type of notation is reasonably convenient for counting, addition, and subtraction. Multiplication and division were based on doubling and tables for doubling were provided. The procedure can be illustrated by multiplying 132 by 5, for example (see Box, equations 1), in which multiplication of 132 by integers less than 5 (some distinguished with an arrow) are written on the left of the equations. The quantity 5 is expressed as  $4 + 1$  (this is the significance of the arrows), and then the items on the right side are added; *i.e.*,  $5 \times 132 = (528 + 132) = 660$ .

The process of expressing a number (for example, 5 above) as a sum of powers of two (numbers of the form  $2^n$ , in which  $n$  is an integer) is readily accomplished from a listing of the powers of two with values less than the given number.

Division is accomplished by repeatedly doubling the divisor. This procedure may be illustrated by dividing 2028 by 39. Again, the calculation is expressed with equations (see 2), on the left of which are products of powers of 2 times 39. In this example, 39 is the divisor and doubling has been continued up to the point at which the next result would be greater than the dividend, which is 2028. It is now possible to express 2028 as the sum of the dashed terms on the right-hand side. Thus (see 3) the dashed (or especially marked) terms involve 32, 16, and 4 as multiples of 39. The answer is 52. If the divisor were not exact, there would be an additional fraction.

The use of two as the base of the powers in this procedure is quite efficient, and, if some other quantity were used, multiples would be required that were not simply powers of the quantity. For example, if three were used instead of two more than powers of three would be needed (see 4).

This procedure for multiplication and division persisted

a long time and became obsolete only when most people received childhood training in forming multiples of a given number by the digits one to nine. If  $p$  is such a digit, shifting the decimal point will yield  $p 10^r \times N$  from the multiple of  $N$  by  $p$ . The modern division process chooses such an expression involving the divisor  $N$  and subtracts it from the dividend, without writing out or even obtaining multiples of  $N$ , which would not be used. In the example (2),  $1 \times 39$ ,  $2 \times 39$ , and  $8 \times 39$  are used only in the formation process.

On the other hand, the procedure using the powers of two can be effectively aided by a table of doubles. Thus the only other capabilities required are those of adding (or subtracting) and comparison, and the notation described can handle these latter operations.

Fractions, as often required by the Egyptian method of division, were dealt with as follows. Fractions with a numerator greater than one could only be expressed in terms of those with numerator equal to one (see 5). The sum of two fractions in this form, however, can be obtained by using a table that expresses a fraction with numerator two as a sum of fractions with numerator one. This is also true of the product of two fractions in the given form, and any numerator can be expressed as a sum of powers of two. One such table, which appeared in a manuscript written before AD 800 (the Akhmin papyrus), used a formula for  $2/pq$  (see 6), in which  $p$  and  $q$  are odd. There is also a relation for  $2/(2p + 1)$  (see 7), in which  $p$  may be either odd or even.

$$(2) \quad \left\{ \begin{array}{l} 1 \times 39 = 39 \\ 2 \times 39 = 78 \\ 4 \times 39 = 156 - \\ 8 \times 39 = 312 \\ 16 \times 39 = 624 - \\ 32 \times 39 = 1248 - \end{array} \right.$$

$$(3) \quad 2028 = 1248 + 624 + 156 = (32 + 16 + 4) \times 39 = 52 \times 39$$

$$(4) \quad 2 \times 3^r \times N, \quad 3^r \times N$$

$$(5) \quad \frac{5}{9} = \frac{1}{3} + \frac{1}{5} + \frac{1}{5}$$

$$(6) \quad \frac{2}{pq} = \frac{1}{q \binom{p+q}{2}} + \frac{1}{p \binom{p+q}{2}}$$

$$(7) \quad \frac{2}{2p+1} = \frac{1}{p+1} + \frac{1}{(p+1)(2p+1)}$$

**Other ancient notations.** Originally the Roman numeral system seems to be similar to that of the Egyptians except that it had a biquinary character. Thus, while the Egyptian notation had symbols for the powers of 10, the Romans had symbols I, V, X, L, C, D, M for 1, 5, 10, 50, 100, 500, 1,000. The indicated aggregations therefore are first by fives, then two fives to make ten, then five tens to make fifty, then two fifties to make a hundred, and so on. Some compactness was achieved by using a subtractive notation; *e.g.*, IX for nine instead of VIII.

The Babylonians used at least two systems for expressing numbers. One of these was decimal, the other sexagesimal, with base 60. There were symbols for the digits, ten, and one hundred, but the quantities that appeared in a single decimal place were expressed by multiplication; for example, 40,000 would be expressed by a sequence of symbols for 4, 10, 10, 100, which was interpreted  $4 \times 10 \times 10 \times 100$ . The sexagesimal system apparently was written as a simple place system, the place on the extreme right being for units and the next for

The Babylonian system

multiples of sixties. Both of these systems were handicapped by the lack of a zero symbol.

The Babylonians (about two millennia BC) divided the circle into 360 degrees, the degree into 60 minutes, and the minute into 60 seconds. Similarly, the day was divided into 24 hours and the hour into minutes and seconds. Associated with this was a tendency to use fractions with a fixed power of sixty as a denominator. The largest such denominator appears to be  $60^4$ , a number that was considered to have mystical significance. Division tables were constructed for those divisors that could be precisely expressed in the notation.

Greek and Chinese notation

Greek astronomers in the 2nd century AD started to use sexagesimal fractions both to record observations and to construct trigonometrical tables, a practice that was continued until the 16th century. The Greeks also used a decimal system that was based on using the alphabet to denote the digits (see 8), the integral multiples of ten (see 9), of 100 (see 10), of 1,000 (see 11), and of 10,000 (see 12). This number system persisted in the place entries in the sexagesimal tables used in Ptolemaic astronomy. The Hebrews also used a system analogous to this.

The Chinese had a place system in which the symbols for successive places were obtained by a rotation of the symbols for the digits. Thus if |, ||, ||| stood for 1, 2, 3 in the units place, —, =, ≡ would stand for 10, 20, 30 in the tens place, whereas |, ||, ||| would stand for 100, 200, and 300 in the hundreds place.

**Decimal notation.** The major difficulty with all these notations is their lack of compactness. The present decimal system with its place value requiring the use of zero was adapted by the Arabs from Hindu (Indian) sources in the 9th or 10th century. Hindu mathematics appears to have arisen from Babylonian and Hellenistic sources and to have been subject to Chinese influence. Indian interest in astronomy and computation, however, resulted in the development of the convenient place system with zero from an earlier native system using nine symbols and names for the powers of ten.

During the 10th century, Roman numerical procedures were reintroduced in western Europe. This was a development due to a churchman, Gerbert, who discovered a copy of the geometry of the 6th-century Roman philosopher and statesman Boethius. He also described the use of the Roman abacus, a calculating device using movable counters. About a hundred years later, a tremendous interest arose in those treasures of Hellenic classical knowledge, which were known to the Arabs and which were made available by translation from Arabic. As part of this process, Leonardo of Pisa (*q.v.*; Fibonacci) published in 1202 an account of Arabian mathematics and advocated the Arabic notation, involving place calculation with the zero. Italian merchants quickly adopted this system, which seems to have become reasonably widespread in Europe by 1300 but not particularly well accepted in learned circles. The formal procedures of com-

(8)	$\begin{cases} \alpha & \beta & \gamma & \delta & \epsilon & \zeta & \eta & \theta \\ 1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 & 9 \end{cases}$
(9)	$\begin{cases} \iota & \kappa & \lambda & \mu & \nu & \xi & \omicron & \pi & \rho \\ 10 & 20 & 30 & 40 & 50 & 60 & 70 & 80 & 90 \end{cases}$
(10)	$\begin{cases} \rho & \sigma & \tau & \upsilon & \phi & \chi & \psi & \omega & \aleph \\ 100 & 200 & 300 & 400 & 500 & 600 & 700 & 800 & 900 \end{cases}$
(11)	$\begin{cases} \alpha & \beta \\ 1,000 & 2,000 \end{cases}$
(12)	$\begin{cases} & \beta \\ M & M \\ 10,000 & 20,000 \end{cases}$

mercial arithmetic, such as simple and compound interest and discount, were developed in this period by the Florentine merchants.

Decimal fractions appeared at first in a somewhat specialized form. It took a considerable time to develop a full appreciation of the fact that the decimal notation permitted both the integral and fractional part of a number to be handled in the same way arithmetically. Decimal fractions were described by Simon Stevin of Bruges in Belgium in 1585 and were used by a number of others. The notation used was relatively clumsy in most instances, and universal European use of the decimal point occurred only in the first quarter of the 18th century. With this came the standardization of today's arithmetical procedures for long division and for extracting the square root (see ARITHMETIC).

For integers, the decimal system is such that each place is treated in a similar way in addition, subtraction, multiplication, and division in which the quotient is integral. For division, in general, it is necessary to use decimal fractions, and by allowing recurring decimals it is possible to obtain a complete description of rational numbers (numbers that can be expressed as integers or as the quotient of integers) and the operations on them.

(13)	1010, 1110, 1001

(15)	$(5 \times 8^3) + (3 \times 8^2) + (5 \times 8) + (1)$
(16)	$5.13 \times 10^{10}, -2.76 \times 10^{-8}$

**Modern notational developments.** The uniformity of the decimal place system permitted the development of mechanical calculators. Electronic devices, however, are most conveniently constructed to use the base two rather than ten. A number expressed in base two, however, is difficult to interpret and it is necessary either to translate into the decimal system or to use an octal (base eight) or hexadecimal (base 16) system. For example (see 13), the binary expression for the number 2793 is actually a shorthand for the coefficients multiplying the appropriate powers of 2 (see 14), but one may express it octally by grouping this expression into threes—101, 011, 101, 001—and interpreting each group as an octal digit. Octally the number is 5351, as can be found by multiplying the digits in this expression by powers of 8 and adding (see 15).

When exceedingly large or small quantities occur, it is convenient to introduce the floating point notation. A positive quantity can be expressed as a number between one and 10 multiplied by a power of 10. Examples are easily constructed (see 16).

An alternate to the floating point notation has been developed in the form of prefixes. One of these prefixes, when applied to a unit, will describe a new unit with a value that is a power of 10 times that of the original unit. For example, kilo is the prefix associated with  $10^3$  so that a kilometre (km) is a unit of a thousand metres. The internationally adopted set of metric prefixes are those shown below:

tera (T),	$10^{12}$	centi (c),	$10^{-2}$
giga (G),	$10^9$	milli (m),	$10^{-3}$
mega (M),	$10^6$	micro ( $\mu$ ),	$10^{-6}$
kilo (k),	$10^3$	nano (n),	$10^{-9}$
hecto (h),	$10^2$	pico (p),	$10^{-12}$
deca (da),	10	femto (f),	$10^{-15}$
deci (d),	$10^{-1}$	atto (a),	$10^{-18}$

**GEOMETRICAL AIDS**

**Applications of geometry.** Egyptian geometry was primarily constructive. It enabled straight lines to be laid out and measured and allowed for the construction of perpendiculars. The sides of the Great Pyramid, built about 2700–2300 BC, agree in length to within 0.01 per-

cent, and the angular errors of the corners do not exceed 12 seconds of arc.

The development of mathematics as a logically structured science occurred in the century or two before Euclid, between 500 and 300 BC. This mathematics permitted a better formulation of geographical and astronomical information as is evidenced by a considerable increase in understanding of these subjects. Aristotle (350 BC), for instance, described the Earth as spherical, and it was customary to assume that the fixed stars were on a larger sphere that rotated once a day, around an axis approximately through the North Star. The seven heavenly bodies, the Moon, Venus, Mercury, Sun, Mars, Jupiter, and Saturn, were described as moving between these. These motions were described mathematically. In the system of the 4th-century-BC Greek astronomer and mathematician Eudoxus of Cnidus (*q.v.*) a body was carried on the equator of a rotating sphere with a system of other rotating spheres, all of which were concentric with the Earth. In the system of the Greek astronomer Ptolemy (about AD 150), a body was believed to move in a circle the centre of which moved on a geometric circle. There were variations of these ideas that were regarded as empirical approximations.

These ideas, however, generated a considerable interest in trigonometry (see GEOMETRY, ANALYTIC AND TRIGONOMETRIC) and in particular in spherical trigonometry. Hipparchus (born 180 BC) worked out a table of chords as functions of angles and dealt with the theory of the projection of a sphere onto various planes, as, for example, the stereographic and gnomonic projections.

A number of estimates of the radius of the Earth were made in ancient times, the most famous of them being that of the Greek scientist Eratosthenes (flourished 3rd century BC). At the summer solstice, the Sun was directly overhead at Syene, a city in the south of Egypt, and had a meridian angular distance from zenith, at Alexandria, as determined experimentally by Eratosthenes, of 0.02 of a full circle. He assumed that these points were on the same meridian and thus the latitude difference was  $7^{\circ}12'$ . The distance between the points was measured by professional pacers, and Eratosthenes concluded that the diameter was about 7,850 miles—about 76 miles less than the equatorial diameter as measured by modern methods.

Greek mathematics was limited in a number of ways and there were problems that they could not solve within their original frame of reference. They did, however, invent procedures that foreshadowed later mathematical developments, in particular, the infinitesimal calculus. Thus the problem of duplicating the cube was solved mechanically by Archytas (428–347 BC) and the curve of Hippias, which required a continuous mechanical construction, was used to trisect angles and “for squaring the circle.” Archimedes used his knowledge of the mechanical principle of the lever to obtain heuristic evaluations of areas such as that bounded by an arc of a parabola and the corresponding chord. These evaluations were then justified by the method of exhaustion. Archimedes' mental model of the cylinder in relation to the sphere and the cone (Figure 1) is an early example of the value of the model in abstract thinking.

**Instruments for observation and navigation.** The value given by Ptolemy for the distance to the Moon was correct to about 3 percent, but the crude procedures for measuring angles used by the ancients yielded solar system distances that were far too small. The meridian line at an observatory could be obtained by a plumbline (the line determined by a string supporting a weight) and line of sight of the North Star. This method could also be used for surveying land. The azimuth (angular position on the horizon) of a body as it rose or set could be obtained by line-of-sight angle measurements relative to a horizontal circle. Zenith angular distances were obtained by a device called a quadrant, a representation of a quarter circle with a movable arm pivoted at the centre along which the observer could sight. In use, the quadrant was suspended in a vertical plane, and the object, the zenith angular distance of which was to be observed, was sighted along the movable arm. The quadrant then indicated the

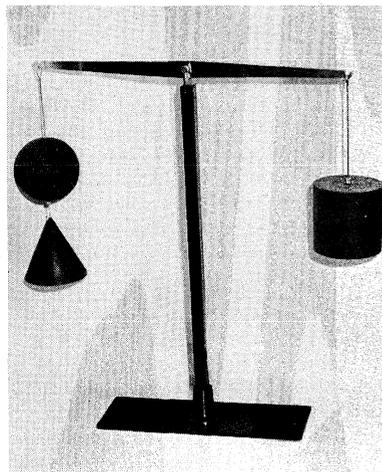

Figure 1: Model of Archimedes' theorem, showing how a balance of physical masses is used to motivate the formulation of or verify the truth of a famous mathematical relationship between the volumes of a sphere, a cone, and a cylinder.

By courtesy of the Museum of Science and Industry, Chicago

angular difference between this arm and a plumbline direction. Another ancient instrument was the planisphere, a disk with a scale of angle measure marked on its rim and having a sighting arm pivoted at its centre.

Optical instruments based on the telescope, however, were needed to obtain angular measurements precise enough to yield correct ideas concerning the size of the solar system. These devices were introduced in the early part of the 17th century and were associated with the acceptance of the concept of the solar system in which the Earth and other planets move around the Sun. This was first suggested by the Polish astronomer Nicolaus Copernicus in 1543. For navigation purposes, the horizon is a more convenient reference than a plumbline, and the sextant was invented by Thomas Godfrey of Philadelphia in 1730 to measure angular height above the horizon, which is complementary to the zenith angular distance of an object.

The sextant determines the angle of elevation of an object. Figure 2 indicates a cross section of the instrument when held vertically. A sighting telescope  $T$  is aimed at the half-silvered piece of glass,  $H$ , which permits one to view the horizon through it and establish the instrument in a vertical plane. The component  $H$  is mounted at an angle to the line  $HT$  so that the point  $I$  is reflected in the mirrored half of  $H$  into the telescope. An upper mirror is mounted on an axis, through  $I$ , perpendicular to the plane of the diagram and has a pointer to indicate a reading on the scale  $OG$ . When the plane of the upper mirror is parallel to that of  $H$ , a point on the horizon,  $A$ , will be reflected at  $I$  to  $H$  and then to  $T$ , and the pointer indicates 0 on the scale  $OG$ . If the upper mirror is rotated through an angle  $x$ , the normal (perpendicular)  $n$  to the upper mirror makes an angle  $\phi + x$  with  $IH$  and thus the point  $S$  will be reflected at  $I$  to  $H$  if  $SI$  also makes the angle  $\phi + x$  with  $n$ . Thus the angle  $SIH$  has the value  $2\phi + 2x$ , and because  $AIH$  has the value  $2\phi$ , then  $SIA$  has the value  $2x$ .  $SIA$ , however, is the angle of elevation of  $S$ ; hence its value can be read on the scale  $OG$ , which is calibrated to show  $2x$ . The maximum range of the scale  $OG$  corresponds to  $x = 60^{\circ}$  of arc—i.e., a sixth of the circle—hence the name sextant.

Astronomical assistance to navigation is based on the use of ephemeris information. For a given celestial object, say, a star, the ephemeris is the location, as a function of time in latitude and longitude, of the point on the Earth's surface for which the object is at zenith. The navigator uses the sextant to determine the angle of this object with the zenith. This determination yields the location of his vessel on a small circle of the Earth the centre of which is the ephemeris point and the angular radius of

Limitations of Greek mathematics

which is the observed zenith angle. The procedure is to obtain two such position circles and the appropriate intersection by graphical means on a chart. The ambiguity is resolved by using dead reckoning (estimation), and further geometrical adjustments may be necessary if the observations are not simultaneous. This procedure illustrates the importance of ephemeris tables and a precise determination of time. These tables required a tremendous amount of calculation and to a degree are responsible for the association of astronomy with calculation.

**Mapping.** There are two aspects of the problem of mapping. One of these is to indicate the longitude (the angular distance between the points of the equator intersected by the meridians through Greenwich and the point in question) and latitude (the deviation of the visible celestial pole) of points of interest. The second problem is to establish the topography; *i.e.*, the height above sea level. The first problem is that of mapping an ideal sphere onto a plane surface. There can be no such map that preserves all distances, but there are maps that permit geometrical constructions of use in the trigonometry of the basic sphere. A specific application, however, may require more than one map.

For example, to plot a ship's course or an airplane's course between two points on the Earth, the arc of the great circle joining the two points is found and divided into smaller segments, each of which can be efficiently approximated by a course in which a constant angle or bearing is maintained with the northern direction. This is known as a rhumb line course.

Gnomonic maps

To obtain great circle courses, a gnomonic map may be used. This map is a projection of the sphere from its centre onto a tangent plane. If the point of tangency is the north pole, then the meridians are mapped onto lines radiating from the pole, and the circles of latitude are

mapped onto concentric circles; these two families will yield a coordinate network for the plane. The value of the gnomonic map lies in the fact that the arcs of great circles on the Northern Hemisphere are mapped onto straight lines in the plane. This correspondence can be seen by intersecting planes through the centre of the sphere with the hemisphere and with the tangent plane. Thus the great circle course between two points on the hemisphere can be plotted by taking the two image points on the plane and drawing the straight line through these points. This permits the latitude and longitude of the division points on the course to be obtained. Similarly, a rhumb line course can be obtained from a Mercator map. This map, named after Gerardus Mercator, a Belgian mathematician and geographer, who first published the map in 1568, represents longitude as the abscissa (horizontal axis); the ordinate (vertical axis), however, is a function of latitude chosen so that straight lines correspond to rhumb line courses on the sphere. It is possible to obtain distances along a rhumb line course by a relatively simple approximate procedure.

Other projection maps can be used to solve triangles in spherical trigonometry. There are maps that yield good approximations for distances that are relatively small and good angular information for polygons of small diameter. Two such types are the Lambert conical projection and the polyconic maps of the United States Coast and Geodetic Survey.

Modern procedures for topographical mapping are based on aerial photography and the determination with great accuracy of specified reference points. The aerial photographs overlap and a stereo-optical system, a technique of photogrammetry, can position these so that one has a model of the topography and the overflight on the scale of the photographs. Measurements on the photographs and trigonometry can be used to determine heights. This system, involving the stereo-optical positioning of the photographs and measurements, was replaced in the 1960s by the digital analysis of photographs using electronic photodetectors and a computer.

**Spherical trigonometry.** Modern spherical trigonometry is based on a set of formulas analogous to the formulas of plane trigonometry. Plane trigonometry is based on certain geometrical relations for solving the triangle with sides  $a, b, c$  and opposite angles  $A, B, C$ . These relations are the law of sines (see 17) and three relations in the form of generalized Pythagorean theorems (see 18) applying to non-right triangles. In a spherical triangle, the sides  $a, b,$  and  $c$  are arcs of great circles and can be measured by the angles subtended at the centre. The radian measure of these angles would correspond to the length of the arc, if the radius had unit length. There are corresponding relations in the spherical case (see 19).

In both the planar and spherical case, the basic trigonometric identities are used to transform these formulas into forms suitable for the use of logarithms (see ARITHMETIC). Because tables of high accuracy are available, they permit astronomical problems to be accurately solved. The development of this form of trigonometry occurred in the 17th and 18th centuries.

Some of the possible geometrical approaches to spherical trigonometry were given by Ptolemy. One procedure was to perform a rotation so that a desired angle could be constructed in a specified plane and thus be obtained by plane geometry. Another method was to map the sphere onto a plane by a projection that takes circles into circles or into curves that can be plotted effectively. An impor-

$$(17) \quad \frac{a}{\sin A} = \frac{b}{\sin B} = \frac{c}{\sin C}$$

$$(18) \quad c^2 = a^2 + b^2 - 2ab \cos C$$

$$(19) \quad \frac{\sin a}{\sin A} = \frac{\sin b}{\sin B} = \frac{\sin c}{\sin C}$$

Nomographic projection

tant example of this is the stereographic projection in which the sphere is projected from its south pole onto the equatorial plane.

The gnomonic projection of the sphere and the stereographic projection have been mentioned. A third type, the nomographic projection, is given by projecting a hemisphere on its basic plane by lines perpendicular to the base. The radius of the hemisphere is taken to be one. Given a point  $P$  on the base circle of the hemisphere, certain great circles of the hemisphere will pass through  $P$ . If the plane of such a circle makes an angle  $\alpha$  with the base plane, the circle is projected on an ellipse with major axis vertex at  $P$  and minor axis  $\cos \alpha$ . The small spherical circle with centre  $P$  and radius  $\beta$  is projected on a straight line perpendicular to the radius for  $P$  and at a distance  $(1 - \cos \beta)$  from  $P$ . Given  $P_0$ , a representation of the basic circular disk can be obtained in which these two sets of projected curves are used as coordinate lines. It is convenient to mark the angle  $\beta$  along the circumference of the disk. A transparent overlay for the disk may also be prepared with a representation of a similar coordinate system with origin designated  $Q$ .

This combination of disk and overlay with their coordinate systems permits the solution of spherical triangles graphically. For example, the side  $a$  and the angles  $\beta$  and  $\gamma$  are given. The overlay is placed relative to the disk so that the arc  $QP_0$  has the value  $a$ .  $QP_0$  is taken to correspond to the side  $BC$  of the triangle. For the overlay, at  $Q = B$ , the elliptic arc is chosen corresponding to  $\beta$  and at  $P_0 = C$ , the elliptic arc is chosen corresponding to  $180^\circ - \gamma$ . The arc  $QP_0$  and portions of these two arcs correspond to the projection of a spherical triangle with side  $a$  and angles  $\beta$  and  $\gamma$ . The intersection of the two elliptical arcs is the projection of the remaining vertex of the desired triangle, and the other coordinates will yield the lengths of the sides  $c$  and  $b$ . A similar construction will yield, given three sides, two angles of a spherical triangle.

**Stereographic projections and the astrolabe.** The stereographic projection can be applied to the celestial sphere of the fixed stars, which appears to revolve around the North Star once a day. A stereographic mapping is taken of this celestial globe on its equatorial plane. During 24 hours, each star traces a circle on this map, and if the position is marked for each hour, a 24-hour clock is produced. Different stars will have different longitudes at the same time so that the markings will have different orientations. Furthermore, because the Sun advances on the celestial sphere one revolution per year, the set of markings for each star must uniformly rotate so as to make one complete revolution a year. For one night, however, the markings can be considered as fixed.

To read this clock, an instrument like a quadrant is used and the zenith angle of the star is determined. The zenith angle determines a spherical circle around the zenith. This circle is projected onto an ellipse in the equatorial plane by the stereographic projection. The star is then on the intersection of the ellipse and the polar circle, which is the projected path of the star. Such intersections are usually found by having one set of curves on a chart and the other set on a transparent overlay.

The stereographic projection is also the basis of the astrolabe. In its simplest form, this instrument can be regarded as consisting of two disks. The basic disk, called the mother, has a representation of the stereographic projection of geometric aspects of the sphere of the observer such as

1. The direction lines: north, east, south, and west.
2. Various circles of latitude, particularly the celestial equivalent of the Tropics of Cancer and Capricorn and the Equator.
3. The projections of the zenith circles, corresponding to number of degrees. These projections are called Almicantaras and are dependent on the latitude of the place at which the astrolabe is used. The largest of these corresponds to  $90^\circ$ ; i.e., the horizon.
4. The projections of 24 equally spaced great circles through the zenith, the azimuths.

Other geometric curves are also on the mother, but these are typical. The reverse side of the mother was usually

arranged as a planisphere with a sighting arm to permit angular measurements.

The second disk, the rete, also called the spider web, is attached to the mother by a pin so that it can rotate around the north pole. It is a stereographic projection of the celestial sphere at an instant of time. It contains the projection of the ecliptic circle and the zone of the zodiac with the constellations and their limits. The rete offered an irresistible space on which to engrave fanciful astrological figures.

The astrolabe can be used in many fascinating ways, but basically the instrument represented the relationship in time between the celestial sphere of the Sun and stars and the Earth's fixed local directions of north, east, west, south, up, and down. For example, if the date and the time of day are known, the position of the various heavenly bodies can be found. On the rete is a pointer, the label, which can be adjusted so that its edge corresponds to the position of the Sun on the ecliptic circle. The label is then held fast relative to the rete and the edge of the label will correspond to 12 noon if it is along the northern direction. The edge of the label can then be considered as the hand of a 24-hour clock and the combined rete and label is rotated until the edge of the label indicates the time of day. Any indicated star is the position of a fiducial mark on the rete, and its position in azimuth and zenith angle can be read from its position on the mother. Conversely, the label can be set for the current date and either the zenith angle or azimuth of a star (or the Sun) can be observed. The rete can then be rotated until the star representation is in the observed position; the edge of the label will then indicate the time of day.

The procedure of obtaining the location of a star on the stereographic map has another application inasmuch as a position on the star circle can be considered as determining the sum of the longitude and the time within the sidereal, or star, day. If the time is known, this will yield the longitude.

Other antique instruments that are associated with Ptolemaic astronomy are the armillary sphere, which contains a simplified model of the Ptolemaic solar system, and the torquetum, which contains a sighting arm mounted on the equivalent of the equatorial mounting, permitting measurements of latitudes and longitudes on the celestial sphere.

**Optical instruments.** Geometry was used initially for terrestrial measurements, such as the height of towers and the distance of ships off shore, either by the trigonometric tables or by similar triangles. The astrolabe had a U-shaped rule to permit the use of similar triangles to determine heights. The use of the telescope to establish accurately a line of sight permitted the development of instruments to measure angles more precisely. Another advance was the use of the vernier, invented in 1631 by a French mathematician, Pierre Vernier, which permits an accurate interpolation between the marks on a graduated scale. The standard surveying instrument is the theodolite (transit), which consists of a telescope mounted so that angles of azimuth and elevation can be obtained. A modern development is the use of a telescopic camera to permit fast observation and improved accuracy.

For small angles, which are of considerable interest in astronomy, a number of hairline optical instruments were developed, which were supplemented later by photographic procedures. To assist navigation, observatories correlate the celestial longitude with time. The transit telescope, a telescope mounted so that it can rotate only in the meridian plane, is used to determine the instant at which a given star passes the meridian. To correlate with modern timekeepers, other photodetectors can be used to note the instant the star is dimmed by the hairline. In another system, interpolation is used in a series of photographs.

The equatorial mounting for a telescope has a basic axis parallel to the axis of the Earth and a rotating axis perpendicular to this basic axis. This mounting permits measurement of celestial longitude and polar distance or their use to position the telescope. The vertical circle, the modern descendant of the astrolabe, will yield zenith angular

The astrolabe

The vernier

distances and is equivalent to mounting a transit telescope on a vertical axis. There is an analogous type of device for measuring azimuths.

**Drawing instruments.** Drawings and diagrams are plane geometric figures that are used for a variety of purposes. Correspondingly, the family of drawing instruments has been developed: pens, straight edge, graduated rule, a variety of compasses for different size circles, T-squares and triangles to draw lines at given angles to one another, dividers to transfer lengths, and French curves to draw curves in a smooth fashion. In addition, the hinged quadrilateral for drawing parallel lines, the pantograph to reproduce figures on a different scale, the ellipsograph to draw ellipses based on the sum-of-distances property, and protractors all facilitate drawing. A number of these instruments are also combined into multiple function drafting machines.

So-called mechanical-drawing engineering (see DRAFTING) uses cross sections, drawings or diagrams showing materials by a code of cross hatching and cross section shapes. Such drawings show the appearance of the objects as seen from a single viewpoint. Geometrically, a drawing is a projection of the object from the point of view onto a plane not containing a line of sight. The theory of such drawings is developed in the discipline entitled descriptive geometry, which is significant not only for engineering and architecture but also for the arts of painting and sculpture. The use of perspective, a valuable technique for painting from the Renaissance on, was based on geometric principles formulated in the early 15th century by Brunelleschi, a Florentine architect.

(F.J.M.)

#### MATHEMATICAL MODELS

In general, the purpose of a mathematical model is to aid or simplify the description of mathematical ideas. Many mathematical models are three-dimensional equivalents of mathematical relationships that cannot easily be understood or conveniently expressed in symbolic form. Models are seldom used in mathematics to prove hypotheses, although they may serve to open up new channels of thought by clarifying difficult concepts.

**Construction of models.** The methods of construction of mathematical models depend very much upon the purpose for which they are required. Models in which only the external structure is to be examined can be made from opaque materials such as cardboard, wood, plaster, etc. If, however, internal structure is to be investigated without dismantling the model, the external surfaces will necessarily be made of transparent materials such as glass or clear plastic. Alternatively, they can be represented by wire, or, as in the case of ruled surfaces (formed by the motion of a straight line), by a network of stretched threads. This latter method of construction can be used, for example, to illustrate the different sections of a cone. The curved surface of the cone can either be made of a transparent material or, more simply, by a series of threads from apex to base depicting generators in the curved surface.

Solid wooden models can be constructed so that they dismantle along certain sections chosen for study (Figure 3). Sectional properties, other than general shape, include such things as area, degree of symmetry, similarity with other sections, curvature, etc. This method of construction can also be used to show how a particular solid shape may be formed from a number of smaller units. Shapes that are symmetrical about any axis can, in general, be formed by turning a block on a lathe, the surface profile being checked at intervals with a template until the final shape is produced. These can then be used as templates for molding plaster or metal replicas if required. Non-symmetrical shapes are more conveniently formed using wire skeletons or by slotting together a cross-grid of cardboard templates, the profiles of which represent the corresponding sections of the solid shape. The more closely spaced these templates are with respect to the size of the solid, then the greater is the definition of the external surface. Surfaces represented by an orthogonal grid (grid composed of curves that intersect only at right angles) of this

Figure 3: Conic sections shown in an expanded wooden model of a cone that is cut along four planes. The intersections of the planes with the surface of the cone define, from top to bottom, cases of the circle, the ellipse, the parabola, and the hyperbola.

type are particularly useful for modelling quantities that are always mutually perpendicular, such as equipotentials and flow lines, which are to be found in many branches of physics.

Models may be constructed also by the use of computer graphics (see below), in which surfaces are composed of lines or dots and viewed stereoscopically to give the illusion of three dimensions. The technique is particularly useful when a mathematical configuration is animated (e.g., the representation on three dimensions of a rotating, four-dimensional figure).

**Simple polyhedra and the sphere.** A polyhedron is a solid shape the surfaces of which consist of polygonal faces; i.e., planes with three or more edges. By a simple polyhedron is meant a polyhedron with no holes in it. Such a surface could be transformed continuously into the surface of a sphere. The 18th-century Swiss mathematician Leonhard Euler was the first to discover that for a simple polyhedron, if the number of faces be designated

Computer models

## The five Platonic solids

by  $F$ , edges by  $E$ , and vertices by  $V$ , then the following relationship always holds:  $V - E + F = 2$ . For large polyhedra of this type, it is difficult to verify this property by counting  $F$ ,  $E$ , and  $V$  from an isometric drawing (*i.e.*, a nonperspective projection), whereas the task is made much easier by using a model. By experimenting with such models, it can also be shown, as was known to the abstract thinkers of Plato's time, that there are only five regular polyhedra (the faces of which are all congruent and the angles at the vertices are all equal), namely, the cube, tetrahedron, octahedron, icosahedron, and dodecahedron (see Figure 4). These polyhedra are called the five Platonic solids.

Solid models of the sphere can be used to clarify such concepts as spherical triangles and geodesic lines (shortest arc between any two points on the surface), while wire skeleton models of a sphere may be used to study navigation problems on the surface of the Earth, angles of latitude and longitude being measured between elastic threads appropriately positioned on the model (see Figure 5).

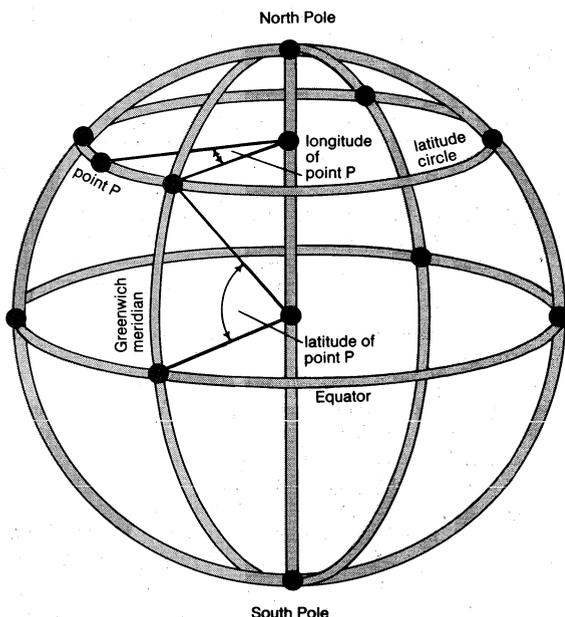

Figure 5: Wire skeleton model of a sphere used to study navigation problems on the surface of the Earth (see text).

**Descriptive geometry.** Models for use in descriptive and projective geometry find much application as teaching aids. Three-dimensional trigonometric problems present much difficulty to the average school pupil even when well-drawn diagrams are provided. A model has the advantage that any desired viewpoint may be obtained by a simple rotation of the model into the required position so that the angles and lines concerned at any step in the problem may be easily isolated from the others. Line segments are represented by elastic threads stretched across rigid reference planes, which are usually chosen to be mutually perpendicular but do not necessarily form part of the constructed figure. For certain purposes, as when projecting from one plane to another, it is useful to represent planes by plates of clear plastic hinged along their line of intersection.

**Models that illustrate identities.** Wooden cubes (blocks) are often useful to represent units of quantity, particularly to young children. Apart from the idea of number, such cubes can also be used to demonstrate such concepts as area and volume. For instance, if it were desired to demonstrate geometrically that  $3^3 = 27$ , then a large cube of edge-dimension three units would be constructed and this would require 27 unit cubes. Alternatively, the same technique can be used to illustrate how the volume of any cuboid (*i.e.*, similar to a cube in having edges mutually at right angles, but not all of the same length) is calculated from its edge dimensions. Blocks can also be

used to verify more involved identities such as the cubic identity for real values of two numbers  $a$  and  $b$  (see 20). This may be verified for positive values of  $a$  and  $b$  by arranging together a set of wooden cuboids the volumes of which are described on the right-hand side of this identity in such a way as to construct a large cube of edge dimension  $(a + b)$  units. This model is better known as the binomial cube. When it is required to compare or verify the volumes of certain geometrical figures, it is also possible to use hollow shapes with an open face so that water may be decanted from one shape to another so as to provide a measure of volume. This method may be used, for example, to show that the volume of any pyramid is equal to one-third that of a prism with the same base area and vertical height.

$$(20) \quad (a + b)^3 = a^3 + 3a^2b + 3ab^2 + b^3$$

$$(21) \quad z^2 = 1 - x^2 - y^2$$

**Topological models.** Topology is a branch of geometry concerned with general transformations of shapes in which a certain correspondence between points is preserved. A general form of topological transformation is a deformation. Deformations can be shown conveniently using models of pliable materials such as clay or malleable plastic in which a basic shape may easily be molded into other shapes that are topologically equivalent; *i.e.*, having the same number of holes in the solid or the same degree of interlocking as the original.

Another field of topology that can be investigated using models concerns itself with one-sided surfaces. The simplest of such surfaces, named after its discoverer, the 19th-century German August Ferdinand Möbius, is known as a Möbius strip (Figure 6). It can be formed by pasting together the ends of a rectangular strip of paper after giving one end half a twist. By cutting such a strip along its centre line, it is found that a single strip is formed with a two-sided surface.

Another rather interesting one-sided surface, on which it is possible to move from the inside to the outside without crossing a boundary, is known as the Klein bottle, which is named after the 19th–20th-century German mathematician Felix Klein.

The Möbius strip

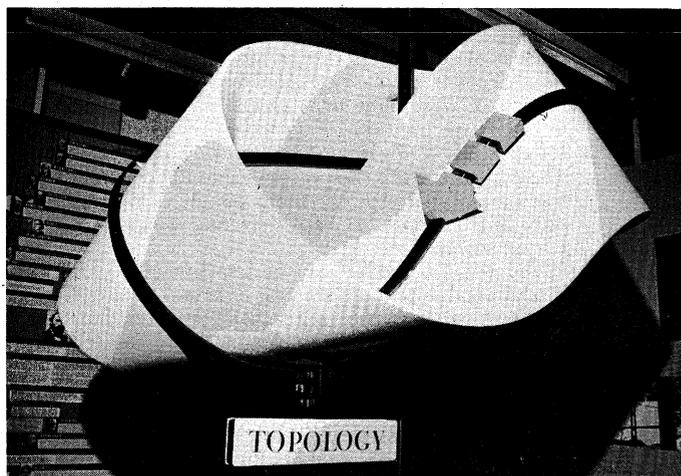

Figure 6: Möbius strip model on which is an electrically controlled car. The motion of the car traces a closed path over the entire surface, without crossing a boundary, illustrating a basic topological property.

**Surface models.** Mention has already been made of the various ways in which surfaces may be represented. Elastic threads can be usefully employed for representing ruled surfaces, as for example, hyperboloids of revolution. If the boundary discs of such a model are constructed so as to rotate relative to one another, then a dynamic

surface can be obtained, which passes from the curved surface of a circular cylinder to the limiting position of a double cone, intermediate positions giving various hyperboloids of revolution. Vertical threads stretched across horizontal bars that rotate relative to one another along a central vertical axis generate hyperbolic paraboloids. Thread models can be used for the most varied and beautiful surfaces (Figure 7).

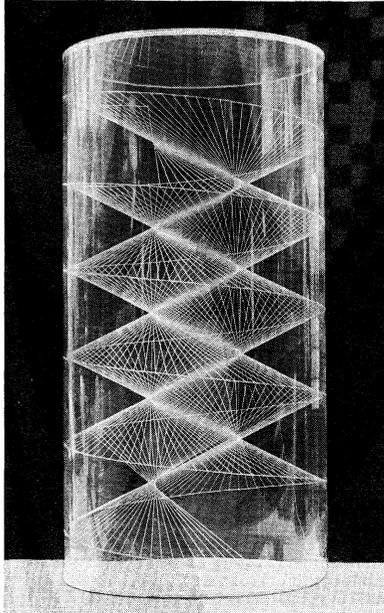

Figure 7: *Thread model of a surface.* The surface is generated by stretching threads tightly from segment to segment of a wire frame that is held in the form of a helix by a plastic cylinder.

Wooden models may be more generally used to illustrate the shapes of solids formed by the revolution of simple curves (those that do not intersect themselves) about any chosen axis. In addition to these solids of revolution, this form of model can also be used to construct three-dimensional graphs of functions defined by two independent variables. The surfaces of such graphs

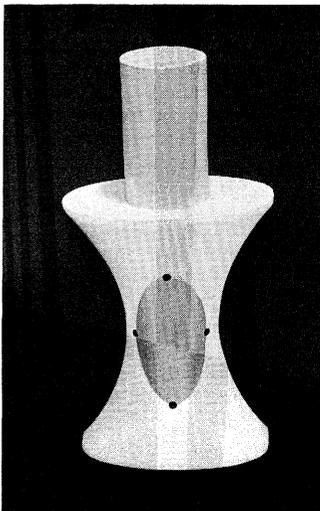

Figure 8: *Stationary points on a model of the intersection of a cylinder with a hyperboloid.* From the model it can be deduced that there are exactly four points (two not visible) on the intersection of the two surfaces that are nearest the centre of symmetry, and four points that are farthest.

are known as quadric surfaces, as, for example, the surface of a unit sphere, which may be defined with reference to the three orthogonal axes  $x$ ,  $y$ , and  $z$  (see 21). Points common to two or more quadric surfaces can be deduced from models (Figure 8). Examples of less symmetrical quadric surfaces include topographical maps and three-dimensional graphs of certain physical functions such as the relationship between volume, temperature, and pressure for a fixed mass of gas.

Many minimal surface problems may be demonstrated using wire models and soap films. One classic example of this is concerned with the solution of a problem posed by the Belgian mathematician Joseph Antoine Ferdinand Plateau (c. 1830), namely, to find the surface of least area bounded by a given closed contour in space. By considerations of the condition giving minimum surface energy, it can be found that soap films naturally tend to form connecting surfaces of least area between the edges of a wire frame dipped in a soap solution (Figure 9). This fact enables Plateau's problem to be solved for general contours because a wire frame may easily be bent into the desired shape.

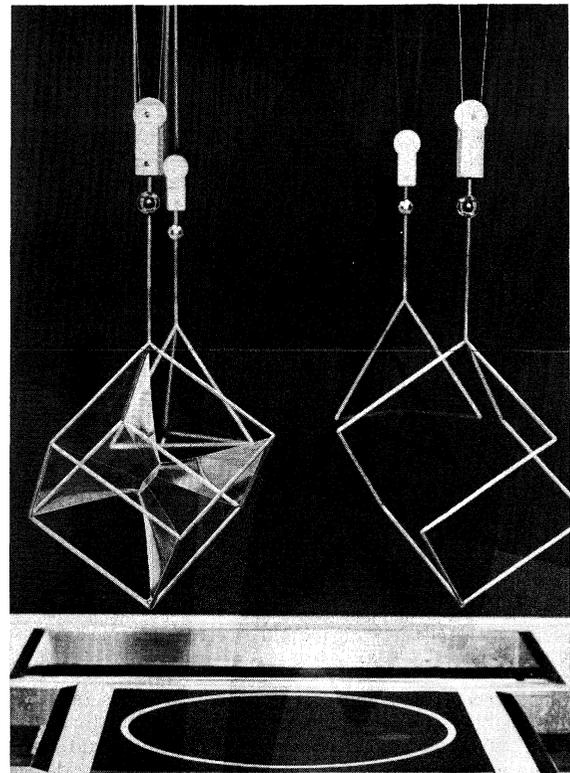

Figure 9: *Soap film model with wire boundary controlled to dip automatically into a vat of soap.*

The different boundary structures and surface tension of the soap film combine to yield minimal surfaces, the precise mathematical description of which is accomplished with the calculus of variations.

**Kinematic models.** There are a certain number of models that illustrate mathematical concepts in both pure and applied mathematics and that rely on the motion of one or more parts of the model during the demonstration (other than the thread models used for illustrating dynamic surfaces). Applied mathematics lends itself well to models of this kind because a large proportion of the subject concerns itself with the motion of bodies through space. The law of conservation of momentum, for example, is demonstrated effectively by a model known as Newton's cradle. This consists of a number of suspended steel balls of equal mass that are constrained to swing in their plane of contact and may be caused to collide with one another in a number of different ways. One such model is composed of five suspended balls, labelled one to five from left to right. If ball number one is swung out

and released, for instance, it causes ball number five to swing outward without affecting the intermediate balls, and the motion would be exchanged between these two until the energy of the system is dissipated.

If physical phenomena are governed by mathematical laws that are not overcomplex, it is possible to construct kinematic models that illustrate with much clarity the underlying mathematical ideas. A kinematic model of the laws of celestial mechanics that govern the motion of planets in the solar system can be constructed (Figure 10).

By courtesy of the Museum of Science and Industry, Chicago

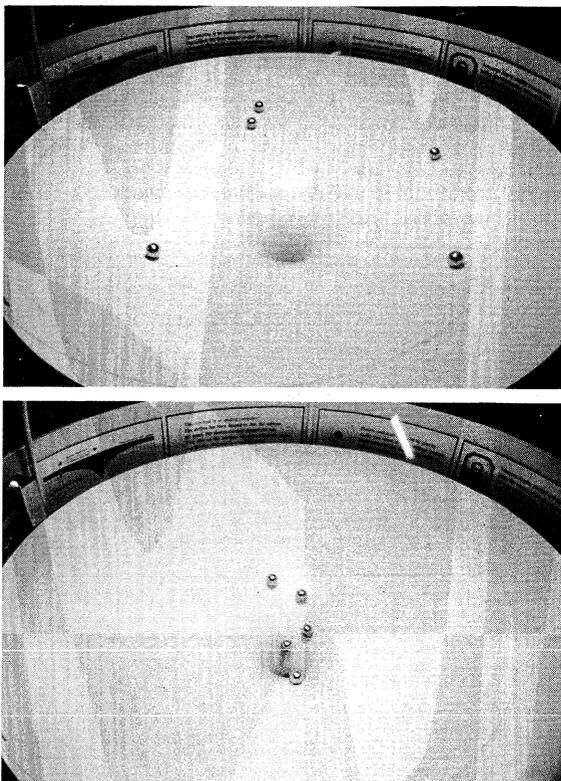

Figure 10: Celestial mechanics illustrated with a dynamic model in which the force (gravity of the Earth acting upon steel balls) and the rolling surface combine to cause an orbital motion that is similar to the motion of the planets about the Sun. When the balls are further from the centre (top), the motion is slow, as with Pluto and Neptune; when they are in an orbit of smaller diameter (bottom), the motion is more rapid, as with Venus and Mercury.

The concept of a convergent geometric series may be demonstrated to a good degree of approximation by means of a rubber ball constrained to bounce vertically within a loose fitting glass cylinder. A geometric series is a progression of numbers in which each term is obtained from the preceding one by multiplying by a constant quantity known as the common ratio; *e.g.*, 1, 2, 4, 6, 8 . . . , etc. If the numerical value of the common ratio is less than unity then the series is said to be convergent; *i.e.*, the sum of a very large number of terms approaches a finite limit. In the case of a ball bouncing vertically, the heights that the ball attains on successive bounces approximates well to the terms of a convergent geometric series and the limit of its sum will be half of the total distance that the ball travels before coming to rest.

The motion of particles in a more random fashion than the latter may be employed in models that visibly represent statistical distributions. Figure 11, for instance, shows a model that may be used to generate a curve in the form of a binomial distribution. Marbles are allowed to drop down a vertical board into which pegs have been inserted to form a grid in the shape of a rectangle. The design of the grid is such as to guide the marbles according to a statistical law, which is binomial, and is illustrated graphically by the way in which, after a large number of trials, the marbles fill the slots provided at the base of

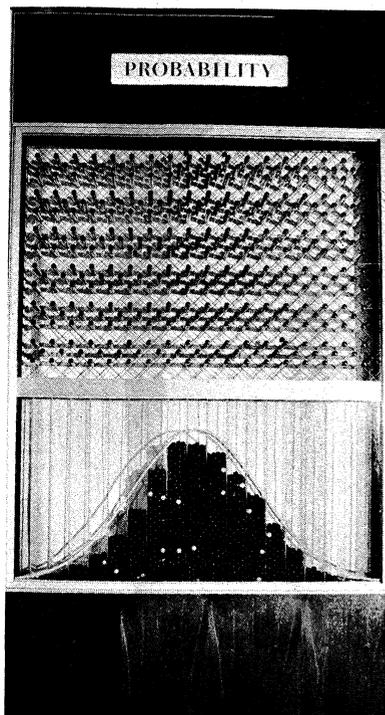

Figure 11: Probability distribution model, a prototype of the basic dispersion of random components of position that results in the binomial distribution. In this model, balls drop one after the other from the top and migrate at random through a maze of pegs to one of the lower channels. In the limit of many trials, the density of probability is described by the continuous curve known as the density function of the normal distribution.

the grid. In the limit of many trials the binomial distribution of probability can be seen to be approximated by the normal density function (see **PROBABILITY, THEORY OF**). (Ed.)

#### ALGEBRA AND LOGARITHMS

**Algebraic notation.** Modern elementary algebra is concerned with solving problems about numbers by reasoning and using a convenient notation that has been developed over many centuries. The numbers and operations on them are represented by letters and symbols (+, −, ×, ÷) and statements about them are expressed in equation form. An unknown quantity can then be represented by a letter (traditionally *x*) and logical reasoning can be applied (to the statements in the form of equations) by manipulating the equations according to rules until equations are obtained which yield the values of the quantities desired.

A considerable amount of ancient non-geometrical mathematics deals with problems to which this process is immediately applicable. The Ahmes manuscript is an example, but there are many others, Egyptian, Mesopotamian, Roman, Arabic, Hindu, and Chinese. The problem is generally stated in a form in which an unknown quantity is stated as the number of a certain kind of thing (for example, loaves of bread, soldiers, bricks), and the desired property is expressed in terms of this particular situation.

It is clear also that the problem giver wishes to imply a greater generality by analogy. In general, the answer is then given by a description of the process by which it is computed. Compared to the modern process, this is equivalent to giving the first equation and then the last and omitting the intermediate reasoning steps.

It is conceivable that the intermediate process as used in antiquity was supplied by some imaginary experience with the specific situation described or it may have been obtained by trial and error or a combination of these. It

was, unquestionably, not done by a sequential deductive argument.

In the case of false position, an intermediate step was supplied. When the initial information was given in a homogeneous form, a nominal value was assigned to the unknown initially and then was corrected after this value had been substituted in the equivalent of the initial equation.

In the geometry of Euclid, many constructions are equivalent to algebraic processes and include methods equivalent to solving the various cases of quadratic equations. The logic is that an analogy is established between the unknown quantity and a line segment or other geometrical quantity, and then a reasonably complete deductive discussion is possible. This analogy permits such concepts as square roots to be expressed.

Hindu mathematics emphasized computations, and systematic procedures for passing to the value of an unknown quantity were given in the work of Āryabhaṭa I (born AD 476). Brahmagupta (born AD 598) had systematic abbreviations for the arithmetical operations, including the square root, and for unknown quantities. Hindu computational procedures were adopted by the Arabs, and they were aware of many algebraic aspects of the Indian work; but they also tended to favour Greek geometric procedures for algebra. In the 16th century, Italian mathematicians solved the cubic and biquadratic equations by essentially algebraic methods; but modern notation is a later development.

The French mathematician François Viète, in the latter half of the 16th century, used letters of the alphabet to denote quantities and the plus (+) and minus (−) signs. The sign for equality and for the square root were also in use at this time. The multiplication signs, × and ·, and parentheses appeared in the period 1600 to 1630, and the division sign, ÷, about 1660. The use of exponents for positive powers is due to Descartes in 1637, but the more general case of negative and fractional powers is due to the English mathematician John Wallis in 1655 and Newton in 1676. It must be admitted, however, that when these notations were introduced they were, in most cases, in competition with other notations and the standardization was really a process of the 18th century. (F.J.M.)

**Logarithms.** *Basic principles.* Logarithms were invented in the early 17th century to speed up calculations, and they were basic in numerical work for more than 300 years. The perfection of the desk calculating machine in the late 19th century and the electronic computer in the 20th has made them obsolete for large-scale computation.

The operation and nature of logarithms can be seen from a table characteristic of logarithms (see 22) that identifies with the number ½ the logarithm −1, with the number 1 the logarithm 0, with the number 2 the logarithm 1, with the number 4 the logarithm 2, and so forth. Here, the constant 2 raised to any logarithmic power gives the corresponding number. A table of this type can be used for multiplication (and division)—the logarithms of the numbers to be multiplied are taken and added and the number corresponding to the answer is the result of the multiplication. For example, two numbers are taken from the first row and multiplied together; say, 2 × 8 = 16. The corresponding values in the second row are 1, 3, and 4; hence, when 2 is taken to the 4th power, 16 is yielded.

The reason for this is that numbers in the first row are the number 2 to the power of the corresponding number in the second. Thus ½ = 2<sup>−3</sup>, 1 = 2<sup>0</sup>, 8 = 2<sup>3</sup>. In the identity 32 = 2<sup>5</sup> the number 2 is called the base. The exponent 5 is the logarithm of 32 to the base 2 and is written 5 = log<sub>2</sub> 32. More generally, the two equations have the same meaning; the first serves to define the second. By this definition y is the logarithm of x to the

Develop-  
ment of  
modern  
notation

$$(23) \log_b mn = \log_b m + \log_b n$$

$$(24) \log_b (m/n) = \log_b m - \log_b n$$

$$(25) \log_b (n^p) = p \log_b n$$

$$(26) \log_b \sqrt[q]{n} = \frac{1}{q} \log_b n$$

$$(27) \log_b \sqrt{n} = \frac{1}{2} \log_b n$$

$$(28) \begin{cases} b^x \cdot b^y = b^{x+y} \\ b^x / b^y = b^{x-y} \\ (b^x)^p = b^{px} \end{cases}$$

$$(29) \begin{cases} m = b^x, & \log_b m = x \\ n = b^y, & \log_b n = y \end{cases}$$

$$(30) mn = b^x b^y = b^{x+y}$$

$$(31) \sqrt[q]{b^x} = b^{x/q}$$

base *b* if and only if  $x = b^y$ . The number *x* is also called the antilogarithm of *y* to the base *b*.

It is evidently easy to find logarithms of numbers that are simple powers of the base, and there are quite efficient methods for calculating logarithms of all numbers to as many decimal places as desired.

Multiplication of any numbers *m* and *n* can be accomplished by adding their logarithms; *i.e.*, the logarithm of the product is the sum of the logarithms (see 23). Division of numbers can also be accomplished by subtracting the logarithms: the logarithm of the quotient is the difference of the logarithms (see 24). This is not all; powers and roots can also be found with logarithms. For example, the cube of 4 is 64 (*i.e.*, 4<sup>3</sup> = 64), and from the table the logarithms of 4 and 64 are 2 and 6. Because 6 = 3 · 2, the logarithm of 4<sup>3</sup> can be found by multiplying the logarithm of 4 by 3. Study of the table will verify that the logarithm of a power can be found by multiplying the logarithm of the number by the index *p* of the power (see 25). Because logarithms transform multiplication into addition, division into subtraction, and the taking of powers into multiplication, it might be guessed that they would transform the taking of square roots into division. This is the case, for example, in computing the square root of 16, its logarithm (which is 4) is divided by 2. The result is 2, which is the logarithm of 4 as expected. In general, the logarithm of a root is the logarithm of the number divided by the index *q* of the root (see 26). Because  $n^{1/2} = \sqrt{n}$ , square roots are given in the logarithmic form as ½ the logarithm of the number for which the square root is being taken (see 27). Logarithms work this way because they are exponents; and exponents are added for multiplying, subtracted for dividing, multiplied to take a power, and divided to take a root. These ideas may be expressed as laws of exponents (see 28).

The exponents in these equations can be thought of as logarithms. For example, a variable may be expressed as a power of a base (see 29), and another variable may be expressed as a power of the same base. Their product (see 30) is similarly expressible in terms of a sum. Therefore,  $\log_b mn = \log_b m + \log_b n$ , the relationship for the addition of logarithms (see 31).

*Common logarithms.* The most convenient tables for numerical calculations are those in which the logarithms are to the base 10. These are called common logarithms. They have the advantage that a table of logarithms of numbers between one and 10 can be used to find the logarithms of all other numbers. For example, from tables, log<sub>10</sub> 2.41 is 0.38202 (this means that 10<sup>0.38202</sup> is 2.41; fractional powers of 10 can be found and tabulated;

Use of  
logarithms  
for multi-  
plication

(22)	$\begin{cases} \frac{1}{8} & \frac{1}{4} & \frac{1}{2} & 1 & 2 & 4 & 8 & 16 & 32 & 64 \\ -3 & -2 & -1 & 0 & 1 & 2 & 3 & 4 & 5 & 6 \end{cases}$
------	--

$$(32) \quad \begin{cases} 2 \cdot 41 \times 10 \\ \log_{10} 24 \cdot 1 = \log_{10}(2 \cdot 41 \times 10) \\ \quad = \log_{10} 2 \cdot 41 + \log_{10} 10 \end{cases}$$

$$(33) \quad y = \log_b x$$

$$(34) \quad e = 1 + \frac{1}{1!} + \frac{1}{2!} + \frac{1}{3!} + \cdots + \frac{1}{n!} + \cdots$$

$$(35) \quad \frac{d}{dx} \log_b x = \frac{1}{x} \log_b e$$

$$(36) \quad \frac{d}{dx} \log_e x = \frac{1}{x}$$

$$(37) \quad \log_e(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} + \cdots$$

$$(38) \quad \log_b x = \log_a x \log_b a$$

$$(39) \quad \log_{10} x = \log_e x \log_{10} e$$

see below). The logarithm of 24.1 can then be found because 24.1 is expressible as a number between two and three times 10 (see 32). Because  $\log_{10} 10 = 1$ , the logarithm of 24.1 is 1.38202. Thus each common logarithm has two parts, an integer and a decimal less than one. The integral part is called the characteristic and is determined by the position of the decimal point in the number. Thus the log of 241.0 is 2.38202 and its characteristic is 2; for 2.41 the characteristic is 0, for 0.241 it is  $-1$ , and for 0.00241 it is  $-3$ . The decimal part of a common logarithm is called the mantissa and is found from a table of logarithms by disregarding the position of the decimal point in the number.

When the characteristic is negative it cannot be written with the minus sign in front of the mantissa without causing confusion. For example, the log of 0.00241 has a mantissa of 0.38202 and characteristic of  $-3$ . It cannot be written  $-3.38202$  because it is, in fact,  $-3 + 0.38202$  (not  $-[3 + 0.38202]$ ). It is customary to write it in the form  $\bar{3}.38202$ .

**Natural logarithms.** The logarithmic function, in algebra, is defined by the relationship that identifies  $y$  with the logarithm of  $x$  (see 33). The problem of finding its derivative involves the problem of finding the limit of an expression of the form  $(1+t)^{1/t}$ , as  $t$  approaches infinity. This limit is an irrational number  $e$  given by the infinite series that sums the reciprocals of factorials (see 34), in which a factorial is a product of consecutive integers beginning with 1 and ending with the integer whose factorial is being taken. The number  $e$  has a value approximated by 2.71828, given here to five decimal places. This result leads to the equation that expresses the derivative of the logarithm to an arbitrary base (see 35). If logarithms to the base  $e$  are used, the equation simplifies to the form basic to calculus, expressing the derivative of the logarithm of  $x$  as the reciprocal of  $x$  (see 36).

Logarithms to the base  $e$  are sometimes called natural logarithms. They are less useful for computation than common logarithms but are used in calculation frequently in terms of the series for the logarithm of  $1+x$  (see 37). In this way natural logarithms can be computed to any required degree of accuracy. Common logarithms can then be obtained by a change of base using the formula that converts from one logarithmic base to another through the operation of multiplication of logarithms (see 38); this follows from the law of exponents. Thus a common logarithm of  $x$  is found by the equation that identifies it with the natural logarithm times a constant (see 39). (Ed.)

**History of logarithms.** The invention of logarithms was foreshadowed by the comparison of arithmetic and

geometric series. In the simple table used above, the top line is a geometric series and the bottom line is an arithmetic series. The first table based on this concept was published in 1620 in Prague by Joost Bürgi. The comparison between the two series was not based on any explicit use of the exponential notation; this was a later development.

John Napier, the Scottish mathematician, published his discovery of logarithms in 1614. His purpose was to assist in the multiplication of quantities that were then called sines. The whole sine was the value of the side of a right angled triangle with a large hypotenuse, say  $10^7$  units long. His definition was given in terms of relative rates.

The logarithm, therefore, of any sine is a number very nearly expressing the line which increased equally in the mean time while the line of the whole sine decreased proportionally into that sine, both motions being equal timed and the beginning equally shift.

In modern terminology,  $L$  is the logarithm and  $X$  the sine. (In modern notation  $X$  would be  $r \sin \phi$ .) Thus, with modern techniques derivatives can be used (see 40). At  $t = 0$ ,  $X = r$  ( $\phi = 90^\circ$ ), and, since the motion is "equally swift" at the beginning,  $a = br$ . Furthermore, the function  $L$  is known to have certain values at specific points (see 41). Thus in terms of present logarithms to the base  $e$  the function  $L$  can be expressed in terms of natural logarithms (see 42). Napier's value of  $r$  was  $10^7$ . This expression does not have the expected property for  $L(XY)$ , but the relationship involving products and division (see 43) does apply.

In cooperation with the English mathematician Henry Briggs, Napier did adjust his logarithms into the form in which it is usually found. For the modern Napierian logarithm (*i.e.*, the logarithm to the base  $e$ ) the comparison would be between points moving on two straight lines, marked in units of length, the  $L$  point moving uniformly from minus infinity to plus infinity, the  $X$  point moving on a half line from zero to infinity at a speed proportional to the distance from zero. Furthermore,  $L$  is zero when  $X$  is one and their speed is equal at this point. The essence of Napier's discovery is that this constitutes a generalization of the relation between the arithmetic and geometric series; *i.e.*, multiplication and raising to a power of the values of the  $X$  point correspond to addition and multiplication of the values of the  $L$  point. In modern terminology,  $\frac{dL}{dt} = k_0$ ,  $\frac{dX}{dt} = k_0 X$  correspond to  $\frac{dX}{dL} = X$ ,  $X = e^L$ ,  $L = \log_e(X)$ .

From the point of view of the user it is better to limit the  $L$  and  $X$  motion by the requirement that  $L = 1$  at  $X = 10$  in addition to the condition that  $X = 1$  at  $L = 0$ . This produces the common logarithms to the base 10. These

The modern Napierian logarithm

$$(40) \quad \frac{dh}{dt} = a, \quad \frac{dX}{dt} = -bX$$

$$(41) \quad \begin{cases} L=0 & t=0 \\ \text{i.e., } L(r)=0 & \frac{dX}{dt} = \frac{-aX}{r} \end{cases}$$

$$(42) \quad \begin{cases} L(x) = r(\log_e r - \log_e x) \\ L(x) = r \log_e \frac{r}{x} \end{cases}$$

$$(43) \quad L\left[\frac{XY}{Z}\right] = L(X) + L(Y) - L(Z)$$

$$(44) \quad \begin{cases} \log\left[\frac{\sin x}{x}\right] \\ \log\left[\frac{\tan x}{x}\right] = \log\left[\frac{\sin x}{x}\right] - \log \cos x \end{cases}$$

are sometimes known as Briggsian logarithms: the natural logarithms are known as Napierian logarithms.

*The calculation of logarithms.* The treatment above differs from that of Napier in that the word "exactly" is applicable rather than "very neerely." This obscures the ingenious procedure used for calculating the early logarithms, in which powers of numbers such as 1.00001 were used so that multiplication was minimized and replaced by addition. Thus,  $X = (1.00001)^n$ ,  $L = n/10^5$  corresponds approximately to  $L = \log_e X$ , or the natural logarithm. To obtain the Briggs or base 10 table, the calculation would be continued until  $X$  exceeded 10 and then the  $L$  scale adjusted so that at  $X = 10$ ,  $L = 1$ .

In addition to the discrete series procedure, Napier and Briggs suggested the calculation of logarithms by extracting roots of 10; *i.e.*,  $\log \sqrt{10} = 0.5$ ,  $\log 10^{1/4} = 0.25$ . This permits the  $n$  computation of the previous paragraph to be shortened, for the Briggs logarithm can be adjusted for by taking  $L = 0.25$  for  $X = 10^{1/4}$ . Power series were not used in the initial construction of the tables. The power series for  $\log(1 + x)$  and  $e^x$  were only available in the 18th century and rigorously established in the early 19th century.

*Logarithm tables.* Napier died in 1617. Briggs published a table of logarithms to 14 places of numbers from 1 to 20,000 and from 90,000 to 100,000 in 1624. Adriaan Vlacq published a 10-place table for values from 1 to 100,000 in 1628, adding the 70,000 values. Both Briggs and Vlacq engaged in setting up log trigonometric tables. Such early tables were either to  $1/400$  of a degree or to a minute of arc. In the 18th century tables were published for 10-second intervals, which were convenient for seven-place tables. In general, finer intervals are required for logarithmic functions in which the logarithm is taken of smaller numbers; for example, in the calculation of the functions  $\log \sin x$  and  $\log \tan x$ . The related functions modified by division by  $x$  in the argument of the logarithm (see 44) are easily calculated by series for small values of  $x$ .

The availability of logarithms greatly influenced the form of plane and spherical trigonometry. Convenient formulas are ones in which the operations that depend on logarithms are done all at once. The recourse to the tables then consists of only two steps. One is obtaining logarithms, the other obtaining antilogs. The procedures of trigonometry were recast to produce such formulas.

*Slide rules.* If a scale of numbers is taken and the values of their logarithms marked on a parallel scale, then a logarithmic scale is produced. In 1620 Edmund Gunter plotted logarithms on a two-foot straight line. With such scales multiplication and division were performed by addition and subtraction of lengths by a pair of dividers. William Oughtred, between 1620 and 1630, used two such scales sliding by each other to obviate the use of dividers. These were the forerunners of the C and D scales found on the modern slide rule. They can also be used in circular and cylindrical form. The linear slide rule may have to be reset to stay on scale, but this does not occur with the circular slide rule. Circular slide rules, however, are more difficult to make. The first known slide rule in which the slide worked between a fixed stock was made by Robert Bissaker in 1654.

The fundamental scales for a slide rule are the C and D scales in which 1 to 10 correspond to the full available interval in the linear slide rule or a circumference in the circular case. The scales A and B for squares are obtained by having the  $L$  length corresponding to  $x$  so that the full interval corresponds to 1 to 100. Thus,  $x$  on the D scale will be associated to  $y = x^2$  on the A scale. Similarly, there is a K scale for cubes. In the centre of Figure 12 is a mid-20th-century example of a two-faced slide rule on which the K, A, and D scales are visible, as well as the S and L scales discussed below.

There may also be a facility for obtaining sines. A number of schemes are possible. There may be a single S scale on which angles are given from  $34'$  to  $90^\circ$  and the sine of this angle is read on the A scale, with the maximum value of the latter corresponding to one. A variation of this is to use two S scales for the angles. One S scale lists angles

from  $34'$  to  $5^\circ 45'$ , with the corresponding sine given on the D scale corresponding to the  $x$  interval 0.01 to 0.1. A second S scale lists angles from  $5^\circ 45'$  to  $90^\circ$  with the sine on the D scale for 0.1 to 1. The tangent can also be given by two scales. For angles between  $34'$  and  $5^\circ 45'$ , the S scale can also be used to yield tangents, with a maximum error of about one part in 200 at the very end of the scale. The second tangent scale would have angles from  $5^\circ 43'$  to  $45^\circ$  and be read on the D scale for 0.1 to 1.

A log scale L may be explicitly given and a log log scale for computation with powers. A log log scale is divided into lengths that are proportional to the logarithms of the logarithms of numbers. The sliding scale has a logarithmic scale. This innovation was made by Peter Roget in 1815. Another possibility is for D and A scales replaced by  $\log \pi$ . These yield the circumference or area of a circle from its diameter or radius in a single setting. For trigonometric purposes, a P scale is sometimes included, the value  $y$  corresponding to  $x$  on the D scale by the relation  $y = \sqrt{1 - x^2}$ .

Another possible shape for the slide rule is obtained by permitting the edge on which the body and slide meet to be wrapped around a cylinder so that this edge has the shape of a helix. This permits an expanded interval length and greater accuracy. The usual cylindrical slide rule is based on a folded scale principle and uses two coaxial cylinders (say D and C cylinders). The D scale is divided into a number,  $k$ , of parts of equal length and each part is laid on an element of the D cylinder; *i.e.*, on a surface line parallel to an axis. These  $k$  elements are equally spaced around the D cylinder. The C scale is set up similarly on the C cylinder. The C cylinder can be displaced along the axis of the D cylinder or rotated relative to the D cylinder around the axis by multiples of  $360^\circ/k$ . The effect of this arrangement can be similar to that of a circular slide rule of circumference equal to  $k$  times the element length. A cylindrical slide rule designed in the 19th century and called a Thacher Calculating Instrument is shown at the top of Figure 12.

Slide rules can serve many purposes beside logarithmic calculation and can consequently assume many forms. A design of the 1970s is composed of two relatively slidable members held together by a third member that acts as a cursor (Figure 12, bottom). Contemporary uses for slide rules besides the familiar arithmetic operations in-

rule scales

clude the generation of random numbers as is the case with the last illustrated slide rule.

#### TABLES

**Integral tables.** If  $y = f(x)$  is a given function, defined and positive for  $a \leq x \leq b$ , the definite integral of the function  $f$  from  $a$  to  $b$  (see 45) is defined by a numerical procedure as a limit of a sum in the integral calculus. The numerical value coincides with the area under the curve,  $y = f(x)$ , between  $x = a$  and  $x = b$ . Many problems, such as finding the volume or surface of a solid of revolution or finding the length of an arc of a curve, can be reduced to evaluating a definite integral.

Archimedes developed procedures for evaluating areas equivalent to definite integrals and the Italian mathematician Bonaventura Cavalieri (1635) generalized the method of Archimedes. Although it did not possess an adequate logical basis, this method yielded correct results in a number of cases including the functions  $y = x^n$ . The calculus of Newton, however, yielded a much more general way of evaluating definite integrals, the method of indefinite integrals. A function  $F(x)$  the derivative  $dF/dx$  of which equals  $f(x)$  is called the indefinite integral or anti-derivative of  $f(x)$ . For such an anti-derivative, the so-called quadrature formula identifies the difference of  $F$  evaluated at two distinct points with the definite integral of  $f$  integrated between the same points (see 46).

$$(45) \quad \int_a^b f(x) dx$$

$$(46) \quad F(b) - F(a) = \int_a^b f(x) dx$$

In elementary calculus, methods are given for differentiating functions, including the so-called elementary functions, which include the algebraic, trigonometric, and exponential functions and functions composed of these. The derivative of an elementary function is also elementary; Joseph Liouville, however, showed that not all elementary functions are themselves derivatives of elementary functions. For example,  $y = \exp(x^2)$  and, in general, square roots of cubics and biquadratics that can not be simplified are not derivative of elementary functions. In view of the quadrature formula, it became desirable to present tables of functions and their anti-derivatives. Examples of such tables are those of Peirce and of Dwight.

In general, when a function  $f(x)$  has an anti-derivative, the methods of the integral calculus will yield the anti-derivative, and these tables present the result. When the anti-derivative is not an elementary function, however, it may still be possible to find the definite integral for certain values of  $a$  and  $b$ . Usually this requires advanced methods of analysis. A compilation of such results was made by D. Bierens de Hahn and published in 1858 and 1864.

**The Monte Carlo method.** In addition to definite integrals relative to one variable, there are definite integrals of two or more variables that are limits of weighted sums taken over areas or regions in the space of the variables. These definite integrals are, theoretically, reducible to the equivalent of integrating the process of taking integrals of one variable; and when the one variable process of integrating by finding anti-derivatives can be carried out, the problem is solved. There are many important cases in statistics, quantum mechanics, and in technology, however, in which this process is not applicable. According to the original definition of these multi-dimensional integrals, the computation required in many cases is excessive even when large-scale digital computers are available. The procedure adopted to handle this problem is to use a statistical interpretation of these integrals as the mean value of a chance variable and perform the computational analogue of an experiment in probability. This Monte

Carlo method was introduced after World War II and can be performed on a slide rule (if speed is not required) or on large-scale digital computers.

The basis of a probability experiment in a digital computer is the choice of a random number. A random number is a sample value in a sequence of statistically independent random variables. It is erroneous to believe that the intermediate digits in a long calculation are distributed randomly; for example, if a number is raised to a high power, using a floating point notation (*i.e.*, no decimal point), the sixth digit of the power may be considered to be random. But this is true only in a qualitative way. The term pseudo random numbers has been ascribed to these numbers because they do not represent the true random numbers of probability theory. Tables of true random numbers have been obtained experimentally and are available for Monte Carlo experiments. Specially designed analogue computers and slide rules have also been designed to yield random numbers (see above *Slide rules*).

**Fourier series and transforms.** In 1807, in his treatise on heat, Fourier proposed that an arbitrary function  $f(x)$  of one variable can be expressed as a series composed of a constant and a linear expression for a trigonometric function (see 47), in which the coefficients are the definite integrals expressed in terms of the given function multiplied by trigonometric functions (see 48). The function  $f(x)$  is either considered to be periodic or defined only for  $-\pi \leq x \leq \pi$ . This raised many questions, especially in connection with the earlier efforts of d'Alembert to analyze the vibrations of a stretched string, and is responsible for the development of much of what is termed modern analysis. Because the coefficients are given by definite integrals, the previously described tables may apply.

Thus a function  $f(x)$ , considered on the interval  $-\pi \leq x \leq \pi$ , is equivalent to two sequences of numbers:  $a_1, a_2, \dots, b_0, b_1, \dots$  in the sense that  $f(x)$  yields the numbers by means of the formulas using the definite integrals and the numbers yield  $f(x)$  by the series expression. The equivalent of this can be obtained on any interval of finite length by a change of variable.

If, however,  $f(x)$  is considered on the infinite interval  $-\infty < x < \infty$ , it is associated with another function  $g(x)$  rather than with two sequences of numbers. The function  $g(x)$  is called the Fourier transform of  $f(x)$ , and the relations between  $f(x)$  and  $g(x)$  are usually expressed by complex exponentials rather than by trigonometric functions (see 49). This concept of the Fourier transform is highly significant in many diverse fields, including mathematical analysis, electrical circuit theory, statistics, and mathematical physics.

Because of the needs of mathematical physics, especially in quantum mechanics, the notion of the Fourier transform has been generalized to apply to a wider class of objects than functions. These objects are called distributions, and tables of distributions and their Fourier transforms appear in works on distribution theory, quantum mechanics, partial differential equations, and abstract linear spaces. For electrical circuits, an analogous transform, that of Laplace, has proved most useful and tables of these transforms appear in works on this topic.

$$(47) \quad f(x) = \frac{1}{2}b_0 + \sum_{n=1}^{\infty} (a_n \sin nx + b_n \cos nx)$$

$$(48) \quad a_n = \frac{1}{\pi} \int_{-\pi}^{\pi} f(x) \sin nx dx, \quad b_n = \frac{1}{\pi} \int_{-\pi}^{\pi} f(x) \cos nx dx$$

$$(49) \quad \begin{cases} g(x) = \frac{1}{\sqrt{\pi}} \int_{-\infty}^{\infty} f(y) \exp(ixy) dy \\ f(x) = \frac{1}{\sqrt{\pi}} \int_{-\infty}^{\infty} g(y) \exp(-ixy) dy \end{cases}$$

$$(50) \quad y'' + \omega^2 y = 0$$

The great practical importance of the Fourier coefficients and the Fourier transform has led to the invention of many specialized devices to perform the computations needed for their use, including the evaluation of convolution integrals.

**Function tables.** The mathematical procedures for handling the theories of gravity, heat, elasticity, fluid flow, electromagnetism, and quantum mechanics are based on solving or manipulating partial differential equations. The problems that are mathematically solvable are limited but of great importance. Certain techniques are based on Fourier transforms, but there is another process that reduces the problem to one involving ordinary differential equations by a method called separation of variables. The ordinary differential equations that appear in this process have as solutions functions of one variable, which have been studied intensely. Usually a parameter, a variable that distinguishes special cases, is involved in the equation; for example,  $\omega$  in the second-order differential equation that describes basic vibrational problems (see 50).

These functions are analytic in general except for certain characteristic singularities. Numerical integration procedures for the differential equations have been developed and the results tabulated. Tables of these functions have been produced by the British Association for the Advancement of Science and by the Works Progress Administration in the United States.

At present, emphasis is on procedures for generating the functions in large-scale digital computers. In certain cases the procedures are used during a calculation. For example, it is more efficient to generate the values of the trigonometric functions in the computer when required than to retain stored values. Electronic computers may also function on the basis of a logarithmic routine for multiplication. Special techniques for approximating functions over fixed intervals by polynomials have been developed using values of the functions. Computers have also been used to produce tables in printed form, the typescript being set automatically by the computer, or by an intermediate punched card stage.

**Mathematical tables.** Printed mathematical tables are widely used in statistics, science, technology, business, numerical analysis, and investigations into number theory. Many types are available. An example of comprehensive tabular publication is the work that was published in 1964 by the National Bureau of Standards, of the United States, which was a result of a conference on mathematical tables considered in the light of electronic computers, held at the Massachusetts Institute of Technology, Cambridge, in 1952.

Tables used in statistics contain probability distributions, such as the normal, binomial, Raleigh, Student  $t$  (named after an anonymous journal contributor), and  $\chi^2$  distributions. In science and technology tables of functions are used, in particular the trigonometric, exponential, elliptic, Bessel, and Mathieu functions. There are also listings of the coefficients of polynomials, such as the Chebychev, Legendre, and Laplace polynomials, and the coefficients of series expansions.

Several types of tables are available for financial purposes. For example, tables can be obtained giving principal amounts earning compound interest, or uniform mortgage payments for specified interest rate and repayment period.

Another type of numerical table is used in number theory; for example, a table of all primes (numbers factorable only by itself and one) less than 11,000,000. There are also tables for computation purposes, such as tables of binomial coefficients, or tables of powers of two for use with binary computers. Numerical procedures such as interpolation and the step by step integration of differential equations are assisted by tables of coefficients.

#### GRAPHS AND GRAPHICAL PROCEDURES

**Graphs.** A common method of expressing a relation between two variable quantities is by a Cartesian graph (named after René Descartes). A Cartesian axis system consists of two mutually perpendicular lines usually

called, respectively, the  $x$  and  $y$  axes. The coordinates of a point are obtained by projecting perpendicularly on these axes and assigning values by means of a scale on the axes. If  $f(x)$  is a function of  $x$ , then for a value of  $x$  there will be a  $y$  value,  $y = f(x)$ , and the function  $f(x)$  is graphed by marking the points with these coordinates,  $x, y$ . Such a graph permits the ready appreciation of certain characteristics of the function. Also a number of different functions can be readily compared by their graphs.

Another graphing method is represented by using polar coordinates. A point  $O$  is chosen as origin and a ray  $OA$  is also chosen. If  $P$  is a point in the plane, it has two polar coordinates,  $\rho, \theta$ , in which  $\rho$  is the distance  $PO$  and  $\theta$  is the angle  $POA$ . Polar graphs can be effectively used to represent functions of the time, which appears as the angle variable, whereas the radial distance,  $\rho$ , corresponds to the other variable, say, temperature. Such functions can be recorded as a polar graph by having the graph itself rotated around its origin by clockwork or by a synchronous electric motor to give an angular displacement with time, and by having the quantity to be recorded produce a linear, radial displacement of a recording pen. Cartesian graphs can be obtained by displacing a diagram in the  $x$  direction and displacing the pen in the  $y$  direction. There are commercial output devices for digital computers, in which numerical information from the computer determines both the  $x$  and  $y$  displacement of a recording pen or a beam in a cathode-ray tube.

Frequently the information recorded is of the type in which a  $y$  value is assigned to an  $x$  value only for discrete values of  $x$ . If the number of  $x$  values is relatively small, it is customary to use bar graphs, in which the quantity is represented by a rectangle of fixed base and variable height, and variables can be compared by placing the bar graphs side by side. This method is often used for quantities available on an annual basis; for example, amounts of imports, amounts of a specific crop, populations, etc. If a given quantity is made up of a sum of other quantities, these others can be indicated by shading rectangles in the graph. The last effect is also obtained by a disk graph, in which the subquantities are indicated by wedges.

**Scales.** It is clear that nothing is essentially changed if the values that are marked on the axes are not proportional to the distances from the origin but more or less arbitrary scales are used. Points, the coordinates of which satisfy a given equation, can be plotted as before and a curve can be drawn from which corresponding values can be read. The form of the curve can be altered and in some cases simplified. These notions were developed by Léon Lalanne in his *Anamorphose logarithmique* (1842) and further advances were made by J. Massau and Charles Lallemand in the 1880s. A basic idea is to use such scales that the graphs of the equations under consideration become straight lines, which are easy to draw. The equation that restricts a linear relationship in a function of  $x$  and a function of  $y$  (see 51) in which  $a, b, c$  are constants, becomes a straight line in an  $X, Y$  plane (see 52) if the distances  $X$  and  $Y$  along the axes to the marks  $x$  and  $y$  are determined by functions (see 53).

$$(51) \quad af(x) + bg(y) + c = 0$$

$$(52) \quad aX + bY + c = 0$$

$$(53) \quad X = f(x), \quad Y = g(y)$$

$$(54) \quad mY = nX + \log a$$

Well-known examples based on this principle are the commercial logarithmic and semilogarithmic papers. The former papers use the scales  $X = \log x, Y = \log y$  and are convenient for plotting the graphs of relations of the form  $y^m = ax^n$ . Because this may be written  $m \log y = n \log x + \log a$ , the graph on this paper is a straight line (see 54). The semilogarithmic papers have the scales of

Use of  
polar co-  
ordinates

$$(55) \quad X = x, \quad Y = \log y$$

$$(56) \quad x^2 + y^2 = z^2$$

$$(57) \quad X_3 = \frac{1}{2}(X_1 + X_2)$$

$$(58) \quad h(z) = f(x) + g(y)$$

$$(59) \quad X_1 = f(x), \quad X_2 = g(y)$$

$$(60) \quad \log z = \log x + \log y$$

which one is linear and the other is logarithmic (see 55). They are useful in plotting the results of experiments in which one quantity is an exponential function of the other.

A logarithmic scale can also be used to compare quantities of greatly varying size. An example of this is the line scale for the frequency of electromagnetic waves, in which the frequency of interest ranges from less than 1 hertz to  $10^{10}$  hertz.

Another example of the use of line scales is that of graphic tables, in particular for logarithms. These serve the same purpose as the usual logarithm tables and are published in book form. In the main part of the text, a long line is depicted, broken up into segments with each segment extending the width of the text on the page. There are about 25 segments to a page. On this long line there are two scales. The upper scale gives a number  $N$  from 1 to 10, the lower scale gives the corresponding logarithm  $L$  from 0 to 1. For five-figure accuracy, a line of approximately 106 metres in total length is used. This indicates a resolution of the order of one millimetre.

(F.J.M.)

**Alignment charts.** The word nomogram is sometimes restricted to a special type of chart that is used by bringing the points of three scales into alignment. There is an alignment chart for the solution of a quadratic equation in three variables (see 56). On the upper and lower horizontal lines are laid off from a vertical axis the scales  $X_1 = x^2$ ,  $X_2 = y^2$  identical with those on the axes. Midway between is a line with a scale half as large,  $X_3 = z^2/2$ . Now let a straight line be drawn across the figure cutting the scales at points marked  $x$ ,  $y$ , and  $z$ . It is seen from elementary geometry that the third coordinate is the arithmetic average of the first two (see 57), whence the equation  $x^2 + y^2 = z^2$  is satisfied. The equation is solved for one of the variables by joining given values of the other two variables on the scales by a straight line and reading the solution where this line cuts the third scale.

A chart for solving any equation containing three variables can be made in a similar manner provided the variables can be segregated into three separate terms so that a function of one variable is equal to the sum of two functions each of single variables (see 58). It is necessary merely to plot the scales that are identified with the two summed functions (see 59) on the outside lines and one-half the sum of the two functions on the middle line. Thus, a scale for multiplication,  $z = xy$ , could be made after first writing the equation in the form of a linear relationship between logarithms (see 60), the three plotted scales then being logarithmic.

This type of chart has certain obvious advantages. Only three scales need be drawn, and they are more easily used than a complicated diagram. Interpolation can be accurately done since the line cuts cleanly across the scale. As a practical matter the line across the chart should not be actually drawn because a few lines in pencil would mar the chart. A fine thread may be stretched across the chart. An excellent line may be made on a transparent ruler with the point of a knife, a little graphite being worked in to give it visibility, and this can be laid across the chart.

The principle of the alignment chart was first described in 1884 by Maurice d'Ocagne of the École Polytechnique

in Paris. He developed the subject in many papers and books and particularly in his treatise of 1899, *Traité de nomographie*, in which were brought together both the general theories and a multitude of practical applications. D'Ocagne may properly be called the creator of nomography.

In its more general forms the alignment chart for the solution of an equation in three variables may employ straight scales arranged in various ways, or one or more of the scales may be curved. A curved scale may be constructed from parametric equations  $X = f(t)$ ,  $Y = g(t)$ . A value of  $t$  gives a point  $(X, Y)$  on the curve. Points for suitably spaced values of  $t$  are marked and the value of  $t$  is attached. Thus,  $X = \cos t$ ,  $Y = \sin t$  gives a circular scale, since  $X^2 + Y^2 = 1$ . Whether the resulting scale is curved or straight depends upon the parametric equations.

Two functions of a variable  $x$ , two functions of  $y$  and two functions of  $z$  can form three scales: an  $x$  scale  $X_1 = F(x)$ ,  $Y_1 = f(x)$ ; a  $y$  scale  $X_2 = G(y)$ ,  $Y_2 = g(y)$ ; and a  $z$  scale  $X_3 = H(z)$ ,  $Y_3 = h(z)$ . Three points  $(X_1, Y_1)$ ,  $(X_2, Y_2)$ , and  $(X_3, Y_3)$ , corresponding to readings  $x$ ,  $y$ , and  $z$ , respectively, on the three scales lie on a line if the slope of the line joining the first two points is equal to the slope of the line joining the last two points (see 61). This condition may be put in a form involving the functions of the problem (see 62) or as a determinant (see 63). The chart will solve this equation for one of the variables when the other two are known. Conversely, an alignment chart can be made for any equation that can be written in this form.

If an equation can be solved by an alignment chart, it can be solved by an infinitude of alignment charts and by applying projective transformations (see 64).

(L.R.F.)

**Planimeters.** The design of a planimeter involves the production of a set of diagrams or drawings. A ship may be described by two sequences of vertical and one sequence of horizontal cross sections. A metal part for a machine may be given by longitudinal or cross sectional diagrams. Design or performance objectives such as the displacement of the vessel or the kinetic energy of a flywheel require the evaluation of certain physical characteristics of the device. Normally, these physical characteristics include volumes, areas, centres of gravity, moments, and moments of inertia. The theory and approximations of the integral calculus will yield these quantities, provided certain definite integrals associated with the diagrams can be evaluated. The quantities of interest may be defined as definite integrals of two or more dimensions, but by using Green's theorem and similar results, the evaluation can be reduced to the evaluation of one-dimensional line integrals in many important cases.

The advantage of the use of line integrals is that the quantities  $y$  and  $x$  on which the integral depends can be entered into a calculating device by tracing the curve. During the 19th century, a number of types of devices were developed for evaluating line integrals by tracing curves on a drawing board.

$$(61) \quad \frac{Y_2 - Y_1}{X_2 - X_1} = \frac{Y_3 - Y_2}{X_3 - X_2}$$

$$(62) \quad F(x)[g(y) - h(z)] + G(y)[h(z) - f(x)] + H(z)[f(x) - g(y)] = 0$$

$$(63) \quad \begin{vmatrix} F(x) & f(x) & 1 \\ H(z) & h(z) & 1 \\ G(y) & g(y) & 1 \end{vmatrix} = 0$$

$$(64) \quad X' = \frac{a_1 X + b_1 Y + c_1}{a_3 X + b_3 Y + c_3}, \quad Y' = \frac{a_2 X + b_2 Y + c_2}{a_3 X + b_3 Y + c_3}$$

$$(65) \quad z = \int f(x) dx$$

Charts for solving equations with three variables

The rotational planimeter

One type, the rotational planimeter, was based on the disk integrator, a device in which a flat disk turns by an amount  $x$ , and a wheel driven by the disk is mounted on an axis parallel to the plane. This wheel is keyed to the axis so that its rotation is transferred to the axis, but it can be displaced an amount  $y$  along this axis. In the integrating devices, the flat disk is rotated an amount  $x$ , while the wheel is displaced an amount  $y$ , that is the function of  $x$ ; i.e.,  $y = f(x)$ . The rotating disk drives the wheel so that the rotation of the keyed shaft gives an integral  $z$  of  $f(x)$  (see 65). This type of device appeared early in the 19th century and was used initially for graphical integration but later on was incorporated into other computing devices such as the mechanical differential analyzer (see below *Multipliers*).

Another type of graphical integrator was a tricycle device that could move on two balls and a steering wheel. If this device is subject to a force that is not large enough to make the wheel skid and that is applied so that the wheel will not pivot about its point of contact, the device will move instantaneously in the direction of the plane of the steering wheel. If this direction is controlled so that the slope of the curve described is the  $y$  coordinate of a given curve, the curve will also correspond to an indefinite integral. This is the principle used in the integrator of Bruno Abdank Abakanowicz and described by him in 1889.

The three-wheel design has been used in more elaborate devices to solve differential equations such as those governing the motion of a charged particle moving through a two-dimensional magnetic field (Figure 13). In a design of this type, the equations to be solved can be shown to be equivalent to  $H\rho = k$ , in which  $H$  is the local magnetic field,  $k$  is a constant, and  $\rho$  is the local radius of curvature. For the analogue device to operate, it is required only that the angle of the steering wheel, as the device moves over the graphical representation of the field  $H$ , be restricted to equal  $\rho$  in the above equation.

By courtesy of Bayard Rankin

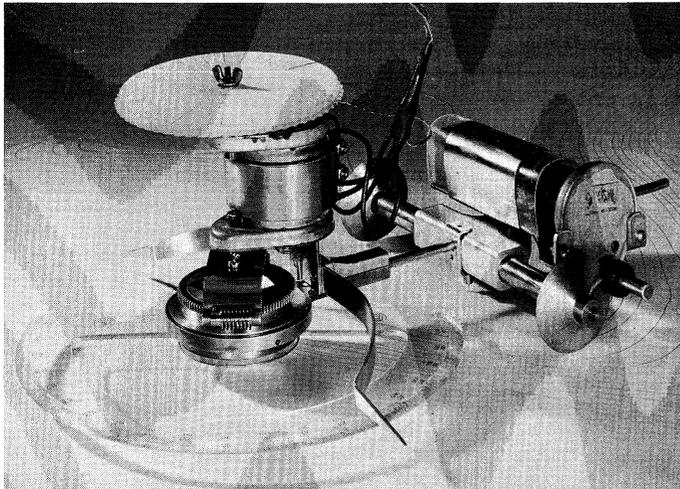

Figure 13: Mechanical particle, so called because it is a particle trajectory plotter that is used to compute, by analogue methods, the orbits of charged particles in a two-dimensional magnetic field. The angle of the front wheel, if controlled according to a mathematical formula that relates to the magnetic field lines (visible), determines that the pen (between the rear wheels) draws the solution to the equations of motion.

The flat disk of the disk integrator can be replaced by any surface of revolution, provided the rotational wheel is maintained in contact with the surface. For example, a sphere can be rotated about a pole and a wheel so mounted that its displacement corresponds to colatitude. If the sphere is considered as rotating around its north pole, the take-off wheel can be mounted on a piece that has essentially the shape of a great circle and that rotates around an axis through the equator. Computation is made in the following way. The wheel axis is mounted on a pivot so that the motion of the point of contact is along a circle of

latitude. If the wheel displacement is  $u$  and the sphere rotates an amount,  $v$ , the rotational output is proportional to the integral of  $\sin u$  with respect to  $v$ .

Using these mechanical principles, drawing board devices have been set up to evaluate Fourier coefficients. Harmonic analyzers, based on tracing drawing board graphs, are commercially available.

The third type of planimeter is the polar planimeter invented by Jakob Amsler in 1858. The device is remarkably simple from the mechanical and operational point of view. It consists, usually, of two hinged pieces associated with an anchor piece and a scribe to follow a closed curve. On one of the hinged pieces is an integrating wheel. When a wheel is moved along a curve in a plane so that the normal to the path makes an angle  $\alpha$  with the plane of the wheel, then the total rotation of the wheel is proportional to the integral of the  $\sin \alpha$  with respect to  $s$ . It is also true that if a line segment is moved in the plane so as to return to its original position with total rotation zero, then the areas enclosed by the motion of the end points can be related to this integral. The anchoring arrangement usually ensures that the area enclosed by one end either is zero or has a fixed value.

The polar planimeter

$$(66) \quad dA = \ell \sin \alpha ds + \frac{1}{2} \ell^2 d\phi$$

The motion of a line segment  $PQ$  of length  $l$  is considered. The point  $P$  moves along a curve with differential of arc  $ds$ . The symbol  $\alpha$  denotes the angle between  $PQ$  and the tangent to the curve, and the total rotation of  $PQ$  from a fixed position is  $\phi$ . The change of area for an infinitesimal motion is given by a differential that can be analyzed into two component differentials, one for arc length and one for total rotation (see 66). It follows that if a motion is such that the original position is returned to  $\phi = 0$ , then the algebraic area covered is  $l$  times the integral with respect to  $s$  of  $\sin \alpha$ .

**Graphics.** A number of relatively simple devices establish the direction of a curve at a point or, what is equivalent, the direction of the normal. For example, if a mirror has an edge on the drawing board that crosses the curve at the point, the curve will appear to have a corner unless the mirror edge is along the normal to the curve. A triangular prism can also be used in a similar fashion, with one face on the drawing board.

One current development in the use of automatic data processing is termed computer graphics. This is a procedure by which a computer does the equivalent of drawing diagrams, producing the drawing on a cathode-ray tube. An operator controls the production of the drawing by a combination of button pushing and use of a light pen (a device that may be used to alter the display on a cathode-ray tube; see COMPUTERS). For example, the operator is able to cause a line segment to appear in the drawing by pressing a specific button and then activating the light pen at two points on the face of the cathode-ray tube corresponding to the desired end points. The completed drawing can be produced either on a plotting device or photographically.

Computer graphics

Computer graphics permits the development of engineering drawings by the original designer without the intervention of other people, and the consequent manpower and time saving is economically significant. Another advantage is that the diagram is mathematically described in the computer, and procedures of numerical analysis can be directly applied to yield the various integrals discussed above.

ANALOGUE COMPUTATION

**Mathematical analogues.** The extraordinary expansion of the physical sciences and technology that began in the 18th century involved mathematical formulations in an essential manner. Questions in understanding and on the design and operation of devices could be expressed mathematically in terms of analytic concepts such as ordinary or partial differential equations, Fourier series or

transforms, systems of linear algebraic equations, or definite integrals.

The mathematical problem that appears in a physical study may require a lengthy computation. Alternatively it may be impractical or impossible to solve it directly as a mathematical problem. The scientific analysis that produced the mathematical problem, however, may also indicate methods of handling it. One method is to obtain analogous physical systems, the behaviour of which can be quantitatively observed; for example, a wind tunnel experiment on an aircraft wing or fuselage shape. In this way it is possible to investigate the behaviour of an aircraft in flight.

More generally, other systems can be sought satisfying the same mathematical relations as the given system of interest. For example, the flow of heat is analogous to the flow of electricity with temperature corresponding to electric potential. Thus, the heat flow in a structure can be analyzed by means of layers of electrically conducting materials arranged to simulate the characteristics of the structure.

Engineering is frequently concerned with complex elastic structures, and methods have been developed for setting up analogies between these structures and electrical networks, with nodes arranged in two- or three-dimensional lattice patterns. The stresses, strains, displacements, and dampening effects of the original structure all have measurable electrical analogues.

#### Network analyzers

A more direct analogue is represented by network analyzers. These are electrical networks intended to simulate power generating and transmission line networks in order to predict possible inadequacies of a present system or to design additions. The simulation concept here is quite direct and of great practical importance.

**Analogue computers.** An analogue computer is a device in which numbers are represented by measured quantities and in which equations or mathematical relations are represented by distinct components corresponding to the individual mathematical operations, such as integration, addition, or multiplication.

It is customary to divide analogue computers into two classes depending on whether numbers are represented by mechanical quantities, such as linear displacements or angular rotation, or by electrical quantities, such as voltages, currents, conductances, and impedances.

If linear displacements are used to represent numbers, there are simple ways in which geometrical relations can appear in mechanical form. A line segment can correspond to a physical bar, the common end point of two line segments can correspond to a common pivot for the bars, and two intersecting lines can be represented by an arrangement of two bars, one of which has a lengthwise slot in which a pivot fixed on the other bar is constrained to move. Circular motion of a point is obtained by fixing a pivot for a bar. Linear displacement is obtained by motion in a groove, but it is frequently more practical to use the fact that a linear displacement is approximated by a circular motion of large radius.

The mathematical operations can then be realized by using a corresponding geometrical relation. For example, three linear bars are constrained to move in three parallel equally spaced grooves. The centre bar has a crosspiece attached to it by a pivot, and the crosspiece has longitudinal slots for pivots attached to the outer bars. The linear displacements  $x$  and  $y$  of the outer bars are then related to the displacement  $z$  of the central bar by the equation  $2z = x + y$  (Figure 14).

The use of this sort of device is, however, limited by mechanical problems associated with the resolution of forces along certain directions and leverage effects. On the other hand, their simplicity and ease of construction makes them suitable for control devices, in which the variables involved usually have a restricted range. They have also been used in conjunction with the representation of quantities by angular rotation for certain mathematical purposes.

One advantage of the representation of quantities by angles of rotation is that total revolutions can be counted and the equivalent of a very large scale obtained. The

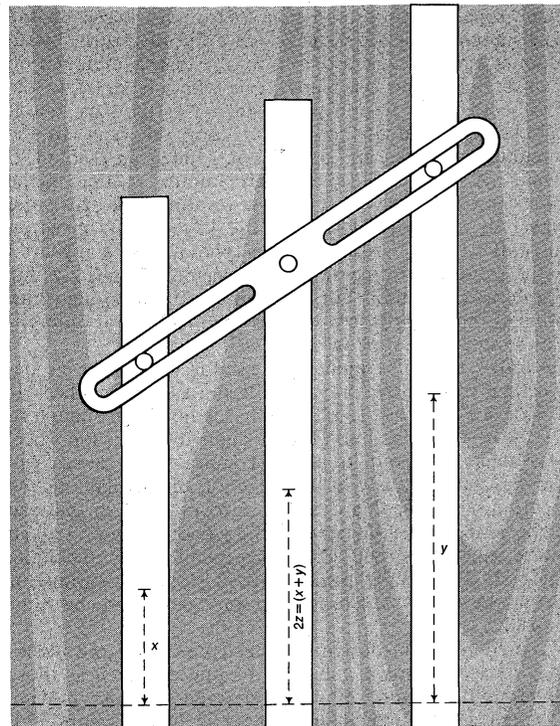

Figure 14: A simple form of analogue computer for addition. The linear displacements  $x$  and  $y$  of the outer bars are related to the displacement  $z$  of the central bar by the equation  $2z = (x + y)$ .

planetary gear differential permits the average of two rotations to be obtained without limit on the size of the rotations. The theory of the shape of gear teeth shows that two shafts can be connected by gears so that the rate of rotation of the driven shaft is a fixed multiple of that of the driving shaft, if the direction is not changed.

The principle of the differential can be easily understood if it is considered to be derived from the previous device in two steps. In step one, the crossbar is replaced by a wheel with an axle mounted on the centre bar. If the wheel is in non-slipping contact with the other two bars, the axle of this wheel on the centre bar will still be displaced by an amount corresponding to the average of the displacements of the two side bars. Now, if the two side bars are replaced by the perimeter of wheels on independent but coaxial axles and the axle of the centre wheel is also mounted on a rotating axle, then the centre of the wheel will rotate by an amount that is the average of the rotation of the side wheels, which in practice are the pitch circles of bevel gears.

**Resolvers.** A number of devices used in rotational mechanical devices depend on translating from a rotational to a linear displacement. A rack and pinion wheel combination will yield this change either way. For limited motion, a double eccentric arrangement is useful. This consists of two bars with a common pivot connection. One bar rotates around a fixed pivot and the other has an end that is constrained to move linearly. In a computer that basically represents quantities by angles of rotation, multipliers are used that involve conversion to linear displacements and the use of similar triangles for the multiplication principle. A linear harmonic displacement—*i.e.*, a linear displacement proportional to  $\cos \omega t$ —is obtained from a uniformly rotating shaft and a projecting bar with a pivot moving in a slot on a sliding piece that can move only in a direction perpendicular to the slot. This type of mechanism, called a Scotch yoke, is used in resolvers, devices that give the sine or cosine of their angular input as an output.

The Scotch yoke

An arrangement of gear wheels also yields a linear displacement. This corresponds to a special case of the hypocycloid, in which a circle of radius  $a$  rolls on the inner side of the fixed circle of radius  $2a$ . Two gear wheels can

be obtained with pitch circles related in this fashion, by mounting the smaller gear on an arm that rotates around the centre of the larger circle. Then a fixed point on the smaller pitch circle moves on a straight line through the centre of the larger circle; and if  $\alpha$  is the rotation of the arm on which the smaller wheel is mounted, the displacement from the centre is  $2a \cos(\alpha + \gamma)$ , in which  $\gamma$  is a constant. The two resolver principles described have an angular input and linear displacement output that can be converted to a rotation if required. For functions other than sines and cosines, cams can be used to produce a linear displacement that is a function of the angle of rotation of the cam.

**Multipliers.** A device called the pin cam produces a rotational output that is a specified function of the input. It can be considered to be derived from the disk and wheel integrator, the output of which is an integral,  $z = \int y dx$ , in which  $x$  is the rotation of the disk,  $y$  is the linear displacement of the wheel, and  $z$  is the rotation of the output shaft (Figure 15). If the displacement  $y$  of the wheel is obtained, not from an arbitrary input, but from a groove cut in the disk so that  $y$  is a specified function of  $x$ , this device will be a function generator for the function  $z$  that is an integral of the function  $y$ . If  $y = 2x$ , this produces essentially  $z = x^2$ ; and if  $y = 1/x$ , it produces  $\log x$ . The first case has been used as a basis for a quarter-square multiplier with differentials being used for the additions and subtractions [i.e.,  $xy = (\frac{1}{4})(x + y)^2 - (\frac{1}{4})(x - y)^2$ ].

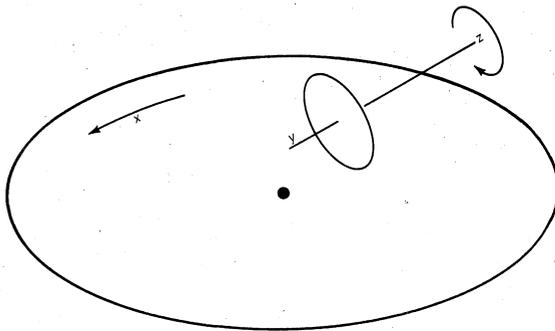

Figure 15: *Disk and wheel integrator.* If the rotation of the disk is  $x$  and the linear displacement of the wheel is  $y$ , then the rotation  $z$  of the output shaft is the integral of  $y$  integrated with respect to  $x$  (see text).

The disk and wheel integrator normally permits two independent variable inputs  $x$  and  $y$  and yields an integral. With proper adjustments of the constants of integration, the relationship that expresses the product of two variables in terms of the sum of two integrals (see 67) is obtained. Thus two integrators with two independent variable inputs will yield a multiplier.

**Harmonic analyzers.** Notions and procedures relative to integrators and resolvers were introduced in the first instance for harmonic analyzers. These obtained successively the various Fourier coefficients of a curve by tracing the curve  $y = f(x)$  on a drawing for each coefficient. From this it was natural to set up a more elaborate apparatus that would obtain a number of Fourier coefficients at once from a single tracing. Two such devices are those of Mader-Ott and Henrici-Conradi (Figure 16). The first name is that of the inventor, the second that of the manufacturer.

There were, however, also a relatively large number of devices that approximated the coefficients by a finite sum containing the values of  $f(x)$  at equidistant points in the interval. Each of these values is multiplied by an appropriate cosine value and summed. Any consistent combination of devices can be used for the individual opera-

$$(67) \quad xy = \int x dy + \int y dx$$

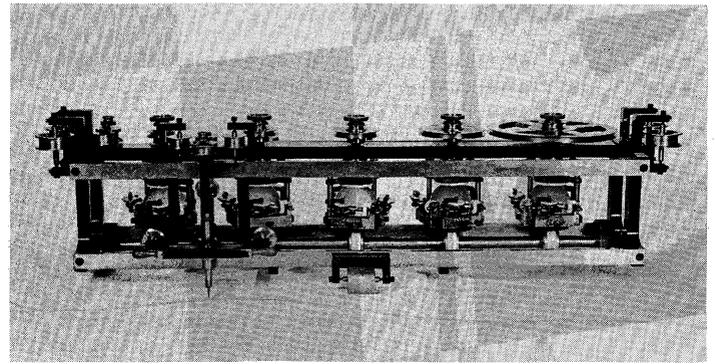

Figure 16: Harmonic analyzer, a highly refined form of a mechanical analogue computing device, with the function of extracting on read-out dials (which bear against the five crystal spheres) the first five coefficients needed, if a linear combination of trigonometric functions is to reconstitute the empirically given curve that is visible. The pointer is held to the empirical curve as the device rolls over the table and relevant motion is transferred to the spheres through wires (not shown).

tions. An early example was constructed by Sir William Thomson (later Lord Kelvin) in 1878.

For a harmonic analyzer, the combined procedure must be relatively simple; a popular method for providing the sum of the quantities is the addition of torques. In an example produced by Walz, the individual term was represented by a torque obtained as follows. A balanced arm is mounted on an axis and on this arm a unit weight is placed at a distance  $f_r$  from the balance point. Now if the torque around the axis of this setup is measured at a position at which the arm makes an angle  $\alpha$  with the horizontal, the torque is  $f_r \times \cos \alpha$ . The procedure for setting up the device permits appropriate  $\alpha$ 's to be chosen for each coefficient.

The addition of torques has also been used in devices for solving linear equations. A torque axis is used for each equation and the value of the unknowns  $x_i$  is represented by hydraulic forces that permit equalization between different torque axes.

**Differential analyzers.** Analogue devices for the solution of systems of ordinary differential equations are referred to as differential analyzers. The concept of this type of device was first described by Thomson in 1876, who pointed out that the output of integrators could be used as inputs for computing devices that yield the appropriate inputs for the integrators. Representation of quantities was by angular rotation, and the components included the disk and wheel integrators, gear sets for multiplying by a constant, and differentials for addition. Because the integrators have two independent inputs, it is possible to obtain an integral that is equivalent to the product of two variables. It followed that an extremely general set of systems of equations can be realized by these components.

A set up of this type, however, requires that the output of the integrators drive various other devices, and this load on the integrators introduced varying slippages resulting in errors. The general concept lay dormant until the development of torque amplifiers permitted the load on the integrators to be decreased, and the development of servo devices (see CONTROL SYSTEMS) permitted operation with negligible loads. Mechanical differential analyzers were revived around 1930, the most famous of these was that constructed at the Massachusetts Institute of Technology in the U.S. by Vannevar Bush. It had a uniform arrangement of components and shafts. Provision was made for introducing arbitrary functions by manual followers. After World War II, mechanical differential analyzers, using servo-followers to eliminate load on the integrators, were constructed, but these became obsolete with the development of electronic differential analyzers and electronic digital computation.

**Automatic controls.** In many circumstances automatic controls are superior to manual controls. Certain chemi-

cal manufacturing procedures of a continuous nature require input to be continuously varied. Other examples are oil refining and navigation. The gyro compass gives an electrical signal proportional to the rate of deviation of direction and thus can be used as a basis for automatic navigation for ships and aircraft and for stabilizing rock-ets.

A control system usually has control inputs that are adjustable to correspond to the desired output. The control inputs must be connected so as to influence the process inputs. When a straightforward functional relation is desired with variables of limited range, linkages are often used, especially because considerable force can be transmitted through such a device. When more complex control relations must be realized, however, a computer is used, supplemented by power amplification using the servo principle.

In the servo principle the purpose is to produce a power driven output with a desired value. The difference between the desired value and the power driven output is measured, and this difference is amplified and used to control the power driven output. This process is known as feedback. For example, the desired output may be given by a shaft rotation. The difference between this shaft position and a powered shaft position can be obtained by a differential, yielding a rotational value.

If rotational agreement is required, this shaft difference can be measured by using a potentiometer to produce a proportional voltage. Such a voltage can be electrically amplified to drive the powered output. If, however, the matching of rates is all that is required, the rate of this difference can be measured by a tachometer, which will also produce a directed voltage. In order to control the rate of a powered shaft the ball cage variable speed drive was used. This device is similar to the disk and wheel integrator, except that the wheel is replaced by a cage containing two spheres that transmit motion from the disk to an output cylinder. The cage can be positioned so that the output is  $\int y dx$ , but the major objective is the increase in the amount of power transmitted.

Thus, the use of servo-controlled outputs meant that an analogue computer need only indicate the desired output. This requirement was also true of subcomputations in the computer, because these could also be power amplified. An associated development was the use of voltages for computation. A potentiometer can be used to transform a shaft position to a voltage, and rotation rate can also be measured by a tachometer yielding a voltage. The difference between this voltage and a desired value of the voltage can be amplified to power the shaft position, or control its rate of rotation, by positioning the cage in a ball cage drive. Thus, a shaft position can be transformed to a voltage, and conversely either the shaft position or its rate of rotation can be made to correspond to a voltage. Thus, quantities can be represented by either shaft rotations or voltages. Nonlinear potentiometers can also be used to produce voltage-valued functions of the shaft rotations, in particular for sines and cosines.

When artillery is to be directed at moving targets such as airplanes or ships, it is essential to predict the motion of the target. Such prediction devices were developed during World War II, using rotational analogue equipment working with voltages and servo-power amplification. The input was obtained by observing the target, relative to range, azimuth, and elevation and their rates of change. A change from polar to Cartesian coordinates was made so that uniform motion would yield constant rates for the coordinates of the target. These constant rates permit a prediction of target position and determination of time of flight for the shell by special two-dimensional cams. The angles of aim are also determined.

**Electromechanical analogue computers.** Bomb sights and computing devices for guns on airplanes were developed on an analogue basis. The mechanical connection of shafts and the arrangement of purely mechanical computing equipment represents a complex problem. The use of voltages greatly simplified the construction of analogue computers, and it was natural to expand this concept into what is referred to as electromechanical ana-

logue computing. Basic quantities are represented by the rotation of shafts. Potentiometers on these shafts can yield voltages corresponding to sums, products, and functions of one variable. Integration in this type of device is represented as follows. The integrand is represented by a voltage and the integral or output by a driven shaft on which is mounted a tachometer the output of which is a voltage corresponding to the rate of rotation. This voltage is compared with the input voltage and the difference used to provide a signal controlling the drive of the output shaft. There are certain advantages in the use of alternating current; for example, transformers can be used to facilitate addition.

Electromechanical analogue equipment of this type was introduced during World War II in trainers for airplane pilots. The devices contain a mathematical simulation of the motion of the aircraft in response to the control of the trainee. The output of the simulation appears on the instruments available to the trainee, and some aspects of the motion of the aircraft may also be simulated. The mathematical simulation of the motion involves computing the aerodynamical forces and solving the system of differential equations corresponding to Newtonian dynamics. Analogue activation of flight trainers was replaced by digital activation during the early 1960s.

**Direct current analogue computers.** During World War II, the laboratories of Bell Telephone Company in the United States introduced a computer to control anti-aircraft guns, the M-9, in which computation was accomplished by means of direct currents. This device was made practical by the development of operational amplifiers that effectively eliminated load effects on computing circuits. Addition and integration were in terms of current. Multiplication by a constant was obtained by potentiometers. Multiplication of variables and arbitrary function representations, however, were electromechanical.

After the war, commercial equipment was introduced on the M-9 principles for electronic differential analyzers. Standard components for integration and addition were introduced, each based on an operational amplifier. Multiplication was electromechanical in the potentiometer, servo-follower sense. A variety of devices were used for the generation of functions, including nonlinear potentiometers and graphical tracing by photoelectronic means. Similarly, many ways were devised to replace mechanical multiplication by various electronic methods. A certain standardization was obtained by means of the diode function generator, which represented a function by segments of linear relationships. Correspondingly, multiplication was based on the quarter-square principle, using two square function generators.

This type of device was widely used by engineering designers. A procedure was developed for basing the design of aircraft on the use of wind tunnel data for aerodynamic forces and Newtonian dynamics. There was a similar development for rockets. Basically, this type of equipment permitted simulations in which formal mathematical procedures were absent and permitted the application of scientific understanding to a wide variety of technical situations. For example, noise analysis, the design of engines, machinery, and even physical experiments were studied by this means. It was possible to use this type of equipment for harmonic analysis and also for Fourier transforms.

Systems of linear equations arise in manufacturing and economic control procedures and in obtaining the least square fit of parameters to data. A linear equation can be realized by a potentiometer or resistance network in which the unknown quantities  $x_i$  are inputs in the form of shaft rotations. A theory of appropriate feedback to position the unknowns is available and such devices have been constructed and used in manufacturing control.

**Hybrid concepts.** The limited precision of analogue equipment and the difficulties associated with multiplication and generation of functions suggested the possibility of using digital circuitry and procedures. Digital devices involve the use of numbers composed of discrete digits, rather than the use of quantities that can vary continuously in magnitude. One major difference between ana-

The M-9  
computer

Military  
applica-  
tions

logue and digital equipment is that the former is parallel, in the sense that for each operation in the mathematical problem, there is a component. In digital equipment, the same components are used repeatedly for the various operations.

Although some efforts have been made to introduce digital equipment in parallel fashion, in general, economic considerations make it desirable to use digital circuitry in the usual manner. Thus, normally, the analogue and digital equipment are separate and the transfer of numerical information from one group to the other is achieved by a conversion of the information from an analogue form to a digital form, or vice versa.

One possibility is the development of specialized digital equipment to perform accurate computations such as forming cosines and multiplication on a serial basis and interacting with the analogue equipment on a multiplex basis; *i.e.*, the results of the digital computation appear serially in different parts of the analogue device in a sequence fast enough to be equivalent to analogue components. The digital equipment is specialized in order to obtain maximum speed and computing capability. In the above possibility, the analogue equipment, in principle, is dominant. Another hybrid concept is to supplement a digital computation by a subsidiary analogue computation. For example, a system of differential equations may be solved by a combination of algebraic and functional computations and integrations. With suitable conversions, the computations are digital and the integrations are done by the analogue equipment. This general procedure has not been successful.

In training and control devices, both the input and output information appear in analogue form, and multiplex conversion is required as, for example, in a flight trainer activated by a digital computer. There are practical computational advantages in performing certain analogue computations on the inputs before analogue to digital conversion and on the outputs after conversion. Another type of situation in which hybrid concepts have proved successful is typified by an experiment in which large amounts of data are obtained initially in analogue form, and it is possible to process this data by analogue means so that the resulting information is more compact. Thus, the conversion to digital form and the digital processing are minimized.

#### DIGITAL CALCULATORS

**Abacus.** Probably the simplest instrument still in use to assist computation is the abacus. Decimal numbers are represented by the position of beads on wires in a frame. For each decimal place, the digits are represented in a biquinary fashion with one or two beads having the value five, and four or five beads having the value one. The framework is divided lengthwise by a partition with the beads having a value of five on one side and the beads with unit value on the other. Zero is represented by all beads pushed away from the central partition and a digit is represented by placing the appropriate value in beads against the partition. The Chinese *suan-pan* is a (2,5) abacus; *i.e.*, there are two five-value beads and five unit-value beads for each decimal place. While the Japanese *soroban* is now a (1,4) device, previously the *soroban* was a (1,5) device.

In ancient times, the Romans used a ten-bead abacus for each position with additional rows for twelfths and twenty-fourths. There was also a type of sand reckoner in which digits were represented by little cones with the digits on their base. The timing of this latter device has been the subject of considerable controversy.

In general, before paper was available, numbers had to be represented in some reusable form, for example, counters of different values, configurations of rods, marks in dust or on a waxed tablet. A more permanent record would be given by notches on a stick; *i.e.*, the tally, or knots on a cord. The early forms of the abacus consisted of a table with ruled lines on which  $\times$  marks or markers were placed in a manner analogous to the beads on the abacus wires. The ruled lines could also have fractional significance.

**Registers and adders.** The abacus can be considered as a simple case of a register; that is, a device in which numbers are represented decimally and provision is made for indicating a digit in each place. People skilled in the use of the abacus can calculate with it at a rate comparable with a modern rotary calculator. Probably the most common type of register is one in which a cylinder corresponds to each place with ten possible positions.

A register can become a counter by providing a carry from one decimal place to another. To make a counter into an adder, it is necessary to provide some form of feed mechanism so that digits can be added into each place. Simple adding machines permit an addend to be entered, place by place, by a simple feed mechanism that may produce a carry into the next highest place but must not affect lower places. Essentially this concept is due to the 17th-century French mathematician Blaise Pascal.

In the simplest case, the feed returns to zero during the addition process and, if repeated addition is required, as in multiplication, then the addend must be entered each time. On the other hand, an effective calculator must retain the addend for repeated use as in multiplication. In addition, in order to introduce the addend simultaneously in all digits, some provision must be made to retain the carry. This might otherwise be lost because of the feed of the digit itself.

Thus, in the full adder invented by the 17th- and 18th-century German Gottfried Wilhelm von Leibniz, the carry is saved in the form of the position of a lever. After the digit feed has occurred, the carries are entered, place by place, in what is called a carry wave. Apparently the Leibniz type device was rediscovered by Charles X. Thomas de Colmar who began the commercial manufacture of this type of device in 1820 in Paris; these devices were produced for 58 years.

The Leibniz feed was based on a cylinder with teeth running lengthwise. The teeth, however, were of successively longer lengths to permit different amounts of feed, and the value of the addend digit was specified by the position of a take off wheel that determined how many teeth on this cylinder were engaged during a revolution. Many other types of feed have been introduced, for example, levers that return to their initial position by an amount of movement corresponding to a pressed key. A rather important type of feed is one in which the pressed key stops a motion at the correct amount rather than causes a motion of a certain amount.

**Rotary calculators.** A critical variation in these devices in which addition is accomplished in a single cycle is in the carry. In addition to the carry wave, a planetary gear carry may also be used. This makes it possible to add two motions into a given place simultaneously. In certain types of devices, it is practical to introduce a standing-on-nines carry. In this procedure, when a carry occurs into a sequence of nines, the carry bypasses the sequence into the next highest place and the nines are all advanced to zero. The principle of the standing-on-nines carry, which is due to Charles Babbage, is based on the fact that a place that stands on nines after the digit feed cannot have produced a carry. This permits all the carries to be performed simultaneously.

The major reason for retaining the addend in a cycle is to permit multiplication by repeated addition and the shifting of places. If appropriate provision is also made for negative down carries, then divisions can be performed by repeated subtractions. Initially both the repeated additions and the shifting of multiplication were done manually, and a similar procedure was used for division. It is possible, however, to incorporate electric motors into these devices so that the sequential procedure is automatic.

Variations on this have been tried at different times. One procedure was the use of the split multiplication table by Léon Bollée. In this device, the product of a digit of the multiplier by the multiplicand was added in the form of two addends. For this multiplier digit and for each digit of the multiplicand, the multiplication table yields two digits, one in the unit place and one in the tens place. One addend is constructed from the unit place digits; the other

The  
Leibniz  
feed

Development of rotary desk calculator

from the tens place digits with a one place shift. Another idea was to calculate the product of the multiplicand and a multiplier digit as a sum of quantities obtained by repeated doubling of the multiplicand, an idea which certainly goes back as far as Ahmes.

Immediately after World War II, rotary desk calculators were developed into devices that would automatically perform addition, subtraction, multiplication, and division and, in some cases, even extract square roots. It was also possible to enter one or more multiplier factors that could be retained during successive operations. These devices were widely used for business, technical, and scientific purposes, and special forms with printed outputs were developed for accounting. By the 1970s, however, a number of factors had tended to make them obsolete, one being the increasingly widespread use of large-scale electronic data processors for the same purposes. In addition, with the development of integrated circuitry, it has been possible to produce electronic calculators with cathode-ray tube output displays and electronic computing circuitry at a competitive price. The electronic calculators can store 16 to 48 numerical quantities and can be programmed either by card sequences or by stored programs up to 256 steps. The programming is done by going through the operations of the programmed sequence once with the calculator in what is called the learning mode.

#### PUNCHED CARDS

**Cards.** In the early forms of the desk calculator, each time a number was used it was transcribed manually into the keyboard, and for each use, therefore, there was a possibility of error. To counteract this, Herman Hollerith introduced the representation of data by holes on cards, first used in analyzing the data of the U.S. census of 1890. The cards were read by making electrical contacts through the holes. These procedures were developed by the Tabulating Machine Company, which in 1924 became the International Business Machines Corporation (IBM).

The IBM card

For the census of 1910, James Powers developed a card system in which holes in a card are sensed by plungers, which, when they penetrate a hole, act like the depressed key in a calculator relative to the mechanism below the card. This type of equipment eventually was produced by Remington Rand in the United States, Samas-Power in England, and Samas in France. It is also possible to read cards by photosensitive methods.

The standard IBM card is rectangular and measures  $7\frac{3}{8}$  by  $3\frac{1}{4}$  inches (187 by 83 millimetres). The length of the card is divided into 80 columns, each of which extends the width of the card. In each column there are 12 positions for holes. These positions are named X, Y, 0, 1, . . . , 9 beginning with the top position or that nearest the leading edge in a reading procedure (see 68). Digits are represented by a single punch in the appropriate digit position. Letters are represented by two punches. The information on such a card is represented by sets of adjacent columns called fields. These fields can contain either numerical or alphabetical information.

(68)	}	A (X, 1)	J (Y, 1)	
		B (X, 2)	K (Y, 2)	S (0, 2)
		C (X, 3)	L (Y, 3)	T (0, 3)
		D (X, 4)	M (Y, 4)	U (0, 4)
		E (X, 5)	N (Y, 5)	V (0, 5)
		F (X, 6)	O (Y, 6)	W (0, 6)
		G (X, 7)	P (Y, 7)	X (0, 7)
		H (X, 8)	Q (Y, 8)	Y (0, 8)
		I (X, 9)	R (Y, 9)	Z (0, 9)

The IBM card is read by electrical contacts. The movement of the card through the reading device is coordinat-

ed with the fundamental machine cycle so that the information appears in the form of time coded pulses.

**Punched card machines.** The original procedures in which punched cards were used involved the sorting and counting of cards. Both the Hollerith and the Powers systems were also developed for accounting purposes, which required the capability of adding the values in fixed fields into totals and subtotals. Printed outputs and machines called tabulators were developed for this purpose. As the possibility for using punched card systems for more general bookkeeping was recognized in the 1930s, machines with various other properties were introduced. The IBM equipment was electromechanical; the Samas-Powers equipment was mechanical. In addition to sorters, collators that could merge decks of cards in an order determined by specified fields were produced, as well as a multiplying punch, which could multiply the numerical values of two fields on a card and enter it in a third. In this way payrolls, insurance premiums, discounts, etc., could be calculated.

The electromechanical tabulators, collators, multiplying punches, and other devices had one advantage in that the choice of fields and operations were controlled by plug boards, with which the operator could route the electric pulses by connections with electric cables and plugs. After World War II, the electromechanical operations were replaced by electronic devices, and the use of plug boards was augmented by the ability of the device to execute a program (a logical sequence of instructions) of operations.

This programming capability was developed much further. A combination of three machines, called the card program calculator (CPC), was introduced that permitted programming by cards. The earliest really widespread electronic program data processing machine was the IBM 650, which had an internal stored program but was, in many business applications, an extremely flexible punched card processor. Even for the later and far more sophisticated large-scale data processors, cards are a desirable input and output, both for data and programs. Programs are generally devised so that new cards for additions or corrections can be added to the deck.

The card program calculator

#### PROGRAMMED MACHINES (DIGITAL COMPUTERS)

**Development.** To produce function tables or perform astronomical calculations requires a more complex mathematical capability than that of the simple arithmetical machines. The concept of devices for such purposes apparently goes back to Johann Helfrich von Müller (1786), and during the 19th century, mechanical machines were constructed with varying degrees of success. They used analytic procedures based on functional differences. The most famous effort along these lines was that of Babbage, who introduced many machine computing concepts including that of the stored program.

The technology available to Babbage was not adequate for the concepts he envisioned, but even later when mechanical procedures were sufficient, their complexity, cost, and slowness continued to limit their practicality. Another alternative for complex computing involved relays, especially those developed for telephone exchange switching. Relay machines were constructed by Bell Laboratories, by H. Aiken at Harvard University, by IBM, and in England, Germany, The Netherlands, and Sweden in the 1940s.

There had also been, however, a tremendous development of vacuum tube technology, including that of radar type circuitry in World War II, and by 1945, the Moore School of Electrical Engineering built the all electronic ENIAC for Aberdeen Proving Grounds, Maryland, for exterior ballistic calculations. This proved to be far too slavish an image of mechanical decimal computation, and succeeding machines, such as the Institute for Advanced Study computer (IAS), constructed under the supervision of John von Neumann, used the binary representation of numbers and binary arithmetic to decrease the amount of electronics and increase the speed. In binary notation a number can be represented by two symbols, 0 and 1. These can be indicated by the presence or ab-

sence of a pulse in an electric circuit or by two states of a component. A critical advance in the adaption of electronics to computation was the formulation of computer circuitry in terms of Boolean algebra by the National Bureau of Standards (1950).

In a binary system, there is also a choice between parallel arithmetic procedures in which operations in different binary positions are done simultaneously or serial procedures in which the places are treated successively. Electronically, parallel arithmetic is usually associated with flip flop circuitry in which bits are represented by the state of the circuitry, while the serial arithmetic is associated with the representation of bits by electrical pulses.

**Instruction and programs.** The major elements of an electronic data processing system are the central processing unit, the storage for data and instructions, and the input-output. The central processor is equivalent to a very fast desk calculator controlled by the set of instructions. The instructions are stored in sequence, and usually the next instruction executed is the next in sequence. There are, however, decision instructions in which the content of a register determines whether the next instruction is to be executed or a jump is to be made to another place for the next instruction. Loops of instructions can be executed by switching back to a previous instruction until a certain criterion is satisfied.

Various formats are used for the instructions. The instructions are stored in the form of a fixed number of binary bits; *i.e.*, zeros or ones. One subset of bits, the instruction code, determines the operation to be performed—addition or multiplication or decision. Other sets determine the address of data or instructions; that is, their location in the memory. Computers have been classified according to the number of addresses in the instructions. For example, a four-address computer is one in which there are two addresses for the operands of the operation, an address to store the result, and the address of the next instruction. A common format is the one-address instruction. These instructions operate relative to certain registers in the central processing unit (CPU). For example, in addition or multiplication one operand is already in the central register, the address of the other operand is in the instruction, and after the calculation, the result is in the register. Clearly, there is a need for load instructions to transfer the data in the address to the register and store instructions with the reverse effect.

In the computer, both data and instructions are transferred to the CPU but, in usual procedures, the paths are quite distinct. The data is associated with the numerical operational registers, the instructions with the instruction register, and the only arithmetic operations applied to the instructions refer to the addresses. This last possibility, however, may be avoided by the use of index registers, which automatically add a base number to an address in the instruction or by indirect addressing, which permits the use of addresses stored in other places.

Thus, it is reasonable to use distinct storage units for instruction and data storage and initially different media were used. The instructions in many relay machines were on a specialized type of broad paper tape that permitted one instruction to be represented on a line in a binary fashion while the numerical data was stored on relays. For special purpose machines, there are certain advantages of speed and reliability in "read only" storage for instructions, but the lack of flexibility may be a serious disability.

**Storage facilities.** The development of computers to the mid-1950s mainly involved a search for fast and reliable memories. Relay registers were slow and unreliable. Electronic registers, using vacuum tubes, were expensive and were limited by the tube's life. Devices, similar to cathode-ray tubes, with special electronic elements, gave memory effects by means of the electrostatic phenomena resulting from the impact of a directed stream of electrons. These proved somewhat difficult to construct, and the information had to be renewed every 50 miliseconds. Another type of device was the mercury acoustic delay line storage unit in which bits were stored in the form of acoustic impulses travelling from an initial to an end

position. This was a serial device in the sense that specific information was available only periodically with intervals of nonavailability while the pulse travelled in the storage line. The temperature of this device had to be carefully controlled for proper operation. A more successful device was the magnetic drum on which pulses were stored as small magnetized areas on a rotating drum. This was also a serial device because there would usually be only one reading or writing head on a channel around the drum.

In 1953 magnetic core storage was introduced. Each bit was represented by the magnetization of a small ring of ferrite material called a core. The cores were strung on criss-crossing wires so that an electric pulse on one set of wires would cause magnetic reversals in cores corresponding to bits with value one, and these reversals would electronically pulse certain output wires. This type of storage was generally adopted as fast storage. In the 1970s, certain types of integrated circuitry were also considered for fast storage.

Magnetic drums have an access time of the order of about 17 miliseconds but usually are of somewhat limited capacity. Disk devices have access times of the order of 75 miliseconds but have a larger capacity. Access on magnetic tape is a matter of position, but tapes have storage advantages. For both disks and tapes, information is preferably stored in long records because, after a record has been located, it can be read very quickly.

**Programming.** When the fastest available storage was of a serial nature, the instruction format usually provided the address of the next instruction. This permitted optimal programming, in which the next instruction or the next operand is placed so as to be available in the serial storage at the appropriate time. To construct an optimal program manually was an onerous job, and special machine programs were devised to lay out the storage assignment for optimal timing. Instruction codes were also represented in alphanumeric mnemonic manner instead of in octal or hexadecimal form.

A program then could be written in assembler language as a sequence of instructions with mnemonic operational codes and with the operands denoted by alphanumeric names. A special program, called an assembler, would then determine the storage layout and assign to each given instruction in assembly language, an instruction in machine language. More complex computer programs were also developed, such as Algol and Fortran, which would take expressions modelled on algebraic formulas and translate these into sequences of machine instructions as well as perform the assembler function.

The programming associated with a computer system is referred to as the software as opposed to the equipment itself—the hardware. Numerous developments have made the production of software an increasingly important and financially significant aspect of data processing. A complex installation requires specialized programming for display processing, checking, and input-output control. The usual operating procedures include various language translators and monitors, which can service an arbitrary sequence of programs. Time sharing on computers by several users involves quite complex software. When a computer system is dedicated to a specific purpose, programs are usually optimized in the assembler or even in machine language form.

**Circuitry.** Vacuum tube electronics in computers was plagued by limited tube life, the heat generated by the filaments, and the complexity of the interconnections. In 1948 the transistor was introduced, a device that provided signal amplification by electrical field effects in certain semiconducting materials such as germanium or silicon. Because no incandescent filaments were involved, computers using transistors required far less expensive cooling systems. A reliability improvement of at least a factor of 10 also was obtained.

Plug-in units were used in the first computers for maintenance reasons. The plug-in units were electronic circuits having a considerable number of components and representing certain logical functions. Only a small number of different logical functions are represented in these units

Use of  
binary  
bits

Magnetic  
core  
storage

Computer  
languages

so that only a small number of different types are required. The complete logical structure of the computer is represented by using the logical functions of these units. If any component on a unit fails, there is a procedure to locate the unit; a special program is run on the machine and the logical consequence of the failure indicates the unit to be replaced. The receptacles for the plug-in units are mounted on racks. The wiring of the receptacles on the rack then corresponds to the logic of the major components. This rack wiring is designed by a computer program, and the actual wiring is done automatically by machines.

As the components developed for use in computers became faster, the size of the circuits became the limiting factor in computing speed. A consequent further development was that of large-scale integrated circuitry in which complete circuits were formed on chips of silicon by the same techniques as those used in making transistors. These techniques produced, in addition to transistors and diodes, resistors and capacitors. By the use of photographically controlled etching techniques, a remarkable reduction in size is possible so that a density of  $10^8$  components per square inch is possible. New storage elements, faster than those based on magnetic cores, have been developed. The indications are that integrated circuitry will permit the production of computers of extremely high speed, reliability, and perhaps lower cost.

**Error detection.** Digital computation must be error free. Errors can be caused by system misdesign, programming mistakes, or faulty components. The initial search for system errors and faulty components in a computer is referred to as debugging. This term is also applied to the testing of programs. When a faulty component continuously produces an incorrect output, maintenance programs based on logical analysis readily locate the plug-in unit containing the component. Intermittent faults or design mistakes that are apparent only under improbable combinations of conditions require specialized techniques such as testing with low or high voltages to maximize the possibility of errors. Even if there is no system or component fault, however, errors can occur because of thermal noise or external causes. If such an error is detected and the operation involved is repeated, it is highly probable that a second attempt will be successful.

Thus the detection of transient errors of low probability is critical. In order to detect errors that occur when data is stored or transmitted, a parity bit is used. The data is represented in the form of a word consisting of a fixed number of bits plus the parity bit, and the value of the parity bit is chosen so that the total number of bits with value one is odd. Thus, if only one bit in the word is in error, an error condition will be detected by an appropriate counter. The word length for parity checking need not be the same as that for the other computations and there has been a standardization on the eight bit plus parity unit. This is called a byte. In the correction of errors additional information must be available to locate the erroneous bit. A system has been developed such that if in a word of  $2^n$  bits,  $n$  bits are used as parity bits, then a single erroneous bit can be detected and located.

Arithmetic operations can be checked by independent modulo computations. To operate in a manner called modulo  $p$  is to ignore multiples of  $p$  so that quantities are considered equal if they differ by a multiple of  $p$ . To use modulo  $p$  relations effectively, it must be possible to reduce numbers by discarding multiples of  $p$ . For integers expressed in decimal form, this can be done for modulo 9, by replacing the integer by the sum of the digits. Thus, 4,735 can be replaced by 19, and this in turn by 1. The checking of decimal arithmetic by modulo 9 is called casting out nines. For modulo 11, the sign of the digits in the sum is alternated, with the digit in the unit place taken positive (see 69).

In a binary machine, in which an integer would be

represented with a radix (base) of two rather than ten, the concept of modulo 1 is useless for checking. Modulo 3, however, in which the bits are added with alternate signs can be used. This form of modulo 3 is readily obtained by circuitry based on Boolean algebra, in either the case of operations performed in parallel for the various binary places or serially. By grouping bits, binary expressions can also be considered as based on radix 4, 8, 16, etc. The equivalent of casting out nines for modulo 3, 7, 15, etc., is possible.

Another approach to eliminating errors is the use of duplicating circuitry. Thus, if a computation has been done by three circuits in duplicate and two answers agree, this result could be accepted if the circuits are fairly reliable. Objections have been raised to this philosophy of reliability by redundant equipment, however, because the extra equipment adds to the unreliability. Some error detection must also be available for improvement of the equipment. In practice improvements in reliability have been most effectively obtained by improving the reliability of individual components rather than by redundancy.

**Input and output.** The initial media for input and output were cards and paper tape. Card readers and card punches were readily adapted to input and output. Another device adapted for input or output was the tape operated typewriter in which each character corresponded to a combination of holes across the width of the paper tape, and such a combination could readily be entered as bit values into the computer or interpreted as output. Output printers were also developed.

Initially, computers were equipped with consoles in which information could be entered into the machine by switch positions and read out by lights. A later development was direct typewriter communication to the computer. There were, of course, applications requiring graphical output, and devices were developed to produce plots and diagrams by moving pens controlled by the computer.

Another graphical output was based on a cathode-ray tube (CRT). The cathode-ray tube output was also developed for military purposes, originally as part of air defense systems in which defensive aircraft are directed against attacking bombers. The CRT displays consisted of background maps with symbolic indications of the position of the various aircraft and their past and projected paths. Because much of the information and activation program of these displays does not change during the exercise, there is frequently associated with each individual CRT display, a local computer that activates the display using local program and local data storage and also information transmitted from the central computer.

The various applications of CRT displays, including computer graphics, require the capability of manually indicating points on the display. This is done by the light pen, a photosensitive device. The display on the CRT is generated in a timing pattern in which different parts of the image are produced at different points in time during a cycle. Thus if the light pen is held against a particular point on the face of the tube, it will be pulsed only at a certain instant in the timing pattern and in this way the position can be entered into the computer. The pen is active only when a button on it is pressed so that it can be moved freely and activated only when desired.

In computer graphics, a drawing or diagram can be constructed on the face of the tube by means of the light pen and a console, consisting of buttons each of which activates a specific program. For example, a particular button will cause a straight line segment to be drawn between two points, and another button will draw a circle with an indicated centre and indicated point on it. Portions of a diagram can be constructed in different planes, and the cathode-ray tube can be used to show a rotated or rotating image of a three-dimensional diagram.

Not all cathode-ray tube displays are complex. A relatively simple display showing lines of alphanumeric characters can be used for many purposes including output without paper. Such a display can also show forms in which the alphanumeric information can be entered from a console typewriter, and these forms can be pro-

Modulo  
computa-  
tions

output

$$(69) \quad 4735 \equiv 5 - 3 + 7 - 4 \pmod{11}$$

cessed completely automatically for various business purposes.

OCR input

A number of desirable forms for input and output have been intensively studied for development, but they were in a tentative state in the 1970s. One highly desirable input procedure is to have the computer read, by a photoelectric method, a printed or written document; this is known as optical character recognition (OCR). It would permit the processing of masses of data already in existence and would be very valuable for the machine translation of natural languages. Documents that are printed with certain specific type fonts can be handled by the present state of the art. The more general problem of pattern recognition, however, appeared in the 1970s to have no economically feasible and generally acceptable solution.

By using audio-magnetic tapes, it is possible to produce a spoken output from the computer of limited vocabulary, and one can simulate the "talking down" procedure used by air controllers for instrument landings in airplane pilot trainers. On the other hand, spoken input to computers, like video input, discussed above, has an intensive development aim of getting an effective input from a specific voice.

**Data processing systems.** There are many applications in which information is processed in the central processor unit at rates of about a thousand times faster than it can input or output. Addition times of less than two microseconds and multiplication times of about four microseconds are now customary for larger computers, while rates of output printers based on conventional procedures are of the order of 35 miliseconds per line. In addition to the difference in speed, it has proved possible to design and expand the central processor so that the registers can be used for a high fraction of the time. Thus, when relatively long arithmetic operations such as multiplication or division are being performed, other registers not involved may be used for transfers. Efforts to use thermal contact and photosensitive printing procedures to produce faster output of data have been made. To use the speed of the central processing unit for assistance in programming, procedures for eliminating routine chores have been developed. These procedures were incorporated into programming languages allowing programs to be expressed in a compact and readily understood form, which was later translated by the computer into machine language.

The CPU speed also permits time sharing, in which a larger number of remote consoles can be connected to the same central processor and communicate with it in the form of input instructions and typed output. The exchange of data with these remote terminals can be interspersed so that there is little interference between different users.

These are relatively inefficient uses of the CPU capabilities. Large amounts of data can be stored and re-entered from mass magnetic storage media such as tapes and disks at relatively fast rates, between 60,000 and 130,000 bytes per second. To the extent that data can be handled without external communication, this provides a reasonable match between computation and storage.

Elements of a modern data processing system

Thus, a modern data processing system will consist of a central processor, a hierarchy of storage facilities including magnetic cores, disks, drums, and tapes, and a complex of input-output devices under certain control units. These control units are essentially processors that execute input-output instructions. For a time, it was customary to use other computers to act as intermediaries between magnetic tape storage and devices such as printers, card readers, and punches. This allowed the central computer to deal only with magnetic tapes. This satellite-computer concept, however, has been replaced by improvements in the design of the central processor and input-output control. The objective is to permit transfers under the input-output control to occur while the longer arithmetical operations are being executed. The fast core storage is organized into subsections, each with an independent access register so that transfers can be made in and out of some sections while other sections are involved in arith-

metical operations or in various operations relative to instructions.

**Applications.** Electronic computation has had extremely important technological, scientific, and economic consequences. The electronic developments required for computers were the main technological advances in the decades following World War II. Many complex systems were developed using the logical possibilities of digital electronic circuitry. In general, those control applications that previously had been developed with analogue computation were expanded and made more reliable by the new circuitry. In the case of airplane computers used for navigation by automatic pilots and military purposes, a considerable saving of weight was obtained. Airplane pilot trainers and similar devices were operated by digital computers rather than analogues.

In World War II, radar beams were directed by turning large dishes, but after the war, electronically directed radars were invented. Their sensitivity depended upon digital circuitry that performed statistical analyses of the radar signals. New and complex defense warning systems based on large digital computers could detect and distinguish between artificial satellites and hostile missiles and, in addition, predict their paths.

In addition to their role in activating complex systems, computers are used for modelling and simulations in designing aircraft, nuclear reactors, and other devices. Specific programs in general purpose computers permit the evaluation of Fourier coefficients and transforms and the solution of systems of algebraic or differential equations.

Modern physics often requires considerable use of computers, especially in the design and construction of devices such as the synchrotron (a device for accelerating subatomic particles; see ACCELERATORS, PARTICLE). Experiments in nuclear physics often result in large numbers of photographic plates showing the reactions of elementary particles. These can be analyzed by computer.

The ability of computers to hold and handle large amounts of information has been the basis of efforts to translate languages and considerable success has been reported. The capabilities of computers in the routine examination of alternatives has been used in programs for automatic chess playing and for dealing with formal logic, algebraic and geometrical proofs, and certain linguistic theories.

Information retrieval systems have also been introduced. Large-scale indexing of medical, scientific, and technical collections is based on the use of key words in the titles of works. Molecular structure listings have been used for patent purposes and medical research.

The application of electronic computing to business has resulted in a tremendous centralization of bookkeeping. Management control is assisted by the central processing of data about sales, stockkeeping, invoicing, shipping, billing, sales analysis, production control, inventory, and receiving. In each of these areas, up-to-date information is of considerable value. For example, maintaining inventories at the correct level avoids the objectionable extremes of overinvestment in supplies or production delays because of inadequate supplies.

Mass production bookkeeping is characteristic of public utilities and insurance companies and there has been a considerable development of business output devices suitable for billing, invoicing, and checkwriting. Airplane reservation systems use a variation of the time sharing concept with remote controls that can query airplane bookings and make reservations.

The automatic processing of accounts in large volumes has resulted in a highly significant cost reduction, even over the previously used punched card procedures. One consequence has been the widespread elimination of customer credit accounts in retail stores by means of credit cards. Charges, as represented by charge slips, are referred to customers' accounts in banks or banking subsidiaries, and handled on a mass basis by electronic equipment. This results in a considerable centralization of accounting. These systems were not free from technical difficulties initially and there has been considerable criticism directed at the mechanization and centralization.

There has also been criticism of the accumulation of information about individuals by the government in computer form. If this information were inert, in written form, rather than in computer form, it would not lend itself to possible manipulation. Part of the reaction, here and in other cases, has been a focussing on computers and data processing of a general emotional reaction against the technological explosion itself. (F.J.M.)

## Mather Family

The prominence of the Mather family in England and the dominance of Richard, Increase, and Cotton in New England, in the 17th century, can hardly be overestimated. Though for 200 years after their time popular history labelled them witch-hunters and bigots, the fact is that they were neither. Being Puritans, with an uncompromising belief in Calvin's doctrine of the elect, who were predestined to be saved, they were men of their times; if they believed in witches, so did their contemporaries at home and abroad. Beyond this frame of reference, they were ahead of their times in many respects. They were, indeed, rebels against the prevailing establishment. Their lives spanned the reigns of many monarchs, who opposed and sometimes even persecuted advocates of Puritanism who, like the Mathers, stood courageously for their principles.

**Richard Mather.** Richard Mather was born in the village of Lowton in Lancaster, England, in 1596. He was of a "credible and ancient family" of an intellectual calibre that was to be perpetuated in his descendants. He attended Winwick school under a severe taskmaster who, however, recommended him, at age 15, to be teacher at a new school at Toxteth Park. There he decided to enter the ministry, gave up his position, and entered Brasenose College, Oxford, where he greatly enjoyed the pursuit of learning. In 1618, at the request of the people of Toxteth, he left the university to become their minister and, bowing to their wishes, was ordained by the Bishop of Chester.

As a thorough Puritan, Richard Mather had rejected all pomp and ceremony retained by the Church of England from its Catholic origins, and he preached at Toxteth without a surplice for 15 years before authorities discovered it. Suspended, and then reinstated, he returned to his dissenting practices and was tried before a court, before which he admitted without apology the matter of the surplice.

Permanently "silenced from Publick Preaching the Word," he retired to private life and resolved to leave for America, where he would be free to preach and do good according to his own convictions. He and his wife (Katherine Holt, whom he had married in 1624) and their four sons sailed for America in June 1635 and arrived at Boston in August. His journal of the voyage is one of his best written works. His reputation had preceded him to New England, where several towns asked for his services. He chose Dorchester, Massachusetts, a post he held until his death. Two more sons, Eleazar and Increase, were born there.

Of Richard Mather's six sons, four became ministers. Samuel and Nathaniel, after being educated at Harvard College, returned to the British Isles in 1650, where Samuel received a degree, became a fellow at Trinity College, Dublin, and later became minister in Dublin, a post he held until his death. Nathaniel preached at Barnstable and later succeeded Samuel in Dublin. Eleazar became minister of Northampton. Richard's first wife, Katherine, died in 1655; a year later he married Sarah Cotton, the widow of John Cotton, an eminent Puritan minister.

Richard's most respected work is his summation of principles as adopted at the Cambridge Synod of 1648 and considered to be the clearest statement of Puritan Congregationalism.

He is remembered for his part, with other ministers, in the literal translation of the Psalms for the *Bay Psalm*

Richard's refusal to wear a surplice

*Book* (1640), which were set to already accepted tunes; in his preface to that work, Richard excused the terrible results by explaining that the editors would not take “poeticall licence to depart from the true and proper sense of David’s words.”

On his deathbed, Richard Mather was troubled about two things: he was not back in his study, and he had not convinced his son Increase of the rightness of the so-called Half-Way Covenant, a plan that provided modified church membership for those who were unable to meet the rigorous tests for full membership. He died April 22, 1669.

**Increase Mather.** Increase Mather, the youngest and most distinguished of Richard’s sons, was active at home and abroad as minister, diplomat, and president of Harvard. Born in Dorchester, June 21, 1639, he entered Harvard at the age of 12 and received his bachelor’s degree at 17. At graduation, his attack on Aristotelian logic, basic to the Harvard curriculum, shocked the faculty and nearly resulted in his dismissal. On his 18th birthday he preached his first sermon in a village near his home and his second in his father’s church in Dorchester. Soon he left for Dublin, where he entered Trinity College and received a master’s degree the following June. At his commencement, he refused to wear a cap and gown, but the assembled scholars were so impressed with him that they hummed their approval of him. Chosen a fellow at Trinity, he refused the post. He preached at various posts in England and was at Guernsey when the Puritan Commonwealth ended and Charles II was proclaimed king (May 8, 1660). He refused to drink the King’s health or sign papers expressing rejoicing. On the appointment of a new governor for Guernsey, unsympathetic to Nonconformists, Increase left a comfortable living and in a few months sailed for New England, where he became minister of North Church, Boston, in 1661, and married his stepsister, Maria Cotton, in 1662.

In 1683 Charles delivered an ultimatum to the Massachusetts colonists: to retain their charter with absolute obedience to the King or to have it revoked. Before an assembly of freemen, Mather proclaimed that an affirmative vote would be a sin against God, for only to Him should one give absolute obedience. The colonists refused submission, and the charter was subsequently revoked in 1686.

After James II became king, in 1688, Increase was sent as the representative of the colonists to thank him for his declaration of liberty to all faiths. He remained in England for several years, and on the accession of William and Mary in 1689, he obtained from them the removal of the hated governor of Massachusetts, Sir Edmund Andros, and his replacement by Sir William Phipps. Increase’s petition for the restoration of the old charter

proved unsuccessful, but he was able to get a new charter in 1691. Both the new governor and the new charter, however, turned out to be unpopular. In 1685 Increase had been made president of Harvard but resigned in 1701, in part because of opposition to the new colonial charter. He received the honorary degree of doctor of divinity in the same year.

Among his books is *An Essay for the Recording of Illustrious Providences*, 1684, a compilation of stories showing the hand of divine providence in rescuing people from natural and supernatural disasters. Some historians suggest that this book conditioned the minds of the populace for the witchcraft hysteria of Salem in 1692. Despite the fact that Increase and Cotton Mather believed in witches—as did most of the world at the time—and that the guilty should be punished, they suspected that evidence could be faulty and justice might miscarry. Witches, like other criminals, were tried and sentenced to jail or the gallows by civil magistrates. The case against a suspect rested on “spectre evidence” (testimony of a victim of witchcraft that he had been attacked by a spectre bearing the appearance of someone he knew), which the Mathers distrusted because a witch could assume the form of an innocent person. When this type of evidence was finally thrown out of court at the insistence of the Mathers and other ministers, the whole affair came to an end.

Increase’s *Case of Conscience Concerning Evil Spirits Personating Men* (1693) is a clear vindication of the Mathers’ part in the witchcraft trials. Yet their enemies, such as William Douglass and Robert Calef, spread denigrating rumors about them. This enmity, together with the Mathers’ part in a campaign for inoculation against smallpox and the failure of their protégé Phipps to measure up to expectations, contributed to the decline of the Mathers’ influence in the last decade of the century. Changing times, more than anything else, had their impact; for people like the Mathers were losing touch with the younger generation. Increase died on August 23, 1723.

**Cotton Mather.** Cotton Mather’s heritage from his two grandfathers, Richard Mather and John Cotton, was both fortunate and unfortunate. Like them, he had an active mind and the will to use it. He lived in the shadow of their greatness and expected to carry on the tradition and to assume their role in the Puritan community. Unfortunately, he could not see that the old order was passing. As colonial communities became more secure from earlier hardships of settlements, they also became more complacent and less in need of a confining spiritual leadership. Cotton fought for the continuance of old order of the ruling clergy, sometimes with frustration, sometimes in anger.

The  
Mathers  
and the  
Salem  
witch trials

Cotton was born in Boston, February 12, 1663. He entered Harvard at 12, easily passing entrance requirements to read and write Latin and to "decline the Greek nouns and verbs." He devoted himself unremittingly to study and prayer. At 18 he received his M.A. degree from the hands of his father, who was president of the college. Unlike his father, he never went abroad but spent all his life in Boston.

He once noted that his life was "a continual conversation with heaven," but he spent agonizing hours convinced that he was damned and equal time in ecstasies that he was not. For a while, he feared he could not enter the ministry because of a speech impediment, and he considered becoming a physician; the subject of medicine was of lifelong interest to him. After a friend persuaded him "to oblige himself to a dilated Deliberation in speaking," he conquered his weakness and returned to religious studies. He preached his first sermon in his father's church in August 1680 and in October another from his grandfather John Cotton's pulpit. He was formally ordained in 1685 and became his father's colleague.

He devoted his life to praying, preaching, writing, publishing and still followed his main purpose in life of doing good. His book, *Bonifacius, or Essays to Do Good* (1710), instructs others in humanitarian acts, some ideas being far ahead of his time: the schoolmaster to reward instead of punish his students, the physician to study the state of mind of his patient as a probable cause of illness. He established societies for community projects.

He joined his father in cautioning judges against the use of "spectre evidence" in the witchcraft trials and in working for the ouster of Sir Edmund Andros. He was also a leader in the fight for inoculation against smallpox, incurring popular disapproval. When Cotton inoculated his own son, who almost died from it, the whole community was wrathful, and a bomb was thrown through his chamber window. Satan seemed on the side of his enemies; various members of his family became ill, and some died. Worst of all, his son Increase was arrested for rioting.

His interest in science and particularly in various American phenomena—published in his *Curiosa Americana*, (1712–1724)—won him membership in the Royal Society of London. His account of the inoculation episode was published in the society's transactions. He corresponded extensively with notable scientists, such as Robert Boyle. His *Christian Philosopher* (1721) recognizes God in the wonders of the earth and the universe beyond; it is both philosophical and scientific and, ironically, anticipates 18th-century Deism, despite his clinging to the old order.

Cotton Mather wrote and published over 400 works. His magnum opus was *Magnalia Christi Americana* (1702), an ecclesiastical history of America from the founding of New England to his own time. His *Manuductio ad Ministerium* (1726) was a handbook of advice for young graduates to the ministry: on doing good, on college love affairs, on poetry and music, and on style. His own style ranged from the over elaborate to the directly simple, as in his biography of Gov. William Bradford. For the most part, his prose was laden with Latinisms and quotations from ancient authorities. In one instance, the posthumously published *Political Fables*, he showed the gift of satire. His ambitious 20-year work on biblical learning was interrupted by his death.

He died on February 13, 1728, only five years after his father, whose colleague he had been for 40 years. Of 15 children by his three wives—Abigail Phillips, Elizabeth (née Clark) Hubbard, and Lydia (née Lee) George—only two survived him.

**BIBLIOGRAPHY.** Contemporary biographies by members of the Mather family revealing the subjects and their times, and incidentally the loyalties of one Puritan family, are COTTON MATHER, *Parentator* (1724), on Increase; INCREASE MATHER, *The Life and Death of That Reverend Man of God, Mr. Richard Mather* (1670); and SAMUEL MATHER, *The Life of the Very Reverend and Learned Cotton Mather* (1728). KENNETH B. MURDOCK, *Increase Mather: The Foremost American Puritan* (1925, reprinted 1966); and BARRETT WENDELL, *Cotton Mather: The Puritan Priest* (1891 and 1926, re-

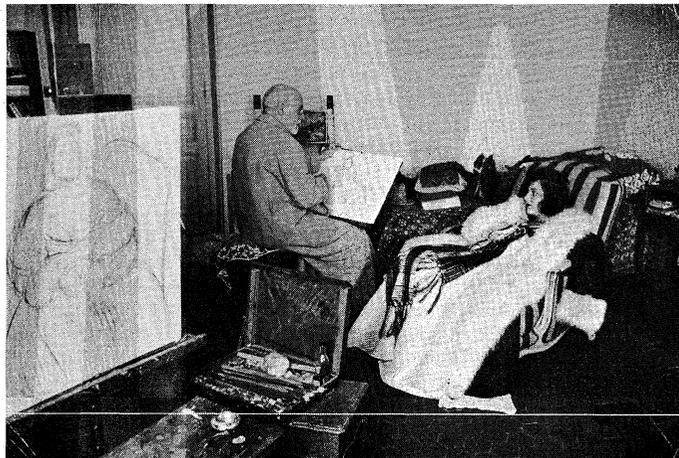

printed 1963), are definitive biographies by distinguished 20th-century writers.

(J.K.P.)

## Matisse, Henri

In the general upheaval that marked the history of Western painting at the close of the 19th century and the opening of the 20th, the first element to undergo drastic change was colour, and one of the principal innovators in colour was the French painter, sculptor, and graphic artist Henri Matisse. In 1905 in Paris he helped to launch the movement known as Fauvism, which rejected chromatic naturalism and favored the use of violent hues calculated to stir the emotions of viewers. But Matisse was more than just a rebel against traditional art. He went on to become the creator of masterpieces that continue, in a modern idiom, an ancient French preference for paintings that are at once sensual and rational. He has often been bracketed with Pablo Picasso as one of the two most important artists of the 20th-century school of Paris.

Henri Cartier-Bresson—Magnum

Matisse sketching a model, photograph by Henri Cartier-Bresson.

Henri-Émile-Benoît Matisse was born on December 31, 1869, at Le Cateau (formerly Cateau-Cambrésis), a small town in Picardy, and raised at nearby Bohain, where his parents had a grain business. He displayed little interest in art until he was 20 years old. From 1882 to 1887 he attended the secondary school in Saint-Quentin; after a year of legal studies in Paris, he returned to Saint-Quentin and became a clerk in a law office. He began to sit in on an early-morning drawing class at the local École Quentin-Latour, and, in 1890, while recovering from a severe attack of appendicitis, he began to paint, at first copying the coloured reproductions in a box of oils his mother had given him. Soon he was decorating the home of his grandparents at Le Cateau. In 1891 he abandoned the law and returned to Paris with the intention of becoming a professional artist.

Although at this period he had, in his own words, "hair like Absalom's," he was far from being a typical Left Bank bohemian art student. "I plunged head down into work," he said later, "on the principle I had heard, all my young life, expressed by the words 'Hurry up!' Like my parents, I hurried up in my work, pushed by I don't know what, by a force which today I perceive as being foreign to my life as a normal man." This 19th-century gospel of work, derived from a middle class, northern French upbringing, was to mark his entire career, and soon it was accompanied by a thoroughly bourgeois appearance—gold-rimmed spectacles; short, carefully trimmed beard; plump, feline body; conservative clothes—which was odd for a leading member of the Parisian avant-garde.

**Formative years.** He did not, however, become a member of the avant-garde right away. In 1891, in order to prepare himself for the entrance examination at the official École des Beaux-Arts, he enrolled in the privately

Cotton's  
interest  
in science

run Académie Julian, where the master was the strictly, even slickly, academic Adolphe-William Bouguereau, then at the peak of a since-departed fame as a painter of beves of naked, mildly provocative nymphs. That Matisse should have begun his studies in such a school may seem surprising, and he once explained the fact by saying that he was acting on the recommendation of a Saint-Quentin painter of hens and poultry yards. But it must be remembered that he himself was for the moment a provincial with tastes that were old-fashioned in a Paris already familiar with the Postimpressionism of Paul Cézanne, Paul Gauguin, and Vincent van Gogh. His earliest canvases are in the 17th-century Dutch manner favoured by the French Realists of the 1850s.

Training  
with  
Gustave  
Moreau

In 1892 he left the Académie Julian for evening classes at the École des Arts Décoratifs and for the atelier of the Symbolist painter Gustave Moreau at the École des Beaux-Arts, without being required to take the entrance examination. Moreau, a tolerant teacher, did not try to impose his own ornate, somberly fantastic style on his pupils but encouraged them rather to develop their personalities and to learn from the treasures in the Louvre. Matisse responded by turning out copies of works by, among others, Raphael, Poussin, Chardin, Fragonard, Ribera, and a Dutch still-life specialist, David de Heem. He continued, with some long interruptions, to study in the atelier until 1899, when Fernand Cormon, an intolerant painter who had become the professor after Moreau's death the previous year, insisted that he leave the École des Beaux-Arts. After that, although he was nearing 30, he frequented for a time a private academy where intermittent instruction was given by the portraitist Eugène Carrière. And as late as 1900 he was not above going to the Louvre to copy Chardin's still life "La Raie."

Few 20th-century modernists, therefore, have had as many years of solidly traditional training as Matisse had; conceivably, he could have gone on to become a favourite of the French art establishment or at least a successful muralist for town halls. But during these years he was learning some untraditional things by arguing with and working alongside sympathetic young companions. In Moreau's atelier he met Georges Rouault, Raoul Dufy, Henri Manguin, and Charles Camoin; at the École des Arts Décoratifs, Albert Marquet; in Carrière's academy, André Derain. During the summer of 1895 he went to Brittany with a Parisian friend named Émile Wéry. "At that time," he remembered, "I had nothing but yellowish browns and earth colours on my palette, while Wéry had an Impressionist palette. Like him, I undertook to work from nature. And soon I was seduced by the brilliance of pure colour. I came back from my trip with a passion for the hues of the rainbow, whereas Wéry returned to Paris in love with bitumen." Although the passion produced inconsistent results for a while, it eventually proved irresistible.

First  
success

In 1896 Matisse exhibited four paintings at the backward-looking Salon de la Société Nationale des Beaux-Arts and scored a triumph; he was elected an associate member of the Salon society, and his "Woman Reading" (1894), painted in relatively dark tones, was purchased by the government as decoration for the château of Rambouillet. From this point onward he became increasingly confident and venturesome, both as an artist and as a man. During the next two years he undertook two more expeditions to Brittany, met the veteran Impressionist Camille Pissarro, and discovered the series of Impressionist masterpieces in the Gustave Caillebotte Collection, which had just been donated—amid protests from conservatives—to the French nation. His colours became, for a while, lighter in hue and at the same time more intense. In 1897 he took his first major step toward stylistic liberation and created a minor scandal at the Salon with "The Dinner Table" ("La Desserte"), in which he combined a Renoir kind of luminosity with a firmly classical composition in deep red and green.

In 1898 he married a young woman from Toulouse, Amélie Parayre, and left Paris for a year, visiting London, where he studied the paintings of Turner, and working for a while in Corsica, where he received a lasting impres-

sion of Mediterranean sunlight and colour. Although he continued to revert to grays and browns, apparently out of a fear of losing control of his forms and tone values, he was no longer the provincial artist who had hoped for a conventional career via the École des Beaux-Arts and the big official shows.

**Revolutionary years.** During 1898, Paul Signac, the theoretician and actively proselyting leader (after the death of Georges Seurat) of the Neo-Impressionists, or Pointillists, published in the literary review *La Revue Blanche* his principal manifesto, "D'Eugène Delacroix au Néo-Impressionisme." Matisse, back in Paris in 1899, read the articles and, without turning into an immediate convert, became interested in the Pointillist idea of obtaining additive mixtures of colour on the retina by means of juxtaposed dots (*points* in French) on the canvas. He furthered his research into new techniques by buying, from the well-known modernist dealer Ambroise Vollard, a painting by Cézanne, "The Three Bathers"; one by Gauguin, "Boy's Head"; and a drawing by van Gogh. Often accompanied by his close friend Marquet, who was also interested in the problem of pure colour, he began to paint outdoor scenes in the Luxembourg Gardens in Paris, in suburban Arcueil, and from the open window of his apartment overlooking the Seine River near Notre-Dame Cathedral.

He also purchased from Vollard the plaster model of the bust of Henri Rochefort by Rodin, and during 1899 he began to attend an evening class in sculpture. His early work in three dimensions, the first of some 60 pieces he executed during his lifetime, reveals the influence not only of Rodin but also of Antoine-Louis Barye, generally considered the greatest of the many 19th-century French sculptors of animals. In fact, for the "Jaguar Devouring a Hare," begun in 1899, Matisse relied on copying a Barye work, with some help from a study of the anatomy of a dead cat. Later on he sometimes used modelling as a way of experimenting with motifs in his painting, and eventually he came to regard the volumes and mass of sculpture as compensating, in the interest of a full creative development, for the flatness of his pictures.

Early  
sculpture

After 1899 he ceased to exhibit at the Salon and gradually became a familiar figure in the Parisian circles where modern art was being produced and ardently discussed. In 1901 he showed for the first time in the juryless, eclectic Salon des Indépendants, which had been founded in 1884, by Signac among others, as a refuge for painters unacceptable to the official exhibition juries. In 1902 he was in a group show at the small gallery of Berthe Weill, and the next year he and a number of his old classmates from Moreau's atelier and the Académie Carrière were the progressive contingent in the liberal, newly created Salon d'Automne. But in spite of such recognition, he was often on the brink of financial disaster. In 1900 he was obliged to accept work on the decoration of the Grand Palais, which was being erected to house part of the new Exposition Universelle in the Champs-Élysées quarter. His wife opened a dress shop in the hope of helping to make ends meet. In 1901 an attack of bronchitis forced him to take a long rest. During part of 1902 he had to return to Bohain with his three children—Marguerite, Jean, and Pierre—and Mme Matisse. He was past 34 when, in June 1904, at Vollard's gallery, he had his first one-man show; it was a success neither with journalists nor with collectors.

Meanwhile, he was trying, partly in a series of still lifes and of views from his apartment, to advance out of the relatively dark realistic style to which he was still partly committed or at least into which he still backslid. Pushing him forward were such comparatively reckless younger contemporaries as Derain and Derain's iconoclastic friend, the painter Maurice de Vlaminck, who boasted of never having seen the inside of the Louvre. Among the older influences pushing in the same general direction were Cézanne, Gauguin, van Gogh, the Impressionists, and possibly some of the 18th-century French masters. But what appears to have been the decisive push was provided by the hues of the Mediterranean coast and by the impact of Signac, which was considerably brighter

than that of the cautious, "scientific" Seurat. Matisse spent the summer of 1904 on the French Riviera at Saint-Tropez, working with Signac and producing, among other things, "Luxe, calme, et volupté"; he got the title from Baudelaire's poem "L'invitation au voyage" and the technique, rather approximately, from the Pointillists. He sent the picture to the Salon des Indépendants in the spring of 1905 and thus became, for a season, something of an official Neo-Impressionist. He was not, however, greatly pleased; he felt, he explained later, that the dabs of contrasting pigment favoured by the Seurat-Signac theory weakened dominant colours and that what was needed was a way "to exalt all colours together, sacrificing none of them." This reasoning pointed toward painting with strong, unrealistic, flat tones—toward a style that in colour, although not necessarily in drawing, was practically abstract.

Development of the Fauve style

He spent the summer of 1905 with Derain at Collioure, a small French fishing port on the Mediterranean, near the Spanish border. In the dazzling sunshine he rapidly freed himself from what he called "the tyranny" of Pointillism. The carefully placed little dabs required by the additive-mixture approach turned into swirls and slabs of spontaneous brushwork, and the theoretically realistic colours exploded into an emotional display of complementaries: red against green, orange against blue, and yellow against violet. Representative of this new freedom were "Open Window," which was finished at Collioure, and "Woman with the Hat," a portrait of Mme Matisse painted back in Paris in September. That fall, the two pictures were exhibited at the Salon d'Automne alongside works by a number of artists—among them Marquet, Derain, Valminck, Rouault, Manguin, and Camoin—who also had been experimenting with violent colour. The Paris critic Louis Vauxcelles called the group *les fauves* ("the wild beasts"), and thus Fauvism, the first of the important "isms" in 20th-century painting, was born. The movement was not very coherent, and Matisse was not its sole initiator and animator. But almost immediately he became its widely acknowledged leader.

Almost immediately, too, his financial situation altered for the better. The Stein family in Paris—Gertrude, her brothers Leo and Michael, and the latter's wife Sarah—became Matisse collectors, beginning with the purchase of "Woman with the Hat" at the 1905 Salon d'Automne. In 1906 the artist had a show at the Galerie Druet in Paris in addition to exhibiting again at the Salons des Indépendants and d'Automne. In 1907 a group of admirers, who included Sarah Stein and the German painter Hans Purrmann, organized for him a Left Bank art school, in which he taught off and on until 1911. In 1908 he exhibited in New York, Moscow, and Berlin; the next year he received commissions from Russia and signed a contract with the Galerie Bernheim-Jeune in Paris. From this point, his international reputation was assured, and he was on his way to becoming one of the wealthiest of 20th-century painters. But it must be remembered that in 1909 he was already 40 years old.

He invested a good deal of his new income in travel. In 1906 he visited Algeria, where he was impressed by the textiles and ceramics of the native craftsmen. The next year he went to Padova (Padua), Florence, Arezzo, and Siena in Italy. In 1908 he travelled to Germany, in 1910 to Spain, and in 1911 to Moscow and Tangier. He became an art collector himself, an intellectual capable of tossing off a quotation from Nietzsche, a lucid commentator on his own work, and a shrewd man of affairs. In 1909 the French poet and critic Guillaume Apollinaire wrote: "Bearded, sheltering behind gold glasses a look full of slyness, Monsieur Henri Matisse lives now at Paris, now at Collioure. This *fauve* is a man of refinement. He likes to surround himself with works of ancient and modern art, with precious textiles, and with those pieces of sculpture in which the Negroes of Guinea, Senegal, and Gabon have represented with a rare purity their most Pan-like passions."

Fauvism was too undisciplined to last very long, and soon its adherents were moving, according to their temperaments, toward Expressionism, Cubism, or some kind

of neo-traditionalism. Matisse had no liking for these directions, and if "Fauve" is taken to mean simply a painter with a passion for pure colour, he can be said to have remained one all his life. He had, however, too much rationalism in his outlook not to wish for some order in a stylistic situation that threatened to become chaotic. In "Notes d'un peintre," an article he published in *La Grande Revue* in 1908, he explained his intentions with examples: "I have an interior scene to paint; I have before me a wardrobe that gives me a lively sensation of red, and I lay down a red that satisfies me. A relationship is set up between this red and the whiteness of the canvas. If I add a green, if I represent the floor with a yellow, there will be a still satisfactory relationship between the green or the yellow and the whiteness of the canvas. But these different colours weaken each other. The various signs I use must be balanced so as not to destroy each other. I have to put some order in my ideas . . ." The danger of becoming cold and meaningless in the course of establishing an aesthetic order was countered in a statement about painting a female nude: ". . . at first I give it grace and charm, and the problem is to give it something more. I'll condense the meaning of this body by finding its essential lines. At a first look the charm will be less apparent, but it will emerge in the long run from the new image, which will also have a larger, more fully human meaning."

His search for chromatic equilibrium and linear economy can be followed in a series of major works produced between the revelation of Fauvism in 1905 and the end of World War I. In 1906 he painted "Joy of Life"; in 1908, "The Dessert, a Harmony in Red," for the famous Russian collector of Matisse's, Sergey Shchukin; in 1911, "The Red Studio"; in 1915, "Goldfish"; in 1916, "Piano Lesson"; and in 1918, "Montalban, Large Landscape."

In such works, the list of which should be much longer, the main characteristics of Matisse's mature style recur constantly. The forms tend to be outlined in flowing, heavy contours and to have few interior details; the colour is laid on in large, thin, luminous, carefully calculated patches; shadows are practically eliminated; and the depicted space is either extremely shallow or warped into a flatness that parallels the plane of the canvas and defies academic rules for perspective and foreshortening. The total effect, although too intense and freehand to be merely decorative, may recall the patterns of the rugs, textiles, and ceramics of the Islāmic world. The choice and treatment of subject matter imply optimism, hedonism, intelligence, a fastidious sensuality, and, in spite of the many studies of pretty women, scarcely a trace of conventional sentiment. "I don't create a woman," the artist once remarked, "I make a picture."

**Riviera years.** He continued, although his innovations were less influential than those of the Cubists, to be regarded as a member of the band of Parisian cultural revolutionaries. In 1912 his sculpture was on view in New York and his painting in both Cologne and London. In 1913 he was represented by 13 pictures in the much discussed, much lambasted New York Armory Show, and when the exhibition arrived in Chicago he was given some useful publicity by the burning, happily merely in effigy, of his "Blue Nude." He continued to work frequently with such old companions as Marquet and Camoin; he was on friendly terms with Pablo Picasso, whom he had met through Gertrude Stein; and in 1914, at Collioure, he came to know Picasso's gifted young Cubist disciple, Juan Gris. But middle age, growing affluence, an established international reputation, the disruptions of World War I, and a distaste for public commotion gradually combined to isolate him from the centres of avant-gardism in Paris. Although he kept, after a period of absence, his Paris apartment and maintained a studio in suburban Issy-les-Moulineaux, he began to winter on the French Riviera, and by the early 1920s he was mostly a resident of Nice or its environs.

In the opinion of many art historians, his painting declined in quality during at least the first part of his so-called Nice period. Certainly his pictures became less daring in conception and less economical in means. Like

Characteristics of mature style

many painters and composers during these years (notably Picasso and Igor Stravinsky), he relaxed into a modernized sort of classicism and into a rather evident attempt to please an art public that was a bit tired of attempts to shock it. His colours became softer, his naturalistic details more numerous, his spatial organization more conventional, and his subject matter—in particular his still lifes with flowers and his exotic nudes with densely patterned Islāmic-style backgrounds—more obviously seductive. He aimed perhaps too directly at what he once referred to as a kind of art that was “like a mental soother, something like a good armchair.” But to say this is to judge by the standards of modern problem-solving art that he himself helped to erect. Judged according to less sophisticated standards, such typically Nice-period works as the “*Odalisque with Magnolias*” and “*Decorative Figure on an Ornamental Background*” are masterpieces that deserve their popularity.

Prosperity did not make him less industrious. In 1920 he did the sets and costumes for Sergey Diaghilev's Ballet Russe production of *Le Chant du Rossignol*, with music by Stravinsky and choreography by Léonide Massine. He returned to sculpture, which he had neglected for several years, and by 1930 he had completed his fourth and most nearly abstract version of “*The Back*” (bronzes of all four versions are in the Museum of Modern Art, New York, and the Tate Gallery, London), a monumental female nude in relief, on which he had been working at intervals since 1909. He relaxed, as he had always done, by travelling: to Étretat, on the coast of Normandy, in 1921; to Italy in 1925, and to Tahiti, by way of New York City and San Francisco, in 1930. He found time to serve on the jury of the Carnegie International Exhibition in Pittsburgh, Pennsylvania, where he had been awarded a first prize in 1927. During 1933 he visited Venice and Padova, and in Merion, Pennsylvania, completed and installed the final version of his large mural, “*The Dance II*” (Barnes Foundation). The first version of the mural (now in the Musée d'Art Moderne de la Ville de Paris) had turned out to be unusable because of an error in measurements, and rather than resort to patching he had done the whole work over again.

Stylistically speaking, although not in terms of actual residence somewhere else, the Nice period in easel pictures can be said to have ended definitely in 1935 with the painting of “*The Pink Nude*.” At about this time, in a conversation with a Paris critic, Matisse made one of the most direct of his many declarations of principle, and in the course of it he implied dissatisfaction with some of his recent work. “*Pictures*,” he said, “that are refinements, subtle shadings, delicacies without energy, need some handsome blues, some handsome reds, some handsome yellows, some substances that stir the sensual depths in men. That was the point of departure for Fauvism: the nerve to rediscover purity of means.” Acting on this premise with a capacity for renewal unusual in an artist approaching 70, he turned toward simple contrasts of fresh colour enclosed in flat motifs that sometimes suggested poster patterns. Examples of this neo-Fauvist deployment of “purity of means” are “*Lady in Blue*,” “*Dancer and Armchair, Black Background*,” and “*Large Interior in Red*.”

Matisse had been interested in etching, drypoint, lithography, and allied printmaking techniques since his first years in Paris and had produced a number of occasional prints. In 1932 he had published, as illustrations for an edition of Stéphane Mallarmé's *Poésies*, 29 etchings, in which his talent for supple contours and linear economy was subtly attuned to the “purity of means” evident in the poems. After the outbreak of World War II, he became increasingly active as a graphic artist, notably with his illustrations for Henry de Montherlant's *Pasiphaé* (published in 1944), Pierre Reverdy's *Visages* (1946), the *Lettres portugaises* (1946), Charles Baudelaire's *Fleurs du mal* (1947), Pierre de Ronsard's *Florilège des Amours* (1948), and Charles d'Orléans' *Poèmes* (1950). Along with these books in mostly black and white techniques, he published *Jazz* (1947), a book consisting of his own reflections on art and life, with brilliantly coloured

illustrations made by a technique he called “drawing with scissors”: the motifs were pasted together after being cut out of sheets of coloured paper (hand-painted with gouache in order to get the desired tint). The idea, a development of the Cubist device of pasting paper into oil paintings, had been in his mind since at least 1931, when he had used cutout forms to experiment with his first designs for the Barnes Foundation murals.

During the last years of his life, he was a rather solitary man who was separated from his wife and whose grown-up children were scattered in Europe and the United States. After 1941, when he underwent an operation for an intestinal disorder, he was bedridden much of the time; after 1950 he suffered from asthma and heart trouble. Cared for by a faithful Russian woman who had been one of his models in the early 1930s, he lived in a large, sunbathed apartment and studio in the Old Hôtel Regina at Cimiez, overlooking Nice. Often he was obliged to work on his mural-sized projects from a studio bed or a wheelchair with the aid of a crayon attached to a long bamboo pole. But there are no signs of flagging creative energy or of sadness in his final achievements; on the contrary, these works are among the most daring, most accomplished, and most serenely optimistic of his entire career. At Vence, a Riviera hill town where he had a villa from 1943 to 1948, he completed in 1951, after three years of planning and execution, his *Chapelle du Rosaire* for the local Dominican nuns, one of whom had nursed him during his nearly fatal illness in 1941. He had begun by agreeing to design some stained-glass windows, had gone on to do murals, and had wound up by designing nearly everything inside and outside, including vestments and liturgical objects. Before the chapel was finished, he was at work on the huge coloured-paper cutouts—amplifications of what he had done in the illustrations for *Jazz*—that made him in many respects the “youngest” and most revolutionary artist of the early 1950s. Striking examples of this ultimate explosion of Fauvism are “*Sorrows of the King*” and “*Souvenir of Oceania*.”

Matisse died on November 3, 1954, at Nice, within two months of his 85th birthday. He is buried in the cemetery of Cimiez.

#### MAJOR WORKS

PAINTINGS: “*The Dinner Table*” (“*La Desserte*”; 1897; Stavros S. Niarchos Collection, London); “*Compote and Glass Pitcher*” (1899; Baltimore Museum of Art, Baltimore, Maryland); “*La Coiffure*” (1901; Philadelphia Museum of Art, Philadelphia); “*Carmelina*” (1903; Museum of Fine Arts, Boston); “*Luxe, calme, et volupté*” (1904–05; private collection, Paris); “*Joy of Life*” (1905–06; Barnes Foundation, Merion, Pennsylvania); “*Open Window*” (1905; John Hay Whitney Collection, New York); “*Woman with the Hat*” (1905; Walter A. Haas Collection, San Francisco); “*The Blue Nude*” (1907; Baltimore Museum of Art); “*Le Luxe*” (1907; Musée National d'Art Moderne, Paris); “*The Dessert, a Harmony in Red*” (1908; Hermitage, Leningrad); “*Red Madras Headdress*” (1908; Barnes Foundation, Merion, Pennsylvania); “*Dance*” (1909; Museum of Modern Art, New York); “*The Red Studio*” (1911; Museum of Modern Art, New York); “*Goldfish and Sculpture*” (1911; Museum of Modern Art, New York); “*The Blue Window*” (1911; Museum of Modern Art, New York); “*Goldfish*” (1912; Barnes Foundation, Merion, Pennsylvania); “*Goldfish*” (1915; Samuel A. Marx Collection, Chicago); “*Piano Lesson*” (1916; Museum of Modern Art, New York); “*Interior with a Violin Case*” (1917–18; Museum of Modern Art, New York); “*Montalban, Large Landscape*” (1918; private collection); “*Odalisque with Magnolias*” (1924; private collection); “*Decorative Figure on an Ornamental Background*” (1927; Musée National d'Art Moderne, Paris); “*The Dance I*” (1931–32; Musée d'Art Moderne de la Ville de Paris, Paris); “*The Dance II*” (1932–33; Barnes Foundation, Merion, Pennsylvania); “*The Pink Nude*” (1935; Baltimore Museum of Art); “*Lady in Blue*” (1937; Mrs. John Wintersteen Collection, Philadelphia); *La Musique*” (1939; Albright-Knox Art Gallery, Buffalo); “*Dancer and Armchair, Black Background*” (1942; private collection); “*Large Interior in Red*” (1948; Musée National d'Art Moderne, Paris); *Chapelle du Rosaire* (1951; Vence, France; entire decoration designed by Matisse); “*Sorrows of the King*” (1952; Musée National d'Art Moderne, Paris); “*Souvenir of Oceania*” (1953; Museum of Modern Art, New York).

SCULPTURE: (all bronze, several examples of each)—“Jaguar Devouring a Hare” (1899; private collection); “The Slave” (1900–03; Baltimore Museum of Art, and elsewhere); “Madeleine I” (1901; Baltimore Museum of Art and elsewhere); “Small Head” (1906–07); “Two Negresses” (1908); “The Back I–IV” (1909–30); “Jeanette I–V” (1910); “Seated Nude” (1925).

**BIBLIOGRAPHY.** ALFRED H. BARR, JR., *Matisse: His Art and His Public* (1951, reprinted 1966), is still, in spite of its date, one of the best critical analyses. A more recent general work, aimed at a wider public, is JOHN RUSSELL *et al.*, *The World of Matisse, 1869–1954* (1969). ALBERT ELSEN, “The Sculpture of Matisse,” *Artforum* (September through December, 1968), reassesses a somewhat neglected aspect of the artist’s achievement. PIERRE SCHNEIDER (ed.), *Exposition Henri Matisse* (1970), is the fact-crammed catalog of the Paris retrospective show of 1970. LOUIS ARAGON, *Henri Matisse, roman*, 2 vol. (1971), is not really, as the title implies, a novel, but rather a poetic evocation by a perceptive French contemporary of the painter. Useful bibliographies are in Barr (*op. cit.*), for the period before 1951; and in JEAN LEYMARIE *et al.*, *Henri Matisse* (1966), the catalog of the UCLA Henri Matisse retrospective, for the period 1951–66.

(R.McMu.)

## Mato Grosso

Mato Grosso is an inland state (*estado*) of Brazil in the Grande Região Centro-Oeste (Grand Central-West Region). It is bounded on the northwest by the states of Rondônia and Amazonas, on the northeast by Pará, on the east by Goiás and Minas Gerais, on the southeast by São Paulo and Paraná, and on the southwest and west by the countries of Paraguay and Bolivia. One of the remaining great frontier regions of the world, its name means “great woods.” The third-largest state of Brazil, after Amazonas and Pará, it has an area of 475,504 square miles (1,231,549 square kilometres). Its population has been growing rapidly since about 1950 and in 1970 was 1,600,000; nevertheless, large areas remain unsettled. The state capital is Cuiabá.

**History.** Mato Grosso was settled first by pioneering gold seekers from São Paulo after they had been forced to retreat by the *emboabas* (Portuguese colonists) of Minas Gerais in the so-called war of the *emboabas* in 1708, over mining rights in gold fields. With the founding of Cuiabá, where rich placer mines had been found, in 1719, Mato Grosso became a district of the captaincy of São Paulo, and in 1748 it became an independent captaincy. In 1761 the capital was transferred to Vila Bela, on the Rio Guaporé, but in 1820 it was returned to Cuiabá. During the colonial period and until deposits were largely exhausted, its placer mines supplied substantial quantities of gold and some diamonds. After the decline of mining, cattle ranching emerged as the principal activity. Mato Grosso became a province of the empire in 1822 and a state of the federal union in 1889.

The entire area’s overall growth and development was long retarded by its lack of access to the sea. Until the railroad was built across southern Mato Grosso in 1914, the only means of communication except by overland trails was by way of the Paraguay and Paraná rivers, 2,000 miles (3,000 kilometres) to the Atlantic. Only in the second half of the 20th century have highways begun to offer more widespread communications. The expedition of Brazilian explorer Marshal Cândido Mariano da Silva Rondon in the early part of the 20th century furnished the first complete, accurate data about Mato Grosso; some sections of the state, however, remained virtually uninvestigated in the 1970s.

**The natural environment.** Most of Mato Grosso lies on the western extension of the Brazilian Plateau, across which runs the watershed that separates the Amazon Basin from the basin of the Río de la Plata system. The elevated region is known as the Planalto do Mato Grosso, or Mato Grosso Plateau, and its elevation is about 3,000 feet. Its northern slope, drained by the Rio Xingu, Rio Tapajós, and Rio Madeira, descends to the valley of the Amazon. The valley of the Rio Araguaia, an affluent of the Rio Tocantins, marks the eastern border of the state. The southern slope drains southward through a multitude of streams flowing into the Paraná in the southeast and its

chief tributary the Paraguay on the southwest. The general elevation in the south is much lower than in the north, ranging from 300 to 400 feet (90 to 120 metres) and large areas bordering the Paraguay are swampy. The basins of the Paraná and Paraguay are separated by low ranges extending north from Paraguay. The western part of the state, chiefly a floodplain (*pantanal*), is among Brazil’s best grazing lands, and ranks as one of the great tropical grazing lands of the world.

The lowlands are hot and humid, the highlands hot and dry. The average temperature is 79° F (26° C). Average annual rainfall is 50 to 60 inches (1,300 to 1,500 millimetres). There is a distinct dry season from May to September.

Natural vegetation includes expanses of grassland, densely wooded areas, and, in the highlands, extensive plains, or *campos*, with scrub growth and light forest.

**Population.** The Grande Região Centro-Oeste, composed of Mato Grosso, Goiás, and the Distrito Federal, since 1950 has had the highest rate of population growth in Brazil. The population of Mato Grosso in 1950 was 522,044; in 1960 it was 910,262; and by 1970 it was 1,600,000. Historically, the state’s population has been concentrated in the southeast, and the greatest growth has been in that area. The state as a whole still has a population density of less than two persons per square mile (less than 0.8 persons per square kilometre), the lowest of any Brazilian state outside Amazonas and the federal territories in the north.

Ethnically, the state includes a relatively high proportion of mestizos (persons of mixed European and Indian ancestry), as do other areas of the interior. Although many of the new immigrants also are mestizos, large numbers have come from various parts of Brazil and represent differing degrees of European, Indian, and Negro extraction, and immigrants of Japanese ancestry have settled along the railroad in the south.

The population is chiefly rural, and there are few cities, the principal ones being Corumbá, Campo Grande, and the state capital, Cuiabá. The influx of new settlers has been distributed about equally between rural and urban areas, expanding both segments of the population.

**Administration and social conditions.** Like the other Brazilian states, Mato Grosso has its own constitution and laws, conforming with the national constitution. The governor and the members of the legislature are elected.

Social conditions are those of an expanding frontier. Public health and welfare services are limited in the growing cities and developing rural areas of the southeast and even more limited in the sparsely settled expanses outside that region. Elementary education is free and compulsory, by law, but there are insufficient numbers of schools and teachers to supply it. Higher education is not available in the state.

**Economy.** Livestock raising and agriculture represent the principal economic activities of Mato Grosso. The state supports over 10,000,000 head of cattle, the principal market being São Paulo. Mato Grosso has important deposits of gold, industrial diamonds, iron, manganese, nickel, and platinum. Manganese deposits south of Corumbá have been mined since the 1940s and some iron ore and nickel are produced, but the inadequacy of transportation facilities has been a major barrier to further development.

Campo Grande is the main agricultural centre in southern Mato Grosso, a position enhanced by the railroad communication with São Paulo, the movement of the coffee frontier toward the west and northwest of São Paulo state, and the concomitant shift of population. The existence of dark, purple-coloured soil, *terra rosa*, and other fertile soils in the area of Campo Grande and south into Dourados, near the southern tip of Mato Grosso, allows a wide diversity of crops to be grown. Coffee, rice, cotton, sugarcane, and corn (maize), the main commercial crops, are produced in that order. Colonization projects instituted by the federal and state governments in the vicinity of Dourados, with emphasis upon coffee cultivation, resulted in that area becoming one of the fastest growing in Brazil.

Mineral  
resources

Highlands,  
river  
valleys,  
and plains

**Transportation.** Mato Grosso has shared with the rest of the Grande Região Centro-Oeste the isolation imposed by distance and the existence of numerous north-south ridges of watersheds that have served as barriers to transport and communications from east to west since colonial times. The only natural communications routes were along the rivers, north to the Amazon Basin, or south to the Paraná-Plata system. Overland travel was by horse or mule. The extension of the railroad across southern Mato Grosso in 1914 made Campo Grande the economic and transport centre of the region and provided the first effective overland link between the state and the national capital at Rio de Janeiro. Both Campo Grande and Corumbá are served by the railroad, and Corumbá also has rail connections with Santa Cruz, Bolivia. Cuiabá has no rail connections but is served by river boats from Corumbá and by road from Campo Grande.

Mato Grosso's 3,850 miles (6,200 kilometres) of federal roads are largely trails, many of which are impassable during the rainy season. Although paved roads are rare outside the principal cities, road transport has become increasingly important in the second half of the 20th century. While the Transamazônica road, under construction since 1970, which is to cross South America from coast to coast, passes to the north of the state, the transportation network which will be linked to it will be of particular significance for the economic development of Mato Grosso. All three principal cities are served by airports, and even remote areas have become accessible by air.

**Cultural life.** The state's cultural life, like many of its other characteristics, is that of an expanding frontier. Except for an academy of letters at Cuiabá, an association for cultural exchange at Guiratinga, and an ethnographic museum at Campo Grande, major cultural institutions—such as state theatres, libraries, and universities—have not yet emerged. Its traditions have been those of the cattle ranch and the farm, being transformed in the second half of the 20th century by the infusion of immigrants, many from similar parts of Brazil.

**BIBLIOGRAPHY.** W.L. SCHURZ, "Conditions Affecting Settlement on the Matto Grosso Highland and in the Gran Chaco," in W.L.G. JOERG (ed.), *Pioneer Settlement: Cooperative Studies by Twenty-Six Authors* (1937), is a scientific study analyzing prospects for immigration, resettlement, and colonization. VESPASIANO BARBOSA MARTINS, *Saudação a Campo Grande* (1943), provides a brief account of the historical development of Campo Grande; see also the IBGE, CONSELHO NACIONAL DE ESTATISTICA, *Campo Grande* (1956), a statistical survey.

## Matter and Antimatter

The substance of every physical object in the known part of the universe is called matter. The ultimate constituents of matter are three elementary particles: the electron ( $e^-$ ), the proton ( $p$ ), and the neutron ( $n$ ). Various combinations of neutrons and protons make up the few hundred different atomic nuclei known today. Each proton has a positive electric charge of  $1.6 \times 10^{-19}$  coulomb, where a coulomb is the practical (mks) unit of electric charge and a mass of approximately  $10^{-24}$  gram. Neutrons have no electric charge; the neutron mass is almost identical to that of the proton. An electron has a negative charge equal in magnitude to that of the proton and a mass approximately  $\frac{1}{2,000}$  that of a proton. The most important subatomic particles and related topics mentioned below are described in more detail in the article PARTICLES, SUBATOMIC.

**Concepts and general properties.** Antimatter is made up of elementary particles that have the mass and charge of electrons, protons, or neutrons, their counterparts in ordinary matter, but for which the charge is opposite in sign. Such particles are called positrons ( $e^+$ ), antiprotons ( $\bar{p}$ ), and antineutrons ( $\bar{n}$ ), or, collectively, antiparticles. First predicted by theory, all antiparticles have been produced in the laboratory. Matter and antimatter cannot coexist at close range for more than a small fraction of a second because they annihilate each other with re-

lease of large quantities of energy. It has been suggested that some distant galaxies may be composed entirely of antimatter, but as the only known process for creating antimatter is the process called pair production, which produces equal masses of matter and antimatter from the same point at the same time, the so far insuperable difficulty of accounting for the wide separation of large quantities of matter and antimatter after production and without annihilation arises.

The concept of antimatter first arose in close connection with the duality between positive and negative charge. The work of P.A.M. Dirac on the negative energy states of the electron led to the prediction and, finally, to laboratory production of a particle identical in every respect but one to the electron, that is, with positive instead of negative charge. Such a particle, called the positron ( $e^+$ ), is not found in ordinary matter. The life expectancy or duration of the positron in ordinary matter is very short. Unless the positron is moving extremely fast, it will be drawn close to a nearby electron by the Coulomb attraction, that is, the attraction between opposite charges. A collision between the positron and electron results in their simultaneous disappearance, their masses being converted into energy in accordance with the Einstein relation  $E = mc^2$ , where  $c$  is the velocity of light. This process is called annihilation, and the resultant energy is emitted in the form of high-energy quanta of electromagnetic radiation or gamma rays. In symbols this process is written as  $e^+ + e^- \rightarrow \gamma$  rays. The inverse reaction  $\gamma \rightarrow e^+ + e^-$  can also proceed under appropriate conditions, and the process is called electron-positron creation. This last process is the one commonly used to produce positrons in the laboratory.

The electron mass is so small that the discovery of the positron did not immediately suggest the existence of antimatter. The antimatter counterparts of the proton and neutron, the antiproton ( $\bar{p}$ ) and the antineutron ( $\bar{n}$ ), were discovered in the mid-1950s after many years of speculation on the possibility of their existence. In principle, all of the building blocks for the construction of higher antiatoms and antimatter are available. Antideuterons, the antiparticles corresponding to the nucleus of deuterium, have been produced in very high energy collisions, at the 30 GeV (gigaelectron volt) synchrotron of the Brookhaven (N.Y.) National Laboratory.

The electrical properties of antimatter are opposite to those of ordinary matter; thus, for example, the  $\bar{p}$  has a negative charge, and the  $\bar{n}$ , although electrically neutral, has a magnetic moment opposite in sign to that of the neutron. Properties other than electrical also are reversed from matter to antimatter (see below), and, therefore, the behaviour of antimatter in contact with matter is not purely electromagnetic (with the consequent symmetry between positive and negative charge).

Antimatter, when not in contact with matter, is as stable as ordinary matter, and the existence of an anti-universe consisting of antigalaxies, antistars, and antiplanets is possible. If an antiproton, however, came within  $10^{-13}$  centimetre of a proton for even  $10^{-23}$  second, the proton-antiproton pair would be annihilated and their masses would be transformed into energy. One gram of antimatter on Earth would annihilate one gram of matter, releasing an energy of  $5 \times 10^7$  kilowatt-hours. The energy released in this annihilation process is not emitted in the form of electromagnetic quanta but as pions ( $\pi^+$ ,  $\pi^-$ ,  $\pi^0$ ), also called pi-mesons. Pions are interpreted, following the suggestion made by H. Yukawa in 1935, as the quanta of the nuclear field, by analogy with photons as the quanta of the electromagnetic field.

**Historical survey.** In early studies of electrical phenomena, the asymmetry between positive and negative charge was considered to be fundamental. For example, glass rubbed on silk could acquire a positive charge, hard rubber on cat's fur a negative charge. When a formal theory of electromagnetism was finally developed by the work of C.A. Coulomb, M. Faraday and A.M. Ampère, and J.C. Maxwell, its laws were symmetrical with respect to positive and negative charges. One can easily verify that Maxwell's equations are not changed in form if the sign of all charges is changed, of course simultaneously changing the

Prediction of the positron

The process of annihilation

sign of all currents and electric and magnetic fields. The deeper meaning of this symmetry was not grasped until the advent of quantum mechanics.

Advent of  
quantum  
mechanics

*Dirac's contributions.* In 1928 Dirac discovered the relativistic equation that now bears his name while developing his contribution to relativistic quantum mechanics. The Dirac equation correctly described the so-called spin  $\frac{1}{2}$  particles (which have a quantum number  $\frac{1}{2}$  associated with and determined by their axial spin) such as electrons and protons. The new equation led to a much better understanding of the properties of the electron, but it admitted solutions corresponding to states with negative energy. Dirac's second great contribution was to show how this apparently incorrect result could be reinterpreted to expand the scope of quantum mechanics.

The following year (1929) he proposed the hole theory, in which he assumed that almost all the negative energy states are already occupied. The few remaining empty negative energy states are called "holes." These holes were shown by Dirac to behave like electrons with positive charge. He thus predicted the existence of a new particle, identical to the electron in all properties except the charge. This particle, today called the positron, was observed for the first time by Carl David Anderson in a Wilson cloud chamber in 1932 when he found the track of a positive electron resulting from the interaction of cosmic rays with matter.

Negative  
energy

The entire problem of negative energy solution and of negative probability density was further clarified in 1934, when Wolfgang Pauli and Victor Weisskopf reinterpreted the Klein-Gordon equation for scalar particles as a field theory. They showed that one can associate both positive- and negative-energy particles with the same field. In other words, for scalar particles as well as for spin  $\frac{1}{2}$  particles, an antiparticle may be expected for each observed particle.

*Positronium.* The Dirac theory of electrons and positrons predicts that an  $e^+$  and an  $e^-$ , because of Coulomb attraction, will bind together into an atom just as an  $e^-$  and a  $p$  (proton) form a hydrogen atom. The  $e^+e^-$  bound system is called positronium; its annihilation into gamma rays has been observed. The tendency of  $e^+$  and  $e^-$  to annihilate each other when close together makes positronium extremely unstable. Its lifetime is of the order of  $10^{-7}$  second when the total spin of the positronium is 1, and of the order of  $10^{-10}$  second when its spin is 0. These lifetimes, computed from Dirac theory, agree well with experimental values and thus lend additional confirmation to the theory, as well as to the concept of symmetry between particles and antiparticles.

*Antiproton and antineutron.* Both protons and neutrons are particles of spin  $\frac{1}{2}$  and thus are expected to be described by the Dirac equation. If this is the case, the existence of the antiproton ( $\bar{p}$ ) and the antineutron ( $\bar{n}$ ) is predicted. Antiprotons can be produced according to the reaction  $p + p \rightarrow p + p + \bar{p}$ , that is, by bombarding protons with protons. In this equation two extra particles of proton mass appear as the end product of the transformation of energy into mass according to the formula  $E = mc^2$  (see above). Such masses can be produced only if enough energy is available, that is, if the incident proton has a kinetic energy of at least 5.6 GeV ( $5.6 \times 10^9$  electron volts). Such energies became available in the 1950s at the Berkeley (Calif.) Bevatron. In 1955 a team of physicists led by Owen Chamberlain and Emilio Segré observed that antiprotons are produced by high-energy collisions. The experiment consisted mainly of a system of detectors and analyzers capable of accepting negatively charged particles whose masses were approximately equal to that of the proton. The particles originated from a target bombarded with approximately  $10^{10}$  protons per second, the bombarding protons having been accelerated to an energy of 6.2 GeV. When the new negatively charged particles came to rest inside a detector, a tremendous release of energy was observed, giving one of the most conclusive proofs that antiprotons had indeed been discovered. Antineutrons also were discovered at the Berkeley Bevatron by observing their annihilation in matter with a consequent release of high energies.

By the time the antiproton was discovered, a host of new

subatomic particles had also been discovered; all of these particles are now known to have a corresponding antiparticle. Thus, there are positive and negative muons, positive and negative pions, the K-meson and the anti-K-meson, plus a long list of baryons and antibaryons (see PARTICLES, SUBATOMIC). As mentioned above, antideuterons have also been observed. Most of these newly discovered particles have too short a lifetime for them to be able to combine with electrons. The exception is the positive muon that together with an electron has been observed to form a muonium atom.

*Production of antimatter. Production in accelerators.* All antiparticles, except positrons, are produced only in high-energy collisions. The positrons, because of their extremely small mass, can be emitted in the disintegration of artificially produced radioisotopes. Beams of antiprotons are now available for experiments at a few accelerators. At the Brookhaven National Laboratory and CERN (Switz.) twin accelerators, some  $10^9$  antiprotons are produced per second. High-resolution beams giving usable intensity of  $10^5$  antiprotons per second have been built. A positron beam of much higher intensity can be produced by a high-energy electron accelerator. Positrons are obtained in this way by first letting the electron beam strike a target; it then produces gamma rays by *Bremsstrahlung*, that is, by emission from decelerated electrons. The gamma rays strike a secondary target producing electron-positron pairs. The positrons are then separated from the electrons by conventional magnetic methods.

*Production by cosmic ray interactions.* No significant flux of antiprotons due to interaction of primary cosmic rays with the upper layers of the atmosphere could reach the Earth's surfaces because of absorption in the atmosphere. The primary cosmic radiation itself is known to be free of antimatter to better than one part in  $10^6$ .

*Invariance principles.* One of the most important consequences of relativistic quantum mechanics was the idea of invariance principles. One such principle of great relevance in the present context is that of invariance of the laws of physics under charge conjugation.

*Operation of charge conjugation.* Charge conjugation in relativistic quantum mechanics is a formal operation whose physical meaning is that of transforming every particle into its antiparticle. A reversal of the electrical properties of all known particles is associated with the particle-antiparticle conjugation, though there have been speculations that this might not always be the case. Other quantum numbers similar in their behaviour to charge ( $Q$ ) are used in particle physics to describe a particle completely. Thus there is the baryon number  $B$ , which has the value of  $+1$  for all baryons (particles with masses greater than or equal to that of the proton) and  $-1$  for all antibaryons, isotopic spin  $T$  and its third component  $T_3$ , and hypercharge  $Y$ . Both  $Q$  and  $B$  for a system are absolutely conserved quantities.  $Y$  and  $T_3$  conservation is not satisfied in weak interactions. Like  $Q$ , the quantum numbers  $B$ ,  $Y$ , and  $T_3$  change sign under charge conjugation. The absolute conservation of  $Q$  and  $B$  implies an absolute differentiation between  $p$  and  $\bar{p}$ , as well as  $n$  and  $\bar{n}$ . This is not the case for other particles. The neutral pion ( $\pi^0$ ) is identical to its antiparticle since it carries no quantum number to distinguish it. Even more interesting is the case of the  $K^0$  meson, which has  $Y = +1$ . Its antiparticle,  $\bar{K}^0$ , has  $Y = -1$ ; thus it is distinct from the  $K^0$ . This distinction is very sharp for a very short time (of the order of  $10^{-10}$  second) after the creation of either a  $K^0$  or  $\bar{K}^0$ . After this period the weak interaction begins to make itself felt by inducing transitions between  $K^0$  and  $\bar{K}^0$ . As a result, the states which are physically observable are neither the  $K^0$  nor the  $\bar{K}^0$  but are two states which are formed by linear superposition of  $K^0$  and  $\bar{K}^0$  and are called  $K_1^0$ ,  $K_2^0$ . Because of the presence of the weak interactions, the mass degeneracy is removed and the mass of the  $K_1^0$  and the  $K_2^0$  now differ by one part in  $10^{14}$ . Following an original suggestion of Abraham Pais and Oreste Piccioni, this unique situation has led to a series of unique interference and regeneration experiments, as well as to the possibility of testing the equality of the gravitational attraction of particles and antiparticles.

The  
definition  
of  
particles

High-  
energy  
role of the  
Bevatron

*Theory of invariance.* The meaning of the invariance of the laws of physics under charge conjugation can be explained in the following way: consider a system of physical objects  $S$  and build a charge conjugate system  $\bar{S}$ . Let the systems  $S$  and  $\bar{S}$  evolve in time, for a time interval  $T$ . Call the evolved systems  $S(T)$  and  $\bar{S}(T)$ . If the charge conjugate of  $\bar{S}(T)$  is identical with  $S(T)$ , then the laws of physics that govern the time evolution of the two systems are said to be invariant under charge conjugation. It is known experimentally that the most important forces governing all phenomena in the universe as it is known to man obey laws that are invariant under charge conjugation. Explicitly, these are the nuclear forces and the electromagnetic forces. It is also known experimentally that the weak interaction is not invariant under charge conjugation. This fact is extremely important because it shows that an invariance principle applicable to a certain rather wide class of phenomena does not have an absolute validity.

Absolute definition of matter

Whether or not the laws of physics are invariant under charge conjugation is relevant to the following somewhat philosophical question: can one give an absolute definition of matter and antimatter or only define one with respect to the other? The answer is, naturally, one can only define the difference between matter and antimatter if all laws of physics are invariant under charge conjugation. Since, however, the weak interaction is not invariant under charge conjugation, some delicate procedure can be prescribed to test whether some isolated system is matter or antimatter. Oddly enough, it turns out that in order to perform the test it is necessary to give an absolute definition of right-handedness. Thus, say, by mere radio communication with an intelligent being in a far galaxy, one could not reach a conclusion with regard to whether their matter would annihilate in contact with ours. This curious fact is the consequence of a more general invariance principle that is valid for nuclear, electromagnetic, and weak interactions. The physical laws governing the above interactions are invariant under the combined operations of charge conjugation and of parity transformation ( $CP$  transformation). An even weaker process has been observed in the decay of  $K^0$ -mesons, which is not invariant under  $CP$ . In principle, this gives a method for determining whether or not the visitor from outer space could be dangerous to Earth.

**Cosmology and antimatter.** Many attempts have been made to investigate the importance of antimatter in cosmological problems. The two main starting points are: (a) there is symmetry between matter and antimatter, (b) in all known processes there is an absolute conservation of baryon number.

*Theory and experiment.* Thus, it seems that theoretical and experimental knowledge of matter and antimatter is relevant to the understanding of the creation and constitution of the universe. The question of the creation of the universe really transcends cosmology, which concerns itself only with the evolution of the universe. Yet it is just the present understanding of the evolution process that makes the hypothesis of the existence of any significant amount of antimatter in the universe unlikely. Obviously no star can contain a close mixture of matter and antimatter; otherwise it would instantaneously explode with more violence than a supernova. Interstellar gas, and even intergalactic gas, cannot be a mixture, either. This is because among the annihilation products of proton plus antiproton into pions there is a certain amount of  $\pi^0$  mesons, which in turn decay into two energetic gamma rays. Satellite experiments have not detected enough of such gamma rays to suggest a significant amount of antimatter annihilation. One could resort to the hypothesis that matter and antimatter are separated on the scale of clusters of galaxies. The creation of baryon-antibaryon pairs, however, is very localized, the particle and antiparticle being created at distances of approximately  $10^{-13}$  centimetre. No present understanding of the evolution of the universe can explain the unmixing of matter and antimatter if they had been originally created together. Thus, as Hannes Alfvén has pointed out, any statement about the existence of

equal amounts of matter and antimatter in the universe has to be founded on an artificial assumption that is not subject to observational tests.

*Quasar hypothesis.* It has been repeatedly proposed that the existence of antimatter might offer a natural explanation of the quasar phenomenon. Quasars, or quasi-stellar objects, if at distances comparable to those of the external galaxies as one hypothesis suggests, are pouring out energy at an enormous rate from a small volume of space; the rate is so high that ordinary processes of physics do not suffice to explain it. Annihilation of matter and antimatter is the most efficient energy-producing process and would easily provide the tremendous energy output observed for these objects. Some scientists, for example Philip Morrison, now feel that a more conventional explanation of such objects is possible without the assumption of matter-antimatter annihilation. No such assumptions are needed to explain cosmic rays and astronomical sources of X-rays. The recent discovery of pulsars (pulsating radio-astronomical sources), their probable association with neutron stars, and the subsequent study of these objects have led to a rather self-consistent picture including good agreement with X-ray and cosmic ray observations.

Nevertheless, the presence of large amounts of antimatter in the universe cannot at present be ruled out completely, nor can the possibility that some cosmic sources of intense radiation might be due to the interpenetration of matter and antimatter. But it can be shown that the total relative amount of antimatter in the Galaxy must be less than one part in  $10^7$ .

Soon after the discovery of the antiproton the question was raised as to whether antimatter would be subject to gravitational attraction or repulsion from ordinary matter. This question is of extreme importance because gravitational repulsion between matter and antimatter is inconsistent with the theory of general relativity. The answers to such questions can be obtained experimentally because of the properties of  $K^0$  and  $\bar{K}^0$  mesons. Observation of the interference phenomena between  $K^0_1$  and  $\bar{K}^0_2$  led to the conclusion, by M.L. Good, that the gravitational interaction between matter and antimatter is identical to that between matter and matter.

**BIBLIOGRAPHY.** C.N. YANG, *Elementary Particles: A Short History of Some Discoveries in Atomic Physics* (1962), an excellent book for the educated layman; R.K. ADAIR and E.C. FOWLER, *Strange Particles* (1963), good descriptions of strange particles, such as the  $K^0$  mesons, for those who know some physics; H. ALFVEN, *Worlds-Antiworlds* (1966), an interesting discourse on the unlikely supposition that matter and antimatter can be polarized.

The following articles in *Scientific American* are good expositions: E. SEGRE and C.E. WIEGAND, "The Antiproton," 194:37-41 (June 1956); P. MORRISON, "The Overthrow of Parity," 196:45-53 (April 1957); M. GELL-MANN and E.P. ROSENBAUM, "Elementary Particles," 197:72-86 (July 1957); G. BURBIDGE and F. HOYLE, "Anti-Matter," 198:34-39 (April 1958); S.B. TREIMAN, "The Weak Interactions," 200:72-78 (March 1959); and H. ALFVEN, "Antimatter and Cosmology," 216:106-112 (April 1967).

## Matthias I Corvinus

Matthias I Corvinus, king of Hungary (1458-90), was one of the most impressive figures of his time in central and eastern Europe. An expert in diplomacy and the military art, he was also one of the first adepts of Renaissance culture among the princes north of the Alps. His reign was a period of great efforts to reconstruct the Hungarian state after decades of feudal anarchy, chiefly by means of financial, military, judiciary, and administrative reforms.

Matthias (Mátyás Hunyadi) was born in Kolozsvár (now Cluj, Romania), on February 24, 1443, the second son of a military leader, János Hunyadi. After the death of his father and elder brother, Matthias became heir to a vast landed propriety and to a great name glorified by the chroniclers of the war against Turkish conquerors. After the death of King Ladislas Posthumus of Austria (Habsburg), and despite dynastic claims of his

Amount of antimatter in universe

Matthias I Corvinus, detail from the gate tower of Ortenburg Castle, Bautzen, now in East Germany, 1486.

#### Election as king

uncle, the Holy Roman emperor Frederick III, and other pretenders to the throne, a general Diet held in Buda and Pest in January 1458 elected Matthias king. This was the first time in the medieval Hungarian kingdom that a member of the nobility, without dynastic ancestry and relationship, mounted the royal throne, although it happened contemporaneously in the neighbouring Bohemian kingdom. Such elections upset the usual course of dynastic succession. Crossing the plans of the Habsburg dynasty (and partly those of the Jagiellós of Poland), they caused a long series of controversies in that part of Europe. In the Czech and Hungarian states they heralded a new era, characterized by the supremacy of the "estates and orders," a dietal system, and a tendency to centralization.

After struggles to stabilize his reign against repeated attacks, mostly from baronial opposition and the foreign dynastic pretenders, Matthias held back Turkish invaders, who had annexed the Serbian and Bosnian territories on his southern frontiers. He reorganized a defensive system against the Turks, taking his lack of forces into consideration.

He did everything he could to increase state incomes and to improve the modern elements of his army and his warfare. One of his first steps was a reform of finances and taxes (1467), ending special exemptions to large proprietors. A few years later the treasury was developed into a well-organized office, collecting regularly the "extraordinary" taxes (originally intended in case of urgent necessity, mostly under the pressure of the Turkish peril). As a result the state income reached a considerable sum. The high taxation burdened mostly the peasants.

The financial reforms were not easily accepted. Revolts endangered the government, occasionally even the reign of Matthias. The opposition, stimulated by foreign forces, won over some old counsellors of the King. But Matthias always succeeded, by force and diplomacy, in calming the opposition and in re-establishing, even reinforcing, the political and social conditions of his sovereignty. Some historians have characterized him as an early representative of modern absolutism; but this was far beyond his possibilities. He increased the influence of the lower nobility against the barons; he tried to oppress or at least to moderate feudal anarchy; he protected merchants and small proprietors and even peasants, not against their own lords but against other troubles; and he tried to improve the system of central government (without disturbing local autonomies), mainly by increasing the governmental role of the chancellors, the royal secretaries, and other offices. His jurists began a great work of codification; a royal decree of 1486 was intended to summarize the main principles of law "for all times." This meant, together with the further development of the

standing army, a certain degree of centralization, within the limits of an essentially feudal state.

Successes in foreign politics, diplomacy, and warfare contributed to the stabilization of his own authority and his country's position. His diplomacy grew more active during the second and third decades of his reign. He maintained constant diplomatic relations with the papacy, with Venice, Naples, and other Italian states and repeatedly exchanged ambassadors with France, Burgundy, Switzerland, and many German territories; later he tried to establish regular contacts with Russia and, occasionally, with Persia and Egypt. His main purpose may have been the creation of a system of alliances against actual or possible rivals and enemies. His diplomatic activity varied with the varying aims of his foreign policy. After gaining suzerainty over Bosnia (1463), Matthias tried to occupy the Bohemian kingdom. This was a grave error; the Jagello dynasty intervened, and a 10-year struggle was followed by a peace that left the Bohemian crown to Vladislav II, while Matthias retained the Moravian and Silesian territories with the royal title.

An almost continuous rivalry with the emperor Frederick III ran through Matthias' reign. He tried repeatedly, but without success, to induce (or coerce) the Emperor to renounce his claims to the Hungarian throne. Following the Polish-Bohemian war, Matthias tried to annihilate the main base of Frederick's dynastic power. After a long series of military successes, aided by the Emperor's German and Austrian adversaries, he occupied Vienna and a considerable part of the Habsburg family possessions. But he could not diminish the Habsburg influence in the German Empire or in central and western Europe. Indeed, Habsburg power began to increase as a result of events in Burgundy. Until his death (April 6, 1490) Matthias remained in possession of his conquests; thereafter, all of them were lost.

Hungary's political relations with the papacy and the Italian states were connected with the interests in Turkish wars. But they were connected also with the special rights of Hungarian kings concerning the distribution of ecclesiastical dignities in their country. This complicated the relations between church and kingdom. After the second marriage of Matthias (1476), to Beatrice of Aragon, princess of Naples, the King's diplomacy became a factor in Italian state affairs. His connections with Florence, Milan, and other Italian states and cultural centres reflected his interest in Italian art and humanistic culture.

Matthias deserved his reputation, mentioned by contemporaries, for being "a friend of the Muses." The knowledge of many languages, classic latinity, modern humanistic ideas, and ancient books and the support of new art and science were all familiar to him since childhood. His education took place partly on battlefields, partly under the control of prominent humanists. He never ceased to read and to learn. Supporting all kinds of art, he founded a considerable library—the famous Corvina. He trusted, like the majority of his contemporaries, in astrology and other semi-scientific beliefs of his age; but he supported many real scientists and participated eagerly in the discussions of philosophers invited to his court.

Matthias possessed high personal qualities, as reported by friends and enemies alike. He tried to strengthen his state, not without success. His name became later—during centuries of Turkish occupation and Habsburg oppression—a symbol of strength and independence. His memory was glorified by statesmen and military leaders as well as by students of cultural progress. And, despite the heavy taxes, it was also glorified by the people, who were reported, a few years after the King's death, as being willing to pay still more, "if only he could rise again." This could be explained by the general decline of the country after Matthias' death but also by a popular saying: "Matthias is dead—justice is lost."

**BIBLIOGRAPHY.** There is no modern English-language biography of Matthias I Corvinus. IMRE LUKINICH (ed.), *Mátyás Király Emlékkönyv*, 2 vol. (1940), contains articles analyzing the family relations, personality, political, military, and cultural activities of the king. VILMOS FRANKÓI, *Hunyadi Mátyás király, 1440-1490* (1890); and ELEMÉR MALYUSZ, "Matthias

#### Foreign successes

#### Intellectual interests

Corvinus," in *Menschen die Geschichte machten*, vol. 2, pp. 187–191 (1931), are two classic biographies; LAJOS ELEKES, *Mátyás és kora* (1956), is an essay on the social and political background of the king's activities.

(L.EI.)

## Maupassant, Guy de

Maupassant is "an almost irreproachable writer in a genre that is not," said the 19th-century French critic Jules Lemaitre. Maupassant wrote novels, poems, plays, and travel books, but his fame rests primarily on his short stories. Their masterly style earned them the admiration of expert writers in the genre, from Henry James to W. Somerset Maugham. They owe their worldwide popularity among less sophisticated readers to a combination of brevity, slickness, and a pervasive sexuality that prompted James to say that Maupassant's work was "little else but a report of its innumerable manifestations."

Archives Photographiques

Maupassant, photograph by Nadar (Gaspard-Félix Tournachon), c. 1885.

**Early life.** Henry-René-Albert-Guy de Maupassant was born on August 5, 1850, the elder of the two children of Gustave and Laure de Maupassant. His mother's claim that he was born at the Château de Miromesnil near Dieppe has been disputed. (It seems probable that for snobbish reasons the parents rented the château, but it cannot be proved that Maupassant was actually born there.) The second son, Hervé, was born in 1856 at the Château Blanc at Grainville-Ymauville near Étretat.

Both parents came of Norman families, the father's of the minor aristocracy; the particle "de" had been dropped during the French Revolution, but it was restored under pressure from the bride shortly before the wedding. The marriage was a failure. There was no provision for divorce in France at that time, but the couple separated for good when Guy was 11 years old, after 15 years of married life. Guy sided strongly with his mother, was a devoted son all his life and, in spite of the help that he received from him, was markedly hostile to his father. The failure of the marriage left its mark on the man and the writer. It explains Maupassant's fears of marriage and the frequent appearances in his stories of the ridiculous persecuted husband and the lonely fatherless child.

Although the Maupassants were a free-thinking family, Guy received his first education from the church. When he was 13 and had learned all he could from the parish priest, he was sent to a small seminary at Yvetot that took both lay and clerical pupils. From the start, he felt a decided antipathy for this form of life and deliberately engineered his own expulsion for some trivial offense in 1868. He moved to the lycée at Le Havre and passed his baccalauréat the following year.

In the autumn of 1869 he began law studies in Paris, which were interrupted by the outbreak of the Franco-Prussian War. Maupassant volunteered, served first as a private in the field, and was later transferred through his

father's intervention to the quartermaster corps. His firsthand experience of war was to provide him with the material for some of his finest stories.

He was demobilized in July 1871 and resumed his law studies in Paris. His father came to his assistance again and obtained a post for him in the Ministry of Marine, which was intended to keep him until he qualified as a lawyer. He did not care for the bureaucracy, but was not unsuccessful and was several times promoted. His father managed to have him transferred, at his own wish, to the Ministry of Public Instruction in 1879.

**Apprenticeship with Flaubert.** Maupassant's mother, Laure, was the sister of Alfred Le Poittevin, who had been the most cherished friend of Gustave Flaubert's youth and who had died in 1848 at the age of 32. She remained on affectionate terms with the novelist for the rest of his life. (The suggestion has been made by more than one of Maupassant's biographers that he was the illegitimate son of Laure and Flaubert, but they have not produced any convincing evidence in support of their view.) Laure de Maupassant had sent her son to make Flaubert's acquaintance at Croisset in 1867. When he returned to Paris after the war, she asked Flaubert to keep an eye on him. This was the beginning of the apprenticeship that was the making of Maupassant the writer. Whenever Flaubert was staying in Paris, he used to invite Maupassant to lunch on Sundays, lecture him on style, and correct his youthful exercises. He also introduced him to some of the leading writers of the time, such as Émile Zola, Ivan Turgenev, Édmond de Goncourt, and Henry James, who visited Flaubert in his Paris flat on Sunday afternoons.

"He's my disciple and I love him like a son," Flaubert said of Maupassant. It was a concise description of a twofold relationship: if Flaubert was the inspiration for Maupassant the writer, he also provided the child of the broken marriage with a foster father. Flaubert's sudden and unexpected death in 1880 was a grievous blow to Maupassant, both as "disciple" and as "son."

Zola described the young Maupassant as a "terrific oarsman able to row fifty miles on the Seine in a single day for pleasure." Maupassant was a passionate lover of the sea and of rivers, which accounts for the setting of much of his fiction and the prevalence in it of nautical imagery. In spite of his lack of enthusiasm for the bureaucracy, his years as a civil servant were the happiest of his life. He devoted much of his spare time to swimming and to boating expeditions on the Seine. One can see from a story like "Mouche" (1890; "Fly") that the latter were more than merely boating expeditions and that the girls who accompanied Maupassant and his friends were usually prostitutes or prospective prostitutes. Maupassant's mother used to boast that his childhood "was absolutely chaste" and that "it was not until he was sixteen that he had his first liaison." Whether she was right or not, there can be little doubt that the early years in Paris were the start of his phenomenal promiscuity.

When Maupassant was in his early 20s, he discovered that he was suffering from syphilis, one of the most frightening and widespread maladies of the age. It is not known whether it was hereditary or caused by his promiscuity, but the fact that his brother died at an early age of the same disease suggests that it might have been hereditary. Maupassant was adamant in refusing to undergo treatment, with the result that the disease was to cast a deepening shadow over his mature years and was accentuated by neurasthenia, which had also afflicted his brother.

During his apprenticeship with Flaubert, Maupassant published one or two stories under a pseudonym in obscure provincial magazines. The turning point came in April 1880, the month before Flaubert's death. Maupassant was one of six writers, led by Zola, who each contributed a war story to a volume called *Les Soirées de Médan*. "Boule de suif" ("Ball of Fat") was not only far the best of the six; it is probably the finest story Maupassant ever wrote. Although the story is Flaubertian in conception, structure, and style, the "disciple" was a follower, not an imitator. He learned from the novelist

Influence of Flaubert on Maupassant

Family difficulties

Flaubert but adapted what he learned to the short story, the best of which, like "Boule de suif," are characterized by economy and balance.

**Mature life and works.** As soon as "Boule de suif" was published, Maupassant found himself in demand by newspapers. He left the ministry and spent the next two years writing articles for *Le Gaulois* and the *Gil Blas*. Although the *Gil Blas* was ostensibly a newspaper, it found little space for news. Its primary aim was to entertain its readers with spicy stories; its sideline was the grooming of youthful courtesans, amusingly known as *horizontales*. It was not inappropriate that many of Maupassant's stories should have made their first appearance there.

Productivity of the 1880s and 1890s

The ten years from 1880 to 1890 were remarkable for their productivity. They saw the publication of some 300 short stories, six novels, three travel books, Maupassant's only volume of verse, and a fair sprinkling of miscellaneous works.

The stories can be divided into groups: those dealing with the Franco-Prussian War, the Norman peasantry, the bureaucracy, life on the banks of the Seine, the emotional problems of the different classes, and—somewhat ominously in a late story like "Le Horla" (1887)—with hallucination. Together, the stories present a comprehensive picture of French life from 1870 to 1890.

There is a strong personal element in Maupassant's work that has invited biographers to treat passages from his fiction as though they were extracts from an autobiography or diary. It is most marked in *Bel-Ami* (1885). It seems at first as though the gap between the novelist and his rascally protagonist is a wide one, that all they have in common is their womanizing. One comes to realize, however, that, in spite of a certain amount of camouflage, Maupassant does identify himself with *Bel-Ami* and that he would have given much to have enjoyed the same sort of outrageous triumphs as well as the same excellent health as his creation. If, in the novel itself, he camouflaged the connection, elsewhere he went out of his way to underline it. A copy of the original edition, discovered in 1932, contains a dedication to a woman friend, which reads: "To Madame B. Homage from *Bel-Ami* himself." And when, as a result of his prosperity, he exchanged the skiffs, which had been the delight of his youth, for yachts, he christened two of them "*Bel-Ami*."

The prosperity was real; he was a best-seller in several countries. He was also a tough Norman businessman. It is estimated that his earnings were the modern equivalent of something over \$70,000 a year at a time when there was still no income tax. He made the most of it. He had a flat in Paris with an annex for clandestine meetings with women, a house at Étretat where he did a good deal of entertaining, and a couple of residences on the Riviera. He began to travel in 1881, visiting French Africa and Italy, and became a yacht owner two years later. In 1889 he made two balloon ascents. The same year he paid his only visit to England. While lunching in a restaurant there as Henry James's guest, he shocked him profoundly by pointing to a woman at a neighbouring table and asking James to "get" her for him.

Fascination with brothels and prostitution

The French critic Paul Léautaud called him a "complete erotomaniac." His extraordinary fascination with brothels and prostitution is reflected in stories such as "La Maison Tellier" (1881; "The Tellier House") and "L'Ami patience" (1863; "A Way to Wealth"). It is significant, however, that as the successful writer became more closely associated with women of the class of Hermine Lecomte du Nouy, marchesa d'Alligri, and the Countess Potocka, there was a change of angle in his fiction: a move from the peasantry to the upper classes, from the brothel to the boudoir. Although Maupassant appeared outwardly a sturdy, healthy, athletic man, his letters are full of lamentations about his health, particularly eye trouble and migraine headaches. With the passing of the years he had become more and more sombre. He had begun to travel for pleasure, but what had once been carefree and enjoyable holidays gradually changed, as a result of his mental state, into compulsive, symptomatic wanderings until he felt a constant need to be on

the move, to rush to one of his dwellings in another part of France or to set out on a cruise in one of his yachts.

A major family crisis occurred in 1888. Maupassant's brother was a man of minimal intelligence—today one would call it arrested development—and could work at nothing more demanding than nursery gardening, undertaken in the south of France and financed by Guy. In 1888 he suddenly became violently psychotic (the family pretended that it was "sunstroke"). Guy escorted him to Paris on the pretext that he was going to a clinic to convalesce. When he discovered the true situation Hervé used words that were to prove prophetic: "But it's you who are mad, do you hear? You're the crazy one of the family." He died in an asylum on November 13, 1889.

Maupassant was reduced to despair by his brother's death; but though his grief was genuine, it cannot have been unconnected with his own condition. On January 2, 1892, when he was staying near his mother, who for her health lived on the Riviera, he tried to commit suicide by cutting his throat. Doctors were summoned, and his mother agreed reluctantly to his commitment. Two days later he was removed, according to some accounts in a straitjacket, to Dr. Blanche's establishment in Paris, where he died on July 6, 1893, one month before his 43rd birthday.

In the early 1970s, it was generally recognized that Maupassant's popularity as a short-story writer had declined and that he was more widely read in Anglo-Saxon countries and in the Soviet Union than in France. This does not detract from his genuine achievement: the invention of a new, high-quality, commercial short story, which has something to offer to all classes of readers.

Decline of Maupassant's popularity

#### MAJOR WORKS

**STORIES:** "Boule de suif," first published in *Les Soirées de Médan* (1880), also in *Boule de Suif, and Other Stories*, trans. by A.R. MacAndrew (1964); *La Maison Tellier* (1881; *The Tellier House*, trans. by D. Flower, 1964), book of short stories; *Mademoiselle Fifi* (1882, enlarged 1883), book of short stories (included in *88 More Stories*, trans. by E. Boyd and S. Jameson, 4 vol., 1932); *Contes de la bécasse* (1883), book of stories (see *The Works*, trans. by M. Laurie, 1923–29); *Clair de lune, Les Soeurs Rondoli* (see *88 Short Stories*, trans. by E. Boyd and S. Jameson, 1930), and *Miss Harriet* (all 1884; see the *Works*); *Yvette* (1885; see *88 Short Stories*); *Toine* (1885), book of stories (see the *Works*); *Le Horla* (1887; see *88 More Stories*); *Le Rosier de Madame Husson* (1888; see the *Works*); *L'Inutile Beauté* (1890; see *88 Short Stories*).

**NOVELS:** *Une Vie* (1883; *A Woman's Life*, trans. by H.N.P. Sloman, 1965); *Bel-Ami* (1885; trans. by H.N.P. Sloman, 1961); *Mont-Oriol* (1887; see the *Works*); *Pierre et Jean* (1888; trans. by M. Turnell, 1962); *Fort comme la mort* (1889; *The Master Passion*, trans. by M. Laurie, 1958); *Notre Coeur* (1890; see the *Works*).

**OTHER WORKS:** "Au bord de l'eau," first published in a periodical (1876), verse.

**BIBLIOGRAPHY.** Collections of Maupassant's work include the Ollendorf edition, illustrated, 29 vol. (1900–04); the Conard edition, with preface by POL NEVEUX, 29 vol. (1908–10); and the edition by RENE DUMESNIL, 15 vol., including his letters and previously unpublished writings (1934–38). In English, *The Works of Guy de Maupassant*, trans. by M. LAURIE, 10 vol., was published in 1923–29. Available correspondence and bibliography may be found in vol. 15 of the *Correspondance inédite de Guy de Maupassant*, ed. by ARTINE ARTINIEN and EDOUARD MAYNIAL (1951).

*Biography:* See ARMAND LANOUX, *Maupassant le "Bel-Ami"* (1967), the fullest and most-up-to-date biography; FRANCIS STEEGMULLER, *Maupassant* (1950), the only satisfactory biography in English; FRANCOIS TASSART, *Souvenirs sur Guy de Maupassant*, 3rd ed. (1911; Eng. trans., *Recollections of Guy de Maupassant by His Valet François*, 1912); and *Nouveaux souvenirs intimes sur Guy de Maupassant* (1962), two useful source books for biographers.

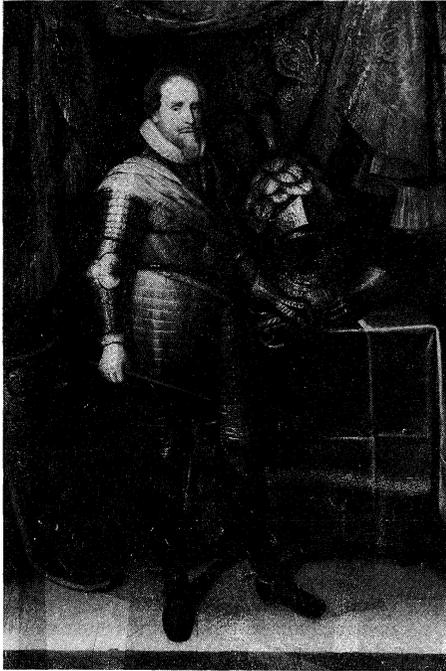

*Criticism:* See HENRY JAMES, *Partial Portraits* (1888) and also in *The Art of Fiction* (1948) and *The House of Fiction* (1957), still one of the finest essays on Maupassant; ARTINE ARTINIEN, *Maupassant Criticism in France, 1880–1940* (1941), a survey of personal judgments, French and other; E.D. SULLIVAN, *Maupassant the Novelist* (1954) and *Maupassant: The Short Stories* (1962), useful studies; and MARTIN TURNELL, *The Art of French Fiction* (1959, reprinted 1970).

(M.Tu.)

## Maurice of Nassau, Prince of Orange

Soldier and statesman, Maurice of Nassau was the military architect of the emergent Dutch Republic during the years between the death of his father, William the Silent, in 1584 and the signing of the Twelve Years Truce (1609), which temporarily halted the Dutch war of independence against Spain.

By courtesy of the Rijksmuseum, Amsterdam

Maurice of Nassau, painting by Michiel Janszoon van Mierrelt (1567–1641). In the Rijksmuseum, Amsterdam.

He was born at Dillenburg on November 13, 1567, the second son of William the Silent. Although known as the Prince of Orange, he did not actually inherit that principality until 1618, on the death of his elder half brother. A child of William's disastrous marriage to the schizophrenic Anna of Saxony and delicate as a youth, Maurice was shuffled from place to place during the most critical years of his father's struggle against Spanish tyranny. His boyhood was further overshadowed by the desertion and betrayal of his father by former allies and finally by William's assassination in 1584. It was hardly surprising that these experiences deepened his natural reserve, leaving him suspicious of friends as well as of enemies.

Stadholder  
of the  
Unified  
Provinces

At the time of his father's death, Maurice was still a student at the newly founded University of Leiden, but the States of Holland swiftly invested him as stadholder (chief executive). He later also became stadholder of Zeeland, Utrecht, Overijssel, and Gelderland. The years 1584–86 were critical. English help for the Netherlands revolt had finally materialized in the person of the Earl of Leicester, who headed an English expeditionary force, temporarily strengthening the provinces' defenses but imperiling the cause of the rebels by political blunders. Fortunately for Maurice, he had the assistance of the master politician Johan van Oldenbarnevelt, advocate of Holland. With Maurice's cousin and loyal supporter, William Louis, stadholder of Friesland, the Advocate, and Maurice formed a powerful triumvirate. Under the three, the northern provinces steadily consolidated their position against Spain, grew progressively richer by trade and shipping, and prepared themselves for independence.

Military  
reforms

Oldenbarnevelt took charge of domestic and foreign affairs; Maurice, as federal commander in chief, attended to military matters with the aid of William Louis. Mathematics, ballistics, and military engineering had fascinated Maurice since childhood; now he was in a position to put his theories to the test. His first task was to reduce the army's size and improve its organization. He did his best to remove the perpetual curse of all contem-

porary armies—mutiny—by ensuring that his soldiers were properly and promptly paid, equipped with better arms, given improved and more regular training, and instructed in the science of fortification and siege warfare. The secret of Maurice's military planning was to bring to the art of siege warfare—the dominant type of warfare of his century—those habits of steady, close observation and attention to detail so characteristic of the Dutch in all the arts and sciences of the time. He was also greatly helped by the advice of Simon Stevin—the great mathematician and philosopher of Bruges, then living in Holland—whose lectures attracted his attention.

The fruits of his efforts were harvested in the 1590s. Beginning with Breda (the Nassau family seat), Maurice captured one enemy stronghold after another. In a series of actions, remarkable less for their audacity than for cool and systematic planning, the Spanish front lines were pushed back to the north, east, and south until the republic's territory began to assume something very much like its modern shape. Joyfully the Holland towns paid homage to their saviour; Maurice was hailed (literally) as the engineer of victory.

He had less success in the south. With great reluctance, Maurice was persuaded by the impatient Oldenbarnevelt to try to reunite the northern and southern Netherlands, divided by Spanish conquests. His attempt to invade Flanders and rouse it to repel its Spanish conquerors failed completely. After an initial victory at Nieuwpoort in 1601, Maurice was compelled to withdraw. Later, Oostende had to be surrendered. Oldenbarnevelt's optimism had proved totally misplaced. The southerners were apathetic, even hostile, to the appeals of the Hollanders. Even Maurice, with his doubts about the wisdom of undertaking such a campaign, was taken by surprise by its outcome. The defeat revealed that there was one department of military reform he had overlooked—intelligence. Unwillingly, and with bitterness, Maurice had to bow to facts. He agreed first to an armistice (1607) and then a 12-year truce with Spain (1609). The division of the Netherlands was to continue.

Defeat in  
Flanders

The problems of war had brought out the strength of Maurice's character. An English visitor noted that he was "of great forwardness, good presence and courage, flaxen haired, endued with a singular wit." With growing confidence, he stood up for his own interests as well as those of his people against the English queen, Elizabeth I, and her emissaries as well as those of France. As Maurice's stature grew to match his responsibilities, he increasingly resented the continual interference by Oldenbarnevelt in military matters. The unsuccessful foray into Flanders was a special cause of friction, and the long siege of Oostende put a heavy strain on their relations. Estrangement was made worse by the negotiations for the truce; Maurice suspected Oldenbarnevelt of sacrificing Dutch independence in his anxiety for a peace with Spain, and the Advocate suspected Maurice of attempting to acquire sovereign power.

During the decade after the truce, the partnership turned into a war, as yet private and undeclared, for supremacy. Maurice's mastery of strategy again stood him in good stead. While Oldenbarnevelt was more deeply drawn into the bitter theological politics of the times, Maurice patiently waited for his moment, quietly consolidating his support in Zeeland and Amsterdam. Oldenbarnevelt, confident of his power in the Holland states, emerged as the champion of Erastianism (which advocated dominance of the state over the church) and of those moderate Protestants who wanted religious toleration, in opposition to the intolerance of the orthodox Dutch Calvinists.

Defeat of  
Olden-  
barnevelt

It was 1617 before Maurice came out publicly as protector of the Calvinists (the so-called Counter-Remonstrants). When Oldenbarnevelt obtained authority for his supporters in the towns to raise levies of professional soldiers (*waardgelders*), Maurice acted swiftly. Marching to the Brill (in South Holland) on September 28–29, he disbanded the levies. Next, he took advantage of his legal right to approve appointments in the local governments in order to purge each *vroedschap* (council) of his

opponents. By the summer of 1618 he had forcibly dismissed all the *waardgelders*. It then only remained to remove Oldenbarnevelt. On August 29, 1618, the old statesman was arrested, and on May 13, 1619, he was executed. The long political trial was marked by persistent bias, petty spite, and inexcusable cruelty and injustice. Maurice did not himself dictate the sentence, but he ostentatiously refrained from exercising his prerogative of pardon, and he personally endorsed the demand for the probably illegal forfeiture of Oldenbarnevelt's property. The trial and execution of his old ally remain a blot upon his character and career.

After this victory, Maurice wielded unprecedented power. In all but name the Stadholder was king. Yet, having forged his alliance with orthodox Calvinism, created an Orangist Party, and packed local, provincial, and federal offices with his supporters, Maurice pressed his "revolution" no further. In 1621 he ended with a flourish the truce with the Spanish that he had detested for 12 long years. Ironically, the Calvinist hero was quickly faced by a Habsburg threat so dangerous that he was compelled to conclude an alliance with Roman Catholic France. Just before he died (of a liver complaint) in 1625, Breda, the scene of his first spectacular victory against the Spanish, was again lost to the enemy.

Assessment  
of  
Maurice's  
life

The last ten years of his life added nothing to Maurice's reputation. He was a great soldier but not a great statesman. In peace he had little or none of those sympathetic qualities that had drawn men to his father to settle issues by advice and discussion. His greatest claim to fame was his repulsion of the Spanish from 1590 to 1609 and the extension and securing of the frontiers of the Dutch Republic. Yet his achievement fell short of reunifying the whole of the Netherlands, and his vindictive pursuit of Oldenbarnevelt helped to divide the republic permanently into Orangists and anti-Orangists. For the latter, Oldenbarnevelt's martyrdom provided a political focus and a rallying cry down to the French Revolution.

Maurice's was an involuted and contradictory character. The circumstances of his childhood left him vulnerable to fears, suspicions, and resentments; yet he was also a man of great courage, capable of magnanimity on the battlefield. His natural caution did not inhibit his capacity for swift and decisive action. Coldly logical, he enjoyed a joke, albeit a sarcastic one. His lack of passion may have prevented him from marrying but did not prevent him from fathering a brood of illegitimate children.

**BIBLIOGRAPHY.** G. GROEN VAN PRINSTERER, *Maurice et Barnevelt* (1875), remains the classic Dutch biography. The outstanding recent work that assesses Maurice's contribution to history is JAN DEN TEX, *Oldenbarnevelt*, 3 vol. (1960; Eng. trans., 2 vol., 1972). A shrewd appreciation of Maurice appears in *The Dutch Nation* by G.J. RENIER (1944). J.L. MOTLEY, *The Life and Death of John of Barnevelt*, 2 vol. (1874), and his *History of the United Netherlands*, 4 vol. (1861-68), contain much valuable information.

(C.H.Wi.)

## Mauritania

The Islāmic Republic of Mauritania (République Islamique de Mauritanie), a state in northwest Africa, forms a geographic link between the North African Maghrib (a region that includes Morocco, Algeria, and Tunisia) and the Senegal region of West Africa. Culturally, it forms a transitional zone between the Arab-Berber region of North Africa and the region to the south of the Tropic of Cancer known as the Sudan (a name derived from the Arabic and meaning "land of the blacks"). With an area of 398,000 square miles (1,030,700 square kilometres) and a population of about 1,100,000, Mauritania takes the form of an indented rectangle measuring about 930 miles from north to south and about 680 miles from east to west. It is bordered to the northwest by the Spanish Sahara, to the north by Algeria, to the east and southeast by Mali, and to the southwest by Senegal. Its Atlantic Ocean coastline, to the west, extends for 435 miles from the delta of the Sénégal River northward to the Cap Blanc Peninsula. The capital is Nouakchott (population about 35,000).

Much of Mauritania's territory forms part of the western Sahara, and a large proportion of the population is nomadic. The country's mineral wealth includes large reserves of iron ore and of copper, which are now being exploited. Mauritania, formerly French administered, became independent on November 28, 1960. By the terms of the constitution proclaimed in 1961, Islām is the religion of the Mauritanian people, and the republic guarantees freedom of conscience and religious liberty to all; Arabic is the national language, and the official languages are Arabic and French. (For associated physical features, see SENEGAL RIVER; SAHARA; for historical aspects, see NORTH AFRICA, HISTORY OF; WEST AFRICA, HISTORY OF.)

**The physical and natural landscape.** *Relief and drainage.* Both land relief and drainage are influenced by the aridity that characterizes the greater part of the country. The impression of immensity given by the landscape is reinforced by its flatness; the coastal plains are lower than 150 feet, while the higher plains of the interior vary between 600 and 750 feet. The interior plains form a plateau of which the culminating heights, occurring at different levels, form many tablelands joined to one another by very long, gentle slopes of about two degrees. The monotony is broken either by vestiges of cliffs (generally *cuestas*); or by sloping plains that terminate at one end of the slope with a steep cliff or faulted scarp, which may reach heights of 900 feet; or by *inselbergs* (steep-sided residual hills) of which the highest is Kediet Ijill (3,002 feet high), an enormous block of hematite.

Plains and  
plateaus

Structurally, Mauritania may be divided into three principal zones. The first of these, located in the north and northwest, consists of the underlying Precambrian rock (570,000,000 to 4,600,000,000 years old), which emerges to form not only the backbone of northern Mauritania's Rigaibāt ridge region but also the Akjoujt rock series which forms a vast peneplain (a land surface worn down by erosion to a nearly flat plain) studded with *inselbergs*. The second zone, located partly in the extreme north but mostly in the centre and east, consists of primary sandstone, which covers the Tindouf Syncline (a fold in the rocks in which the strata dip inward from both sides toward the axis), in the north, and the vast synclinal basin of Taoudeni in the centre (bounded by the Adrar, Tagant, and 'Assāba plateaus), scarcely indented to the south by the Hodh Depression, with the Affollé Anticline (a fold in which the rock strata incline downward on both sides from a central axis) lying in its centre. The third zone is formed by the Senegalese-Mauritanian sedimentary basin, which includes coastal Mauritania and the lower Sénégal River Valley of the southwest.

The Mauritanian landscape, in general, as a result of the arid phases it underwent during the Quaternary Period (*i.e.*, within the last 7,000,000 years), presents three different aspects; these are represented by skeletal soils, regs (desert surfaces consisting of small, rounded, tightly packed pebbles), and dunes.

Skeletal soils are formed where outcrops of the underlying rock have been slightly weathered, or where they have been covered with a patina or chalky crust. To these may be added the salty soils of the *sebkhas* (saline plains), formed from the caking of gypsum or of salt derived from the evaporation of former lakes.

The regs form plains often of great extent, carpeted with pebbles and boulders.

The dunes cover about 50 percent of the total area of the country. They are stretched out, often for several dozen miles, in long ridges known as *alāb*, which are sometimes 300 feet high; they frequently overlap with one another, forming a network of domes and basins.

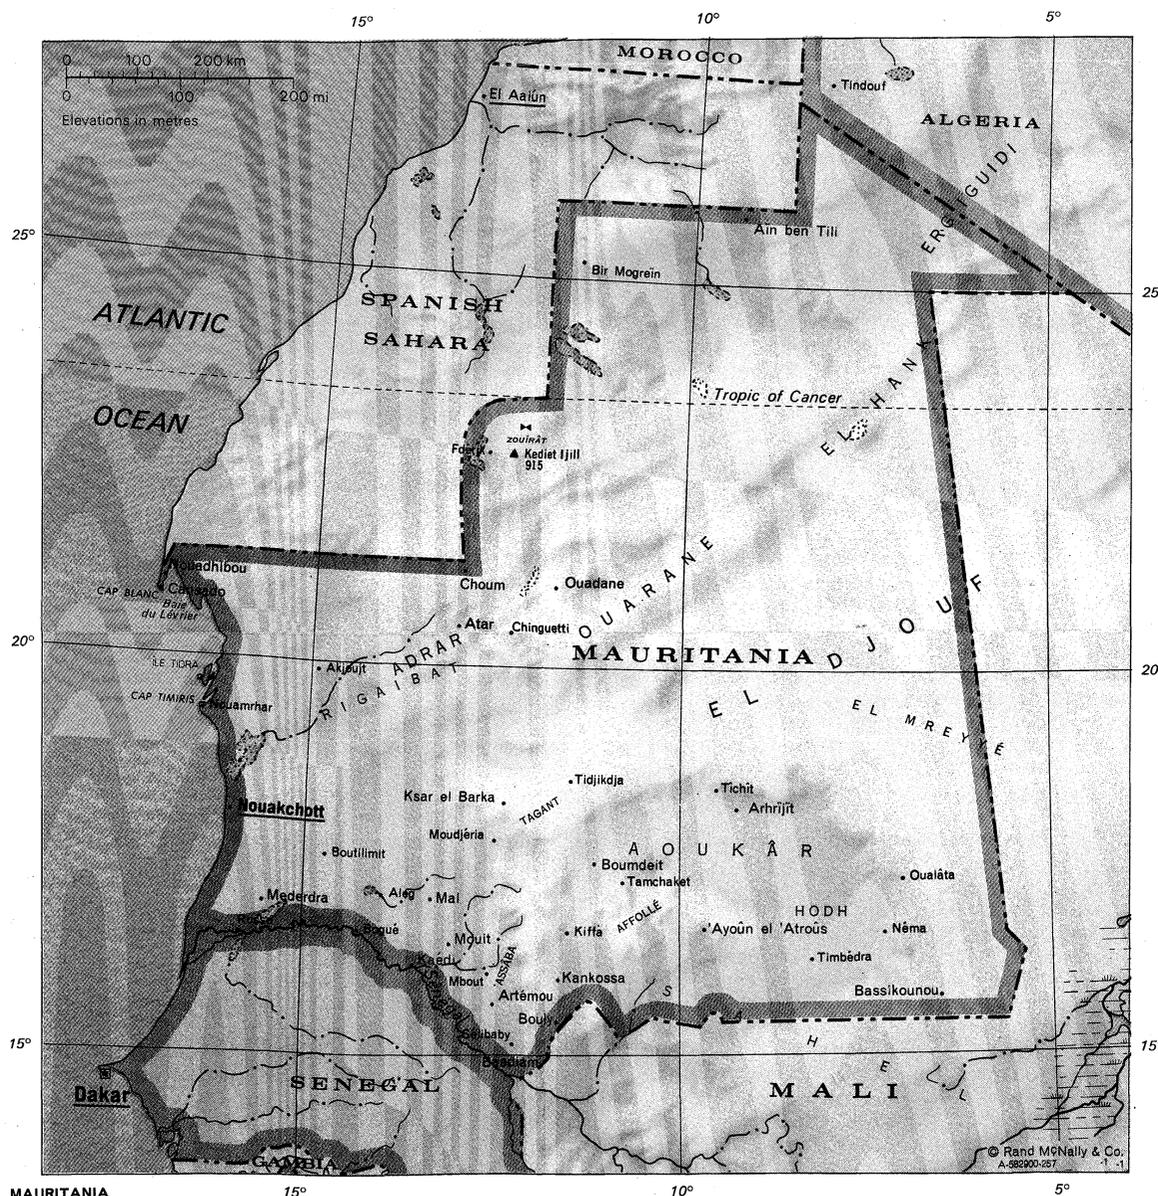

It is only to the south of the ten-inch isohyet (an imaginary line connecting points with equal rainfall) that the sands bear a brown type of soil. This soil is characteristic of the steppe (treeless plains) and contains 2 percent of humus; it is also only in the extreme south of the country that the iron-bearing tropical soils of the Sudanic zone begin; in the lowest places, patches of hydromorphic soils (*i.e.*, soils that have been altered by waterborne materials) occur.

The drainage system is characterized by a lack of pat-

tern. Normal drainage is limited to inland southwestern Mauritania where tributaries of the Sénégal River, which forms the frontier between Mauritania and Senegal, flow southward and are subject to ephemeral flooding in summer. In the greater part of the country, however, the plateaus are cut into by wadis (dry riverbeds) where the rare floods that occur dissipate their waters into a few permanent drainage basins called *gueltas*. In the wastes of the north and the east rainfall is so rare and slight that there is practically no runoff.

*Climate.* The climate owes its aridity to the northeast trade winds, which blow constantly north of the Tropic of Cancer, and throughout most of the year to the south of it; the drying effect produced by these winds is increased by the harmattan, or east wind. With the exception of the few winter rains that occur as a result of climatic disturbances in the polar regions, precipitation essentially results from the rain-bearing southwesterly winds, which progressively extend throughout the southern half of the country at the height of the summer. duration of the rainy season, as well as the total annual amount of rainfall, diminishes progressively from south to north. Thus, Sélibaby in the extreme south receives about 25 inches between June and October; Kiffa, further north, receives 14 inches between mid-June and mid-October; Tidjikdja receives 7 inches between July and September; Atar receives 7 inches between mid-July and September; and Nouadhibou (formerly Port-Étienne) receives between one and two inches, usually between September and November. Because of the opposition between the wet southwesterlies and the harmattan, rains often take the form of stormy showers or squalls.

The strength of the sun's rays and the lack of haze in these latitudes result in high temperatures. The average temperature in the coldest month is in the region of 68° F (20° C), while the average temperature during the hottest month rises to about 75° F (24° C) at Nouakchott in September, to about 79° F (26° C) at Kiffa in May and 81° F (27° C) at Atar in July, and to 84° F (29° C) at Néma in May.

**Vegetation.** Vegetational zones depend upon the degree of aridity, which increases from south to north. The Sudanic savanna (grassy parkland), studded with baobab trees and palmyra (*rônier*) palm trees, slowly gives way, toward 16° N, to a discontinuous belt of vegetation known as the Sahel (an Arabic word meaning riverbank or shore, which is also used to designate the southern Sahara borderlands). In the Sahel, trees are rare and consist principally of acacias, euphorbia bushes (plants of the spurge family, having a milky juice and flowers with no petals or sepals), big tufts of morkba (*Panicum turgidum*, a type of millet), or fields of cram-cram, or Indian sandbur (a bristly herb). Between the six-inch and four-inch isohyets the steppe rapidly disappears, giving way to desert. Vegetation is restricted to such places as the dry beds of wadis, beneath which water still flows, or to oases.

**Animal life.** In the savanna, big antelopes are hunted by lion, in the Afollé region of southern Mauritania, herds of elephants are found. The steppe is frequented by gazelles, ostriches, warthogs, panthers, and lynx; crocodiles are found in the *gueltas*. Only the addax antelope ventures out into the waterless desert. In recent years animal life has been much reduced by hunting, obliging the authorities to introduce measures for conservation.

**The landscape under human settlement.** The Sahara region to the north, where life is generally limited to oases, stands in contrast to the Sahelian steppelands to the south, where regular rainfall permits extensive stock raising and some agriculture. While transition occurs between one zone and another, a convenient line of demarcation is represented by the four-inch isohyet.

The heartland of Mauritania consists of the vast Adrar and Tagant plateaus, known as the Trab el-Hajra, or country of stone. Here, at the foot of cliffs, are to be found several oases among which some—such as Chinguetti, Ouadane, Tichit, Tidjikdja, and Atar—were the sites of well-known cities in the Middle Ages. To the north and the west extend the vast desert peneplains. The exploitation of the Zouïrât mines and the development of Nouadhibou have transformed this once-abandoned region into the focus of Mauritania's economic life.

Coastal southwestern Mauritania (the former *Trarza cercle*) is covered with regularly aligned dunes and is important for stock raising; Arab-Berber culture is represented by important marabout (priestly) families.

Inland southwestern Mauritania (the former *cercles* of Brakna, Gorgol, and 'Assâba) is inhabited both by Moors and Fulani (Peuls), who engage both in stock raising and agriculture. In the extreme south (the former *Guidimaka cercle*), large villages are surrounded by fields of millet constituting the first sign of the Sudan landscape, which comes into view further south.

In the southeast, the vast Hodh Basin, with its dunes, sandstone plateaus, and immense regs, is a major stock-raising region the economy of which has many links with neighbouring Mali.

Mauritania is a country suited for nomadic life; nomads represent 78 percent of the total population. Livestock

supplies the nomads with milk and meat, while transport is provided by riding camels and pack camels, and, in the south, by pack oxen and donkeys as well. The women dye sheep's wool with which they then braid long brown bands that are sewn together to make tents; they also tan goats' skins to make *guerbas* (waterskins). Movement is governed by the search for water and pasturage. In the Sahara, nomadic movements are irregular because of the extreme variability of rains; in the Sahel, however, seasonal movement occurs—to the south in the dry season, and to the north in the wet season. The size of nomadic encampments also varies from south to north. In the coastal southwest, groups of 300 tents may be found, whereas in northern Mauritania, only small groups of a few tents are to be seen.

For various reasons—including changes in political and commercial relations; a series of dry years, which resulted in a slow population movement from the north to the south; and a decrease in the camel population which has coincided with the coming of the milk cow—the nomadic way of life has been declining in recent decades. Dams to conserve floodwaters have been built in the wadis, and palm-tree culture has been considerably extended. The cumulative result of these developments has been that the nomads remain longer in the south near their millet fields and palm groves—becoming, in sum, seminomads.

Since the 1960s, a movement toward settlement has been evident, largely because of growing dissatisfaction with the harsh conditions of nomadic life; this embryonic movement has, however, been restricted by the constant lack of water. Only in the extreme south—on the banks of the Sénégal River (the Chemama)—is a normal, settled agricultural life possible.

The exploitation of the iron-ore reserves of Kediet Ijil as well as the coming of independence have transformed the urban geography of Mauritania. The ancient cities that lived by caravan traffic—e.g., Tichit, Chinguetti, Ouadane, and Oualata—and traded with Casablanca and above all with Dakar grow idler beneath their palm trees. Only Tidjikdja and Atar have maintained a certain activity. Kaédi, on the Sénégal River, is expanding and is expected to grow still larger. Three new towns have been built: Nouakchott, the capital, which had a population of 35,000 in 1971; F'Dérik (formerly Fort-Gouraud; 16,000 population); and Nouadhibou (11,000).

Nouakchott was founded in 1958 after the government decided to replace the former capital, Saint-Louis in Senegal, with an authentically Mauritanian city. Located near the sea, and providing access to the Sahara and Sahel regions alike, Nouakchott—in addition to being the seat of government and administration—has a printing works, a hospital, and numerous schools. Although it remains essentially a town for officials, its commerce is growing. Its water supply is provided by a plant that desalinizes seawater.

F'Dérik is an administrative centre situated about 15 miles from the mining town of Zouïrât, where the employees of the Miferma company (Société Anonyme des Mines de Fer de Mauritanie) live and to which many traders and unemployed have been drawn. The port of Nouadhibou, long stagnant, owes its recent expansion both to iron-ore exports and to the establishment of a fishing complex there. A few miles to the south lies a residential city, Cansado, built by Miferma.

**People and population.** *Ethnic and linguistic groups.* The Moors constitute 80 percent of the population; about half of them are white, or *bidân*, Moors, and about half are black, of Sudanic origin. Moorish society is traditionally divided into a hierarchy of castes. At the head of it are the noble castes, composed of warriors and of marabouts, or people of the Book (the Qur'ân). The warriors are usually Arab, and the marabouts are usually Berber. The mass of the *bidân* population are vassals who receive protection from the warriors or marabouts in return for tribute. There are two artisan classes—the blacksmiths and the griots (who are at once musicians and genealogists). The servant classes are formed of black Moors and are subdivided into "servants" and

The decline of nomadism

The Sahara and Sahel regions

The Moors

freedmen. Since the beginning of the century, social divisions have been modified by the disappearance of traditional insecurity and by the suppression of slavery. Members of the "servant" caste, above all, have become aware of their rights as citizens. Only by stages, however, do concepts of modern law penetrate traditional society.

The Moors speak Ḥassāniyah, a dialect that draws most of its grammar from Arabic and uses a vocabulary of both Arab and Berber words. Most of the white Moors also know literary Arabic.

The remaining 20 percent of the population consists of Tukulors (Toucouleurs), who inhabit the Sénégal River Valley; Fulani, who are dispersed throughout the south; Soninke (Sarakole), who inhabit the extreme south; and Wolof, who are found in the vicinity of Rosso in coastal southwestern Mauritania. The Tukulors and the Fulani speak Fulfulde (Poular), and the other groups their respective tribal languages. The non-Africans in Mauritania are mostly French; no more than a few thousand, they are engaged in technical assistance and in mining.

**Religious groups.** All Mauritians are Muslim. Most Moors belong to the Brotherhood of the Qādirīyah, which practices the Mālikite rite. Some of the Tagant tribes, and the Tukulors, follow the Tijāniyah rite.

**Demography.** Precise demographic statistics cannot be compiled, because of the nomadic mode of life of much of the population. Until recently, the only statistical sources were administrative censuses held for purposes of taxation; because of nomadic mobility, however, as well as failures to report all the women, slaves, and children to the census takers, the final statistics were unreliable. A census based on sampling resulted in the 1965 population being estimated at 1,071,000, of which 802,000 were nomadic, 158,000 were sedentary farmers, and 82,000 were urban dwellers. The birth rate was estimated at 45 per thousand, and the death rate at 29, resulting in a rate of increase of 16 per thousand. (The rate of increase among nomads was estimated at 15 and among sedentary farmers at 18 per thousand.) Between 1965 and 1970 the population movement to the towns increased. About 90 percent of the population lives south of the four-inch isohyet.

**The national economy.** In the Sahel region, a traditional subsistence economy is maintained, composed of stock raising, agriculture, crafts, and petty trading. In the Sahara region, however, a modern economy is developing, based on iron-ore and copper resources and on the fish resources of the continental shelf; the modern economy receives capital investment and technical assistance from abroad. More than 85 percent of the Mauritanian population still live by traditional activities, among which stock raising is the most significant. In 1970 the livestock consisted of about 2,600,000 cattle, more than 5,200,000 sheep and goats, more than 500,000 camels, about 225,000 donkeys, and about 23,000 horses. The cattle are located primarily in the southern region, whereas the sheep and goats are dispersed as far north as the limits of the Sahara. The camels are found mostly in the north and the centre, especially in the Adrar region.

**Agriculture.** Agriculture is necessarily dependent upon rainfall. Where the rainfall exceeds 17 inches a year,

millet is the principal crop, supplemented by beans, yams, maize, and cotton. Seasonal agriculture is practiced on the easily flooded riverbanks, and in the wadis of the Sahelian zone, upstream from the dams. Here, too, millet, sorghum, beans, and watermelons are grown. Irrigated agriculture is practiced at oases where well water is available; corn, barley, a little millet, and some vegetables are grown. In the country as a whole, two agricultural crops predominate—millet and dates. The output of gum arabic is declining; annual production varies between 3,000 and 5,000 tons.

**Mining.** The iron-ore deposits of Kediet Ijill amount to 200,000,000 tons of hematite, obtainable from surface workings. A rail link 419 miles long connects the mining town of Zouirât with the port of Nouadhibou, the only deepwater roadstead on the Saharan coastline, accommodating ships of up to 150,000 tons. Exploitation is conducted by Miferma, of which 56 percent of the financing is by French groups, the remainder by English, German, and Italian groups and the Mauritanian government. Exports increased from 1,300,000 tons in 1963 to about 9,000,000 tons in 1970.

The copper deposits of Akjoujt amount to 500,000 tons of pure metal. Exploitation was begun in 1969 by Somima (Société Minière de Mauritanie), of which 54 percent of the shares are held by Anglo-American interests, 25 percent by the Mauritanian government, and the remainder by French interests. Processed copper is to be exported along a 173-mile highway to the wharf at Nouakchott; it was estimated that 34,000 tons were exported in 1971. Other mineral resources are minor. Salt output is declining. There are some gypsum deposits near Nouakchott. Reserves of ilmenite (the principal ore of titanium) have been located, and indications of copper have been found in the extreme south. Oil prospecting has so far yielded no results.

**Fishing.** Rich fishing grounds lie off Mauritania's Lévrier Bay. It is estimated that about 300,000 tons of fish are caught there each year by fishing boats of all nationalities; about 30,000 tons are landed at Nouadhibou, of which the greater part are dried. About 8,000 tons of fish are exported to other African countries each year.

**Sources of national income.** The gross domestic product in 1966 amounted to 41,200,000,000 CFA francs (CFA Fr.277.71=\$1 U.S.; CFA Fr.666.50=£1 sterling on December 1, 1970). Of this, agriculture represented 27 percent (compared to 84 percent in 1959), and mining 38 percent (compared to 4 percent in 1959). There is no doubt that the percentage represented by mining will grow still further in future. While the proportion contributed by agriculture has declined (chiefly because of adherence to rudimentary techniques), the mining and industrial sector has greatly increased in productivity. Since 1965 income from Miferma alone has represented about 47 percent of the total budgetary receipts.

**Foreign trade.** Foreign trade is difficult to estimate since, while imports and exports of the modern sector are well-known, there are no statistics for the traditional sector. Mauritania is nevertheless known to import from or via Senegal quantities of millet, tea, rice, sugar, cotton goods, and hardware, while it exports to Mali and to Senegal about 100,000 cattle and 900,000 sheep and goats each year. Livestock is second in value only to iron ore as an export.

**Management of the economy.** The four-year plan from 1963 to 1966, which covered all aspects of social and economic development, encountered serious difficulties; it was to be followed by a second plan covering the period 1970 to 1974. In agriculture the aim is to increase the amount of irrigated land in the Sénégal River Valley and, above all, to increase production of rice, of which Mauritania is still obliged to import 20,000 tons a year; to plant fresh palm trees to replace those destroyed by the cochineal insect; to drill fresh wells; to improve the quality of dates; and to encourage the cultivation of vegetables. To promote the export of meat, two slaughterhouses are to be constructed, one at Kaédi, and one at Nouakchott. Investment in fisheries is to be concentrated on Nouadhibou, where plans include the formation of a

Iron ore  
and copper

Stock  
raising

Mauritanian fishing fleet, establishment of a training centre for professional personnel, construction of a fishing port, and establishment of three fish-freezing depots, as well as a plant for manufacturing fish flour and fish oil, and a fish-drying factory.

**Taxation.** The state imposes direct taxes on the number of cattle owned and also levies an income tax. Investment by private enterprise in developmental projects is encouraged; taxes affecting concerns such as Miferma and Somima are on a long-term basis.

**Transportation.** Transport by pack animals—camels in the north, oxen and donkeys in the south—has retained considerable importance in a society in which a subsistence and barter economy prevails, although transport between cities and regions is increasingly by truck. Considerable hazards, however, confront road builders; among these are moving sand dunes, flash floods in the south, and steep cliffs. Only the main road running from Rosso via Nouakchott, Akjoujt, Atar, F'Dérik, and Bir Mogreïn to Tindouf, Algeria, is passable throughout the year. The road between Rosso and Nouakchott is surfaced, as is the section between Nouakchott and Akjoujt. A road between Nouakchott, Kaédi, Kiffa, 'Ayoïn el 'Atroûs, and Néma is under construction; it will link the eastern region to the capital. A railroad from Zouirât to Nouadhibou is used only for transporting iron ore. Cities are linked by regular air services.

The irregularity of the flow of the Sénégal River limits its use as a waterway; Kaédi can only be reached by ships drawing about seven feet at the high-water season, which is from August to October. The port facilities at Nouakchott, which could accommodate 50,000 tons of shipping in 1970, were to be expanded in the early 1970s. Nouadhibou, in addition to being an iron-ore and fishing port, is also a commercial port.

**Administration.** The Mauritanian state has a presidential regime. The president of the republic is the head of government and the secretary general of the Parti du Peuple Mauritanien (PPM). Legislative power belongs to a national assembly of 40 elected members. The primary task of the government has been to transform a community of diverse tribes, which are hierarchical in structure and strongly differentiated, into a nation. The results have been encouraging; many local barriers to cooperation have been overcome. Traditional regional boundaries have been redrawn; seven regions and one capital district now exist, each directed by a governor, with the capital forming a separate district. One remaining difficulty consists of the latent opposition that exists between Moors and Negroes; this difference, which is cultural rather than racial, is due to the fact that the Negroes have become more educated than the Moors, who have been traditionally suspicious of nonreligious education. Consequently, the Negroes hold a large proportion of governmental positions. A campaign to Arabize the public service is now in progress.

The judicial authority is independent of both the executive and legislative branches. The legal code is inspired by the universal principles of Islâm.

The army has a strength of 1,800 men, including infantry, cavalry, and parachutists.

**Cultural life.** Moorish society is justly proud of its Arab and Muslim heritage. Theology, poetry, and music have flourished throughout recent centuries. Architecture is inspired by that of the Maghrib, and goldsmithing is a fine art. Traditional culture, represented by the great marabout families, such as the Ahel Shaykh Sīdiyā family, is nevertheless declining. The elite are increasingly conscious that modern education taught in an international language—French—is an indispensable prerequisite of development. Primary education is making inroads, despite the enormous difficulties posed by the dispersion and mobility of the people. Instruction is given in Arabic and French alike. The government is seeking principally to promote secondary and technical education. A number of students are pursuing higher studies abroad, either at the University of Dakar in Senegal, in European (above all, French) universities, or at the University of al-Azhar in Cairo. Mauritanian society as a whole is linked

by radio, which reaches the remotest encampments. There is a broadcasting station at Nouakchott.

**Prospects for the future.** Mauritania is pursuing the double aim of achieving internal development and of affirming its political personality. Economic growth is favoured by the existence of considerable mineral resources. Annual per capita income has risen from U.S. \$65 in 1959 to U.S. \$165 in 1969. But development will not realize its full potential unless professional and general education is made available, and unless the resources drawn from the Sahara permit the transformation and modernization of the traditional Sahel economy.

The Mauritanian nation is overcoming ethnic contradictions in order to become a link between Arab Africa and black Africa; it adheres to the principles of Arab policy while at the same time cooperating with other African states through the Organization of African Unity (OAU).

Since Morocco renounced its territorial claims to Saharan Mauritania in 1969, Mauritania has followed with vigilance the evolution of a neighbouring territory—the Spanish Sahara—in which it has been decided, at least in principle, that a referendum be held under United Nations' auspices. Finally, Mauritania, together with Mali, Guinea, and Senegal, is a member of the Organisation des États Riverains du Sénégal—the Organization of Senegal Riparian States—of which the purpose is the joint development of the resources of the Sénégal River Valley.

(C.H.T.)

## Mauritius

Mauritius is the central island of the Mascarene group. It is situated in the Indian Ocean about 500 miles (800 kilometres) east of Madagascar. It is 38 miles (61 kilometres) long by 29 miles (47 kilometres) wide and has an area of 720 square miles (1,865 square kilometres). The island's population is more than 800,000. The capital is Port Louis, on the northwest coast. Mauritius, an independent state, is a member of the Commonwealth of Nations. Its economy is primarily agricultural, but it is also an important link for sea and air transport in the Indian Ocean region. Its outlying territories comprise (1) the island of Rodrigues, which lies 344 miles (550 kilometres) eastward and which has an area of over 42 square miles (110 square kilometres) and a population of over 23,000; (2) the Cargados Carajós Shoals or the St. Brandon Rocks, 250 miles (400 kilometres) northeastward and consisting of a cluster of 22 islets, with a fishing station established on the largest; (3) the Agalega Islands, 580 miles (930 kilometres) northward, which are also small. They are leased to a coconut oil company. (For a detailed discussion of the physical setting, see INDIAN OCEAN.)

**The natural and human setting.** *Relief features, drainage, and soils.* Mauritius is volcanic, is shaped like an oyster, and is fringed by coral reefs. The northern part is a plain; the centre is a plateau rising to a height of about 2,200 feet (670 metres) and bordered by diminutive mountains, which are remnants of a huge volcano;

the south is largely mountainous. The highest peak on the island is the Piton de la Petite Rivière-Noire (Little Black River Peak) in the southwest, which is 2,711 feet (826 metres) high. There are many streams, generally flowing through deep ravines. During heavy rains these streams become torrents. On the plateau are two lakes, Grand Bassin and Mare aux Vacoas; the latter is the chief source of water supply. Four other large reservoirs are used for irrigation. Six major soil types are recognized. Of basaltic origin, formed from a fine-grained, dark-coloured igneous rock, they are fairly fertile but are extremely rocky.

**Climate, vegetation, and fauna.** The climate is maritime subtropical, with only two seasons—hot from November to April and cool from May to October. The southeast trade winds blow most of the year, and the climate is generally humid. The average temperature at Port Louis, on the coast, during the hot summer months is about 84° F (31° C), and in the cooler winter months it is about 77° F (25° C); at Curepipe, on the inland plateau, the temperature averages about 75° F (24° C) in summer and about 68° F (20° C) in winter. Heavy rains and cyclones occur during the hot season. Annual coastal rainfall varies between 35 inches (900 millimetres) on the west coast to 60 inches (1,500 millimetres) on the southeast coast. The central plateau receives about 200 inches of rain. The vegetation includes some 600 indigenous species, even though little original forest is now left. Many plants have been introduced since the 18th century, and in 1770 a botanical garden, which still exists, was formed at Pamplemousses to nurse them. The original fauna comprised insects, birds, reptiles (including chelonians, which are related to tortoises or turtles), and one mammal, the fruit-eating bat. Of particular interest were a number of wingless birds, such as the dodo and the *Aphanapteryx* (a large long-billed rail, a species of wading bird related to the crane), all now extinct. Among imported mammals are the sambar (long-tailed dark brown deer), tenrec (spiny insectivore), and mongoose. There are no venomous animals, but about 1865 the *Anopheles* mosquito, which carries malaria, was introduced and spread the disease, which remained endemic for nearly a century.

**The landscape under human settlement.** The island is divided into seven coastal and two inland districts. Most of the rural population still lives in the coastal districts, chiefly in the north and east, which were settled first. The original slave population lived on plantations. After emancipation in 1835 the freed slaves left to settle in coastal fishing villages. The Indian labourers who replaced them lived in estate camps until, in the 1860s, they spread out over the island, forming straggling villages. The first towns were Port Louis, on the leeward (westward) side of the island, then Mahébourg, on the windward (eastward) side. After a malaria epidemic that lasted from 1866 to 1868, the wealthier inhabitants of the towns migrated inland. Port Louis, nevertheless, remained the capital, as well as the business and administrative centre, as it is today. It is laid out on the French gridiron pattern and has a population of 139,000. It achieved city status in 1966. Some inland towns grew up

in the 1870s on the Plaines Wilhems. These are Beau Bassin-Rose Hill (population 70,700), Quatre Bornes (population 45,000), Vacoas-Phoenix (population 48,480), and Curepipe (population 51,460). All are residential and have few commercial activities. Mahébourg is now little more than a village.

**People and population.** The first settlers imported slaves from Madagascar and East Africa. The languages then spoken were French and Creole, a French patois. French remains the predominant European language, and Creole has become the lingua franca of the island. English, the official language, was introduced after 1810, as also were some Asian languages. The chief Indian dialect is Bhojpuri, which is associated with the Bihar region of India. Many Chinese speak Cantonese.

The largest ethnic group is Indian, comprising both Hindus and Muslims, followed by a general group composed of those who are either European, African, or Malagasy, or who are of mixed parentage. All are Christians, principally Roman Catholic. The Chinese, who are also largely Christian, form the smallest group. Despite cultural and community differences, the population tends to divide into two broad groups—one European-oriented and the other Asian-oriented. In January 1970 the population was estimated at slightly more than 800,000—an average of over 1,000 persons per square mile (380 persons per square kilometre). The crude birth rate in 1970 was over 27 per 1,000, and the crude death rate was 8. The rate of natural increase thus was over 19 per 1,000.

**History.** Known to Arab or Swahili seamen since the 10th century, or earlier, Mauritius and Réunion were visited by the Portuguese about 1510. Rodrigues was not visited until later. The name of Mascarenhas, first applied to Réunion, was subsequently extended to the whole group of islands. Finding Mauritius still uninhabited in 1598, the Dutch named it after their *stadhouder* (head of state) Maurice (Maurits) of Nassau. After two attempts to settle the island, made in 1638–58 and again in 1664–1710, the Dutch abandoned it, and it was then haunted by pirates. In 1721 the French East India Company, after annexing Réunion, sent a party to occupy Mauritius, which they renamed Ile de France. Under the rule of the company, which lasted from 1721 to 1767, the progress of settlement was slow. Port Louis was founded and was used as a base for attacking the British in India. During the Seven Years' War, from 1756 to 1763, a further attempt to use it as a base against the British again failed. In 1767 the French Ministry of Marine took over administration and a new era began. During the American Revolution, French naval units and privateers, based at Port Louis, gained many successes. Port Louis then became a vital way station, being visited by many French, Danish, and American ships. When, after the French Revolution, the government in Paris tried to abolish slavery in 1796, the island's settlers broke away from France. Even without French governmental support, however, the settlers, by conducting successful privateering expeditions and engaging in foreign trade, managed to maintain themselves. In 1810 the British captured Mauritius, restored its Dutch

Extinct species

Languages

First settlement of the island

name, and occupied it with its dependencies as a crown colony. From a commercial and military outpost it was then transformed into a plantation colony, with sugar as its sole product. In language, laws, and customs, however, it remained largely French. In 1835 slavery was abolished, the slaves being replaced by Indian labourers. From 1850 to 1860, Mauritius prospered, until competition from beet sugar caused a decline. The malaria epidemic of 1866–68 caused much misery and for a time drove shipping away from Port Louis. Shipping also visited the island less frequently after the change from sail to steam and after the opening of the Suez Canal in 1869. The last years of the 19th century were difficult. World War I caused further distress, but after the war, sugar prices rose and a brief revival ensued. The economic depression of the 1930s, however, culminated in labour unrest in 1937. The situation did not improve during the uncertain years of World War II. After 1945 economic reforms were introduced. Important administrative and political reforms also were initiated; these led to self-government and independence, which was attained in 1968.

Importance  
of sugar

**The nation.** *Economy.* The economy is dominated by sugar, which accounts for about 90 percent of the export trade. A yearly average of 650,000 metric tons is processed by 23 factories. The secondary crop is tea, with eight factories producing over 3,000 tons annually. Some food crops, and tobacco, are grown, and there is a minor meat and dairy industry. Fish are caught in the lagoons, and two local companies in the Cargados area, as well as Japanese fleets with a wider range, engage in open-sea fishing. Tourism is becoming increasingly important. Mauritius is a member of the sterling area, and its currency is the rupee, which is divided into 100 cents and is worth 18 cents U.S., or 7½ new pence (sterling). The private sector of the economy is the most active, with the sugar companies, which are largely familial, overshadowing other types of enterprise. Taxation is not onerous. Efforts are being made to develop duty-free zones, as well as to provide hotel accommodation, in order to encourage foreign investment and tourism.

*Transport and communications.* Mauritius has 1,100 miles (1,770 kilometres) of roads, of which about 990 miles (1,590 kilometres) are tarred. Railways have been discarded, but there is an extensive bus transport system. Port Louis harbour has deepwater quays and dry-dock facilities and usually handles over a million tons of shipping a year. A government project for a second harbour at Mahébourg is under consideration. Regular cargo and passenger services to and from Europe are provided by British, French, and Scandinavian companies. A Dutch line operates a passenger and cargo service to Asian, South African, and South American ports; there are cargo services to India and South Africa. A local company links Mauritius to Rodrigues and runs ships to Madagascar, Africa, and Australia. The airport at Plaisance receives about 30,000 passengers a year. Air services are operated by eight companies. Another airport is planned in the north. The Mauritius Broadcasting Corporation runs television and radio programs.

*Administration and social conditions.* Queen Elizabeth II, as head of the Commonwealth of Nations, is represented by a governor general. The Legislative Assembly consists of (1) the speaker, (2) 62 elected members, (3) 8 additional members, and (4) the attorney general. The Cabinet consists of the prime minister and 20 other ministers. For electoral purposes, Mauritius is divided into three-member constituencies, of which there are 20. Rodrigues returns two members. The official language of the Assembly is English, but French may also be used. Local government is exercised at the village level by 98 village councils whose activities are coordinated by 3 district councils. In the urban areas, administration is vested in municipalities, with 24 elected members each. Port Louis has a fully elective 30-member council. There are 34 social welfare centres, mainly in the rural areas. Old age pensions, family allowances, and outdoor relief are also provided. Unemployment, however, is often high, with between 30,000 and 40,000 persons out of work.

*Cultural life and institutions.* Interest in arts, letters, and science is maintained chiefly by private societies. The national cultural institutions are the Mauritius Institute and the Mauritius Archives. Although there are five municipal and many institutional libraries, their work is not coordinated by a central authority. The theatre is popular. British, French, and Indian culture are all promoted by agencies of the respective governments. Book production is slight. There are 9 daily newspapers and 10 weekly publications. The standard of secondary education is relatively high, and a university college, providing technical education, has been founded.

**Conclusion.** While Mauritius has achieved the status of an independent state, its economy, being overly reliant upon the dominant sugar industry, is not strong. The relatively rapid population growth has caused concern and has tended to result in conditions that aggravate race problems. The growth of tourism has, however, been an encouraging development.

(Au.T.)

## Maximilian I, Emperor

One of the foremost princes of his age, the German king and Holy Roman emperor Maximilian I forged an elaborate dynastic structure that made his family, the Habsburgs, the dominant power in 16th-century Europe.

He was born at Wiener Neustadt, Austria, on March 22, 1459, the eldest son of the emperor Frederick III and Eleanor of Portugal.

By his marriage in 1477 to Mary, daughter of Charles the Bold, duke of Burgundy, Maximilian acquired the vast Burgundian possessions in the Netherlands and along the eastern frontier of France. He successfully defended his new domains against the attacks of Louis XI of France, defeating the French at the Battle of Guinegate in 1479. After Mary's death (1482) Maximilian was forced to allow the States General (representative assembly) of the Netherlands to act as regent for his infant son Philip (later Philip I the Handsome, of Castile); but having defeated the States in war, he reacquired control of the regency in 1485. Meanwhile, by the Treaty of Arras (1482), Maximilian was also forced to consent to the betrothal of his daughter Margaret of Austria to Charles VIII of France.

In 1486 he was elected king of the Romans (heir to his father, the emperor) and crowned at Aachen on April 9.

By courtesy of the Albertina, Vienna

Maximilian I, charcoal drawing by Albrecht Dürer, 1518. In the Albertina, Vienna.

With the military help of Spain, England, and Brittany, he continued his war against France and the rebellious Netherlands. In order to surround France, Maximilian in 1490 married Duchess Anne of Brittany by proxy but could not forestall an invasion of Brittany by the French. A dramatic setback occurred when Charles VIII sent his fiancée Margaret back to her father and required Anne to sever her marriage with Maximilian and to become the queen of France.

Through the archduke Sigismund, his cousin, Maximilian obtained the Tirol. Because of its favourable situation politically as well as its silver mines, its chief city, Innsbruck, became his favorite centre of operations.

By 1490 he regained control of most of his family's traditional territories in Austria, which had been seized by Hungary. He then became a candidate for the vacant Hungarian throne. When Vladislav (Ulászló) II of Bohemia was elected instead, he waged a successful campaign against Vladislav. By the Treaty of Pressburg in 1491 he arranged that the succession to Bohemia and Hungary would pass to the Habsburgs if Vladislav left no male heir.

The Treaty of Senlis (1493) ended the conflict against the Netherlands and France and left the duchy of Burgundy and the Low Countries secure in the possession of the house of Habsburg.

On the death of Frederick III in 1493, Maximilian had become sole ruler over the German kingdom and head of the house of Habsburg; he then drove the Turks from his southeast borders, married Bianca Maria Sforza of Milan (1494), and handed over the Low Countries to his son Philip (1494), reserving, however, the right of joint rule. The flourishing culture of the Low Countries influenced literature, art, government, politics, and military methods in all the other Habsburg possessions.

Charles VIII's invasion of Italy (1494) upset the European balance of power. Maximilian allied himself with the pope, Spain, Venice, and Milan in the so-called Holy League (1495) to drive out the French, who were conquering Naples. He campaigned in Italy in 1496, but although the French were expelled, he achieved little benefit from it. More important were the marriages of his son Philip to the Spanish infanta Joan (the Mad), in the same year, and of his daughter Margaret to the Spanish Crown Prince, in 1497. These marriages assured him of the succession in Spain and the control of the Spanish colonies.

At a meeting of the Reichstag (Imperial Diet) at Worms in 1495 Maximilian sought to strengthen the empire. Laws were projected to reform the Reichskammergericht (Imperial Chamber), taxation, and to give permanency to the public peace; however, no solution was forthcoming for many military and administrative problems. The princes would permit no strengthening of the central authority, and this limitation of power neutralized imperial policies. To thwart the opposition, which was led primarily by the lord chancellor Berthold, archbishop of Mainz, Maximilian set up his own extra-constitutional judicial and financial commissions.

In 1499 Maximilian fought an unsuccessful war against the Swiss Confederation and was forced to recognize its virtual independence by the Peace of Basel (September 22). At the same time, the French moved back into Italy, in cooperation with Spain, and occupied the imperial fief of Milan.

In 1500 the imperial princes at the Reichstag in Augsburg withdrew considerable power from Maximilian and invested it in the Reichsregiment, a supreme council of 21 electors, princes, and others. They even considered deposing him, but the plan miscarried because of their own apathy and Maximilian's effective countermeasures. He strengthened his European position by an agreement with France, and he regained prestige within the empire by victories in a dynastic war between Bavaria and the Rhenish Palatinate (1504). At the same time, the death of Berthold of Mainz rid him of one of his main opponents. Credit arrangements with south German business firms, such as the Fuggers, assured Maximilian of funds for foreign and domestic needs; and a campaign against

Hungary in 1506 strengthened the Habsburg claim to the Hungarian throne. Though he was German king, he had not been crowned as emperor by the pope, as customary. Excluded from Italy by the hostile Venetians, he was unable to go to Rome for his coronation and had to content himself with the title of Roman emperor elect that was bestowed on him with the consent of Pope Julius II on February 4, 1508.

To oppose Venice, Maximilian entered into the League of Cambrai with France, Spain, and the pope in 1508. Their aim was to partition the Republic of Venice. In the war that followed, Maximilian was labelled an unreliable partner because of his lack of funds and troops. Pope Julius's severe illness prompted Maximilian to consider accepting the office of pope, which the schismatic Council of Pisa offered him. At times pious, at other times anti-papal, he thought he might win financial help from the German Church if he were a rival pope; but in the end he let himself be dissuaded from this by Ferdinand II the Catholic, of Aragon. Turning away from his French alliance, he entered into a new Holy League (1511) with the pope, Spain, England, and their allies; with the help of England he scored a victory against the French in the Battle of the Spurs (1513), while his allies concentrated on regaining Milan and Lombardy. The French were victorious in Italy at the Battle of Marignano in 1515, and Maximilian's efforts to re-win Milan failed miserably. The Treaty of Brussels granted Milan to the French and Verona to the Venetians, leaving Maximilian with only the territorial boundaries of Tirol.

In the east, by making overtures to Russia, he was able to put pressure on Poland, Bohemia, and Hungary to acquiesce in his expansionist plans. In 1515, advantageous marriages were arranged between members of the Habsburg family and the Hungarian royal house, thus strengthening the Habsburg position in Hungary and also in Bohemia, which was under Hungarian influence. His intricate system of alliances, embracing both central Europe and the Iberian Peninsula, made Maximilian a potent force in European affairs.

On January 12, 1519, having spent the previous year trying to have his grandson Charles elected emperor and to raise a European coalition against the Turks, he died at Wels in Upper Austria. He was buried in Georgskirche at Wiener Neustadt. (His magnificent tomb at the Hofkirche in Innsbruck was erected later.) His plans did come to fruition when his grandson, already king of Spain, became emperor as Charles V later the same year.

Great as Maximilian's achievements were, they did not match his ambitions; for he had hoped to unite all of western Europe by reviving the empire of Charlemagne. Adhering more often to medieval patterns of thought, he was nevertheless open to new ideas, enthusiastic about promoting science as well as the arts. He not only planned a Latin autobiography but wrote two poetical allegories, *Weisskunig* ("White King") and *Teuerdank* (both largely autobiographical), and the *Geheimes Jagdbuch*, a treatise on hunting, and kept a bevy of poets and artists busy with projects that glorified his reign. His military talents were considerable and led him to use war to attain his ends. He carried out meaningful military and administrative reforms, but he was ignorant of economics and was financially unreliable.

**BIBLIOGRAPHY.** HEINRICH ULMANN, *Kaiser Maximilian I*, 2 vol. (1884-91, reprinted 1967), was the basic biography of Maximilian but now is completely out of date not only with respect to its sources and literature but also because of its emphatic Kleindeutsch (favouring the confederation of German states excluding Austria)-Prussian viewpoint. ROBERT W. SETON-WATSON, *Maximilian I, Holy Roman Emperor* (1902); and CHRISTOPHER HARE, *Maximilian the Dreamer, Holy Roman Emperor, 1459-1519* (1913), are the most important of the older presentations in English. GLENN E. WAAS, *The Legendary Character of Kaiser Maximilian* (1941), is primarily concerned with his character and personality; this very valuable work offers an imposing bibliography of the sources and literature as well as full scholarly apparatus. The catalogs of the *Ausstellungen Maximilian I*. (1959 and 1969), contain important contributions, especially concerning special problems of cultural history, and copious illus-

trations. HERMANN WIESFLECKER, *Maximilian I., Österreich, das Reich und Europa an der Wende zur Neuzeit*, vol. 1 (1971), is the first part of a projected four-volume biography of Maximilian that was prepared according to modern principles of historical research and that also contains a nearly complete bibliography of the sources and literature.

(H.Wi.)

## Maxwell, James Clerk

Though familiar to every physicist, the majority of whom would rank him next to Sir Isaac Newton for the fundamental nature of his contributions to the subject, the name of James Clerk Maxwell is less well-known to the general public. To the physicist, the name Maxwell means Maxwell's equations, the basis of the field theory of electricity and magnetism. Maxwell saw the space surrounding charged bodies as the seat of an electric field, and from this view, field theories have since become of widespread importance. Though the English physicist Michael Faraday, not Maxwell, must be given the credit for the origin of the field theory, he was no mathematician, and the idea could not have developed in his hands. Had it not been for Maxwell, it would have remained imprecise and of little use. After it had left the hand of Maxwell, it had been given a precision that made it the model for all field theories to follow.

Like Newton before him, Maxwell made contributions of fundamental importance to many branches of physics. He developed a quantitative theory of colour vision—even producing one of the first, if not the first, colour photographs. His contribution to the kinetic theory of gases has been of the greatest importance. He worked out the distribution of velocities among the molecules of a gas, their mean free path between collisions with each other, and tested his conclusions by experiments on the viscosity of gases. His interest in velocity distributions may well have arisen from his early work on the rings of Saturn, which earned him the important Adams Prize at Cambridge.

Early life  
and  
education

Though born in Edinburgh, on November 13, 1831, Maxwell was brought up in the country and not as a townsman. His father inherited an estate, Glenlair, in Kirkcudbrightshire and built a substantial house there. James's mother died when he was eight years old, and he continued to live in the house with his father, to whom he became deeply attached. He thus spent his childhood surrounded by the colour of the lakes and hills of Galloway, playing in the stream that ran by his house, and even in later life always managed to spend much of his time there. He went to school at Edinburgh Academy. Joining a class of sophisticated town boys already in their second year, he became something of a misfit. His country clothes and manners quickly earned him the nickname "Dafty." Anything less appropriate can hardly be imagined, but the episode may have had much to do with his shy, introspective character. Maxwell's father mixed with the distinguished scientific circle of Edinburgh of the time, and even before he left that city at the age of 19, James had had two papers published by its Royal Society.

On leaving Edinburgh, where he had spent three years at the university, Maxwell went up to Peterhouse, Cambridge, in the autumn of 1850. A number of very able mathematicians had been attracted to this college, including P.G. Tait, a schoolfellow of Maxwell and a year his junior. Maxwell soon afterward migrated to Trinity College, where the chances of obtaining a mathematical fellowship (which he later achieved) were thought to be better. He graduated in mathematics in 1854 with high honours.

Conservative by nature and conformist in religion, Maxwell generally sided with the clerics in the arguments over evolution, which were at their height in his time. He was athletic—walking, swimming, gymnastics, rowing, and riding provided him with exercise; he was also an expert horseman. One of his simple hobbies was the "diabolo," or "devil on two sticks" as he called it; its mastery called for a measure of scientific judgment.

Maxwell was appointed to the professorship of natural philosophy at Marischal College, Aberdeen, in 1856. He

Maxwell, oil on china by an unknown artist, after a photograph. In the collection of the National Portrait Gallery, London. By courtesy of the National Portrait Gallery London

had hoped from there to be able to spend much time with his father at Glenlair, but his father died before he took up his duties. He married Katherine Mary Dewar, the daughter of the principal of the college. After four years, Marischal College was combined with King's College to form Aberdeen University; and Maxwell, the junior partner in his department, had to seek another post. He tried unsuccessfully for a professorship that became vacant at Edinburgh, but in the summer of 1860, he was appointed to King's College, London.

He held this post for five years, during which he was at the height of his powers. He had just completed a very important paper on the kinetic theory of gases, which was published in 1860. This was later followed by other papers on the same subject, which must have remained constantly in his mind since he published his *Theory of Heat* in 1877. His electrical studies had started in Cambridge with a paper, "On Faraday's Lines of Force," read to the Cambridge Philosophical Society in two parts in 1855 and 1856. A second paper "On Physical Lines of Force," was contributed to the *Philosophical Magazine* in 1861. His electromagnetic theory was first fully set out in a paper to the Royal Society in 1864 entitled "A Dynamical Theory of the Electromagnetic Field." The best exposition of his theory, however, is to be found in the *Treatise on Electricity and Magnetism*.

Maxwell's work on electricity constituted his supreme achievement. It involved the extension of Faraday's ideas and their interpretation in terms of a mathematical notation. Like Faraday he looked upon the role of conductors in electricity as a minor one, since they served only as terminations of the lines of force of the surrounding electric field. He viewed all space as occupied by an ether that is capable of being electrically polarized. From this conception he postulated that a changing electric field should lead to what he called a displacement current in the ether, behaving in all respects like any other current of electricity. This concept made possible his electromagnetic theory.

The results of William Thomson (later Lord Kelvin), who calculated the velocity of a signal along an electric cable, were supported in 1857 when the German physicist Gustav Kirchhoff calculated the velocity of a signal along an isolated wire of circular cross-section. Kirchhoff found that the velocity should equal the ratio of the electromagnetic to the electrostatic unit of charge. This ratio had also been measured in 1856 by the German physicists Friedrich Kohlrausch and Wilhelm Weber and, although not of high accuracy, was very close to the measured value of the velocity of light. Kirchhoff, however, because of his view that electric current consists of positive and negative electricities,

Significance of work on electrical-field theory

missed its significance. To Maxwell, who thought that electrical phenomena took place in the field surrounding the conductors (which merely guided the lines of force), the result was highly significant. He commented upon it in a letter to Faraday in 1861 and added that he had worked out his formula before seeing the results of Kohlrausch and Weber. Maxwell's first attempt at an electromagnetic theory of light, published in 1862, established the velocity of propagation of a signal along a wire as the ratio measured by Kohlrausch and Weber. "We can scarcely avoid the conclusion," said Maxwell, "that light consists in the transverse undulations of the same medium which is the cause of electric and magnetic phenomena." In 1868 Maxwell himself measured the ratio of the two units of charge by a better method. His theory was strikingly confirmed by the experiments of Heinrich Hertz some years later, when he demonstrated the production of electromagnetic waves. Maxwell's theory led to advances in science and technology that have transformed the modern world.

Maxwell left King's College, London, in the spring of 1865 and retired to his estate at Glenlair. His time was mainly spent in quiet country life and in perfecting his electrical theory for the writing of the treatise. He paid periodic visits to Cambridge, where he acted as moderator or examiner for the Mathematical Tripos. In 1871 he accepted, somewhat reluctantly, an invitation to become the first Cavendish Professor of Physics. It fell to him to design the Cavendish Laboratory and recruit the initial staff; and it is to Maxwell's genius that the eminence that that institution achieved by the turn of the century is due. Maxwell died after a short illness on November 5, 1879.

**BIBLIOGRAPHY.** LEWIS CAMPBELL and WILLIAM GARNETT, *The Life of James Clerk Maxwell* (1882, reprinted 1969), the standard biography; R.A.R. TRICKER, *The Contributions of Faraday and Maxwell to Electrical Science* (1966), on the life and electrical studies of Maxwell, including reproductions from some of his most important papers and descriptions of the development of the electromagnetic theory of radiation; C. DOMB (ed.), *Clerk Maxwell and Modern Science* (1963), a collection of essays of varying relevance to the work and life of Maxwell; SIR EDMUND T. WHITTAKER, *History of the Theories of Aether and Electricity*, 2 vol. (1960), a well-known standard work giving a full account of Maxwell's contributions and their relation to the work of his contemporaries and predecessors. Maxwell's philosophical attitude to physics as well as accounts of some of his contributions to the subject may be found in the books by Maxwell himself: *Theory of Heat*, 3rd ed. (1872), and his *Treatise on Electricity and Magnetism*, 2 vol. (1873, reprinted 1953). The latter contains the best exposition of his electromagnetic theory of radiation. For his original papers, see *The Scientific Papers of James Clerk Maxwell*, 2 vol. (1890; reprinted in 1 vol., 1965).

## Mayan Religion

The religion of the Maya of southern Mexico and Central America influenced the development of some of the most impressive architectural, calendrical, and mathematical accomplishments of mankind.

The Maya civilization, the most brilliant pre-Columbian civilization known to modern man, flourished from the 3rd to the 16th centuries in an approximately 125,000-square-mile (325,000-square-kilometre) area that included the peninsula of Yucatán and the eastern part of Chiapas in Mexico, most of Guatemala, the western region of the Republic of Honduras, and the territory of British Honduras. The peoples who brought this civilization to a very high level of artistic and intellectual achievement spoke dialects belonging to a common stock: the Maya language. The present-day Maya Indians speak about 20 different idioms, the most important being the Yucatec or Maya proper, the Quiché of Guatemala, the Tzeltal, Tzotzil, and Chol of Chiapas. There is no means at present, however, to determine which language or languages were in use during the Classic period (3rd–9th century). Knowledge of such Maya terms as the names of deities or of the day-signs is based on post-Columbian documents with reference mainly to Yucatec Maya or sometimes to Quiché.

Religion dominated every aspect of Maya civilization. Although external influences brought about deep changes during the post-Classic era (see below), the role of religion in the Maya cultural complex remained paramount until its collapse under the onslaught of Spanish invasion in the 16th century.

**Sources.** The four main categories of documents that provide knowledge of the Maya civilization and its religion are: archaeological remains; native books in hieroglyphic writing; books in native languages written in Latin script by learned Indians; and early accounts written in Spanish by conquerors or priests.

**Archaeological remains.** From surviving temples, tombs, sculpture, wall paintings, pottery, and carved jades, shells, and bone, a significant amount of valuable information can be gained; e.g., representations of god-heads and ritual scenes. The interpretation of such remains, however, is delicate, especially in regard to the Classic period, because there is no proof that more recent concepts may validly apply to it. The hieroglyphic inscriptions should supply a wealth of information, but modern scholars still cannot decipher most of them.

**Native books in hieroglyphic writing.** Only three of the books written in hieroglyphics have survived: the Dresden Codex (Codex Dresdensis), discovered in Vienna in 1739, then kept at the former Royal Library of Saxony (Sächsische Landesbibliothek) in Dresden; the Madrid Codex (Codex Tro-Cortesianus) of the Museo de América, in Madrid; and the Paris Codex (Codex Peresianus) of the Bibliothèque Nationale. These three remaining books deal with astronomical calculations, divination, and ritual. They appear to be relatively recent copies of early originals. Their hieroglyphic writing is a simplified form of the glyphs carved on Classic stelae (inscribed stone pillars) but similar to those that were painted on the walls of a 5th-century tomb at Tikal.

**Books in native languages written in Latin script by learned Indians.** After the Spanish conquest, books were written by learned Indians who transcribed or summarized hieroglyphic records. Such is the case of the *Books of Chilam Balam*, in Yucatec Maya, and of the *Popol Vuh*, in Quiché, a highland Maya language. The former consist of historical chronicles mixed with myth, divination, and prophecy, and the latter (which shows definite central Mexican influences) embodies the mythology and cosmology of the post-Classic Guatemalan Maya. The *Ritual of the Bacabs* deals with religious symbolism, medical incantations, and similar matters.

**Early accounts written in Spanish by conquerors or priests.** The most important of these sources is Diego de Landa's *Relación de las cosas de Yucatán* ("The Things of Yucatán"), written about 1566. It is the best description of post-Classic religion in Yucatán and other details of late Maya history and life.

**Other sources.** To these sources may be added the observations recorded by modern anthropologists and ethnologists about present-day Maya, such as the Lacandonés. In the Guatemalan highlands, ceremonies connected to the 260-day sacred calendar of the Maya survive, as do ancient prayers and information about Maya gods and goddesses in Yucatán and other areas.

**History. Early history.** The oldest Maya dates recorded on monuments are found at Tikal (from AD 292) and at Uaxactún (328) in the Petén rain-forest lowlands of Guatemala. Little is known of the Formative period, which must have lasted several centuries before those dates. Obvious similarities connect Maya architectural features (pyramids, sculptured altars, stelae) and chronological hieroglyphs with the Olmec civilization of the Gulf Coast (see AZTEC RELIGION), but the characteristic jaguar-baby image of the Olmecs is nowhere represented in Maya art. Early Maya religion probably revolved around rain and vegetation gods, much like that of Teotihuacán in the Mexican highlands. Apparently, an aristocracy with theocratic tendencies developed over the peasants, who retained their agricultural deities.

**The Classic period.** The Classic period (c. AD 300–900) can be accurately dated because of the most original feature of Maya religion: the stela cult; i.e., the cus-

The stela cult

tom of erecting carved stelae at the end of each *katun* (a 20-year period, with each *tun*, or year, lasting 360 days). From Tikal and Uaxactún in the Petén area, the custom spread to ceremonial centres in northwestern Yucatán, Chiapas, and the Usumacinta Valley (Palenque, Yaxchilán, Piedras Negras) and to Copán between 435 and 534, then to new cities in Yucatán (Tulum, Cobá, Edzná, Jaina), to Quiriguá in the Motagua Valley, and to Tzandales, Lacanhá, and Tilá in Chiapas.

The 7th and 8th centuries can be considered the Maya Golden Age. Majestic monuments of the Copán Acropolis, exquisite sculptures and stuccos of Piedras Negras and Palenque, carved lintels of Yaxchilán, huge hieroglyphic stelae of Quiriguá, and delightful statuettes from Jaina all bear witness to the extraordinary dynamism of Maya civilization. In the year AD 790 (end of the 18th *katun* of the 9th *baktun*, 20 *katuns* each, in the Maya count), dated stelae were erected in 19 cities from Yucatán to Copán. From then on, archaeological remains show a marked decline in building and artistic activities. The last recorded dates are found in the Petén area (889 at Uaxactún). An engraved jade from Tzibanché, Quintana Roo, bears the date 909. Most of the classic centres had been abandoned by the end of the 9th century.

*The post-Classic period.* In the general collapse of the Classic civilization—which very well may have been caused by social and religious peasant revolts leading to the overthrow of the theocracy—the Yucatán sites such as Uxmal and Chichén-Itzá also were abandoned. In that area, however, the invasion of a foreign tribe, the Itzá, introduced (c. AD 1000) a completely new set of ideas and behaviours. Under the leadership of Kukulcán (Maya equivalent of the Mexican Quetzalcóatl, or Feathered Serpent god), the foreigners imposed upon the Yucatec Maya the central Mexican Toltec customs of human sacrifice and militarism and built grandiose Toltec-style monuments, such as the Temple of the Warriors at Chichén-Itzá. Other gods such as Tlalchitonatiuh, the rising sun and patron of the warrior orders of the Jaguars and Eagles, and phallic worship and other erotic practices were also introduced, all of which was not well accepted by the conquered Yucatec Maya. The alien deities little affected the peasant class. That renaissance lasted for two centuries; then the oppressive hegemony of the Mexican Maya city of Mayapán (c. 1200–c. 1450) followed by constant warfare between petty states, accelerated a cultural decline that ended only in the Spanish conquest in 1541.

*The post-Spanish conquest period.* Only a few Maya Indians (e.g., the Lacandonones) have resisted conversion to Christianity. Present-day religion of the Maya peasant, however, often combines Roman Catholic rites and beliefs with ancient cults, such as that of the Chac rain gods in Yucatán or the Year-Bearers' cult in the Guatemalan Highlands. In effect, the Maya absorbed Christianity, equating their pagan gods with Roman Catholic saints. Their moon-goddess came to be identified with the Virgin Mary, their Chacs with SS. Michael and James (depicted on horses), and the sun with Joseph or, sometimes, with Jesus. Even the cross is accorded a divine status, as both rain god and oracle.

*Myths.* The nature worship of the pre-Classic Maya probably began to undergo deep modifications as early as the 4th century BC with the introduction of astronomy, chronology, and hieroglyphic writing. An elaborate world view was evolved. Divinized heavenly bodies and time periods were added to the rain and maize gods.

Most deities were thought of as being simultaneously one and four, in connection with the four world directions, and as being both benevolent and malevolent. Concepts derived from priestly speculation were imposed upon the earlier pantheon, and religion became more and more esoteric, with a complex mythology interpreted by a closely organized priesthood.

*Creation.* The Maya, like other Middle American Indians (see AZTEC RELIGION), believed that several worlds had been successively created and destroyed before the present universe had come into being. The Dresden Codex holds that the end of a world will come about

by deluge: although the evidence derived from Landa's *Relación* and from the Quiché *Popol Vuh* is not clear, it is likely that four worlds preceded the present one. Men were made successively of earth (who, being mindless, were destroyed), then of wood (who, lacking souls and intelligence and being ungrateful to the gods, were punished by being drowned in a flood or devoured by demons), finally of a maize gruel (the ancestors of the Maya). The Yucatec Maya worshipped a creator deity called Hunab Ku, One-God. Itzamná (Iguana House), head of the Maya pantheon of the ruling class, was his son, whose wife was Ix Chebel Yax, patroness of weaving.

Four Itzannas, one assigned to each direction of the universe, were represented by celestial monsters or two-headed, dragon-like iguanas. Four gods, the Bacabs, sustained the sky. Each world direction was associated with a Bacab, a sacred ceiba tree, or wild cotton tree (*yaxché*), a bird, and a colour according to the following scheme: east—red, north—white, west—black, and south—yellow. Green was the colour of the centre. In one myth, the thunder god released white maize from a mountain for the benefit of man. During a blast from the thunderbolt, parts of the maize were untouched, lightly scorched, burned, or charred, hence white, yellow, red, and black ears, corresponding with the colours of the four directions.

The main act of creation, as stated in the *Popol Vuh*, was the dawn: the world and mankind were in darkness, but the gods created the sun and the moon. According to other traditions, the sun (male) was the patron of hunting and music, and the moon (female) was the goddess of weaving and childbirth. Both the sun and the moon inhabited the earth originally, but they were translated to the heaven as a result of the moon's sexual license. Lunar light is less bright than that of the sun because, it was said, one of her eyes was pulled out by the sun in punishment of her infidelity.

Because the Maya priests had reached advanced knowledge of astronomical phenomena and a sophisticated concept of time, it appears that their esoteric doctrines widely differed from the popular myths.

*Cosmology.* The Maya believed that 13 heavens were arranged in layers above the earth, which itself rested on the back of a huge crocodile or reptilian monster floating on the ocean. Under the earth were nine underworlds, also arranged in layers. Thirteen gods, the Oxlahuntiku (from *oxlahun*, 13), presided over the heavens; nine gods, the Bolontiku (from *bolon*, nine), ruled the subterranean worlds. These concepts are closely akin to those of the post-Classic Aztecs, but archaeological evidence, such as the nine deities sculptured on the walls of a 7th-century crypt at Palenque, shows that they were part of the Classic Maya cosmology.

According to the present-day Lacandonones, the sun spends the night in the underworld, where he gets rest and food with his brother Usukunkyum, who protects him from the hostile earthquake god Kisin (Cizin). This myth reflects the strong dualistic tendency of Maya thought, which conceived the life of the universe as a struggle between benevolent and malevolent forces.

Time was an all-important element of Maya cosmology. The priest-astronomers viewed time as a majestic succession of cycles without beginning or end. All the time periods were considered as gods; time itself was believed to be divine.

*The gods.* Among the several deities represented by statues and sculptured panels of the Classic period are such gods as the young maize god, whose gracious statue is to be seen at Copán, the sun-god shown at Palenque under the form of the solar disk engraved with anthropomorphic features, the nine gods of darkness (also at Palenque), and a snake-god especially prominent at Yaxchilán. Another symbol of the maize god is a foliated cross or life tree represented in two Palenque sanctuaries. The rain god (Chac) appears to have been much more important in Yucatán, an utterly dry country, than in the southern rain-forest area. His mask with characteristic protruding fangs, large, round eyes, and proboscis-like nose orates the facades of most Yucatec monuments.

Myths  
about the  
creation  
of man

Agricultural  
and  
astral  
deities

The three hieroglyphic manuscripts, especially the Dresden Codex, depict a number of deities whose names are known only through post-Classic documents. Itzamná, Lord of the Heavens, who ruled over the pantheon, was closely associated with Kinich Ahau, the sun, and with the moon-goddess Ixchel. Though Itzamná was considered an entirely benevolent god, Ixchel, often depicted as an evil old woman, had definitely unfavourable aspects.

The Chacs, the rain gods of the peasants, were believed to pour rain by emptying their gourds and to hurl stone axes upon the earth (the lightning). Their companions were frogs (*uo*), whose croakings announced the rains. Earth gods were worshipped in the highlands, and wind gods were of minor importance in Maya territory.

By courtesy of the Museo de América, Madrid

The maize god (left) and the rain god, Chac. Drawing from the Madrid Codex (Codex Tro-Cortesianus), one of the Mayan sacred books. In the Museo de América, Madrid.

The maize god, a youthful deity with an ear of corn in his headdress, also ruled over vegetation in general. His name, Yum Kaax, means Lord of the Forests. He is sometimes shown in combat with the death god, Ah Puch, a skeleton-like being, patron of the sixth day-sign Cimi (Death) and lord of the ninth hell. Several other deities were associated with death; e.g., Ek Chuah, a war god and god of merchants and cacao growers, and Ixtab, patron goddess of the suicides.

To these deities must be added divinized stars or planets, such as the North Star and Venus, the Oxlahuntiku and the Bolontiku (see above), and the gods of the *katuns*, of the months, the days, and the numerals.

In post-Classic times, central Mexican influences were introduced; e.g., the Toltec Feathered Serpent (Nahuatl: Quetzalcóatl), called Kukulcán in Yucatán and Gucumatz in the Guatemalan highlands. The *Popol Vuh* also mentions an important lightning god, Hurakan (One-Leg), similar to the one-legged Tezcatlipoca of central Mexico, and a deity named Ah Toltecac, the Toltec Lord. The Bacabs are represented in Toltec-Maya sculptures at Chichén-Itzá together with the Feathered Serpent.

Modern Lacandonese worship Itzananohk'u (the Great God Itzana), K'in (Sun), and Kanank'ash (Protector of the Forests), which appear as recent forms of Itzamná, Kinich Ahau, and Yum Kaax. They also revere Metsabok, a cloud and rain god.

The ancient Maya's attitude toward the gods was one of humble supplication, since the gods could bestow health, good crops, and plentiful game or send illness and hunger. Prayers and offerings of food, drink, and incense (*pom*) were used to placate the gods. A strong sense of sin and a belief in predestination pervaded the Maya consciousness. Man had to submit to the forces of the universe. The priests, because of their astronomical and divinatory knowledge, determined favourable days for such undertakings as building houses and hunting.

**Death.** The Classic Maya buried the dead under the floors of their houses. High priests or powerful lords were laid to rest in elaborate underground vaults. The most striking example of the latter kind of burial is the Temple of Inscriptions crypt at Palenque, where a priest or ruler was buried in AD 633 in a wonderfully sculptured sarcophagus. The practice of cremation was introduced in post-Classic times, doubtless from central Mexico. The ashes were kept in urns or hollow statues.

Present-day Maya Indians bury their dead with mixed Catholic and native rites. Among the latter is the *bool keban*, in which the body is washed with *atole*, a maize (corn) gruel, which the family then drinks to assume the deceased's sins.

The dead were believed to descend to the nine underworlds, called Mitnal in Yucatán and Xibalba by the Quiché. There is no evidence of a belief among the Maya in a heavenly paradise, such as that which prevailed in central Mexico. The Lacandonese, however, believe that the dead live forever without work or worry in a land of plenty located somewhere above the earth.

**Eschatology.** The present world, the Maya believed, is doomed to end in cataclysms as the other worlds have done previously. According to the priestly concept of time, cycles repeated themselves. Therefore, prediction was made possible by probing first into the past and then into the future: hence the calculations, bearing on many millennia, carved on temples and stelae. Evil influences were held to mark most of the *katun* endings. The *Chilam Balam* books are full of predictions of a markedly direful character. The priests probably believed that the present world would come to a sudden end, but that a new world would be created so that the eternal succession of cycles should remain unbroken.

**Practices and institutions.** *The calendar.* Maya mathematics included two outstanding discoveries: positional numeration and the zero. It may rightly be deemed one of the most brilliant achievements of the human mind. The same may also be said of ancient Maya astronomy. The duration of the solar year had been calculated with amazing accuracy, as well as the synodical revolution of Venus. The Dresden Codex contains very precise Venesian and lunar tables and a method of predicting solar eclipses.

Maya chronology consisted of three main elements: a 260-day sacred year (*tzolkin*) formed by the combination of 13 numbers (1 to 13) and 20 day names; a solar year (*haab*), divided into 18 months of 20 days numbered from 0 to 19, followed by a five-day unlucky period (*Uayeb*); and a series of cycles—*uinal* (20 *kins*, or days), *tun* (360 days), *katun* (7,200 days), *baktun* (144,000 days), with the highest cycle being the *alautun* of 23,040,000,000 days. All Middle American civilizations used the two first counts (see AZTEC RELIGION; CALENDAR), which permitted officials accurately to determine a date within a period defined as the least common multiple of 260 and 365: 18,980 days, or 52 years.

The Classic Maya Long Count inscriptions enumerate the cycles that have elapsed since a zero date in 3113 BC. Thus, "9.6.0.0.0," a *katun*-ending date, means that nine *baktuns* and six *katuns* have elapsed from the zero date to the day 2 Ahau 13 Zec (May 9, AD 751). To those Initial Series were added the Supplementary Series (information about the lunar month) and the Secondary Series, a calendar-correction formula that brought the conventional date in harmony with the true position of the day in the solar year.

Both Classic and recent Maya held the *tzolkin* as the most sacred means of divination, enabling the priests to detect the favourable or evil influences attached to every day according to the esoteric significance of the numbers and the day-signs.

*Temples and ceremonial centres.* Maya cities were primarily ceremonial, government, and market centres, with the temples and palaces built on pyramids or terraces. Dwellings in which people lived were thatched wooden houses or huts. The ruling class and the craftsmen probably lived close to the monuments, though this is not certain, and the peasants' settlements were scattered in clear-

The end  
of the  
world

ings over the countryside. The priests lived in the ceremonial centres, usually for long periods of the isolation prior to important ceremonies. The ceremonial centre and the adjoining territory formed an independent city-state. Labour for constructing the numerous structures was supplied by the peasants, who also supported the quality of living of the ruling class.

Religion permeated the whole fabric of the social and political order. In Classic cities, governmental power seems to have belonged to the priesthood. Lay war chiefs, however, are represented on Piedras Negras stelae and Bonampak murals, but, because wars were infrequent, their power was probably limited. In post-Classic Yucatán, militaristic states were governed by rulers called "true men" (*halach uinic*).

**Sacrifice.** Sacrifices in return for divine favour were numerous: animals, birds, insects, fish, agricultural products, flowers, rubber, jade, and blood drawn from tongue, ears, arms, legs, and genitals. Evidence of human sacrifice in Classic times is scanty: two Piedras Negras stelae, an incised drawing at Tikal, and some scenes in native manuscripts. Only in the post-Classic era did this practice become as frequent as in central Mexico. Toltec-Maya art shows many instances of human sacrifice: removal of the heart, arrow shooting, or beheading. At Chichén-Itzá, in order to obtain rain, victims were hurled into a deep natural well (*cenote*) together with copper, gold, and jade offerings. Prayers for material benefits (usually recited in a squatting or standing position), fasting and continence (often for 260 days), and drawing blood from one's body often preceded important ceremonies and sacrifices.

These practices had become so deeply rooted that, even after the Spanish conquest, Christian-pagan ceremonies occasionally took place in which men were sacrificed by heart removal or crucifixion. The last recorded case occurred in 1868 among the Chamula of Chiapas.

**The priesthood.** Jewelled, feather-adorned priests are often represented in Classic sculpture. State administrators as well as scholars, astronomers, and architects, priests dominated the entire life of ancient cities. The high priests of each province taught in priestly schools such subjects as history, divination, and glyph writing. The priesthood, as described by Landa, was hereditary. *Ahkin*, "he of the sun," was the priests' general title. Specialized functions were performed by the *nacoms*, who split open the victims' breasts, the *chacs* who held their arms and legs, the *chilans* who interpreted the sacred books and predicted the future. Some priests used hallucinatory drugs in their roles as prophets and diviners.

Though the military nobility had acquired increased power in post-Classic Yucatán, the priesthood remained the most influential single group in Maya society until the Spanish conquest.

**Rites.** Ritual activities, held on selected favourable days, were complex and intense. Performers submitted to preliminary fasting and sexual abstinence. Features common to most rites were: offerings of incense (*pom*), of *balche* (an intoxicating drink brewed from honey and a tree bark), bloodletting from ears and tongues, sacrifices of animals (human sacrifices in later times), and dances. Special ceremonies took place on New Year's Day, 0 Pop, in honour of the "Year-Bearer"; i.e., the *tzolkin* sign of that day. Pottery, clothes, and other belongings were renewed. The second month, Uo, was devoted to Itzamná, Zec (fifth month) to the Bacabs, Xul (sixth) to Kukulcán, Yax (tenth) to Venus, Mac (13th) to the rain gods, Muan (15th) to the cocoa-tree god. New idols were made during the eighth and ninth months, Mol and Ch'en, respectively.

Every social group (priests, sorcerers, warriors, hunters, fishermen, beekeepers, and others) celebrated its own religious feast. Most ceremonies ended in feasting and heavy *balche* drinking.

Both the Classic and post-Classic Maya practiced a typically Middle American ritual ball game, as evidenced by numerous grandiose ball courts at Tikal, Copán, and Chichén-Itzá. No court, however, has been found at Ma-

yapán, and Landa does not mention that game. It appears, therefore, that the Yucatecs had ceased to play it, while it remained of the utmost importance in central Mexico.

Archaeological remains at Uxmal and Chichén-Itzá point to phallic rites, doubtless imported into Yucatán from the Gulf Coast. The *Chilam Balam* books strongly condemn the Mexican immigrants' sexual practices, which were quite alien to Maya tradition.

**Sorcery.** *Ahmen*, "he who knows," was the name given to sorcerers and medicine men, who were both prophets and inflicters or healers of disease. They made use of a mixture of magic formulas, chants, and prayers and of traditional healing methods, such as administering medicinal herbs or bleeding. Belief in witchcraft is widespread among present-day Maya Indians, as it most probably was in pre-Columbian times.

**Conclusions.** The evolution of Maya religion parallels that of Mexican religions from the Classic to the post-Classic era, with the sun worship and human sacrifice complex gaining importance as it did in Mexico proper.

The profoundly original feature of Maya religious thought, in comparison with that of other pre-Columbian civilizations, is the extraordinary refinement of mathematical and astronomical knowledge, inextricably mixed with mythological concepts. Even the most learned Aztec priests never reached the intellectual level of their Maya counterparts of the 1st millennium, nor did they conceive of the eternity of time and of its "bearers," the divinized time periods. The ancient Maya may be said to have been among the very few people in history (along with the Zurvanites of Iran) who worshipped time.

The simple, naturalistic religion of the maize-growing peasants, however, subsisted apart from the priesthood's abstract speculations and has partly survived to this day among the Christianized Maya Indians or the unevangelized Lacandonese.

## Mayo Family

Probably the most famous group of physicians in the United States, three generations of the Mayo family, pioneers in the practice of group medicine, established the world-renowned Mayo Clinic and the Mayo Foundation for Medical Education and Research at Rochester, Minnesota.

By courtesy of the Mayo Clinic, Rochester, Minnesota

(From left) Charles Horace Mayo, William Worrall Mayo, and William James Mayo; photograph c. 1890.

William Worrall Mayo, father of the doctors Mayo who developed a large-scale, world-renowned practice of medicine, was born May 31, 1819, near Manchester, Lancashire. He attended Owens College in Manchester, majoring in chemistry, and, after immigrating to the United States in 1845, studied medicine with a private physician in Lafayette, Indiana, subsequently receiving degrees from Indiana Medical College, La Porte, and the University of Missouri, Columbia. In 1863 he moved to Rochester, where he soon had an extensive surgical practice. After taking care of the casualties of a disastrous tornado in Rochester, with the assistance of the Sisters of St. Francis, Mayo, his two sons, and the sisters planned to erect a new hospital. St. Mary's Hospital was opened on October 1, 1889, and Mayo and his two sons became responsible for care of the patients. After the father retired, the work was continued by his sons. William W. Mayo died in Rochester on March 6, 1911.

William James Mayo, eldest son of William Worrall Mayo, was born June 29, 1861, at Le Sueur, Minnesota. He received his M.D. degree in 1883 from the University of Michigan, Ann Arbor, and then engaged at Rochester in the private practice of medicine and surgery with his father and later with his younger brother Charles Horace Mayo. Though William J. Mayo became the administrator in the practice, no important decisions were made without the full agreement of both brothers. He and his brother performed all the surgery at St. Mary's Hospital until about 1905. From this surgical partnership of the two brothers evolved the cooperative group clinic, later known as the Mayo Clinic. William James Mayo, who became a specialist in surgery of the abdomen, pelvis, and kidney, remained active in surgery at the clinic until 1928 and in administration until 1933. From 1907 until his death, he served on the board of regents of the University of Minnesota. He died in Rochester on July 28, 1939.

Charles Horace Mayo, younger son of William Worrall Mayo, characterized as a "surgical wonder," was born in Rochester on July 19, 1865. He received an M.D. degree from the Chicago Medical College (later part of Northwestern University Medical School) in 1888 and in the same year began private practice of surgery with his father and brother.

Charles Mayo had the ability to work in all surgical fields; he originated modern procedures in goitre surgery

and in neurosurgery; he performed highly successful operations for cataract of the eye and originated procedures for several orthopedic operations. In 1930 he retired from surgery at the clinic and three years later from administration. He was professor of surgery at the University of Minnesota Medical School from 1919 to 1936 and at the University of Minnesota Graduate School from 1915 to 1936. W.J. Mayo said about his brother, "Charlie has . . . an intuitive mind, from his knowledge of physiology and anatomy and his understanding of the personality of the patient." At one time he was a member of the advisory board of *Encyclopædia Britannica*. With his brother, he alternated as chief consultant for all surgical services in the U.S. Army during World War I, serving with the rank of colonel. After the war, each brother was commissioned a brigadier general in the medical-corps reserve. Charles Horace Mayo died in Chicago on May 26, 1939.

Charles Horace's son, Charles William, was born on July 28, 1898, at Rochester, Minnesota. He was a skilled surgeon and member of the board of governors of the Mayo Clinic, chairman of the Mayo Association, and a member (chairman 1961-67) of the board of regents of the University of Minnesota. He is still remembered for his speech given in the fall of 1953 as a member of the United States delegation at the eighth plenary session of the United Nations. He died at Rochester, Minnesota, on July 28, 1968.

The group began to grow in size in the early 1900s, when many young physicians began to apply for positions as interns and assistants. At the same time, outstanding scientists in basic medical subjects were added to the clinic's training and research programs. In 1919 the Mayo brothers transferred property and capital to the Mayo Properties Association, later called the Mayo Association, a charitable and educational corporation having a perpetual charter. About 1900 the Mayo Clinic was changed from a partnership to a voluntary association of physicians and specialists in allied fields. In the early 1970s, the clinic staff included about 500 physicians. Over 200,000 patients were seen annually, and the practice is increasing.

In 1915 the Mayo brothers gave \$1,500,000 to the University of Minnesota to establish the Mayo Foundation for Medical Education and Research at Rochester in connection with the clinic. The foundation, which is part of the University of Minnesota Graduate School, offers graduate training in medicine and related subjects. In 1934 the endowment was increased by \$500,000; by the early 1970s it amounted to more than \$5,250,000. At that time, about 700 graduate physicians were attending as resident students. About 7,000 physicians have received some or all of their residency training at the Mayo Clinic and Mayo Foundation. The Mayo Graduate School of Medicine also has started an intern program, and an undergraduate medical school is in the formative stages.

## Ma Yüan

Recognized as one of the most influential Chinese landscape painters, Ma Yüan (Pin-yin romanization Ma Yuan) was among the most gifted artists associated with the late-12th-century court of the Sung dynasty at Hangchow. His works and those of his contemporary, Hsia Kuei, formed the basis of a style of landscape painting called the Ma-Hsia school, which was widely imitated in eastern Asia.

Ma Yüan was born c. 1160-65 into a family of court painters: his great grandfather, Ma Fen, had been *tai-*

*chao* (i.e., painter in attendance) at the Northern Sung Court, c. 1119–25; both his grandfather, Ma Hsing-tzu, and his father, Ma Shih-jung, held the same rank at the Southern Sung Court in the middle decades of the 12th century. Ma Yüan began his career under the emperor Hsiao Tsung, became *tai-chao* under Emperor Kuang Tsung, and received the highest Chinese honour, the Golden Belt, under Emperor Ning Tsung. He died in about 1225. His son, Ma Lin, the last of the Ma artistic dynasty, rose to be painter-in-waiting, *chih-hou*. Apart from these bare facts, practically nothing is known about Ma Yüan's life. Being neither a scholar nor an official, he neither left a body of his own writings nor earned a biography in the dynastic history. He seems, however, to have been in high favour at court, particularly under Ning Tsung, who, with his empress, Yang Mei-tzu, wrote poems or short inscriptions on a number of his paintings.

Ma Yüan occasionally painted flowers and figure subjects. A group of small, delicate flower paintings in the National Palace Museum, Taipei, Taiwan, are attributed to him. Typically, a single spray of blossoms lies poised in empty space across the square album leaf. One is signed, and two bear couplets written by Yang Mei-tzu. There are also three paintings of Zen masters in simple landscape settings, two of them in Tenryū-ji, Kyōto, the third in the Tokyo National Museum, which, though not signed, bear inscriptions considered to be in the handwriting of Yang Mei-tzu. They all have certain similar features of technique that have led some Japanese authorities to attribute them to Ma Yüan.

It was in landscape painting that Ma Yüan's genius lay. He executed a number of large landscape screens, all of which are now lost. He also painted tall, hanging scrolls in which, according to an early Chinese writer, "there are steep mountains rising imposingly, with streams winding around them and waterfalls partly hidden among the trees." He also wrote that Ma Yüan made his pine trees "very tall and strong as if they were made of iron wire; sometimes he painted them with a stump brush; the effect is vigorous, beautiful and elegant." Typical of this kind of picture is a tall, unsigned "Rain over Trees on a Rocky Shore" in the Seikadō Foundation, Tokyo. The monumental composition, the expressive use of monochrome ink, the powerful angularity of the brushwork, in which the artist hacks out the facets of his rocks by means of a slanting "axe-cut" stroke, are features that first had been developed by Li T'ang, the senior landscapist in the Imperial Academy in the last years of the Northern Sung dynasty. Although Li T'ang may not have lived long enough to see the Sung court re-established at Hangchow in 1136, his influence there was profound, and his style of landscape painting became the orthodox manner for Southern Academy painters, being transmitted down to Ma Yüan through a follower, Hsiao Chao, and through Ma Yüan's own forebears.

By the late 12th century, however, this style was changing, and the new elements that were appearing reflected the nostalgic and somewhat precious atmosphere of the exiled court at Hangchow. In some hanging scrolls attributed to Ma Yüan, and in many of the exquisite small album and fan paintings, the mountains are pushed to one side, creating a "one corner" composition; between the distant mountains and the strongly accented foreground rocks, where a scholar may be sitting enjoying the view, lies a vast expanse of empty space with but a suggestion of mist or water. Many of Ma Yüan's pictures are romantic night scenes. A particularly moving hanging scroll of this kind, attributed to him and bearing a long poem composed by the Emperor and written by Yang Mei-tzu, is the unsigned version of the "Banquet by Lantern Light" in the National Palace Museum, Taipei, Taiwan.

Such paintings are redolent of a poetic melancholy that hints at the decay of Sung culture, and the pictorial expression of this feeling is often rather conventional. The one-sided composition, the jutting pine tree silhouetted against empty space, the meditating scholar, the brilliant brush technique of Ma Yüan himself, all lent themselves easily to imitation. His style was very popular with

late Sung painters, men and women, professionals and amateurs, and it is difficult to separate the genuine fans and album leaves from those of his followers. Among the best of them are "Early Spring" and "Two Sages and an Attendant Beneath a Plum Tree," both in the Museum of Fine Arts, Boston; "Watching the Deer by a Pine-shaded Stream," in the Mr. and Mrs. Dean Perry Collection, Cleveland; and "On a Mountain Path in Spring," a signed album leaf bearing a couplet written by the emperor Ning Tsung, in the National Palace Museum in Taiwan.

Finally, a small group of hand scrolls show another facet of Ma Yüan's genius. Most striking, and most likely to be from his hand, is the picture "The Four Sages of Shang-shan" (recluses who lived at the beginning of the Han dynasty), in the Cincinnati Art Museum. Although damaged and poorly restored, the picture presents a dramatic contrast between the vital handling of the landscape and raging torrent and the extreme delicacy and precision of the figures of the scholars and their attendants, which suggests the hand of a great master. The scroll is signed and bears 40 colophons or seals of the various owners, including one by the noted Yüan dynasty scholar-painter Ni Tsan (1301–74). A signed long scroll of mountains and pine trees in deep winter snow in the Imperial Museum in Peking, though roughly painted, is an extremely impressive work that may be a product of Ma Yüan's old age.

The romantic landscape style of the Southern Sung academicians such as Ma Yüan, his son Ma Lin, and Hsia Kuei went out of fashion after the fall of the dynasty in 1279. It was revived in the Ming dynasty (1368–1644) as a form of decorative academicism by professional painters of the so-called Che school. The style was not greatly admired by gentlemen and connoisseurs, who considered it too brilliantly professional for their taste. As a result, few high-quality paintings of the Ma-Hsia school survived in China outside the Imperial collection. Their work, however, found favour in Japan, where it was a powerful influence in forming the style of the great ink painters Shūbun (early 15th century) and Sesshū, and of the early masters of the Kanō school during the Muro-machi period (1338–1573).

#### MAJOR WORKS

Active c. 1190–1225. The following are some examples of his work: "Mountains in Snow," attributed (Shanghai Museum); "A Scholar Beneath a Pine Tree" (National Palace Museum, Taipei, Taiwan) and "Through Snowy Mountains at Dawn" (National Palace Museum, Taipei, Taiwan), album leaves from the *Ming-hua chi-chen*; "Rain over Trees on a Rocky Shore" (Seikadō Foundation, Tokyo); "Scholar Contemplating the Moon" (Hakone Museum, Kanagawa, Japan); "Solitary Angler on Wintry Lake" (National Museum, Tokyo); "The Four Sages of Shang-shan" (Cincinnati Art Museum, Ohio); "Playing the Lute by Moonlight" (National Palace Museum, Taipei, Taiwan); "Early Spring: Bare Willows and Distant Mountains" (Museum of Fine Arts, Boston); "Mountains and Tall Pine Trees by a Cottage in the Snow" (National Palace Museum, Taipei, Taiwan); "An Immortal on a Dragon in Clouds and Mist" (National Palace Museum, Taipei, Taiwan); "Banquet by Lantern Light" (National Palace Museum, Taipei, Taiwan); "Ducks in the Water Beneath an Overhanging Plum Tree" (Hui-hua-kuan, Peking); "The Ch'an Monk Tung-shan Wading a Stream" (National Museum, Tokyo); "Hsiao Ssu-hua Seated Beneath a Tree Playing the Ch'in" (Museum of Fine Arts, Boston); "Two Sages and an Attendant Beneath a Plum Tree" (Museum of Fine Arts, Boston).

**BIBLIOGRAPHY.** OSVALD SIREN, *Chinese Painting: Leading Masters and Principles*, 7 vol. (1956–58), is the standard history of Chinese painting. There is no book in any Western language devoted to Ma Yüan, but there are sections on his work in SHUJIRO SHIMADA and YOSHIHO YONEZAWA, *Painting of Sung and Yüan Dynasties* (1952); KOJIRO TOMITA, *Portfolio of Chinese Paintings in the Boston Museum of Fine Arts*, 2nd rev. ed. (1938); SHERMAN E. LEE, *Chinese Landscape Painting*, 2nd ed. (1962); LAURENCE SICKMAN (ed.), *Chinese Calligraphy and Painting in the Collection of John M. Crawford, Jr.* (1962); JAMES CAHILL, *Chinese Painting, XI–XIV Centuries* (1960); and MICHAEL SULLIVAN, *A Short History of Chinese Art*, rev. ed. (1970). The little available evidence on his position at the Southern Sung court is discussed in CHIANG CHAO-SHEN, "The Identity of Yang Mei-

Flower  
and figure  
subjects

## Mazarin, Jules, Cardinal

Mazarin, successor to the great French minister the cardinal de Richelieu, completed Richelieu's work of establishing France's supremacy among the European powers and crippling opposition to the power of the monarchy at home.

By courtesy of the Musée Condé,  
Chantilly, France; photograph, Giraudon

Mazarin, portrait by Philippe de Champaigne (1602-74). In the Musée Condé, Chantilly, France.

**Service as papal diplomat.** Born a papal subject on July 14, 1602, at Pescina, in the Abruzzi, near Rome, Giulio Mazarini spent his childhood in a region whose temperament, ways of thought, and Roman Catholic outlook were to permeate his whole existence. His father, Pietro, was a romanized Sicilian in the household of the constable Filippo I Colonna; his mother, Ortensia Bufalini, of a noble Tuscan family, was related to the Colonna house by marriage. From the beginning Mazarini recognized the benefits of having powerful patrons and learned to exploit them to his advantage. Thus, in spite of financial difficulties and the expenses of a large family (another son, who became a monk, and four daughters), the Mazarini were able to send Giulio to the Jesuit school in Rome, where he was an excellent student. Accompanying a young member of the Colonna family to Spain, he completed his education at the university at Alcalá de Henares (now the University of Madrid) where he studied law and then returned to Rome eager to learn more about aristocratic ways of life and secular affairs. From the Colonna he obtained a captaincy in the papal army in 1624, and, while serving in Loreto, on Christmas night 1625 he underwent an unusual mystical religious experience, or "tranquility of soul," which was to exert a certain influence on his life. He entered the diplomatic service of the Holy See and in 1628 was appointed secretary to the papal legate of Milan, G.F. Sacchetti; in this post he had his first opportunity to play an active political role. In January 1630, during the war between Spain and France over the succession to the crown of Mantua, Sacchetti's successor, Antonio Cardinal Barberini, sent Mazarin to France to negotiate with the great Cardinal de Richelieu. The young man was fascinated by the powerful minister: "I resolved," he wrote, "to devote myself to him entirely." Soon afterward the young secretary acquired an international reputation when he dramatically galloped between the two opposing armies about to do battle at Casale in Monferrato on October 26, 1630, shouting "Peace, peace!" as if peace had been concluded.

Role in  
the War  
of the  
Mantuan  
Succession

ed. For the rest of his life he would be remembered as the intrepid knight who risked his life between two armies in order to stop the fighting. Though the Spaniards raised their siege at Casale, much remained to be done in order to bring about a general settlement. By the Treaty of Cherasco (June 19, 1631), negotiated by Mazarin, the French candidate was installed in Mantua, but the agreement settled only the differences between France and Savoy.

Mazarin's resolution to devote himself to Richelieu did not prevent him from also obtaining the patronage of Cardinal Barberini, the youngest nephew of Pope Urban VIII. After Mazarin's return to Rome in 1632, Barberini included him in a circle of artists, painters, and musicians, before obtaining for him a mission as extraordinary nuncio (ambassador) to the French court in 1634. There, at Richelieu's side, Mazarin acquired the favour of those in power and became devoted to the French nation, whose "openness of heart and of mind" impressed him. He did not forget his mission, however, which was to negotiate the peace between Spain and France sought by Urban VIII; hence it was with despair that he watched Richelieu bring France openly into the Thirty Years' War in May 1635.

Recalled to Avignon in his capacity as legate, then to Rome (December 1636), he continued to exert an influence on French politics through his correspondence with Richelieu and his adviser, Father Joseph. With his friends Cardinals Barberini, Nicholas Bagni, and Alessandro Bichi, Mazarin directed the French faction within the papal court. Louis XIII of France rewarded his efforts by recommending him as the royal candidate for a cardinalate in 1638, gave him ecclesiastical pensions and benefices (in order to be eligible for them Mazarin was granted French naturalization papers in 1639), and finally invited him to return to Paris, where he arrived on January 5, 1640. Disappointed because his ambitions in Rome had been frustrated by the Spanish faction, Mazarin left the papal service to enter the service of France. It was to France and, in particular, to Richelieu that he owed the cardinal's hat bestowed upon him by the Pope on December 16, 1641, though Urban VIII had himself been favourably impressed by the efforts his former subject was making in favour of the general peace.

**Career as first minister of France.** Mazarin's ambition was to put an end to the rivalry between the Catholic powers of Europe. On Richelieu's death, however (December 4, 1642), and especially after that of Louis XIII (May 14, 1643), he became first minister of France, an office that the regent, Anne of Austria, entrusted to his experience and his ability in the name of the child Louis XIV. Mazarin used this new power to promote the peace negotiations that opened at Münster, in Westphalia, on April 10, 1644, although he now had to subordinate his ideal of peace to French foreign policies and ambitions. He was aided by a good diplomatic team, over which he exercised firm control, and by extremely competent generals, Louis II de Bourbon, prince de Condé, and Henri de Turenne. Their brilliant victories over the Spanish and imperial troops helped bring about the Peace of Westphalia (October 1648), a general European settlement that established peace in Germany. As the war between France and Spain still continued and as grave issues were developing in the north and east, Germany could easily have been involved again in a general war. No one believed in the power of the Emperor to safeguard the empire from this danger. Mazarin took advantage of the weakened imperial power of the Habsburgs to organize a defensive alliance between France and the German states closest to the French frontier (the League of the Rhine, August 1658). Spain, however, encouraged by the defection of the United Provinces of the Netherlands, who had signed a separate peace in January 1648, refused to agree to the peace. In order to force Spain to make a settlement, Mazarin continued the war and formed an alliance with England (March 23, 1657), surrendering to the English the fort of Dunkirk, which had been captured from the Spaniards after the Battle of the Dunes (June 14, 1658). Peace with Spain was finally negotiated in a general

Cardinal-  
ate

Negotiation of the Peace of the Pyrenees

treaty signed on November 7, 1659, at the Pyrenees frontier. Mazarin completed this settlement by arbitrating the "northern peace" (the treaties of Oliva and of Copenhagen on May 3 and June 6, 1660) and by returning Lorraine to its duke (Treaty of Paris, February 28, 1661). Thus, at his death, the former diplomat of the Holy See could rejoice at having "returned peace to Christendom." He would have liked to have seen Europe take advantage of this peace by uniting in a crusade against the Turks and, above all, to have "let these peoples enjoy the fruits of the tranquility" they had regained now that fighting had ended in their home territory.

France, indeed, needed a rest. Mazarin therefore had to limit his activities within the realm to thwarting intrigues at court and multiplying financial expedients to meet war expenditures. The new taxes imposed upon leading Parisians contributed to the discontent that precipitated the revolts known as the Fronde. These rebellions, which lasted more than five years, originated in the judicial oligarchy of the Parlement of Paris; they spread to the upper nobility, and soon found popular support even in the provinces largely because of "Mazarinades," inflammatory pamphlets written against the Cardinal. Mazarin was obliged to leave the court twice and was only able to maintain his post because he was in favour with Anne of Austria and the boy king Louis XIV, whose education he had carefully directed. The Fronde was finally suppressed in 1653, and Louis XIV was crowned the following year. Mazarin increasingly involved the young sovereign in affairs of government, encouraging him to stand firm against the Parlement and helping him train a staff of great administrators for his reign: Jean-Baptiste Colbert, Nicholas Fouquet, Hughes de Lionne, and Michel Le Tellier. He re-established the role of the intendants or commissaries of the king, who administered the provinces; they gradually assumed the power of the provincial governors who had shown themselves to be unreliable during the rebellions. He thus succeeded in sustaining order through a policy of moderation, which he applied even to popular revolts such as the peasant uprising of Sologne in 1658.

Reputation and character

Mazarin's enemies reproached him for his greed. He had accumulated offices and benefices and had sometimes confused royal income with his own. Yet, on several occasions, when the state faced desperate financial situations, he put his own fortune at its disposal. A lover of the arts, he acquired fine collections, decorated his Parisian mansion (today the home of the Bibliothèque Nationale) with works by Italian artists, and brought the Roman opera into favour in France. His library remains in the palace (now called the Institut de France) that he ordered built to house the College of the Four Nations, intended for the education of young men from the four provinces that had been acquired by France during his ministry: Alsace, Roussillon, Flanders-Artois, and the region of Pinerolo. He founded the Royal Academy of Painting and Sculpture (1648) and gave pensions to several men of letters.

According to the Roman tradition of nepotism, Mazarin offered rich dowries and arranged noble marriages for his nephews and especially for his Mancini and Martinozzi nieces. Yet he did not allow his affection as an uncle to win out over political considerations; thus, he thwarted the desire of Louis XIV, who by treaty was bound to marry the Spanish infanta, to marry Marie Mancini. Anne of Austria felt a strong attraction for him: he was a handsome man, eloquent and charming; devoid of political experience herself, she accepted his advice unquestioningly. The "Mazarinades" accused them of having an illicit relationship, but the evidence is conflicting. The hypothesis of a secret marriage between the Regent and her minister is also unlikely, for the cardinalate, even that of a layman, implied the obligation of celibacy. Mazarin was not an ordained priest (in 1632 he had received only minor orders), though he thought of entering the priesthood on several occasions, especially in 1651 and even in 1660 shortly before his death. Faithful to the Catholicism as he had practiced it in his youth, he had defended Roman orthodoxy against the heterodox Jansenist move-

ment, yet without advocating persecution of the Jansenists. After a painful illness, he died at the château of Vincennes on March 9, 1661.

**BIBLIOGRAPHY.** Mazarin's correspondence while minister was published by ADOLPHE CHERUEL, *Lettres du Cardinal Mazarin pendant son ministère*, 9 vol. (1872-1906); this monumental edition is supplemented by fragmentary publications, the most important of which are those of M. RAVENEL, *Lettres du Cardinal Mazarin à la Reine . . . en 1651 et 1652* (1836), and the letters of the young Mazarin, translated from the Italian, as an appendix to GEORGES DETHAN, *Mazarin et ses amis* (1968; Eng. trans. in prep.). The *Carnets*, or notebooks, in which the Minister wrote brief reflections and guides for his conduct at court and his relations with the Queen, have only been published in incomplete form by VICTOR COUSIN in *Journal des Savants* (1854-56).

Standard works on Mazarin include: VICTOR COUSIN, *La Jeunesse de Mazarin* (1865); and especially ADOLPHE CHERUEL, *Histoire de France pendant la minorité de Louis XIV*, 4 vol. (1879-80), a monumental work; *Histoire de France sous le ministère de Mazarin (1651-1661)*, 3 vol. (1882). Recent works of synthesis include: *Mazarin* (1959), a collective work with articles by Georges Mongrédien, Pierre du Colombier, Maurice Schumann, and Georges Dethan; *Mazarin* (1961), the catalog of the *Exposition Mazarin* of the Bibliothèque Nationale; and GEORGES DETHAN (*op. cit.*). The chief works in English are ARTHUR HASSALL, *Mazarin* (1903); and JAMES B. PERKINS, *France Under Mazarin*, 2 vol. (1886).

(G.Det.)

## Mazzini, Giuseppe

A political thinker, writer, propagandist, and revolutionary, Giuseppe Mazzini was a champion of Italian unity and independence, even though he lived most of his life in exile. He gave 19th-century Italy the impetus and inspiration that were essential factors of the national movement of liberation and unification known as the Risorgimento.

Born in Genoa, on June 22, 1805, Giuseppe Mazzini was a doctor's son; his birthplace, formerly a republic, was annexed to the kingdom of Piedmont in 1814. As a child, he gave promise of high intellectual ability, fully confirmed when he entered Genoa University at 14. Two years later, strongly influenced by seeing a patriot fleeing from Italy after an unsuccessful insurrection, he began to think "that we Italians *could* and therefore *ought* to struggle for the liberty of our country."

Mazzini, oil painting by Luigi Zuccoli, 1865. In the Museo del Risorgimento, Milan.

By courtesy of the Museo del Risorgimento, Milan

On graduating in law in 1827, he practiced as a "poor man's lawyer," wrote articles for progressive reviews, and hoped to become a dramatist or historical novelist. But his life was already shaping itself differently. His love of freedom led him to join the Carbonari, a secret society pledged to overthrow absolute rule in Italy; in 1830 he was betrayed to the police, arrested, and interned at Savona, where for three months he reviewed his political beliefs and conceived the outlines of a new patriotic movement to replace the decaying Carbonari.

Exile in  
Marseilles

When released early in 1831, he was ordered either to leave Piedmont or to live in some small town; he chose exile and went to Marseilles, where his slight figure, handsome olive features, black hair and beard, and black velvet suit were soon familiar to the other Italian exiles, who accepted him as their leader. His first public gesture was an "open letter" to Charles Albert, the king of Piedmont, urging him to give Piedmont constitutional government, to lead a national movement, and to expel the Austrians from Lombardy-Venetia and their other Italian strongholds. The letter was circulated in Italy, but Charles Albert's only reaction was to threaten Mazzini with arrest if he returned to Piedmont. As a lifelong republican, Mazzini was afterward censured for this friendly approach to an autocratic sovereign; he explained that he had meant to expose Charles Albert as one who would never fight for Italian freedom.

Founda-  
tion  
of Young  
Italy

At Marseilles, Mazzini spent two of his most rewarding years. He founded his patriotic movement for young men and called it *Giovine Italia* (Young Italy). It was designed as a national association for liberating the separate Italian states from foreign rule and fusing them into a free and independent unitary republic. Its methods were education and insurrection, and it had a moral basis derived from Mazzini's own belief in God (though he was not a Christian) and in permanent laws of progress, duty, and sacrifice. It was the first Italian democratic movement embracing all classes, for Mazzini believed that only a popular initiative could free Italy. "Neither pope nor king," he declared. "Only God and the people will open the way of the future to us."

The new movement captured the imagination of Italian youth. Branches were secretly formed in Genoa and other cities; by 1833 there were 60,000 members. Mazzini edited the propagandist journal *Giovine Italia*, which was smuggled into Italy with other revolutionary pamphlets. He also became the lover of a fellow exile, the beautiful Modenese widow Giuditta Sidoli.

Young Italy's attempted insurrections were failures. A projected rising in Piedmont in 1833 was discovered before it had begun; 12 conspirators were executed, one committed suicide, and Mazzini was tried in absence and condemned to death. He said prophetically, "Ideas ripen quickly when nourished by the blood of martyrs." A few months later, when he had moved to Switzerland to escape from the French police, he tried to rally 1,000 volunteers to invade Savoy (then part of the kingdom of Piedmont). Only 200 could be mustered, and the force was disbanded.

These failures destroyed Young Italy as an organization, though its spirit lived on. Mazzini turned to wider revolutionary plans, based on his faith in the brotherhood of man and his hopes for a world republican federation. He founded Young Europe and helped to establish Young Germany, Young Switzerland, and Young Poland, but his three years in Switzerland were unhappy and frustrated. Giuditta Sidoli had gone back to Italy to rejoin her children; he suffered an emotional crisis through doubts and disillusionment. In 1837 he went with a few Italian friends to live in London.

Stay in  
England

England was now his real home. He lived in modest London lodgings, surrounded by books, papers, and the tame birds, in which he delighted; he studied at the British Museum and wrote for English periodicals. Though he had little money, he started a school for Italian boys in London and a newspaper, *Apostolato popolare* ("Apostleship of the People"), in which he published part of his essay "On the Duties of Man." In 1840, with the help of Giuseppe Lamberti in Paris, he revived Young Italy, primarily as a means of building up a national consciousness among Italians everywhere. He wrote innumerable letters to his new agents in Europe and North and South America; he also became acquainted with Thomas and Jane Welsh Carlyle and began to make many other literary and political friends.

In 1844 he was in touch with the Bandiera brothers, who made an ill-fated attempt to start a revolt in Calabria. After their execution, he told two friends, who were members of Parliament, of his fears that the British gov-

ernment was opening his letters and had passed on information about the Bandieras' plans to the Neapolitan authorities. The matter was raised in Parliament, and the government was compelled to admit that it opened private letters. There was much public indignation and widespread sympathy with Mazzini. The affair made him better known in England and brought him into contact with a notable liberal family, the Ashursts. Many English liberals supported him when he founded the People's International League in 1847.

In that year he wrote an "open letter" to the new pope, Pius IX, who had introduced liberal reforms in the Papal States. He urged the Pope to unify Italy, but Pius made no comment. Mazzini returned to Italy for the first time in the revolutionary year of 1848, when the Milanese drove out their Austrian masters and Piedmont began a war to expel the Austrians from Italy. Milan welcomed him, but he was soon unpopular because he wanted Lombardy to become a republic and he thought that union with the kingdom of Piedmont, as proposed by the Milanese provisional governments, was the wrong kind of pattern for the future Italy. When the Piedmontese armies withdrew and the Austrians re-entered Milan, he served briefly with an irregular force under Giuseppe Garibaldi before returning to England.

Mazzini was again in Italy in 1849, first in Tuscany and then in Rome, where a revolution had driven out the Pope, and a republic had been proclaimed. He had long believed that the imperial and papal Romes would be followed by a third Rome—a Rome of the people; now his dream had come true. He was acclaimed as a great patriot, was elected a triumvir of the republic, and became the effective head of the government, showing great administrative talent in ecclesiastical and social reforms. His rule was short-lived. The Pope appealed to Catholic countries for help, and a French army landed in Italy; after heroic resistance, the republic was crushed, and Mazzini left Rome.

Triumvir  
of  
republican  
Rome

Back in London, he founded another society—the Friends of Italy—in 1851 and was soon involved in new revolutionary activities. In 1853 he backed the Milanese workers in their unsuccessful rising against the Austrians. In 1853–54 he sent Felice Orsini on two unproductive missions to raise revolt in Carrara. In 1856 he went secretly to Genoa to plan a number of simultaneous insurrections. The only one that was seriously attempted was Carlo Pisacane's disastrous landing in Calabria in 1857. Even the apparently futile conspiracies of this period had the useful effect, however, of keeping Italian problems before the governments of Europe. For these plots Mazzini was reviled in Piedmont, where the new moderate party was working for orderly progress without revolution. Cavour, the prime minister, called him "chief of the assassins," but this charge was unfair; Mazzini's plots were for insurrection, not assassination, and he expressly disclaimed the "theory of the dagger."

In 1858 Mazzini founded another journal in London: this was *Pensiero ed azione* ("Thought and Action"), a title reflecting his view that thought is only of value when it results in action. He had no part in the Franco-Piedmontese war against Austria in 1859, by which Cavour with the help of Napoleon III vainly sought to free Italy from the Alps to the Adriatic; nor did he belong to the "party of action," which sponsored Garibaldi's expedition to Sicily in 1860. Yet this expedition has been called "Mazzini's gift to the 'party of action,'" for it followed plans devised by himself in earlier years. He went to Naples during Garibaldi's brief dictatorship of southern Italy but was back in London when the new united Kingdom of Italy (excluding Venice and Rome) was proclaimed in 1861.

Impactical schemes for seizing Venice and Rome occupied Mazzini's mind in the 1860s. This was the decade of the Socialist First International; he had early contact with its members but soon withdrew, since the moral and religious basis of his own political thought prevented him from accepting either Marx's Communism or Bakunin's anarchism. Messina repeatedly elected him as its parliamentary deputy, but the elections were quashed by the

Accomplishments and reputation

Italian government. In 1870 he misguidedly agreed to lead a republican rising in Sicily; however, he was arrested on his way there and interned at Gaeta but was released and pardoned after the occupation of Rome by Italian troops.

Mazzini's life was ending in disappointment, even though both Venice (acquired in 1866) and Rome were now part of the new kingdom. Italy had been united by fusion, as he had always advocated against strong opposition, rather than by federation, but it was a monarchy and not the republic he had wanted. "I thought I was awakening the soul of Italy, and I see only the corpse before me," he said.

In his last years he founded another paper, *Roma del popolo* ("Rome of the People"), which he edited from Lugano, and made plans for an Italian workingmen's congress. He died from pleurisy at Pisa on March 10, 1872. He had never married.

Mazzini's reputation has fluctuated greatly. In his earlier years, he was an almost legendary hero in his own country, but he was later denounced by many of his compatriots as an enemy of the state. For two generations after his death, most historians considered that his useful work ended in 1849 and that he should then have withdrawn from conspiracy.

A different view, though, is now widely accepted. Many believe that all his plots were valuable, since they held out a permanent threat of violent revolution if Italy were not freed and united. By spurring on the Piedmontese government, and later the Italian government, to work for the national cause, he is now considered to have played an indispensable part in the making of modern Italy.

**BIBLIOGRAPHY.** The standard collection of Mazzini's works and letters is the comprehensive *Scritti editi ed inediti* (Edizione nazionale), 100 vol. (1906-43), but the older *Life and Writings of Joseph Mazzini*, 6 vol. (1864-70), which is partly autobiographical, is still valuable. BOLTON KING, *Mazzini* (1902); and GWILYM O. GRIFFITH, *Mazzini: Prophet of Modern Europe* (1932), are the best general biographies; his life story is told by old friends in EMILIE VENTURI, *Joseph Mazzini* (1875), which also contains the essays "Thoughts upon Democracy in Europe" and "On the Duties of Man"; and in JESSIE WHITE MARIO, *The Birth of Modern Italy* (1890). Excellent detailed studies are E.E.Y. HALES, *Mazzini and the Secret Societies* (1956), for the earlier years; SALVO MASTELLONE, *Mazzini e la "Giovine Italia," 1831-1834*, 2 vol. (1960), for Young Italy; and EMILIA MORELLI, *Mazzini in Inghilterra* (1938), for his English experiences. Mazzini's charm and humanity are delightfully revealed in the Ashurst correspondence: *Mazzini's Letters to an English Family*, 3 vol. (1920-22).

(E.C.H.)

## Measurement, Principles and Instruments of

Measurement is the process used to answer the questions: how many? and how much? Measurements, broadly defined, can be made by the unaided human senses and brain—for example, in estimating distances, dimensions, temperatures, and weights; identifying and matching colours; estimating chemical composition by smell and taste; and evaluating roughness by touch. In general, however, man's capabilities need to be both extended and refined by instruments.

Some instruments, such as magnetometers and Geiger counters, measure physical quantities such as magnetism and nuclear radiation to which human senses do not respond. Some provide access to places that human senses cannot reach, for example, the space probes. Nearly all refine human capabilities by providing greater sensitivity, range, accuracy, precision, and speed. Measuring instruments are also often employed to replace human observers as a matter of convenience, as in monitoring industrial processes.

Instruments range from simple tools to large and complex systems, from the metre or yardstick to the instrument systems used in the launch and control of a space vehicle. To treat so vast a topic in detail is impossible in a brief space; the following article is intended to identify

the elements and explain the principles and processes by which measuring instruments work.

A history of the development of measuring instruments and instrumentation can be found in the article INSTRUMENTATION. A list of articles containing details on specific types of measuring instruments appears at the end of this article. In what follows, the quantity being measured will be referred to as the measurand to distinguish it from other quantities and variables included in the context.

### THE MEASUREMENT PROCESS

Measurement begins with a definition of a quantity, condition, property, or other characteristic that is to be determined. These definitions of measurables may be conceptual or operational. If conceptual, they must be converted to operational definitions in preparation for measurement. That is, they must be defined in terms of a sequence of steps or operations that describe a procedure for accomplishing the measurement. The measuring instrument is an embodiment of these operational steps. If the measurand is not fully defined, the measurement process becomes, itself, an essential part of the definition. An example is the measurement of hardness. Several kinds of hardness scales—e.g., Brinell hardness, Knoop hardness, Rockwell hardness—are each defined by the particular method or device used to measure them. Another example is octane number of gasoline, which is determined by evaluating the fuel when used to operate an internal-combustion engine of specified design under defined conditions. In general, the translation of a conceptual definition into an operational definition is not perfect, and the measurand defined by the measurement process consequently differs in varying degree from the intended or ideal.

The information sought by the measurement process is always a comparison of the measurand with a reference quantity of the same kind. If a scaled series of reference quantities of all possible sizes is available, the comparison of measurand to the reference reduces to a demonstration that the measurand is equal in magnitude to a particular member of the set of reference values. Alternatively, the measurand may itself be subdivided into equal parts of uniform size shown to be equal to a unit reference magnitude, and the number of such parts is counted. Examples of scaled reference quantities are the subdivision of the metre or yard into centimetres or inches and its multiplication to kilometres or miles.

Frequently the measurand is not accessible or not suitable for direct comparison with a reference, as, for example, the radiation intensity inside a nuclear reactor. The measurand may then be transduced (converted) into an analogous measurement signal, a physical quantity of a more suitable kind that is related to the measurand in such a way that a given value of the signal represents a definite measurand magnitude. The reference quantity must then be similarly transduced to provide a reference signal of the same kind so that the measurand signal and the reference signal may be compared, after suitable multiplication or subdivision. Equality is established by opposing the measurand and reference, or the analogue signals that represent them, so that a transfer of energy occurs in one direction or the other depending on the relative magnitudes of the two. The approach to equality is then evidenced by reduction of the energy transfer to a minimum.

Because energy is required by the comparison process, there is always interaction between the observed measurand and the observing instrument. The value of the measurand observed is, therefore, not the same as that of the undisturbed measurand. If the disturbance is large enough to be significant, the exact value of the measurand must be inferred from knowledge of the disturbing process. The time required for accumulation and transfer of energy limits the capability to measure rapidly changing or dynamic phenomena.

Most measuring instruments are more or less complex systems in which a number of functional elements are joined to accomplish the desired measurement and to

Comparison with reference quantity

Instruments as systems of joining of functional elements

express the results in desired form. In some cases the functional elements are discrete units interconnected by the user to form the complete measuring instrument. In other cases the elements are so integrated that the individual functions are not readily discernible. Thus, light may be measured by connecting together a phototube, a power supply, an amplifier, and a voltmeter, or all of these may be integrated into a single instrument which is called a photometer.

Some of the measurement functions performed by the functional elements are basic to the measurement process. Thus, in any measuring instrument an element must be present that discriminates the measurand from all other conditions and senses its magnitude. In any measurement system this magnitude must be compared with the reference magnitude and the results of that comparison must be communicated to an observer or to a device that performs a control function. Other measurement functions enable the results to be presented in the desired form at a desired time and place. Examples of the latter are signal generation, excitation, modulation, demodulation, magnification, attenuation, amplification, quantizing, counting, coding, digitizing, timing, transmission, telemetering, computation, display, and recording.

Although a specific sequence of functions exists in a given system, there is no standard order in which the functions are performed. Some may even be performed more than once. Many of the functional elements are themselves measuring instruments because they accept a signal as input and produce an output signal related quantitatively to the magnitude of the input.

#### FUNCTIONAL ELEMENTS

Functional elements may be treated from the point of view of an ideally complete instrument system in which all measurement functions are performed without human intervention except for noting the final results. In practice, measurement systems are often only partly instrumented, some of the measurement functions being performed by operators or observers who are, therefore, participants in the measurement system. Thus, a spectrometer for measurement of chemical composition may produce a record of an infrared spectrum that must be interpreted by the observer to produce the desired composition information.

Measurands are often not measured directly but are instead inferred by combining the results of a number of separate measurements. Analogues of most instrument functions can be found in biological systems; *e.g.*, the temperature sensors of most living organisms. Conversely, most measurement functions that are performed by humans can also be accomplished by devices, although the performance of living systems has in some instances, such as in the sense of smell, not yet been equalled in nonliving systems.

**Basic functions.** Measurement information is transferred throughout the instrument system by physical signals. If the measurand is itself energetic or active—for example, motion, temperature, pressure, or flow—it may provide the power required for the measurement signal. Passive measurands, such as location of an object in space, electrical resistance, and properties of materials, are not sources of signal power. To measure such phenomena, a measurement signal must be excited by causing the measurand to interact with an energetic probe or with a carrier signal.

Probes or sources of excitation signals take a variety of forms. Examples are light sources of various kinds, X-ray tubes, cathode-ray guns, particle accelerators, nuclear reactors, radioactive materials, sources of voltage and current, waveform generators, magnets, mechanical-force generators, vibration exciters, acoustic generators, and heaters.

Interaction of the carrier or probe with the measurand generates a measurement signal that carries information about the magnitude of the measurand. This information may be carried in the form of modulation of the exciting signal or carrier, a modification of a quantitative property of the carrier. If the carrier is an alternating voltage or

current, as is quite frequently the case, then amplitude, frequency, and phase-angle modulation are commonly used.

If pulsed electrical signals are used as the carrier, pulse height, pulse frequency, pulse position, pulse duration, pulse interval, or pulse time may be used to carry measurement information. The properties of the carrier or probe that affect the recovery (demodulation) of the information it carries must be accurately controlled at the source (see also RADIO; TELEPHONE AND TELECOMMUNICATIONS SYSTEMS).

A reference signal corresponding to the measurand and with which the measurand is to be compared is derived, ultimately, by a process of calibration accomplished basically by applying the instrument to measurands of known magnitude. The reference signal is often derived indirectly through a sequence of intermediate reference quantities.

Calibration may be effected automatically, but more often an operator is involved in the process. Examples of highly stable intermediate references are the cadmium standard cell and the Zener diode for voltage reference, the quartz-crystal controlled oscillator for frequency and time reference, and spectrum-line radiation emitted by elements such as sodium, cadmium, mercury, and krypton for length reference.

To effect comparison of measurand and reference, these, or the analogue signals that represent them, must be brought to equality, accomplished, for example, by subdividing or multiplying the reference to provide a series of references of suitable resolution over the ranges of interest. Detection of equality, which closes the basic measurement process, is frequently performed by the observer—*e.g.*, by noting the coincidence of a pointer and a scale graduation. It can also be performed by an instrument element.

An alternative comparison technique is quantization followed by counting. A signal is quantized by breaking it into parts, or quanta, of equal and known size. Counting the quanta then completes the measurement. Many measurands of interest occur in nature in quantized form, notably chemical species such as atoms and molecules, so that measurement of these can sometimes be accomplished by counting alone.

**Amplification.** The energy impressed upon or withdrawn from the measurand and from the reference quantity to provide power for the measurement signals must be kept small enough to avoid changing their magnitudes significantly. The permissible power level is frequently too small to permit performance of desired measurement functions, especially when the requirement for high accuracy is coupled with the need for high sensitivity and high speed. Amplification is the instrument function by which a signal carrying measurement information is increased in power without degrading its information content.

Electrical amplification is widely used in instrument systems. Pneumatic amplification, in which the measurement information is represented by pressure or flow of a gas, and hydraulic amplification, in which liquid pressure or flow is the information carrier, are also frequently used. Pneumatic amplification is employed in the technology of fluidics (*q.v.*), whereby pneumatic signals are manipulated rapidly and transmitted at speed of sound by means of devices of small dimensions that involve no moving parts other than the gaseous fluid itself. Hydraulic amplification finds application especially in cases in which large amounts of power are to be transmitted in a relatively small space, as for controlling the aerodynamic surfaces of aircraft, for controlling the motion of heavy machine elements, and for manipulating fluids (as in process control). Hydraulic and pneumatic amplification are also used to avoid certain hazards, such as those of electrical currents in explosive atmospheres, and, in nuclear radiation environments, to avoid the effects of radiation damage to which electronic components are sometimes susceptible.

Electrical amplification is important for measurement applications because of the extremely rapid response that

Active and passive measurands

Use of pneumatic amplification

can be achieved; the speed with which electrical signals can be transmitted; the relative simplicity of the physical laws involved; the relative freedom of electrical parameters, such as resistance and capacitance, from environmental influences; the availability of electrical conductors that can transmit large amounts of power with little loss within the confines of small dimensions; the ease with which electrical signals can be confined by insulators and by shielding; and the enormous versatility of the devices available for manipulation of electrical signals. Microcircuitry and integrated circuits based on semiconductor electronics have added to the already great versatility of electrical amplification.

Amplifiers function by using the low-power measurement signal to control power drawn from a relatively unlimited source other than the measurand. Electrical devices used for amplification include the vacuum electron tube, the transistor and related semiconductor devices, and the saturable core reactor, a type of transformer in which a small current in one winding controls a large amount of power in another winding. Electromechanical amplifiers include such devices as relays and magnetic clutches.

The relationship between input and output signals governed by amplifier principles and devices is, in general, only approximately correct and is subject to many environmental influences and to changes that occur in characteristics of components. If greater accuracy is required than can be achieved by isolation and correction or compensation, the principle of negative feedback, or closed-loop operation, is employed.

**Negative feedback.** The feedback principle is of general utility to avoid distortion of measurement signals throughout the instrument system. Its operation may be understood by noting that it involves two signal channels—an information channel and a power channel. The information channel operates at the lowest possible power level and employs signal manipulation and transmission principles and devices selected for their freedom from error and instabilities.

The output signal of the power channel, including distortions introduced by processes taking place in the channel (such as amplification, transmission, etc.) is compared with the signal from the information channel, which is assumed to be correct, and the difference between the two, the error signal, is returned to a control element in the power channel in such a way that a positive error (power channel signal greater than the information channel signal) causes a reduction in the gain, or amplification factor, of the power channel and a negative error produces the opposite effect. The result is a reduction in the error signal until the difference between the two channels becomes negligible.

Clearly, the automatic adjustment of gain of the power channel to correct the power channel signal must be effected before a significant change in magnitude of the measurand has time to occur. Lags in signal transmission in the two channels will result in incorrect adjustment of gain and unstable operation unless they are small relative to the rate at which the measurand changes (see also CONTROL SYSTEMS).

**Digitalization.** Another powerful tool for avoiding degradation of measurement information is conversion of the signal to coded or digital form. The analogue signals are subject to instability and to noise interference. As long as the signal remains an analogue, each operation is in essence a new measurement subject to error, so that the measurement information becomes progressively degraded at each step. Once the measurement information is represented by a number, however, such degradation is enormously reduced. Thus, if it is desired to evaluate a measurand with an error as small as one part in 1,000,000, each manipulation of an analogue signal must be performed with an accuracy of at least one part in 1,000,000. If, however, the magnitude of the measurand is represented by a decimal number, the signal simply transmits each individual digit. An accuracy of only one part in 10 permits each digit to be unambiguously identified, which is all that is required.

Furthermore, if binary-number representation is used, an accuracy of only one in two suffices. Digital signals in measurement systems are generally manipulated in binary form, by presence or absence of signal or by positive or negative direction of signal, decimal digits being represented by binary codes. The possibility of error in transmission or manipulation can be further reduced by introducing redundancy—that is, repetition of each signal as a double check.

In the manipulation of analogue signals, small errors are more probable than large, resulting in a normal (Gaussian) distribution of error. In digital signals the various digits represent different orders of magnitude, but the probability of an error in a given digit is independent of the magnitude it represents. Thus, in digital communication of measurement information, large and small errors are equally likely, but their probability of occurrence can be made as small as desired.

Techniques for high-speed manipulation of digital information in electrical form are highly developed so that digital transmission is competitive with analogue transmission even where speed or high-frequency response is important. Digital instruments are rapid enough in their response to permit their use for measurement and control of aircraft operating at supersonic speeds, of space vehicles millions of miles removed from their control centers, and of many manufacturing processes.

Many techniques are available for accomplishing conversion from analogue to digital form with high accuracy. For measurement information carried by an electrical voltage signal, a digital voltmeter may be used for the conversion. When the measurement information is a periodic signal whose frequency is the analogue of the measurand magnitude, an electronic counter that presents in digital code the number of cycles occurring during a fixed counting period provides the measurement information in digital form. When linear or angular displacement is the analogue signal to be converted (for example, the motion of a pointer), digitally coded scales are commonly used. Because of the desirability of early conversion to digital form, much attention has been given to development of so-called digital transducers, in which digitalization is immediately associated in a single device with the first conversion of the measurand magnitude into a measurement signal.

**Magnification.** Enlarging a measurement signal without increasing its power is called magnification. Mechanical, optical, and electrical techniques are all employed. Examples of mechanical magnifiers are the lever, the screw, pulley and gear systems, and hydraulic- and pneumatic-force multipliers. Optical magnifiers include the lenses and mirrors used to produce or modify images in microscopes, telescopes, and cameras and the optical lever used for instrument indication. Electrical magnification is provided by transformers.

The purpose of magnification is primarily to perform an interfacing function: to match the output of one element of the measurement system to the input requirements of the next. An early application (and still a major one) is to condition the measurement signal for presentation to the human senses at the interface, or point of contact, between the instrument and the observer. Its frequent function there is to match the magnitude of the readout indication to the resolution capability of the eye. It serves analogously at the interface between instrument elements, as in impedance matching between stages of an electrical measuring circuit.

**Analysis.** One of the most widespread characteristics of physical systems is resonance, or characteristic periodic variation. For this reason an important measurement is the determination of the resonance frequencies associated with a system. To determine these resonances, the output of the system may be subjected to harmonic analysis. This may be done by mathematical computation, or the signal may be analyzed by using resonant detection devices.

The most commonly encountered example of harmonic analysis is that of a radio receiver, in which a complex electromagnetic-field signal that is picked up by an anten-

Advantages  
of digital  
form

Analysis of  
resonance  
frequencies

na is sorted into a number of separate signals characterized by the resonant frequency of the transmitter from which the signal was broadcast. By scanning across the receiver dial and noting the points at which signals are received, a spectrum analysis of the incoming signal is performed.

**Computation.** General-purpose computing operations for mathematical manipulation of measurement signals include analogue computation, in which the magnitude of the signal (usually in the form of an electrical voltage) is operated upon, and digital computation, in which the magnitudes of signals are first converted to digital form and then operated upon as numbers. Both of these methods are of growing importance as components of measuring instruments.

The basic element of analogue-computing devices is the operational amplifier (opamp), a high-gain, direct-coupled, wideband amplifier available in compact modular form. Operational amplifiers are combined in various ways with other electrical-circuit elements, such as resistors, capacitors, and inductors, to perform mathematical addition, subtraction, multiplication, division, integration, and differentiation.

Digital computers combine large internal memories for storing numerical information, or any information convertible to numerical form, with arithmetic-manipulation capability. The essential characteristics of modern digital computers are very high speed operation and capability for storing and operating from a program of instructions for performing complex computation. This high-speed-computation capability, when incorporated into an instrument, permits direct automatic performance of complex measurements that would otherwise require combination by an observer of a number of separate measurement results.

The computer also identifies and monitors signals, normalizes data, linearizes or otherwise transforms instrument response, and corrects measurement data for various influences that can be measured if knowledge of their effects is programmed into the computer; in addition, it performs several different kinds of analysis, summarizes measurement data, and generates reports (see also COMPUTER).

The ability of the computer to store and manipulate instructions as well as measurement data is also used to automate the operation of instruments performing large numbers of complex measurements. Both speed and accuracy of measurement can be improved in this way. Computer generation of complex displays for presentation of interpreted data enlarges the scope of instrument communication with the observer, and it permits the observer to interact with the instrument system, as described further in the discussion of display techniques below.

**Telemetry.** It is often necessary for results of measurement to be presented, essentially instantaneously, at a location remote from the point of measurement. Space exploration, biomedical research, oceanography, and meteorology are fields in which such requirements are common. Telemetry (*q.v.*), or telemetering, the art of remote measurement, makes use of communication channels, especially wireless transmission, to transmit measurement data. In modern telemetry, data are frequently transmitted in digital form.

**Display.** Communication of measurement information to the observer is a function of all instruments except those that are used for automatic-control-system actuation. Even in automatic control, the results of measurement are usually displayed so that the performance of the system may be monitored. Display serves not only to present results of measurement but also to communicate with the observer when he participates in the measurement process. Display is usually visual, but presentation to the other senses is also common. Auditory display is used for alarms that indicate that some limiting value of measurand has been exceeded; *e.g.*, a fire alarm activated by a thermostat. The auditory sense is also enlisted negatively for detecting the absence of sound when a measurand signal and a reference signal are to be compared or when a feedback error signal is to be brought to zero.

The commonest visual display is the pointer moving relative to a graduated-length scale; the graduations of the scale are usually marked to read directly in measurand units. The relationship between measurand and pointer movement may be expressed as either a linear (that is, direct one-on-one relationship) or as a nonlinear relationship, such as logarithmic, in which the relationship between the measurand and the pointer deflection is exponential.

Linear relationship between measurand and pointer movement and uniform spacing of graduations facilitate interpolation between graduations. A logarithmic relationship between measurand and pointer deflection has the characteristic that the percent error of reading is uniform over the scale. Logarithmic scales permit larger ranges of measurand magnitude to be covered usefully by a given length of scale.

An important contributor to pointer-reading error is the parallax, or apparent difference in position, when the pointer and the scale are not in the same plane. Parallax is reduced by providing a mirror sector in the plane of the scale or by using a pointer configured as a thin vane rather than a needle. With the former, the eye of the observer, the pointer, and the mirror image of the pointer are aligned for reading; in using the vane, the eye is positioned for minimum pointer profile to improve consistency of reading.

A special kind of pointer, a cathode ray (beam of electrons) impinging on a phosphor screen, is used in oscilloscope and television-raster types of display. Deflection of the cathode ray is controlled by electric or magnetic fields, and its intensity may also be modulated to provide simultaneous display of the relationship among three variables. Addition of colour permits limited display of a fourth variable.

The high-speed writing capability of the cathode ray has made the oscilloscope one of the most important components of instrument systems and has contributed significantly to the desirability of using electrical signals to transmit measurement information. The oscilloscope has been developed to a very high level of sophistication for measurement of electrical variables and, hence, for any measurand that can be converted into an electrical signal. In special types of equipment, the observer can interact with the measurement system through the cathode-ray tube by use of a hand-held probe that is applied to the screen at the light spot and thereby assumes control of the cathode ray and operates upon the information being displayed.

To improve the precision obtainable by analogue display, scale expansion and zero suppression are used, the total measurement range being covered by more than one span of the scale. Unlimited precision of indication can be obtained with a digital display that relieves the observer of the measurement function involved in reading a scale.

Digital display may take the form of a set of digits arrayed in the usual way, with the significance of each digit being indicated by its position relative to a decimal point. By using a floating or movable decimal point, a wider range of values can be covered by a given number of digits.

Digital display is accomplished by mechanical, electrical, and electro-optical means. Mechanical devices may use rotatable disks or cylinders the peripheries of which carry the numerals. The automobile odometer is an example.

Another mechanical type of digital display uses a series of pointers, one for each digit, that point to numerals in a circular array, as in the common gas meter, water meter, and watt-hour meter. Analogue and digital display are frequently combined in mechanical displays, the former being used for the less significant digits. One form of this uses an analogue pointer that reads on a scale covering a full circle and one or more auxiliary pointers the indications of which count the number of full rotations performed by the analogue pointer.

Electronic and electro-optical devices for digital display frequently use illuminated numerals. Preformed numer-

Use of a beam of electrons as a pointer

Communicating information to the observer

als may be selected and illuminated electrically, numerals may be formed by selection and illumination of dots in a matrix, or numbers may actually be written, as required, by cathode-ray beams. Cathode-ray tubes and television-scan displays permit the presentation of complex information in combined analogue and digital form. Graphs, tabulations, and a great variety of symbolic information may be communicated in this way.

When large quantities of measurement information must be communicated to the human observer at high speed and with high accuracy and reliability, the display art becomes especially critical. Such situations arise, for example, in air-traffic control when the observer must assimilate large amounts of measurement information and make rapid decisions based upon it.

**Recording.** The recording function in instrument systems serves two distinct purposes: first, it provides a record of measurement results for future use by the observer, and, second, it stores intermediate measurement information for later automatic use by the instrument system. While the requirements of the second purpose are somewhat more restrictive than the first, records in machine-readable form can serve both purposes. It is also common to combine in a single device the functions of recording and display.

Recording techniques have a number of variable characteristics. Among these are the visibility of the record (for simultaneous display), machine readability, immediate availability of the record, permanence, erasability, susceptibility to accidental erasure, operating-power requirement, standby-power requirement, writing and reading speed, time required for access to a specific item in the record, form of the data (analogue or digital), precision of recording, number of variables accommodated, and, finally, the techniques used to achieve the characteristics desired.

The combination of recording and display is frequently accomplished by devices that produce visible markings on a surface. One very general way to do this is to substitute for the usual indicating pointer a writing stylus that produces a mark on a moving chart. The writing stylus may be an inked pen, a sharply pointed stylus used on a waxed surface, a heated stylus on a heat-sensitive surface, or electric current carried by the pointer on an electro-sensitive surface.

By using a light beam as an indicating pointer, or the spot of light produced by a cathode ray, a photographic surface may be used to record the measurement information, leading to higher recording speeds. A stream of electrically charged ink particles directed to the proper point on the recording surface by an electrostatic field under control of the measurand has been used similarly to avoid recording friction.

The recording surface may be a circular disk, frequently of paper, a flat sheet, a drum, or a continuous strip. To record the measurand value as a function of time, the recording surface or chart is moved by a clock motor at adjustable or selectable speeds. To record the measurand as a function of a variable other than time, the chart may be moved under control of the independent variable, or the marking pointer may be moved in two mutually perpendicular directions: one, usually called the *Y* direction, being used for the measurand and the other, the *X* direction, indicating the independent variable.

While any readout principle that uses mechanical motion for indication may be adapted to recording if sufficient power is available, general purpose recorders are usually designed for electrical input. Some recorders operate with negative feedback, that is, a portion of the output is fed back to the input out of phase with the incoming signal; this operation serves to decrease distortion and increase stability. Though it slows the operation somewhat, it permits precision on the order of a few parts in a thousand.

The non-feedback (open-loop) type is characterized by somewhat lower precision, errors on the order of a few percent, but faster operation, with frequency response on the order of 100 hertz (0.01 second for full-scale traverse) for mechanical pointer types and several thousand

hertz for the photographically recording types called oscillographs.

When the measurand is the position or motion of an object that can be illuminated or is self-luminous, photographic recording is often used directly. This may be done by recording the streak produced as the object's image on the photosensitive surface moves. Alternatively, extremely short pulses of light may be used to produce separate images at the pulse-repetition rate of the light source. Electric sparks or flash-tube discharges are used as sources of light for this type of recording.

Visible recording is also accomplished in digital form by devices such as printers and teletypewriters. Very high speed printers have been developed for this purpose. When the rate at which measurement information is produced by the instrument system is beyond the capabilities of available recording means, buffers may be used to store the information temporarily.

Although techniques and devices are available to enable visible records to be read automatically into instrument systems, such records are not generally best suited for machine reading. Recording means have, therefore, been developed that have characteristics dictated primarily by the requirements of internal use in the instrument system. Such recording means are frequently called memory systems or devices. Apart from reliability, the most important of these requirements are high-speed writing capability and high-speed access to the recorded data.

Serial-recording techniques in instrument systems frequently involve magnetic recording on wires, tapes, drums, and disks. By use of multiple channels, limited partial random access is achieved with these recording media.

Access to the record is relatively slow not only because of serial access but also because mechanical motion is involved in the reading process. Magnetic recording with high-speed random access is provided by magnetic-core memory systems and related magnetic memories that involve no moving parts. It has been estimated that up to 90 percent of random-access memory in instrument systems is provided by magnetic cores; however, a variety of other techniques are used, and many new principles are being actively pursued in efforts to develop large-scale memories with desirable characteristics. Further information on memory systems is included in the article COMPUTER.

#### PERFORMANCE CHARACTERISTICS

Errors in measurement may result from imperfect definition of the measurand, from imperfect understanding of the physical laws applied to converting the measurand into a measurement signal, from failure to establish completely the conditions prescribed for performing the measurement, and from imperfect operator performance. Errors also result from deficiencies inherent in the instrument. Some of the characteristics that describe the accuracy performance of instruments on a general level that is independent of the nature of the measurand or of the specific operating principles used in the instrument are described below.

*Interaction of instrument and measurand.* As already mentioned, all instruments either withdraw energy from the measurand or transfer energy to the measurand. In some cases the power derived from or transmitted to the measurand is negligibly small. In other cases it contributes significantly to measurement error. The measurement-signal power reacts upon the measurand so that the magnitude of the latter differs from that of the undisturbed measurand. It is the modified value that is "seen" by the measuring instrument.

*Noise.* The elements of which the instrument is comprised generate internal disturbances that are indistinguishable from the signals that represent the magnitudes of measurand and reference. These disturbances are called noise by analogy with unwanted sounds. By extension the term is also applied to any unwanted signal, regardless of source. Noise interferes with the ability to evaluate the measurand. The ratio of the desired signal magnitude to the unwanted noise magnitude often sets an

Serial-recording techniques

Electrical input

Signal-to-noise ratio

upper limit on the accuracy of measurement. The signal-to-noise ratio is characteristic of a particular instrument system for noise originating within the instrument. A given level of noise is most damaging when the level of the signal is low, as in the early stages before amplification.

The first stage of amplification is therefore critical for establishing a good signal-to-noise ratio. Amplification of the measurement signal as early as possible in the sequence of functions is beneficial. Thermal agitation is an important source of noise, so that operation of the first functional elements at low temperature is often used to achieve low-noise operation.

*Interference.* The environment in which the instrument operates contributes influences that interfere with the measurement. Once these interfering influences enter the instrument system, they become, like any other noise, indistinguishable from the measurement signal. Unlike noise, however, they differ from the measurand before they enter the system and, hence, can be dealt with by isolating the instrument from them or by providing compensation against them. Neither the isolation nor the compensation is, in general, perfect.

*Dynamic response.* The physical system of the measuring instrument does not respond instantaneously to the value of the measurand. In mechanical systems inertia, elasticity or imperfect rigidity, and friction or dissipation of energy all introduce lags in response. In electrical systems analogous effects are produced by inductance, capacitance, and resistance. And in thermal systems lags are introduced by thermal capacity and by thermal resistance.

The result of these lags is that the output of the instrument is not a true representation of the instantaneous value of the measurand if the latter is changing. Instead, the indicated value may be an average that is characteristic of the instrument system. This characteristic is related to the natural frequency of the system (the frequency at which the output of the instrument would oscillate if left free after a momentary input disturbance) and to its degree of damping or internal dissipation of energy.

*Drift.* Unless the measuring elements in the instrument are completely stable, which is never entirely the case, the indication of the instrument will drift from the correct value in the interval between calibrations. A major cause of short-term drift is self-heating, causing changes in temperature of various parts of the instrument. It is common practice to allow a minimum warm-up time before making measurements, and instruments are often maintained in continuous operation to minimize drift for important measurements.

Changes caused by drift

Instrument drift may cause two changes: (1) change of zero indication and (2) change of sensitivity, the ratio of output to input. For accurate measurement, frequency of calibration must be appropriate to the drift characteristics of the instrument. Continuous calibration based on local reference standards that are built into the instrument system may be used in critical measurement situations.

*Hysteresis.* Measuring instruments may not respond equally to a measurand value that is approached from a lower value and to the same value approached from a higher value. Lagging of response behind input is called hysteresis by analogy with the similar phenomenon in magnetization of materials. More complex dependence of measurement results upon the past history of the measuring instrument may also be present. To reduce such effects, the measurement may be made in both ascending and descending directions, or the instrument may be cycled through a range of values preparatory to making the final measurement.

The dead band

A special case of hysteresis is the dead band. The output of an instrument may not respond to a change of magnitude of the measurand until that change has reached some finite magnitude characteristic of the instrument. Thus, a dead band exists that sets a lower limit to the magnitude of change that can be detected. A cause of dead band in mechanical instruments is backlash or lost motion in gear systems and other linkages.

*Linearity.* It is desirable that the relationship of the output to the input signal can be described by a simple mathematical statement. The actual characteristic of an instrument always departs more or less from the ideal, and the precise relationship, ascertained by the process of calibration, must usually be expressed either by a tabulation of outputs and corresponding inputs or, graphically, by a curve relating the two. A linear relationship is frequently desired because this greatly simplifies the calibration process.

*Resolution.* The closeness to each other with which two values of measurand may approach and still be distinguished by the measuring instrument is described as the resolution capability of the instrument.

*Precision.* The ability of an instrument to determine with a high degree of discrimination the relationship between two values of measurand that fall within its nominal measurement range, independently of a reference standard external to the instrument system itself, is its precision. To be capable of high precision, an instrument must be capable of a high degree of resolution, but the converse does not follow. A partial measure of precision is the dispersion or scatter of measurement results obtained when the same measurand is repeatedly measured with all conditions of measurement maintained within the range specified for proper operation of the instrument.

Precision of a measurement can be improved by averaging a number of separate readings. Precision usually increases as the square root of the number of repetitions. Similar improvement is obtained by allowing the instrument to average its measurement over a period of time during which the measurand remains constant.

*Accuracy.* The capability of an instrument to yield the correct (or true) value of the measurand is its accuracy. Of special importance is the accuracy with which the indications of an instrument system agree with the true value defined by international agreement. This kind of accuracy provides the most broadly significant measurement data in the sense that the widest possible range is provided for communication about the data resulting from the measurement process. The International System of Units, abbreviated SI, is a modernized version of the metric system established to provide a logical and interconnected framework for all measurement (see WEIGHTS AND MEASURES). Traceability of measurements to SI is provided by a hierarchy of intercomparisons of standards performed through the agency of the International Bureau of Weights and Measures, located at Sèvres, near Paris. National laboratories of various countries provide access to the International Bureau for the purpose of achieving international compatibility of measurements.

Dissemination of the internationally defined true values, the SI units, is accomplished in a variety of ways starting with the establishment of national standards that are the physical embodiments of the units of measurements. Methods of dissemination include calibration services, development and distribution of standard reference materials that embody measurands of known value, determination and publication of standard reference data, or best values, relating to materials and phenomena that are widely accessible for measurement, round-robin tests in which standards laboratories cooperate to compare results of measurements performed on identical measurands, and broadcast of time and frequency signals.

The basic units of SI are the metre, the unit of length; the kilogram, the unit of mass; the second, unit of time; the kelvin, unit of temperature; the ampere, unit of electric current; the candela, unit of luminous intensity; and the mole, unit of quantity of matter. To these are added the radian and steradian, the units of plane angle and solid angle, respectively. From these units all other units of physical measurement are conceptually derived. Except in the case of the unit of mass, the base units are defined so that they can be realized independently of the calibration hierarchy described above. High accuracy, however, is in most circumstances more readily achieved through the hierarchy.

Basic SI units

**Safeguards against failure.** A measuring instrument may fail completely, ceasing to operate, or its performance may gradually deteriorate until its accuracy degrades below the level of acceptability, without giving any indication of failure. A common safeguard in measuring instruments is visibility, as in the liquid-in-glass thermometer, in which the condition of the instrument is easily ascertained by inspection. Instrument systems in which reliable operation is critically important may have built-in self-diagnosis capabilities.

#### DEVELOPMENT OF MEASURING INSTRUMENTS

Five phases can be distinguished in the evolution of instrument systems: a definition phase, a research and development phase, a production design phase, a production phase, and an application phase. These phases are not clearly separable; even in the last phase, it is frequently desirable to return to earlier phases to improve operation of the instrument.

The first phase includes a definition of the measurand and a set of requirements that define performance desired and conditions of operation under which this performance is to be attained. Unless the measurand is directly observable and accessible to the human senses, it must be defined in terms of other measurables. The conversion of the measurand is called transduction, and the devices that effect the conversions are transducers. The first conversion is unique in that the measurand and the circumstances in which it occurs are not subject to choice by the instrument engineer but must be accepted as presented. The first, or primary, transducer must discriminate the measurand from among all accompanying conditions and convert it into a signal accurately related to the measurand and of such a form that it can be, in turn, measured without degradation of accuracy.

Next is formulation of a schematic functional design, a sequence of transductions that will provide the measurement information in the time, place, and format desired under the prescribed conditions of operation. After this, each of the functional elements is designed or selected to have the desired characteristics and to connect (or interface) appropriately with other contiguous elements and with the human observer or operator wherever he participates in the measurement process.

Detailed design is then effected and implemented by constructing a prototype. When the desired performance has been successfully demonstrated, the instrument enters the production-development stage, including design for production, selection or development of fabrication techniques, and design of the system of tests and inspections to be used for quality control. Production of the instrument is followed by application, including installation, operation, maintenance and repair, and assurance of accuracy of measurement results by standardization and calibration.

Specific measuring instruments and their applications are described in the following articles: COMPASS; HAND TOOLS (rulers and calipers); HYDROGRAPHIC CHARTING; MATERIALS TESTING (instruments for measuring such physical properties of materials as hardness, ductility, thermal conductivity, etc.); METEOROLOGICAL MEASUREMENTS (a range of instruments used in atmospheric measurement); MICROSCOPE; NAVIGATION; PHOTOGRAPHY, TECHNOLOGY OF (light meters, range finders, etc.); SEISMOGRAPH; SURVEYING (transits, theodolites); TELESCOPE; THERMOMETRY; UNDERSEA EXPLORATION (instruments for measuring salinity, temperature, wave motions, water depth); and VACUUM TECHNOLOGY (instruments for measuring low pressures).

**BIBLIOGRAPHY.** The very extensive literature on measuring instruments is scattered throughout science and technology—in the sciences that are the sources of instrument principles, in the technologies that provide its techniques, and in association with the fields of application of measurements. A key to these sources of information is provided by JULIAN F. SMITH and WILLIAM G. BROMBACHER, *Guide to Instrumentation Literature* (1965). BRIAN ELLIS, *Basic Concepts of Measurement* (1966), is an analytical treatment of the philosophy and logic of measurement. CHESTER H. PAGE and PAUL VIGOUREUX (eds.), *The International System of*

*Units (SI)* (1972), describes the system of units and standards that are the internationally accepted basis for communication of the results of measurement. DOUGLAS M. CONSIDINE (ed.), *Encyclopedia of Instrumentation and Control* (1971), treats comprehensively the broad field of the applications of measuring instruments in research, development, manufacturing, medicine, etc. (emphasis is on guidance for the instrument user). CHARLES S. DRAPER, WALTER MCKAY, and SIDNEY LEES, *Instrument Engineering*, 3 vol. (1952–55), is a detailed and sophisticated treatment of principles and methods for solution of problems in measurement and control, with emphasis on the needs of the developer and designer of instrument systems. See also LESLIE W. LEE, *Elementary Principles of Laboratory Instruments*, 2nd ed. (1970). BERNARD M. OLIVER and JOHN M. CAGE (eds.), *Electronic Measurements and Instrumentation* (1971), covers many of the instrument system functions that follow conversion of a measurand to an electrical signal. THOMAS N. WHITEHEAD, *The Design and Use of Instruments and Accurate Mechanism* (1934, reprinted 1954), develops fundamental principles for achieving accuracy in the operation of measuring instruments. The NATIONAL BUREAU OF STANDARDS, *Precision Measurement and Calibration*: vol. 1, *Statistical Concepts and Procedures*; vol. 2, *Temperature*; vol. 3, *Electricity: Low Frequency*; vol. 4, *Electricity: Radio Frequency*; vol. 5, *Frequency and Time*; vol. 6, *Heat*; vol. 7, *Radiometry and Ionometry*; vol. 8, *Mechanics*; vol. 9, *Colorimetry*; vol. 10, *Photizing Radiation*; vol. 11, *Image Optics* (1968– ), accumulate important papers that deal with precise, fundamental measurements. C.F. HIX and R.P. ALLEY, *Physical Laws and Effects* (1958), includes a compilation and description of the phenomena that provide the basis for conversion of measurands into instrument signals.

The following treat of the devices that perform the function of converting the measurand to instrument signals: KURT S. LION, *Instrumentation in Scientific Research: Electrical Input Transducers* (1959); HARRY N. NORTON, *Handbook of Transducers for Electronic Measuring Systems* (1969); KENNETH ARTHUR, *Transducer Measurements* (1971); GLENN F. HARVEY (ed.), *ISA Transducer Compendium*, 2nd ed., 3 vol. (1969–72).

The following treat in detail specific instrument functional elements: RICHARD F. SHEA (ed.), *Amplifier Handbook* (1966); HERMANN SCHMID, *Electronic Analog/Digital Conversions* (1970); MYRON H. NICHOLS and LAWRENCE L. RAUCH, *Radio Telemetry*, 2nd ed. (1956); CESAR A. CACERES (ed.), *Biomedical Telemetry* (1965); MISCHA SCHWARTZ, *Information Transmission, Modulation, and Noise* (1959); CLAUDE E. SHANNON and WARREN WEAVER, *The Mathematical Theory of Communication* (1949); WILLIAM R. BENNETT and JAMES R. DAVEY, *Data Transmission* (1965); C.B. PEAR, JR. (ed.), *Magnetic Recording in Science and Industry* (1967); HAROLD R. LUXENBERG and RUDOLPH L. KUEHN (eds.), *Display Systems Engineering* (1968); JOSEF CZECH, *Oszillografen-Messtechnik* (1959; rev. Eng. trans., *Oscilloscope Measuring Technique: Principles and Applications of Modern Cathode Ray Oscilloscopes*, 1965); JULIUS S. BENDAT and ALLAN G. PIERSON, *Measurement and Analysis of Random Data* (1966).

## Measurement, Psychological

The Bible records that Gideon was instructed to reduce the number of men who were to accompany him into battle by proclaiming, "Whoever is fearful and trembling, let him return home." This constituted a test, and 22,000 left; but the 10,000 remaining still were too numerous. A further test was ordered: only those who lapped water with their tongues, as dogs do, in contrast to those who knelt to drink, were to be retained. They had passed a second test, or hurdle, thus providing an early example of what is known today as the successive-hurdles method of personnel selection.

Again, when Gileadites captured the fords of the Jordan River against the Ephraimites, a simple test was used to detect those who were attempting to masquerade as Gileadites. They were required to say "shibboleth," which Ephraimites could pronounce only as "sibboleth." It is recorded that 42,000 Ephraimites failed this simple, one-item test and were put to death.

The Greek Olympic games were of the nature of tests. And the idea of behavioral tests to reveal latent abilities is found in Plato's *Republic*:

No two persons are born exactly alike, but each differs from each in natural endowments, one being suited for one occupation and another for another . . . It will belong to us to

choose out, if we can, that special order of natural endowments which qualifies its possessors for the guardianship of the state.

Plato envisaged tests of military aptitude not unlike those used today.

Not until the end of the 19th century, however, did influences from German experimental psychology, British statistical methods for describing individual differences, and French concern for deviant individuals merge to provide a springboard for modern psychological-measurement technique and theory.

Tests:  
ability,  
aptitude,  
achievement,  
personality

The word test refers to any means (often formally contrived) used to elicit responses to which behaviour in other contexts can be related. When intended to predict relatively distant future behaviour (e.g., success in school), such a device is called an aptitude test. When used to evaluate the individual's present academic or vocational skill, it may be called an achievement test. In such settings as guidance offices, mental-health clinics, and psychiatric hospitals, tests of ability and personality may be helpful in the diagnosis and detection of troublesome behaviour. Industry and government alike have been prodigious users of tests for selecting workers. Research workers often rely on tests to translate theoretical concepts (e.g., intelligence) into experimentally useful measures.

#### GENERAL PROBLEMS OF MEASUREMENT IN PSYCHOLOGY

Physical things are perceived through their properties or attributes. A mother may directly sense the property called temperature by feeling her infant's forehead. Yet she cannot directly observe his colicky feelings nor share his personal experience of hunger. She must infer such unobservable private activities from hearing her baby cry or gurgle; from seeing him flail his arms, or frown, or smile. In the same way, much of what is called measurement must be made by inference. Thus, a mother suspecting her child is feverish may use a thermometer, in which case she infers his temperature by looking at the thermometer, rather than by directly touching his head.

Indeed, measurement by inference is particularly characteristic of psychology. Such abstract properties or attributes as intelligence or introversion never are directly measured but must be inferred from observable behaviour.

Nominal,  
ordinal,  
interval,  
and ratio  
scales

*Types of measurement scales.* To measure any property or activity is to assign it a unique position along some kind of numerical scale. When numbers are used merely to identify individuals or classes (as on the backs of athletes on a football team), they constitute a nominal scale. When a set of numbers reflects only the relative order of things (e.g., pleasantness-unpleasantness of odours), they constitute an ordinal scale. An interval scale has equal units and an arbitrarily assigned zero point; for example, one such scale is for Fahrenheit temperature, extending well below zero. Ratio scales not only provide equal units; they also have absolute zero points; examples include measures of weight, density, and distance.

Although there have been ingenious attempts to establish psychological scales with absolute zero points, psychologists usually are content with approximations to interval scales; ordinal scales often are used as well.

*Primary characteristics of methods or instruments.* The primary requirement of a test is validity—traditionally defined as the degree to which a test actually measures whatever it purports to measure. A test is reliable to the extent that it measures consistently, but reliability is of no consequence if a test lacks validity. Since the person who will draw inferences from a test must determine how well it serves his purposes, the estimation of validity inescapably requires judgment. Depending on the criteria of judgment employed, tests exhibit a number of different kinds of validity, as follows:

Empirical validity (also called statistical or predictive validity) describes how closely scores on a test correspond (correlate) with behaviour as measured in other contexts. Students' scores on a test of academic aptitude, for example, may be compared with their school grades

(a commonly used criterion). To the degree that the two measures statistically correspond, the test empirically predicts the criterion of performance in school. Predictive validity has its most important application in aptitude testing (e.g., in screening applicants for work, in academic placement, in assigning military personnel to different duties).

Alternatively, a test may simply be inspected to see if its content seems appropriate to its intended purpose. Such content validation is widely employed in measuring academic achievement but with increasing recognition of the inevitable role of judgment. Thus, a geometry test exhibits content (or curricular) validity when experts (e.g., teachers) believe that it adequately samples the school curriculum for that topic. Interpreted broadly, content covers desired skills (such as computational ability) as well as points of information in the case of achievement tests. Face validity (a crude kind of content validity) reflects the acceptability of a test to such people as students, parents, employers, and government officials. A test that looks valid is desirable, but face validity without some more basic validity is nothing more than window dressing.

In personality testing, judgments of test content tend to be especially untrustworthy, and dependable external criteria are rare. One may, for example, assume that a man who perspires excessively feels anxious. Yet, his feelings of anxiety, if any, are not directly observable. Any assumed trait (anxiety, for example) that is held to underlie observable behaviour is called a construct. Since the construct itself is not directly measurable, the adequacy of any test as a measure of anxiety can be gauged only indirectly; e.g., through evidence for its construct validity.

A test exhibits construct validity when low scorers and high scorers are found to respond differently to everyday experiences or to experimental procedures. A test presumed to measure anxiety, for example, would give evidence of construct validity if those with high scores ("high anxiety") can be shown to learn less efficiently than do those with somewhat lower scores.

Test reliability is affected by scoring accuracy, adequacy of content sampling, and the stability of the trait being measured. Scorer reliability refers to the consistency with which different people who score the same test agree. For a test with a definite answer key, scorer reliability is of negligible concern. When the subject responds with his own words, handwriting, and organization of subject matter, however, the preconceptions of different raters produce different scores from one rater to another; i.e., the test shows scorer (or rater) unreliability. In the absence of an objective scoring key, a scorer's evaluation may differ from one time to another and from those of equally respected evaluators. Other things being equal, tests that permit objective scoring are preferred.

Reliability

Reliability also depends on the representativeness with which tests sample the content to be tested. If subjects' scores on some items of a test that sample a particular universe of content designed to be reasonably homogeneous (e.g., vocabulary) correlate highly with those on another set of items selected from the same universe of content, the test has high content reliability. But if the universe of content is highly diverse in that it samples different factors (say, verbal reasoning and facility with numbers), the test may have high content reliability but low internal consistency.

For most purposes, the performance of a subject on the same test from day to day should be consistent. When such scores do tend to remain stable over time, the test exhibits temporal reliability. Fluctuations of scores may arise from instability of a trait; for example, one may be happier one day than the next. Or temporal unreliability may reflect injudicious test construction (e.g., poor selection of items).

Included among the major methods through which test reliability estimates are made is the comparable-forms technique, in which the scores of a group of people on one form of a test are compared with the scores they earn on another form. Theoretically, the comparable-

Reliability  
estimates

forms approach may reflect scorer, content, and temporal reliability. This ideally demands that each form of the test be constructed by different but equally competent persons, the forms being given at different times and evaluated by a second rater (unless an objective key is fixed).

In the test-retest method, scores of the same group of people from two administrations of the same test are correlated. If the time interval between administrations is too short, memory may unduly enhance the correlation. Too long an interval can result in different effects for each person of forgetting, practice, or learning. Except for very easy speed tests (*e.g.*, in which one's score depends on how quickly he is able to do simple addition), this method may give misleading estimates of reliability. Some people, for example, may look up words they missed on the first administration of a vocabulary test and thus be able to raise their scores the second time around.

Internal-consistency methods of estimating reliability require only one administration of a single form of a test. One method entails obtaining scores on separate halves of the test, usually the odd-numbered and the even-numbered items. The degree of relationship (which is expressed numerically as a correlation coefficient) between scores on these half-tests permits estimation of the reliability of the test (at full length) by means of a statistical correction.

This is computed by the use of the Spearman-Brown prophecy formula (for estimating the increased reliability expected to result from increase in test length). More commonly used is a generalization of this stepped-up, split-half reliability estimate, one of the Kuder-Richardson formulas. This formula provides an average of estimates that would result from all possible ways of separating a test into halves.

*Other desirable characteristics of tests.* A test that takes too long to administer will be useless for most routine applications. What constitutes a reasonable period of testing time, however, will depend in part on the decisions to be made from the test. Each test should be accompanied by a practicable and economically feasible scoring scheme, one scorable by machine or by quickly trained personnel being preferred.

A large, controversial literature has developed around response sets; *i.e.*, tendencies of subjects to respond systematically to items regardless of content. Thus, a given test taker may tend to answer questions on a personality test only in socially desirable ways or to select the first alternative of each set of multiple-choice answers or to mangle (*i.e.*, to purposely give wrong answers). Ways to correct for undesired response sets are becoming increasingly available.

#### TYPES OF INSTRUMENTS AND METHODS

*Psychophysical scales and psychometric or psychological scales.* The concept of an absolute threshold (the lowest intensity at which a sensory stimulus, such as sound waves, will be perceived) is traceable to a German philosopher, Johann Friedrich Herbart. A German physiologist, Ernst Heinrich Weber, later observed that the smallest discernible difference of intensity is proportional to the initial stimulus intensity. Weber found, for example, that, while people could just notice the difference after a slight change in the weight of a ten-gram object, they needed a larger change before they could just detect a difference from a 100-gram weight. This finding is expressed more technically in the statement that the perceived (subjective) intensity will vary mathematically as the logarithm of the physical (objective) intensity of the stimulus.

In traditional psychophysical scaling methods, a set of standard stimuli (such as weights) that can be ordered according to some physical property is related to sensory judgments made by experimental subjects. By the method of average error, for example, subjects are given a standard stimulus and then made to adjust a variable stimulus until they believe it is equal to the standard. The mean (average) of a number of judgments is obtained. This

method and many variations have been used to study such experiences as visual illusions, tactual intensities, and auditory pitch.

Psychological (psychometric) scaling methods are an outgrowth of the psychophysical tradition just described. Although their purpose is to locate stimuli on a linear (straight-line) scale, no quantitative physical values (*e.g.*, loudness or weight) for stimuli are involved. The linear scale may represent one's attitude toward a social institution, his judgment of the quality of an artistic product, the degree to which he exhibits a personality characteristic, or his preference for different foods. Psychological scales thus are used for reporting one's own characteristics, as well as for rating other individuals in terms of such attributes, for example, as leadership potential or initiative.

An American psychologist, Louis L. Thurstone, offered a number of theoretical-statistical contributions that are widely used as rationales for constructing psychometric scales. One scaling technique (comparative judgment) is based empirically on choices made by people between members of any series of paired stimuli. Statistical treatment to provide numerical estimates of the subjective (perceived) distances between members of every pair of stimuli yields a psychometric scale. Whether or not these computed scale values are consistent with the observed comparative judgments is a problem that can be tested empirically.

Another of Thurstone's psychometric scaling techniques (equal-appearing intervals) has been widely used in attitude measurement. In this method, judges sort statements reflecting such things as varying degrees of emotional intensity, for example, into what they perceive to be equally spaced categories; the average (median) category assignments are used to define scale values numerically. Subsequent users of such a scale are scored according to the average scale values of the statements to which they subscribe. Another method, developed by another American psychologist, requires no prior group of judges, depends on intensive analysis of scale items, and yields comparable results. A more general technique (successive intervals) does not depend on the assumption that judges perceive interval size accurately. The widely used graphic rating scale presents an arbitrary continuum with preassigned guides for the rater (*e.g.*, adjectives such as superior, average, and inferior); for examples, see PERSONALITY, MEASUREMENT OF: *Methods of assessment: Rating scales.*

*Tests versus inventories.* The term test most frequently refers to devices for measuring abilities or qualities for which there are authoritative right and wrong answers. Such a test may be contrasted with a personality inventory, for which it is often claimed that there are no right or wrong answers. At any rate, in taking what often is called a test, the subject is instructed to do his best; in completing an inventory, he is instructed to represent his typical reactions. A distinction also has been made that in responding to an inventory the subject controls the appraisal, whereas in a test he does not. If a test is more broadly regarded as a set of stimulus situations that elicit responses from which inferences can be drawn, however, then an inventory is, according to this definition, a variety of test.

*Free-response versus limited-response tests.* Free-response tests entail few restraints on the form or content of one's response, whereas limited-response tests restrict his responses to one of a smaller number presented (*e.g.*, true-false). An essay test tends toward one extreme (free response), while a so-called fully objective test is at the other extreme (limited response).

Response to an essay question is not completely unlimited, however, since the answer should bear on the question. The free-response test does give practice in writing, and, when an evaluator is proficient in judging written expression, his comments on the test may aid the individual to improve his writing style. All too often, however, writing ability unfortunately affects judgments of how well the test taker understands content, tending to reduce test reliability. Another source of unreliability for essay

Essay and objective tests

tests is found in their limited sampling of content, as contrasted with the broader coverage that is possible with objective tests. Often both the scorer and the content reliability of essay tests can be increased, but such attempts are costly.

The objective test, which minimizes scorer unreliability, is best typified by the multiple-choice form, in which the subject is required to select one from two or (preferably) more responses to a test item. Matching items that have a common set of alternatives for matching are of this form. The true-false test question is a special multiple-choice form that may tend to arouse antagonism because of variable standards of truth or falsity.

The more general multiple-choice item is more acceptable when it is specified only that the best answer be selected; it is flexible, has high scorer reliability, and is not limited to simple factual knowledge. The ingenious test constructor can use multiple-choice items to test such functions as generalization, application of principles, and the ability to educe unfamiliar relationships.

Forced-choice items

Some personality tests are presented in a forced-choice format. They may, for example, force the person to choose one of two favourable words or phrases (*e.g.*, intelligent-handsome) as more descriptive of himself or one of two unfavourable terms as less descriptive (*e.g.*, stupid-ugly). Marking one choice yields a gain in score on some trait but may also preclude credit on another trait.

The forced-choice technique for self-appraisals is exemplified in a widely used interest inventory. Forced-choice ratings were introduced for evaluation of one military officer by another during World War II. They were an effort to avoid the preponderance of high ratings typically obtained with ordinary rating scales.

Falling between free- and limited-response tests is a type that requires a short answer, perhaps a single word or a number, for each item. When the required response is to fit into a blank in a sentence, the test is called a completion test. This type of test is susceptible to scorer unreliability.

A personality test to which a subject responds by interpreting a picture or by telling a story it suggests resembles an essay test except that responses ordinarily are oral. A personality inventory that requires the subject to indicate whether or not a descriptive phrase applies to him is of the limited-response type. A sentence-completion personality test that asks the subject to complete statements such as "I worry because . . ." is akin to the short-answer and completion types.

*Verbal versus performance tests.* A verbal (or symbol) test poses questions to which the subject supplies symbolic answers (in words or in other symbols, such as numbers). In performance tests, the subject actually executes some motor activity; *e.g.*, he assembles mechanical objects. Either the quality of performance as it takes place or its results may be rated.

The verbal test, requiring no special equipment and often being scorable by relatively unskilled evaluators, tends to be more practical than the performance test. Both types of devices also have counterparts in personality measurement, in which verbal tests as well as behaviour ratings are used.

*Written (group) versus oral (individual) tests.* In the 19th century, academic-achievement tests were usually given orally. The oral test is administered to one person at a time; written tests can be given simultaneously to a number of subjects. Oral tests of achievement, being uneconomical and prone to content and scorer unreliability, have been supplanted by written tests; notable exceptions include the testing of illiterates and the anachronistic oral examinations to which candidates for graduate degrees are liable.

Proponents of individually administered intelligence tests (*e.g.*, the Stanford-Binet) state that such face-to-face testing optimizes rapport and motivation, even among literate adult subjects. Oral tests of general aptitude remain popular, though numerous written group tests have been designed for the same purpose.

The interview may provide a personality measurement and, especially when it is standardized as to wording and order of questions and with a key for coding answers, may amount to an individual oral test. Group-administered personality inventories can be regarded as written group tests.

Interviews viewed as tests

*Appraisal by others versus self-appraisal.* In responding to personality inventories and rating scales, a person presumably reveals what he thinks he is like; *i.e.*, he appraises himself. Other instruments may reflect what one person thinks of another. Because self-appraisal often lacks objectivity, appraisal by another individual is common in such things as ratings for promotions. Ordinary tests of ability clearly involve evaluation of one person by another, although the subject's self-evaluation may intrude; *e.g.*, he may lack confidence to the point where he does not try to do his best.

*Projective tests.* The stimuli (*e.g.*, inkblots) in a projective test are intentionally made ambiguous and open to different interpretations in the expectation that each subject will project his own unique (idiosyncratic) reactions in his answers. Techniques for evaluating such responses range from the intuitive impressions of the rater to complex, coded schemes for scoring and interpretation that require extensive manuals; some projective tests are objectively scorable.

*Speed tests versus power tests.* A pure speed test is homogeneous in content (*e.g.*, a simple clerical checking test), the tasks being so easy that with unlimited time all but the most incompetent of subjects could deal with them successfully. The time allowed for testing is so short, however, that even the ablest subject is not expected to finish. A useful score is the number of correct answers made in a fixed time.

In contrast, a power test (*e.g.*, a general vocabulary test) contains items that vary in difficulty to the point that no subject is expected to get all items right even with unlimited time. In practice, a definite but ample time is set for power tests.

Speed tests are suitable for testing visual perception, numerical facility, and other abilities related to vocational success. Tests of psychomotor abilities (*e.g.*, eye-hand coordination) often involve speed. Power tests tend to be more relevant to such purposes as the evaluation of academic achievement, for which the highest level of difficulty at which a person can succeed is of greater interest than his speed on easy tasks.

In general, tests reflect unknown combinations of the effects of speed and power; many consist of items that vary considerably in difficulty, the time allowed being too limited to allow a large proportion of subjects to attempt all items.

Speed tests also are used in evaluating aspects of personality. The time for responses to key words in word-association tests (which call for one to respond to a word with the first word he thinks of) may be used to infer such personality disturbances as feelings of guilt. Speed of response may suggest temperamental characteristics, particularly at the extremes, excessively slow responses typifying depressed people and extremely rapid reactions being observed among elated, manic subjects.

Temperament

*Teacher-made versus standardized tests.* A distinction between teacher-made tests and standardized tests is often made in relation to tests used to assess academic achievement. Ordinarily, teachers do not attempt to construct tests of general or special aptitude or of personality traits. Teacher-made tests tend instead to be geared to narrow segments of curricular content (*e.g.*, a sixth-grade geography test). Standardized tests with carefully defined procedures for administration and scoring to insure uniformity can achieve broader goals. General principles of test construction and such considerations as reliability and validity apply to both types of test.

*Special measurement techniques.* Sociodrama and psychodrama were originally developed as psychotherapeutic techniques. In sociodrama, group members participate in unrehearsed drama to illuminate a general problem. Psychodrama centres on one individual in the group whose unique personal problem provides the theme. Re-

lated research techniques (*e.g.*, the sociometric test) can offer insight into interpersonal relationships. Individuals may be asked to specify members of a group whom they prefer as leader, playmate, or coworker. The choices made can then be charted in a sociogram, from which cliques or socially isolated individuals may be identified at a glance.

Research psychologists have grasped the sociometric approach as a means of measuring group cohesiveness and studying individual reactions to groups. The degree to which any group member chooses or is chosen beyond chance expectation may be calculated, and mathematical techniques may be used to determine the complex links among group members. Sociogram-choice scores have been useful in predicting such criteria as individual productivity in factory work, combat effectiveness, and social leadership.

#### DEVELOPMENT OF STANDARDIZED TESTS

*Item development.* Once the need for a test has been established, a plan to depict the content to be covered in it may be prepared. For achievement tests, the test plan may also indicate thinking skills to be evaluated. Detailed content headings can be immediately suggestive of test items. It is helpful if the plan specifies weights to be allotted to different topics, as well as the desired average score and the spread of item difficulties. Whether or not such an outline is made, the test constructor clearly must understand the purpose of the test, the universe of content to be sampled, and the forms of the items to be used.

*Tryouts and item analysis.* A set of test questions is first administered to a small group of people deemed to be representative of the population for which the final test is intended. The trial run is planned to provide a check on instructions for administering and taking the test and intended time allowances, and it can reveal ambiguities in the test content. After adjustments, surviving items are administered to a larger, ostensibly representative group. The resulting data permit computation of a difficulty index for each item (often taken as the percentage of the subjects who respond correctly) and of an item-test or item-subtest discrimination index (*e.g.*, a coefficient of correlation specifying the relationship of each item with total test score or subtest score).

If it is feasible to do so, measures of the relation of each item to independent criteria (*e.g.*, grades earned in school) are obtained to provide item validation. Items that are too easy or too difficult are discarded; those within a desired range of difficulty are identified. If internal consistency is sought, items that are found to be unrelated to either a total score or an appropriate subtest score are ruled out, and items that are related to available external criterion measures are identified. Those items that show the most efficiency in predicting an external criterion (highest validity) usually are preferred over those that contribute only to internal consistency (reliability).

Estimates of reliability for the entire set of items, as well as for those to be retained, commonly are calculated. If the reliability estimate is deemed to be too low, items may be added. Each alternative in multiple-choice items also may be examined statistically. Weak incorrect alternatives can be replaced, and those that are unduly attractive to higher scoring subjects may be modified.

*Cross validation.* Item-selection procedures are subject to chance errors in sampling test subjects, and statistical values obtained in pretesting are usually checked (cross validated) with one or more additional samples of subjects. Typically, it is found that cross-validation values tend to shrink for many of the items that emerged as best in the original data, and further items may be found to warrant discard. Measures of correlation between total test score and scores from other, better known tests are often sought by test users.

*Differential weighting.* Some test items may appear to deserve extra, positive weight; some answers in multiple-choice items, though keyed as wrong, seem better than others in that they attract people who score high general-

ly. The bulk of theoretical logic and empirical evidence, nonetheless, is that unit weights for selected items and zero weights for discarded items and dichotomous (right versus wrong) scoring for multiple-choice items serve almost as effectively as more complicated scoring. Painstaking efforts to weight items generally are not worth the trouble.

Negative weight for wrong answers is usually avoided as presenting undue complication. In multiple-choice items, the number of answers a subject knows, in contrast to the number he gets right (which will include some lucky guesses), can be estimated by formula. But such an average correction will overpenalize the unlucky and underpenalize the lucky. If the instruction is not to guess, it is variously interpreted by persons of different temperament; those who decide to guess despite the ban are often helped by partial knowledge and tend to do better.

A responsible tactic is to try to reduce these differences by directing subjects to respond to every question, even if they must guess. Such instructions are inappropriate for some competitive speed tests, since candidates who mark items very rapidly and with no attention to accuracy will seem to excel if speed is the only basis for scoring; that is, unless wrong answers are penalized.

*Norms for standardized tests.* Test norms consist of data that indicate the relative standing of individuals who have taken a test. Usually, a subject's raw score (*e.g.*, the number of his answers that agree with the scoring key) is compared with the raw scores of other subjects through some system of norms. In the absence of such a comparison the raw score has little meaning.

Numerical values called centiles (or percentiles) serve as the basis for one widely applicable system of norms. From a distribution of a group's raw scores, the percentage of subjects falling below each raw score can be found. Thus, any raw score can be interpreted relative to the performance of the reference (or normative) group—eighth graders, five-year-olds, institutional inmates, job applicants. The centile rank corresponding to each raw score, therefore, will show the percentage of subjects who scored below that point. Thus, 25 percent of the normative group earn scores lower than the 25th centile; and an average called the median corresponds to the 50th centile.

Another class of norm system (standard scores) is based on how far each raw score falls above or below an average score, the arithmetic mean. One resulting type of standard score, symbolized as  $z$ , is positive (*e.g.*,  $+1.69$  or  $+2.43$ ) for a raw score above the mean and negative for a raw score below the mean; its further interpretation requires some statistical understanding, and it usually shows fractional (or equivalent decimal) values. Negative and fractional values can, however, be avoided in practice by using other types of standard scores obtained by multiplying  $z$  scores by an arbitrarily selected constant (say, 10) and by adding another constant (say, 50, which changes the  $z$  score mean of zero to a new mean of 50). Such changes of constants do not alter the essential characteristics of the underlying set of  $z$  scores.

The French psychologist Alfred Binet, in pioneering the development of tests of intelligence, listed test items along a normative scale on the basis of the chronological age (actual age in years and months) of groups of children that passed them. A mental-age score (*e.g.*, seven) was assigned to each subject, indicating the chronological age (*e.g.*, seven years old) in the reference sample for which his raw score was the mean. But mental age is not a direct index of brightness; a mental age of seven in a ten-year-old is different from the same mental age in a four-year-old.

To correct for this, a later development was a form of IQ (intelligence quotient), computed as the ratio of the subject's mental age to his chronological age, multiplied by 100. (Thus, the IQ made it easy to tell if a child was bright or dull for his age.)

Ratio IQs for younger age groups exhibit means close to 100 and spreads of roughly 45 points above and below 100. The classical ratio IQ has been largely supplanted by

Planning  
the test

Centiles;  
standard  
scores;  
mental age  
and  
IQ norms

the deviation IQ, mainly because the spread around the average has not been uniform due to different ranges of item difficulty at different age levels. The deviation IQ, a type of standard score, has a mean of 100 and a standard deviation of 16 for each age level. Current practice with the Stanford-Binet test reflects the finding that average performance on the test does not increase beyond age 18. Therefore, the chronological age of any individual older than 18 is taken as 18 for the purpose of determining his IQ.

#### ASSESSING TEST STRUCTURE

*Factor analysis.* Test items that measure the same characteristic tend to be positively correlated with one another. A British psychologist, Charles Edward Spearman, systematically explored such intercorrelations to provide evidence that much of the variability in scores that children earn on tests of intelligence depends on a general underlying factor that he called *g*. In the United States, Thurstone developed a statistical technique called multiple-factor analysis, with which he was able to demonstrate additional (special rather than general) factors that tend to crystallize as people grow older. He provided evidence that, among adults, one specific talent (such as verbal comprehension) is distinguishable from another (e.g., numerical ability).

Early computational methods in factor analysis have been supplanted by mathematically more elegant, computer-generated solutions; and the general technique is widely applicable beyond the field of psychological measurement.

Rooted in extensive applications of factor analysis, a structure-of-intellect model developed by an American psychologist, J.P. Guilford, posited a very large number of factors of intelligence. Guilford envisaged three intersecting dimensions corresponding to four kinds of test content, five kinds of intellectual operation, and six kinds of product. Each of the 120 cells in the cube thus generated was hypothesized to represent a separate ability, each as a distinct factor of intellect. Educational and vocational counselors usually prefer a substantially smaller number of scores than the 120 that are implied by this model.

*Alternatives to factor analysis.* Especially with respect to personality measures, simple techniques called cluster analysis have been proposed as alternatives to the statistical complications of factor analysis. In one form of cluster analysis, tables of correlation coefficients are simply inspected in an effort to find sets (clusters) of items or test scores that show high relationships among themselves.

Early forms of cluster analysis introduced in the 1930s required laborious visual inspection and time-consuming computations. With the advent of high-speed computers, new methods proliferated rapidly. Although it has been argued that clusters bear a closer relation to reality than do statistically defined factors, the correspondence appears to be at a descriptive rather than at an interpretive level. Taken separately or together, various types of cluster analysis fail to yield equivalent results; a number of authorities thus regard them as adjuncts to, rather than substitutes for, factor analysis.

Techniques that are quite similar to the usual factor-analytic approach but provide different insights are those related to inverse factor analysis (based on intercorrelations among persons instead of among tests). One such method begins with what is called a *Q-sort*, in which a subject sorts words or other stimuli into categories on the basis of his preference so that they form a bell-shaped (normal) distribution.

This method is widely applicable to items from personality tests; first, correlations of data obtained from two persons' *Q*-sorts of the same items are computed. The inverse factor analysis of a matrix of such intercorrelations yields factors indicative of common ways people have of reacting to stimuli.

Another popular technique (the semantic differential) for detecting underlying variables was offered by Charles E. Osgood, an American psychologist. In this method,

the name of any object or concept (e.g., religion or piety) is presented to an individual, who rates it on a series of seven-point scales defined semantically by pairs of adjectives (such as "good" versus "bad" or "valuable" versus "worthless"). When different concepts receive similar ratings on the semantic scales, they show evidence of representing the same underlying factor. The method has been applied mainly to psychological problems involving attitudes.

*Profile analysis.* With the fractionation of tests (e.g., to yield scores on separate factors or clusters), new concern has arisen for interpreting differences among scores on the underlying variables, however conceived. Scores of an individual on several such measures can be plotted graphically as a profile; for direct comparability, all raw scores may be expressed in terms of standard scores that have equal means and variabilities. The difference between any pair of scores that have less than perfect reliability tends to be less reliable than either, and fluctuations in the graph should be interpreted cautiously. Nevertheless, various features of an individual's profile may be examined: scatter (fluctuation from one measure to another) and relative level of performance on different measures. (The particular shape of the graph, it should be noted, partly depends upon the arbitrary order in which measures are listed.) One may also statistically express the degree of similarity between any two profiles. Such statistical measures of pattern similarity permit quantitative comparison of profiles for different persons, of profiles of the same individual's performance at different times, of individual with group profiles, or of one group profile with another. Comparison of an individual's profile with similar graphs representing the means for varied occupational groups, for example, is useful for vocational guidance or personnel selection.

*Prospects.* Despite progress over the last century, psychological measurement warrants improvement. Brief appraisals of individual potentiality—whether in educational, vocational, or personal adjustment settings—are recognizably far from perfect. The complexities of human behaviour attributable to the myriad effects of unanticipated combinations of genes, prenatal influences, and vagaries of environmental effects make it surprising that a relatively brief test or even a full day of testing can predict future behaviour to any extent at all beyond a chance level.

Predictions are successful beyond chance expectations, however. And clearly the forecasts of psychometricians and other specialists in educational and psychological measurement have much to commend them in contrast with subjective appraisals of sooth-sayers, phrenologists, astrologers, or untrained personnel interviewers who happen to like people.

## Measurement, Theory of

Measurement theory studies the practice of associating numbers with objects and empirical phenomena. It attempts to understand which qualitative relationships lead to numerical assignments that reflect the structure

Q-sort;  
inverse  
factor  
analysis

of these relationships, to account for the ways in which different measures relate to one another, and to study the problems of error in the measurement process.

#### HISTORY AND NATURE OF MEASUREMENT THEORY

An early and relatively abstract theory of magnitudes was developed in the 4th century BC by two mathematicians, Eudoxus of Cnidus, probably a member of Plato's Academy, and Theaetetus, author of the book on the regular solids and one of those on irrational numbers in Euclid's *Elements*, in which their theory of magnitudes was given its fully developed presentation. Theirs was a highly sophisticated theory of measurement. Historical evidence suggests that it was developed for purely theoretical purposes, to account for incommensurable magnitudes—pairs of numbers, such as 1 and the square root of 2, for which no third number exists of which both are even (or integral) multiples—rather than to solve any practical problems, such as those of surveying. Problems of measurement, of both a theoretical and a practical sort, continued to be discussed throughout ancient times and during the Middle Ages.

In modern times, Euclid's view of the theory of magnitudes was still relevant as late as the 18th century; it appeared, for example, in Isaac Newton's *Arithmetica Universalis* (2nd ed., 1728). The modern, axiomatic treatment of the theory—*i.e.*, its logical development from fundamental concepts and axioms—can be dated from a famous paper by Herman Ludwig Ferdinand von Helmholtz, a German philosopher and wide-ranging scientist, entitled "Zählen und Messen erkenntnistheoretisch betrachtet" (1887; Eng. trans., "Counting and Measuring," 1930). Considerable impetus was given by a classical work of Ludwig Otto Hölder, a German mathematician, entitled "Die Axiome der Quantität und die Lehre vom Mass" (1901; "The Axioms of Quantity and the Theory of Measure"), in which he provided two sets of axioms, one for the measurement (or, as he said, "the quantity") of additive attributes, such as mass, which can be built up by addition of parts to form a total bulk, and another set for nonadditive attributes involving the measurement of intervals, as in temperature or longitude. The tradition of Helmholtz and Hölder has been of importance primarily in the physical sciences.

The consideration of measurement in the social sciences, especially in economics, also has had a long history. As early as the 18th century, Jeremy Bentham, a British Utilitarian moralist, in a treatise, *The Principles of Morals and Legislation* (1789), attempted to provide a theory for the measurement of utility, or value. In the 19th century there was an effort to establish that much of economic theory could be developed solely on the basis of ordinal preferences among the economic goods being studied, without any more demanding kind of numerical measurement. The work of Vilfredo Pareto, an Italian economist and sociologist, entitled *Manuale di economia politica* (1906; "Handbook of Political Economics"), was especially important in this connection. In the mid-20th century the study of measurement in economics and in psychology was stimulated by the theory of utility set forth in *Theory of Games and Economic Behavior* (1944) by the mathematician John von Neumann, a scientist of unusual breadth, and the economist, Oskar Morgenstern. It makes use of the formation of so-called risky alternatives (see below *Economics and psychology*).

An examination of specific examples of axiomatic measurement can lead to a general view of measurement theory. The first problem for any such theory is to justify the assignment of numbers to objects or phenomena—to pass from empirical procedures and operations to a numerical representation of these procedures. From an axiomatic standpoint, the problem—known as the representation problem—is first to characterize the formal or abstract properties of these procedures and observations and then to show mathematically that these axioms permit the construction of a numerical assignment in which familiar abstract relations and operations, such as "is greater than or equal to" (symbolized  $\geq$ ) and "plus"

(+), correspond structurally to the empirical (or concrete) relations and operations.

The second fundamental problem is that of the uniqueness of the representation—*i.e.*, how close it is to being the only possible representation of its type. The representation of mass, for example, is unique in every respect except the choice of unit; *e.g.*, the representation is different for pounds than for grams or grains. Ordinary measurements of temperature, however, are unique in everything except the choice of both unit and origin—the Celsius and Fahrenheit scales differ not only in the size of unit but also in the zero point. A U.S. psychophysicist, S. Smith Stevens, was among the first to place great emphasis on the uniqueness of measurement in relation to the problem of units and the consequences that this uniqueness has for data handling.

A subject closely related to the uniqueness of physical measurement is dimensional analysis, which, in a broad sense, attempts to explain why the various physical measures exhibit simple relations in the fundamental equations of classical physics. If length, time, and mass are taken to be the fundamental dimensions of mechanics, for example, then all other quantities, such as force or momentum, can be represented simply as products of powers of these dimensions—a fact that has strong implications for the forms of physical laws (see below *Universal, system, and material constants*).

A third central problem for the theory of measurement is error. In spite of the early development of precise astronomical measurement, no systematic theory of observational error appears to have been developed until the 18th century, first in an article by Thomas Simpson, an English mathematician, in 1757, and then in the fundamental work of two French mathematicians, Joseph-Louis, comte de Lagrange, who worked on the theory of numbers and celestial mechanics, and Pierre-Simon, marquis de Laplace, also an astronomer, famous for his fundamental work, *Traité de mécanique céleste* (1798–1827; *Celestial Mechanics*, 1966). Today, any really significant physical measurement is routinely reported together with some indication of the probable error, and theories are tested by confirming them within the errors of measurement. In the classical tests of Albert Einstein's general theory of relativity, for example, the discrepancies between predictions and observations fell mainly within the estimated errors of measurement (for further discussion of errors of measurement, see below *The problem of error*).

#### AXIOMATIC BASIS OF MEASUREMENT

Axiom systems for measurement differ in the amount and type of structure involved. All include an ordering relation, but that alone is not enough to formulate many scientific laws because its numerical representation is not closely prescribed. Additional structure and an increased uniqueness of the representation arise either by having an empirical operation of addition (extensive measurement), or by having entities that have several independent components (difference and conjoint measurement), or by other primitives that lead to a geometric representation.

**Axioms of order.** Whenever a measurement is made, it is done in such a way that the order induced on the objects by the assigned measure is the same as that obtained by the basic empirical operation in question. Such measures are said to be order preserving. Of course, every numerical inequality involved in measurement is transitive (*i.e.*, such that  $x \geq y$  and  $y \geq z$  implies that  $x \geq z$ ) and connected (*i.e.*, either  $x \geq y$  or  $y \geq x$ ). It is therefore necessary that the empirical ordering—symbolized  $\geq$  (with  $\sim$  instead of  $-$  to suggest real entities)—be transitive and connected in order for a representation of it to be possible by means of  $\geq$ . Relations exhibiting these two properties are called weak orders, in which "weak" simply means that indifference (symbolized  $\sim$ )—in which  $x \sim y \equiv x \geq y$  and  $y \geq x$ —is not necessarily equality (using  $\equiv$  to mean "if and only if"). Not every weak order, however, has an order-preserving numerical representation; the lexicographic

Axioms for binary relations

History of magnitudes theory

The three basic problems of measurement theory

order in the plane  $(x,y) \geq (x',y') \equiv x > x' \text{ or } x = x' \text{ and } y > y'$ , is a counterexample. A second, independent property of numbers, which must in turn be reflected in the empirical ordering, is that rational numbers—*i.e.*, numbers expressible as the quotient of two integers—are order-dense (*i.e.*, they are such that between any two distinct real numbers lies a rational number) and countable (*i.e.*, they can be placed in one-to-one correspondence with the integers).

In 1895 it was shown by Georg Cantor, a German mathematician, that, for any empirical ordering, the existence of a numerical representation that preserves its order is equivalent to the ordering's being a weak one that includes in its domain a countable, order-dense subset. Any two such representations are so related that one can be mapped upon the other in a strictly increasing fashion.

Though various ordinal categorizations are widely used (*e.g.*, brightness of stars, magnitude of earthquakes, hardness of minerals), the fact that equivalent ordinal representations are seldom in simple proportion to one another makes them unsatisfactory in the statement of many scientific laws. To increase the uniqueness of the representation, some structure in addition to order must be preserved by the representation.

**Axioms of extension.** For many physical attributes—including mass, length, time duration, and probability—the objects or events exhibiting the attribute may be combined, or concatenated, to form new objects or events that also exhibit the attribute. Both alone and combined, for example, objects have mass. Denoting the concatenation of  $a$  and  $b$  by  $a \circ b$ , the assignment (designated  $\phi$ ) of a given set of numbers to the objects is called an extensive representation of the empirical ordering  $\geq$  and the concatenation  $\circ$ , provided that it is not only order preserving but also additive in the sense that  $\phi(a \circ b) = \phi(a) + \phi(b)$ .

Theories that are intended to account for the existence of such numerical representations must state empirical laws about ordering and concatenation separately, as well as how they interrelate. The key property of an empirical ordering is that it is a weak order, and that of a concatenation is that it is insensitive to the order of combination—concatenation is weakly commutative (*i.e.*, its order can be reversed),  $a \circ b \sim b \circ a$ , and weakly associative (*i.e.*, its terms can be regrouped),  $(a \circ b) \circ c \sim a \circ (b \circ c)$ —in which  $\sim$  indicates an equivalent formulation. The key property relating them, weak monotonicity, is that the empirical ordering  $a \geq b$  holds if and only if the ordering of its concatenation with any object  $c$ ,  $a \circ c \geq b \circ c$ , also holds. As in ordinal measurement, a further and more subtle property, called Archimedean, is needed; this asserts that the elements within the structure are commensurable with one another. This property is formally analogous to the numerical Archimedean property that if  $x > y > 0$ , then for some integer  $n$ ,  $ny \geq x$  (meaning  $y$  is not “infinitesimally” small relative to  $x$ ). With these stipulations, the numerical representation can be constructed.

The basic idea of the construction is simple and, in somewhat modified form, is widely used to carry out fundamental measurement. The measurer first chooses some object  $u$ , such as a foot rule, to be the unit of measurement. For any object  $a$  (say a house stud), he then finds other objects (studs) that are equivalent to  $a$  in the attribute in question (length). He concatenates these by laying them end-to-end in a straight line. Denoting by  $na$  the concatenation of any  $n$  of them, he now finds how many copies of  $u$ , say  $m(n)$ , are needed to approximate  $na$ ; *i.e.*,  $[m(n) + 1]u \geq na \geq m(n)u$ . The limit toward which  $m(n)/n$  tends as  $n$  approaches infinity exists and is defined to be  $\phi(a)$ , which is the measurement sought; it can be shown to be order preserving and additive. In contrast to ordinal measurement, such an extensive representation is almost unique: it is determined except for a positive multiplicative constant or coefficient setting the scale; or, what is the same thing, only the choice of the unit is arbitrary. As a result, such a representation is called a ratio scale.

Sequences such as  $na$ ,  $n = 1, 2, \dots$ , being ubiquitous in measurement practice, are called standard sequences. Practical examples are standard sets of weights in multiples of a gram and the metre rule, subdivided into millimetres.

For some purposes, including the development of other kinds of measurement—*e.g.*, difference and probability measurement—it is necessary to generalize the theory to cover concatenation operations ( $\circ$ ) that are defined only for some pairs of objects and not for others. Probability, for example, is not additive over all pairs of events, but only over those that are disjoint. Such theories, developed during the 1950s and 1960s, all assume that certain empirical inequalities have solutions. One form of such solvability is: if  $a > b$ , then there exists a  $c$  such that  $c$  and  $b$  can be concatenated and  $a \geq c \circ b$ .

**Axioms of difference.** Length, but not mass, may be treated also in terms of intervals  $(a, b)$  on a line. Here the empirical ordering  $\geq$  is a quaternary rather than a binary relation, since it involves the comparison of two pairs, and so four points, such as the end points of two intervals; and concatenation is defined only for adjacent intervals; *i.e.*,

$$(a,b) \circ (b,c) = (a,c).$$

In addition to weak ordering, solvability, and Archimedean properties, various other axioms, depending on the exact representation to be constructed, must be satisfied. Two important representations are the algebraic difference one, in which an empirical ordering holds if and only if the differences of its elements form an ordered representation; *i.e.*,

$$(a,b) \geq (c,d) \equiv \phi(a) - \phi(b) \geq \phi(c) - \phi(d),$$

for which a key axiom is that the ordering is preserved through an interchange of arguments; *i.e.*,

$$(a,b) \geq (c,d) \equiv (a,c) \geq (b,d),$$

and the absolute difference representation, in which an empirical ordering holds if and only if the absolute values (symbolized  $|\dots|$ ) of such differences are ordered; *i.e.*,

$$(a,b) \geq (c,d) \equiv |\phi(a) - \phi(b)| \geq |\phi(c) - \phi(d)|,$$

for which key axioms are that any interval is at least as large as the null interval; *i.e.*,  $(a,b) \geq (a,a)$  and that an interval is unordered, or the same when measured “backwards”; *i.e.*,  $(a,b) \sim (b,a)$ .

Such representations are called interval scales, because they are unique in every respect except for the possibilities of multiplication by a positive constant and addition of a constant; *i.e.*, both the unit and zero of the measure are arbitrary, and the equality of intervals is preserved through all transformations generated by altering these two scale factors.

**Axioms of conjointness.** A major hindrance to the development of fundamental measurement, other than probability, outside physics has been the failure to uncover suitable empirical concatenation operations for attributes such as utility, loudness, intelligence, or hunger. An alternative approach, implicit in much derived measurement in classical physics, has recently been made completely explicit in the behavioral sciences. It rests on the fact that many—indeed, most—attributes are defined for entities having at least two independent components, each of which affect the attribute: kinetic energy and momentum, for example, are both affected by mass and velocity; mass is varied by both changing density and volume; preference among gambles is manipulated both by outcomes and by the probabilities of their occurring; and loudness of tones depends on frequency as well as intensity. In conjoint-measurement theories, the way in which each component affects the attribute in question is studied by discovering which changes must be made in one component to compensate for changes in the other. When measures for the components already exist, the exchange relationship between the two components is often presented graphically in the form of so-called equal-attribute (or indifference) curves.

The simplest representation is additive—or, by making

Order  
and  
concatenation

Axioms  
for  
quaternary  
relations

Additive  
and  
poly-  
nomial  
representations

an exponential transformation, multiplicative (which is the way it is usually represented in physics)—in the sense that numerical functions  $\phi_1$  and  $\phi_2$  of the two components exist such that an empirical inequality holds if and only if the sums of these functions of its elements exhibit a numerical inequality in the same direction; *i.e.*,

$$(a_1, a_2) \geq (b_1, b_2) \equiv \phi_1(a_1) + \phi_2(a_2) \geq \phi_1(b_1) + \phi_2(b_2).$$

Axioms sufficient for such a numerical representation consist of weak ordering, a form of solvability, an Archimedean property, and what amount to analogues of weak monotonicity. The simplest of these, independence, states that an inequality of one component with a common value—*e.g.*,  $(a_1, x) \geq (b_1, x)$ —is not altered by substituting any other common value  $y$  for  $x$ . When this property is appropriately generalized to three or more components, no more stipulations are needed; for only two components, however, it must be supplemented by another property, called the Thomsen condition. In the special case when the components each have only a finite number of elements, a theoretical schema of necessary and sufficient conditions is known. Such additive measures are interval scales; but the multiplicative constant or scale factor is the same for all  $\phi_i$ .

Other ordered representations also have been studied. Especially well understood are certain simple polynomials on several components. For three components there are four such simple polynomials: additive ( $\phi_1 + \phi_2 + \phi_3$ ), multiplicative ( $\phi_1\phi_2\phi_3$ ), or a combination of both, either  $(\phi_1\phi_2 + \phi_3)$  or  $\phi_1(\phi_2 + \phi_3)$ . (In these expressions the subscripted indices 1, 2, 3 can, of course, appear in any of their permutations.)

**Axioms of geometry.** Historically, numerical-representation and uniqueness theorems for geometry have been at least as important as those for extensive measurement and more important than the other kinds of measurement considered above. Since the discovery of analytic geometry in the 17th century, by René Descartes, the earliest important modern philosopher, the representation of geometric points by a pair of numbers (the coordinates), in the case of a plane, or a triple of numbers, in the case of space, has been of fundamental importance not only in geometry but also in much of the physical sciences.

The view that the formal adequacy of axioms for geometry is established by proving a representation theorem became explicit in the latter part of the 19th century. The most important single work may have been the classic *Grundlagen der Geometrie* (1899; *The Foundations of Geometry*, 1902), by David Hilbert. Today the distinctive feature of geometric measurement is that the representation is made in terms of pairs or triples or, in some applications in the social sciences,  $n$ -tuples of numbers, rather than in terms of simple numbers, as in extensive, difference, or conjoint measurement.

Much of the literature on the foundations of geometry has been devoted to showing the different sorts of qualitative concepts that can be taken as basic or primitive in stating the axioms of geometry. One of the simplest sets of axioms, given by Alfred Tarski, a Polish-U.S. mathematician and logician, employs the concept of equidistance and that of betweenness for three points that lie on a line. Many of the properties of the quaternary relation of absolute difference discussed above (see above *Axioms of difference*) are also properties of equidistance viewed as a quaternary relation among four points, *viz.*,  $(a, b) \sim (c, d)$  just when the distance between  $a$  and  $b$  is equivalent to that between  $c$  and  $d$ .

#### GENERAL PRINCIPLES AND PROBLEMS OF MEASUREMENT THEORY

**Dimensions and units of measurement.** Each measurable attribute constitutes a dimension; inasmuch as these are not all independent, some can be expressed as (power) functions of others—a fact that underlies both the method of dimensional analysis and the existence of coherent sets of units.

*Dimensions and their algebra.* Many attributes are extensively measurable. Some dimensions, however, such as density, are not extensive; and in such cases a law can be

stipulated that allows the derived, nonextensive measure to be expressed as a product of powers of two extensive measures. This possibility arises from two empirical facts. First, mass varies both with substance and volume, and the ordering that it induces over substance-volume pairs is such that a multiplicative conjoint representation exists. Thus, the conjoint measure of substance can be expressed as a product of its measure of mass and the reciprocal of its measure of volume. Both of these attributes, of course, have independent extensive measures. Second, a qualitative law, known as a law of similitude, relates concatenations of volume to those of mass via the conjoint ordering. From this law, it is possible to prove that the conjoint and extensive measures are power functions of each other; indeed, in this case, the conjoint measure of substance is, for an appropriate choice of exponent, simply the ratio of the extensive measure of mass to that of volume; *i.e.*, density. In cases such as the dependency of kinetic energy and momentum on mass and velocity, the conjoint components are both extensive and the law relating them via the conjoint ordering is called a law of exchange; interesting cases of such laws appear to involve quantities that enter laws of conservation, such as that of momentum and energy. In any event, all nonextensive measures of classical physics are expressible as products of powers of extensive ones. Some such model is the usual starting point of dimensional analysis.

*Universal, system, and material constants.* Sometimes two apparently distinct attributes are not independent but covariant. In the classic example of inertial mass and gravitational mass, the covariation is described by a constant known as the universal gravitational constant. This example should be contrasted with the covariation of two measures for specific systems. Mass and volume, for example, covary perfectly for any homogeneous substance, or length and force (within limits) for a specific spring. The constants describing such local covariation, called material or system constants (depending on the context), constitute a form of derived measurement.

Many more complex physical laws may be described as stating combinations of values—configurations—of certain dimensions that can obtain in a particular class of physical system. Such laws include not only measurable dimensions of the system but also system and material constants characteristic of the particular system in question. A curious and not fully understood fact of physical theory is a principle first explicitly enunciated in 1914 by the U.S. analyst Edgar Buckingham, the so-called  $\pi$ -theorem, according to which, when the dimensional measures and constants of some physical law are grouped into one or more terms in which the dimensions all cancel out, some function of these dimensionless quantities (or  $\pi$ -arguments) must equal zero for any realizable configuration of the system.

*Dimensional analysis.* In dimensional analysis, the investigator in part attempts to discover a particular physical law by assuming that it has the character of a  $\pi$ -theorem and that the relevant variables and constants are known. When they are known (an important proviso), a simple calculus permits him to discover all of the dimensionless terms. In many cases, this yields considerable insight into the law describing the system; sometimes empirical observations, as in a wind tunnel, are used to obtain an empirical approximation to the unknown function of the  $\pi$ -arguments.

*Primary and derived units.* One is free to choose the unit of measurement for each dimension, whereupon all other values are uniquely determined. Since some dimensions are related to others as products of powers, considerable simplicity is effected by choosing arbitrarily only the units of the dimensions in a maximum set of independent dimensions (base) and then letting the known dependencies determine all of the other units. Such a system of units is called coherent; those of the base are said to be primary, and all others are derived, or secondary. At the Tenth General Conference on Weights and Measures (1954), length, mass, time duration, temperature, and either charge or current were adopted as the base dimensions, with units: metre, kilogram, second,

Units of  
measure-  
ment

Dimen-  
sions and  
constants

degree absolute (Kelvin), and the coulomb or ampere, respectively. This system is abbreviated MKSA.

For effective scientific communication, it is essential that each unit be specified and reproducible to some known degree of accuracy. The ideal definition of a unit is in terms of some highly invariant and readily reproduced or observable natural phenomenon, such as the wavelength of a highly reproducible, monochromatic light source. Less ideal, although still used, are carefully made and maintained unique objects, such as the standard metre in Paris, which have the drawback of being in danger of damage or deterioration.

**Measurement via nonmeasurement theories.** Few actual measurements are carried out in a fundamental manner using only ordering and concatenation information, because such procedures, when possible, are too slow and expensive, and in fact they are not always possible. It will be helpful to describe some of the alternative procedures employed in physics and psychology.

Indirect  
measure-  
ment

*In physics.* At least three kinds of indirect measurement occur in physics. First, permanent standard sequences are sometimes constructed—as for weight and length—and measurement then involves approximate matching against members of the sequence. Precision and standardization of conditions are important in making such measurements.

Second, when a law is found to hold between two or more variables, and system or material constants enter—such as the density and viscosity of a fluid—these constants are measured indirectly in terms of other measures by means of the law.

Third, various theories of specific physical phenomena may provide indirect means of measuring an attribute that may otherwise be difficult to measure; and such theories may, in some cases, lead to convenient measuring devices. A mechanical displacement in a piece of equipment—a spring balance, for example, or a voltmeter—may be systematically related to some other attribute (force or potential). In such measurement, considerable care must be taken to calibrate the apparatus in terms of fundamental measures of the two attributes. Another sort of example is provided by the measurement of astronomical distances in terms of the shift of the object's spectral lines toward the red, a technique that is based on a theory of the existence of a systematic relation between the velocity of recession and the distance of a galaxy, and one about the Doppler effect, which spreads out the waves from a receding light source and thus reduces their frequency.

*In psychology.* Since few, if any, psychological attributes are currently measured fundamentally, no approximate measurement using standard sequences is possible. Whether conjoint measurement will alter this situation is not yet clear.

Most formalized theory in psychology is stated in terms of physical characteristics of the stimuli and responses: various physical and temporal aspects of the stimuli, the physical nature and probability structure of the rewards provided for appropriate performance, and the time and nature of the response made. Frequently, some of the data are collapsed into relative frequencies, which are interpreted as estimates of conditional probabilities. Though, in principle, a theory could simply assert the dependence of response measures upon the various physical measures of the independent variables, this has not proved practicable; and in most theories some sort of internal representation of the stimuli is postulated to exist in the subject. Decision processes are assumed to operate on these representations, which decisions then lead to the response. Such models include free parameters that often have natural interpretations as psychological measures. If these can be estimated from the observable data, as is frequently possible, they constitute a type of indirect psychological measurement not unlike the second class of physical ones. In many cases, the parameters seem to play a role much like that of time constants in physical systems.

There is no satisfactory analogue to the third method enumerated above for physics, because no sufficiently

elaborate and accepted psychological theories yet exist. Many so-called operational measures of psychological concepts—hours of deprivation for hunger or skin resistance for anxiety—pretend to be of this type, but they are not. The absence of questions of calibration is but one indication of the inadequacy of such measures.

**The problem of error.** Inasmuch as measurement, in practice, is always fraught with error, the types and basic theory of error must be examined.

*Types of error.* The classification of errors used in the theory of observations has been of great importance, both historically and practically, especially in astronomy. In that theory, four kinds of errors of observation are ordinarily distinguished. There are instrumental errors, such as those of the telescope in astronomy, that have as their source inaccuracies in the instruments used for observation. There are personal errors, sometimes called errors due to the personal equation, that arise from the different practices and reactions of human observers. Nevil Maskelyne, the fifth astronomer royal of Great Britain, provided a famous example of such personal differences in observation when he discharged his assistant in 1796 because he had observed the transits of stars and planets about a half a second later than Maskelyne himself. Systematic errors are a third kind of error of observation. A typical example of this kind would be the measurement of atmospheric pressures corrected to sea level in terms of a faulty value for the height of the station. Such an error would introduce a systematic discrepancy in all observations of atmospheric pressure for that station. The fourth and most important kind of error of observation is that of random error, so called because its causes are not understood. This type of error reflects the fact that, when observers make repeated measurements, some variation in the results will occur no matter how accurate the instruments may be.

In principle, all four types of error need to be taken into account in refining observations. In practice, however, the attention of theorists has been directed mainly to random errors. Since the end of the 18th century, the application of probabilistic methods through the estimation of random errors has been extensive.

Next to errors of observation, perhaps the most important kind of error is that due to sampling. If an investigator, for instance, wishes to know something about the television-viewing habits of the population, he ordinarily cannot plan to observe the viewing habits of each and every member of the population. He selects, instead, a sample of the population and from that sample infers the viewing habits of all. Errors of sampling, of course, are expected; but, the larger the sample, other things being equal, the smaller the sampling error will be. An elaborate statistical theory, both for constructing the kind of sample that should be drawn and for making inferences from the sample data to the characteristics of the population, is widely used (see STATISTICS).

Still another classification of errors involves the division into direct and indirect errors. If a surveyor, for example, measures the angles of a triangle, direct errors can arise from the measurement of the first two angles. These errors will induce errors of measurement indirectly into the value of the third angle, which he will compute instead of measuring directly. In advanced scientific practice, a large number of errors of measurement are indirect, because elaborate theory and a wide variety of ancillary measurements enter into the measurements of significant quantities, such as the velocity of light or the magnitude of the Earth's mass.

Still other kinds of errors are concerned with interpolation and extrapolation. In using mathematical tables, for example, one often wants to read a table to one more decimal place than those tabulated, and it is common to make a linear interpolation between two adjacent figures in order to extend the table. Since the curve reflected in the figures, however, may in fact be parabolic or exponential or the like, such an assumption of linearity may generate error. Similar problems arise in extrapolating beyond the limits of a given set of values. In both cases it is possible to compute the approximate error introduced.

Errors of  
observa-  
tion

Other  
kinds of  
error

Standard error and variance

*Theory of errors.* The theory of errors has received a great deal of attention in the development of science and mathematics, especially in that of probability theory. Though, historically, the concept of standard error has been most widely used in reporting the results of measurement, in modern statistics the concept is of less importance. The computation of the standard error is based on the assumption that repeated observations of the same phenomenon—for example, the velocity of light—are to be assigned equal weight. It is useful to explore a case of  $n$  observations of a phenomenon,  $x_1, \dots, x_n$ . If  $\bar{x}$  is the mean of these observations—i.e.,  $\bar{x} = \frac{1}{n}(x_1 + x_2 + \dots + x_n)$ —and  $s$  is the sample standard deviation, defined as the square root of the mean squared deviation—i.e.,

$$s = \sqrt{\frac{1}{n}[(x_1 - \bar{x})^2 + \dots + (x_n - \bar{x})^2]},$$

then the standard error of  $\bar{x}$  is  $s/\sqrt{n}$ , and it is said that the “true” value of the observed variable lies in the interval between  $\bar{x}$  plus  $s/\sqrt{n}$  and  $\bar{x}$  minus  $s/\sqrt{n}$ . A more detailed interpretation of the standard error and a critical scrutiny of the assumptions underlying its use are beyond the scope of this article (see STATISTICS; also see below *Bibliography*, the work by I. Todhunter). A few brief remarks will have to suffice here.

Under very general assumptions, it may be shown that the sum of independent random errors of observation has, as the number of terms becomes large, a normal (bell-shaped) distribution with mean  $\mu$  and standard deviation  $\sigma$ , in which  $\mu$  is the sum of the means of the individual sources of error and  $\sigma^2$  is the sum of their individual variances (standard deviations squared); i.e.,  $\sigma^2 = \sigma_1^2 + \sigma_2^2 + \dots + \sigma_q^2$ , in which there are  $q$  sources of error. (For discussion of the normal distribution with population mean  $\mu$  and variance  $\sigma$ , see STATISTICS.) This formulation, known as the central limit theorem, is one of the fundamental theorems of modern probability theory. Its importance lies in the fact that it is largely independent of the particular character or distribution of the individual errors. It was first stated by Laplace in 1812 and given its first rigorous proof in 1901 under fairly general assumptions by the Russian Aleksandr Lyapunov, known for his mathematical studies of stability and probability.

Probabilistic models

In recent years different probabilistic models have been developed for the study of human behaviour, especially behaviour that expresses a choice or preference among several alternatives. Such models are devised to measure the strength of preference so as to predict the probability of choice—for experience in everyday life and in the laboratory has shown that men and animals will vary their choice of one alternative over another in what are externally identical conditions. One simple and useful model is this: if  $v(x)$  is defined as the utility or value of  $x$ —i.e., the numerical measure of the strength of preference for  $x$ —and  $p(x,y)$  as the probability of choosing  $x$  over  $y$ , then the model postulates that  $p(x,y) = v(x)/[v(x) + v(y)]$ . The problem for the theory of measurement is to show what properties the observed probabilities  $p(x,y)$  must have in order for such a utility function  $v$  to exist. If a child, for instance, chooses chocolate ice cream ( $c$ ) over licorice ( $l$ ) with probability two-thirds, licorice over a banana ( $b$ ) with probability two-thirds, and  $b$  over  $c$  with probability two-thirds, then no such strength of preference function  $v$  can be found for the set  $\{b,c,l\}$ .

#### MEASUREMENT IN SPECIAL DISCIPLINES

Classical physics

**Measurement in physics.** The development of the central concepts of classical physics—such as the mechanical concepts of mass, force, momentum, and kinetic energy, and electromagnetical concepts such as those of current, voltage, resistance, and impedance—has been closely intertwined with the development of procedures for measuring quantitatively the properties of the phenomena associated with the concept. The theory and practice of extensive measurement, as discussed above (see above

*Axiomatic basis of measurement*), and the theory of dimensions and units (see above *Dimensions and units of measurement*) have been developed mainly in the context of classical physics.

One of the most important attitudes toward measurement in classical physics was the firmly rooted belief that, with sufficient effort, errors of measurement could be eliminated in principle and that there would be no limitation to the precision of measurement and, consequently, to the accuracy to which theories might be pushed in testing their validity. Although classical physics continues to be of major importance in applied science, a much more restrained attitude toward measurement now is customary. In the applications of classical electromagnetic theory, for example, it is customary to impose a lower limit defining the smallest admissible length to be considered: a typical restriction is to keep all lengths greater than one-tenth of a millimetre in order to avoid any atomic or subatomic effects that would fall properly within quantum theory.

A central concept of Einstein's theory of relativity and one that has had an enormous impact on modern physics is its revision of the classical concept of simultaneity, which restricts it to immediately adjacent events. There is no well-defined concept of two events at astronomical distances occurring simultaneously; this means that classical procedures for the measurement of simultaneity have been shown to be mistaken in their fundamental assumptions and that the concept of simultaneous distant events is as mistaken as that of absolute position in space.

Modern physics

At another level of analysis are the so-called Lorentz transformations of special relativity, which formulate the relations between two differently moving space-time frames. It is possible to give a self-contained and elementary derivation of these transformations (without any assumptions of continuity or linearity) from a single axiom asserting that the relativistic interval between any two space-time points connected by a possible inertial path of a particle remains the same in all inertial frames of reference. In other words, just two stipulations—that the macroscopic measurement of such relativistic distances be conducted along inertial paths (those followed naturally by unaccelerated particles) and that these measurements be invariant for any inertial frame of reference—are sufficient to establish the fundamental principle that any two inertial frames of reference are related by Lorentz transformations.

The theory of measurement has been important in quantum mechanics for two distinct but related conceptual reasons. One deals with the fundamental discovery that it is not possible to measure simultaneously with arbitrary precision the position and momentum of subatomic particles such as, for example, electrons or photons. The best known way of expressing this fact is in terms of the Heisenberg uncertainty principle, so-called after Werner Heisenberg, a German quantum physicist, which states that the product of the standard error of measurement of position and momentum must exceed a certain positive constant (for a more detailed discussion, see MECHANICS, QUANTUM).

The strangeness of this discovery, from the standpoint of classical physics, has been one of the most discussed problems of modern physics. Efforts to account for the theoretical uncertainties in measurement or the theoretical limits on the precision of measurement have been a central focus of conceptual discussions of the foundations of quantum mechanics. From the standpoint of classical statistical theory, perhaps what is most surprising about the Heisenberg uncertainty principle and related aspects of quantum mechanics is that one is not able to study the covariance of position and velocity measurements. The necessity of looking only at the marginal probability distributions of position and momentum and at the marginal distributions of other conjugate observables in quantum mechanics is the source of the sharpest break between the methodology of quantum mechanics and that of classical statistical theory as used both in classical physics and in other domains of science.

The second aspect of measurement that has been funda-

mental in quantum mechanics is the interaction between the measurement instrument and the measured object. In classical physics it was assumed that the interference of the measuring instrument can in principle be reduced to zero; in quantum mechanics the complicated and detailed analysis of the situation, in which the opposite is a fundamental assumption, has proved to be difficult and elusive.

**Measurement in the social sciences and psychology.** These fields pose special problems for measurement theory.

*Economics and psychology.* An important reason why economics is the most advanced of the social sciences—advanced in predictive power, social usefulness, and formal theory—is that the many important economic variables may be easily measured. Much of both economic theory and data are cast in terms of price and quantity. The problems associated with these concepts are not so much ones of measurement as they are of aggregation to provide representative measures for large economic units, such as an entire industry or a whole economy. Social indices, such as cost of living or gross national product, involve subtle questions of equivalence, statistical sampling, and the like.

In spite of their success in using the concepts of price and quantity, economists recognize that individuals often base their decisions on more subjective concepts. One approach is to suppose that such individuals have a numerical measure of utility, which they try to maximize. Early attempts to introduce utility into economics employed a representation that, in essence, assumed that the utility of a bundle of commodities is the sum of the utilities of the several commodities; but little attempt was made to axiomatize the representation, and, for various reasons, that hypothesis was discredited. In the 1940s it was suggested that utility could be measured by taking into account the risky character of decision alternatives. Taking  $a$  and  $b$  as the alternatives and  $P$  as a probability, these scholars symbolized by  $aPb$  the risky alternative in which one receives either  $a$  or  $b$ , the former with probability  $P$  and the latter with probability  $1 - P$ . They then axiomatized orderings over such structures to show that an order-preserving numerical assignment exists with the expected-utility property:  $u(aPb) = u(a)P + u(b)(1 - P)$ . Under these conditions, decision making becomes equivalent to maximizing expected utility. This idea has received considerable development since the end of World War II. Its main thrust has been the more careful formulation of what an alternative is in terms of various outcomes associated with different chance events and the generalization of the representation theorem to one in which, in addition to constructing the utility function, a (subjective) probability function over events is also constructed from the preference ordering of the alternatives in such a way that subjective expected utility is order preserving.

Although these ideas originated in economics and statistics, psychologists were quick to recognize the problem as one of individual preferences, and they have run numerous experiments to assess its descriptive adequacy. To oversimplify considerably, the major qualitative property known as the (extended) sure-thing principle is not valid. Roughly, this property asserts that if, no matter what possibility is realized, the outcomes of one gamble are at least as satisfactory as the corresponding ones of another, then the former gamble will be preferred or indifferent to the latter one—in the above notation,  $aPb \geq a'P'b' \equiv (aPb)Qc \geq (a'P'b')Qc$ . This principle is analogous to independence in additive conjoint measurement and to weak monotonicity in extensive measurement. As a postulate of rational behaviour, however, it has not been seriously questioned; thus, interest in the theory remains.

As was noted above (see above *In psychology*), some psychological theories include parameters that may be interpreted as measures of psychological attributes, parameters of which prototypic examples are found in the study of the detection and recognition of simple sensory signals. Perhaps the best known example is the theory of signal detectability, adapted from electrical engineering, which has two main parameters:  $d'$ , which in effect de-

scribes how detectable the signal is against its background noise, and  $\beta$ , which describes how willing the subject is to interpret evidence as favouring the hypothesis that the signal is present. The former is affected by the signal-to-noise ratio, whereas the latter is manipulated by payoffs and the proportion of trials on which signals are presented. Given these two numbers, the theory specifies how to calculate the response probabilities for a variety of experimental designs.

Another type of psychological research attempts to treat the person as a null-measuring instrument—*i.e.*, as a sensor that records the point at which a difference becomes imperceptible—by having him establish equivalent intensity ratios in different sense modalities, such as sight and sound. These procedures of cross-modality matching yield approximate power relations among the usual physical measures of intensity. Various attempts are being made to place these results in either of two contexts: fundamental measurement theory or elaborations of existing theories of local psychophysics.

*Sociology and demography.* The main object of sociology as a science is the study of social groups and institutions and the causes of change within them. Many traditional theories in sociology have been of a speculative sort, not easily subjected to quantitative test. An increasing emphasis on quantitative theories and concepts, however, has inspired a greater concern with problems of measurement. The one part of sociology that from its beginning has emphasized quantitative data and analysis is demography, which is concerned with the quantitative study of human populations and the causes of changes in population. Though demographers are interested mainly in the measurement of factors of population change—including births, deaths, and migrations—they are also concerned with questions of population composition in terms of age, sex, and other characteristics. As in the case of sociology in general, there have been few fundamental problems of measurement of a direct sort in demography; the problems have been primarily of a statistical sort—to infer, for example, future birth trends from intensive field studies of selected samples of a population, although the trend is toward greater accuracy. Perhaps the most successful application of measurement in demography has been in the construction of the mortality tables used by insurance companies and government agencies.

## Meat and Meat-Packing

Meat, commonly defined as the edible portion and associated parts of mammals, is usually restricted to beef, veal,

Measurements of price, quantity, and utility

Recent efforts at quantification

Sensation

lamb, and pork, thus distinguishing meat from fish and fowl. Beef refers to meat from cattle; veal to that from calves; pork to that from pigs; lamb to that from young sheep; and mutton to that from sheep over one year old.

The meat industry purchases livestock, converts meat animals into food and nonfood products, and distributes and sells both the fresh and processed food products and the by-products of a nonfood nature. Meat-packing facilities vary in capacity. Plants range from those processing only a few head of livestock each year to those with a processing capacity of several million. Many plants conduct no slaughtering operations, buying meat at wholesale for further processing and sale to the retail and institutional trade. This group includes sausage manufacturers, meat canners, and other companies specializing in processed meat products.

**World production and consumption.** Perhaps the most striking statistic about world food production and consumption is that the United States produces and consumes 35 percent of the world's meat supply. Britain, the United States, and Germany are major importing countries; Argentina, Australia, New Zealand, and Denmark are major exporting countries. Many countries are both exporters and importers of meat products, importing one kind of meat and exporting another. The United States, for example, imports processed meat and canned hams and exports processed meat products to the Caribbean and United States territories. The world's major meat-exporting areas are South America, Oceania (Australia, New Zealand), and western Europe; North America and western Europe are major importing areas. The world's chief cattle-producing countries include India, with 176,000,000 head; the United States, 109,000,000; Soviet Union, 97,000,000; Brazil, 90,000,000; and China, 63,000,000. The leading sheep-producing countries are Australia, 167,000,000; New Zealand, 60,000,000; Argentina, 48,000,000; India, 42,000,000; Republic of South Africa, 38,000,000; United States, 22,000,000; and Ethiopia, 13,000,000. The major hog-producing countries are Brazil, 63,000,000; United States, 55,000,000; and West Germany, 19,000,000.

The major producers are also, generally speaking, the major consumers. The highest per capita red-meat consuming countries are New Zealand, 224 pounds (102 kilograms) per capita per year; Uruguay, 218 pounds (99 kilograms); Australia, 204 pounds (92 kilograms); Argentina, 220 pounds (100 kilograms); United States, 185 pounds (84 kilograms). But the United Kingdom, not a major producer, is a major consumer with 138 pounds (63 kilograms) per capita, while certain countries, like India, rank low in consumption, despite high production, apparently owing to religious prohibitions.

The meat of rabbit, horse, goat, and deer are regularly consumed in some countries, and various other mammalian species are eaten in small quantities in some parts of the world. Seal and polar bear are included in the Eskimo diet, while rhinoceros, hippopotamus, and elephant are occasionally consumed by the tribes of Central Africa.

**Meat in the human diet.** Meat is outstanding for its nutritive value. Based on the daily recommended allowances for a 22-year-old man, a 3½ ounce (99 gram) serving of cooked meat provides 45 percent of the needed protein, 9 percent of the calories, 36 percent of the iron, 31 percent of the thiamine, 15 percent of the riboflavin, and 26 percent of the niacin. Because of its appearance, aroma, and flavour, meat has almost universal appetite appeal. Such palatable food aids in digestion by stimulating the flow of the digestive juices. Meat has a high satiety value, giving a feeling of satisfaction and well-being that staves off hunger for longer periods than other foods.

Protein is essential to growth and life. Differences among proteins are reflected primarily in the amount and kind of amino acids they contain. Amino acids, consisting of carbon, hydrogen, oxygen, nitrogen, and sulfur, are the building blocks of proteins. Eight of the amino acids that humans cannot synthesize are essential for growth and maintenance of body tissues. Proteins containing all

of the essential amino acids in the proportions most useful to the body are described as having biological value. Meat proteins are among the most important of these. Extreme protein deficiency may result in poor muscle tone and posture, lowered resistance to disease, premature aging, anemia, stunted growth in children, tissue degeneration, edema, and slow recovery from illness or surgery. Severe cases of protein-deficiency disease in children, known clinically as kwashiorkor and often found in tropical countries, can be avoided by supplementing diets with high-quality protein.

Meat is an excellent source of B vitamins, including thiamine, one of the most important. Pork is the best source of thiamine, liver is next, and skeletal muscle, from any meat source, is third. Extreme thiamine shortage may result in beriberi, a deficiency disease common in the Far East. Liver is an excellent source of riboflavin, another B vitamin that combines with protein in the body to form important oxidative enzymes. All meats supply niacin, which helps to build and maintain a healthy skin, nervous system, and digestive system. Extreme niacin deficiency leads to pellagra. Meat also provides other essential B vitamins, such as pyridoxine, involved in amino acid metabolism, and vitamin B<sub>12</sub>, needed for formation of red blood cells.

Meat is also a good source of the essential minerals iron, phosphorus, potassium, sodium, and magnesium.

#### MEAT STRUCTURE, CHEMISTRY, AND MICROBIOLOGY

**Meat structure.** Most edible meat portions are made up of skeletal muscle, connective tissue, fat, and bone.

**Muscle.** There are three types of muscle: involuntary muscle associated with the digestive system; involuntary cardiac muscle; and voluntary skeletal muscle. Muscle is composed of approximately 75 percent water and 20 percent protein, with fats, carbohydrates, and minerals composing the remaining 5 percent. Muscles are made up of fibres, or muscle cells, each covered by a thin membrane, the sarcolemma. Small groups of fibres, joined by connective tissue (endomysium) into bundles, or fasciculi, are sheathed, together with fatty deposits, by more connective tissue, the perimysium, to form an entire muscle.

Meat grain is determined by the size of the muscle bundles and the connective tissue, small bundles producing fine grain, and large bundles producing coarser grain. Fibre-bundle size varies in different muscles of the same animal and in different species. The number of fibres present at birth does not increase; increased size results from growth of existing fibres. Muscles receiving the greatest use, such as the neck, leg, and shoulder muscles, develop thickened cell walls and connective tissue, producing meat without the tenderness of less developed muscles but with stronger flavour. Juiciness in meat results from high water retention. Muscles vary in ability to hold water, an ability partly affected by the degree of alkalinity present.

**Connective tissue.** The amount and type of connective tissue, affecting meat tenderness, is increased by muscle use and age. This tissue, covering muscle fibres, fibre bundles, and the entire muscle, is primarily composed of the proteins collagen and elastin. Collagen, the major component of white connective tissue, softens during cooking and is eventually converted to gelatin, producing greater tenderness in the meat. For this reason, prolonged cooking methods are most suitable for the tougher meat cuts. Elastin, the chief component of yellow connective tissue, is tough and resistant to change and is not affected by the heat of cooking.

**Fat.** Fat, present in all meat, exists in the live animal as small oil droplets, increasing in number and size as fattening, or finishing, proceeds. As the animal fattens, the proportion of lean and bone is reduced and the proportion of fat increases. Fat deposits cover the organs, separate muscles, and are distributed as marbling within the muscles. Marbling increases flavour and contributes to meat tenderness and juiciness by exerting an internal basting effect during cooking.

**Meat chemistry.** Muscle is a colloidal system of approximately 72–73 percent water, 18 percent protein,

Major importers and exporters

Muscle composition

Amino acids in proteins

1–2 percent soluble nonprotein substances, variable amounts of fat (1–20 percent), and small amounts of ash (1 percent) and carbohydrate (1 percent).

**Protein.** Muscles contain two kinds of proteins: muscle-cell proteins and connective-tissue proteins. Protein percentage decreases as the amount of fat increases. Myosin, comprising the greatest portion of muscle-cell protein, is soluble in salt solutions and will gel when heated. Actin, another protein, is water soluble. Actomyosin, protein formed from the combination of actin and myosin, is the substance producing muscle contraction.

Colour changes

Myoglobin, a water-soluble muscle protein, affects meat colour. Originally purplish-red, when combined with oxygen it forms bright-red oxymyoglobin, visible on the surface of fresh meat after exposure to oxygen. The application of heat changes the colour to brown.

**Fat.** As fatty tissue increases during growth and fattening, a higher proportion of the extra fat is deposited in the fatty tissue, and a smaller portion in the muscular tissue. Fats, insoluble in water but soluble in organic solvents, are composed primarily of tryglycerides, mixtures of glycerol and fatty acids. Animal fat provides arachidonic, an essential unsaturated fatty acid.

**Carbohydrates.** Glycogen, the principal carbohydrate in skeletal muscle, changes to lactic acid immediately after the animal is slaughtered.

**Postmortem meat changes.** Muscle, soft at the time the animal is slaughtered, hardens soon after, becoming extremely tough with reduced water-retention capacity. The meat is hung in a cooler for several days until the hardening passes, apparently by enzyme action, and the muscle softens and regains its water-holding ability.

Rigor mortis

When circulation stops, absence of oxygen encourages the breakdown of the carbohydrate glycogen into glucose, which is in turn reduced to lactic acid. Rigor mortis occurs when the pH (range from acidity to alkalinity) is sufficiently lowered (high acidity), usually reaching its greatest degree within 24 hours, after which the muscle begins to soften. The amount of glycogen present in the muscle at slaughtering, because of the time required for its change to lactic acid, will affect the pH level. Rapid pH drop produces a condition called acid rigor, in which the muscle loses its water-holding capacity, becoming pale, soft, and “weepy.” When the pH remains fairly high, alkaline rigor develops, and the muscle retains its dark colour and juices. Extreme alkaline rigor, however, will result in “dark cutting” meat—*e.g.*, meat that is darker in colour than normal.

**Tissue changes and their causes.** Relaxed muscle fibres are long; contracted muscle fibres are short. Some shortening occurs during rigor mortis, the extent varying with lactic acid accumulation and physical restraint on the muscle caused by vertical suspension of the carcass.

**Cold-produced changes.** Upon completion of slaughter, including removal of the viscera and the skin (beef), pelt (lamb), or hair (pig), carcasses are usually placed in coolers at 32° F (0° C) to remove body heat, and carcass temperature decreases from approximately 100° F (38° C) to the temperature of the holding cooler. Muscle temperature at the time of rigor mortis influences meat quality.

Muscle shortening

Responses of surface-exposed muscles in a 32° F (0° C) environment vary according to species. In beef and lamb, exposed, unrestrained muscles undergo extreme “cold shortening,” resulting in tough meat. Prevention of shortening is more important than actually stretching the muscle. Pork muscle, particularly, when held in a warm environment during rigor mortis development, experiences acceleration of glucose fermentation (glycolysis), decreasing meat quality. When beef is held at close to body temperature, the unrestrained muscles will shorten, although not as severely as at 32° F (0° C).

Muscle frozen before rigor and allowed to thaw in an unrestrained state, may shorten to 20–25 percent of original length. Because of this severe shortening, resulting in excessive juice loss and toughening, muscle is not immediately excised and frozen after slaughter. Although retention on the carcass prevents many of the deleterious

effects, there is no assurance of prevention of localized shortening, a phenomenon that even precludes carcass freezing before rigor onset. The sudden release of calcium ions during thawing causes violent contracture; the same phenomena apparently occur during cold shortening.

**Enzyme tenderization.** The use of enzymes, such as papain or bromelain, produces significant meat tenderization. When these enzymes are injected in the animal before slaughter, the carcasses are sold as especially tenderized products. Some firms also inject enzymes post-mortem; other establishments place the enzymes on the cut surface. The enzymes are presumably activated only over a narrow range of temperature during cooking, and although they would ideally act primarily on the connective tissues, some may also act on the muscle fibre proteins.

**Aging.** In aging, meat is held at 32° F (0° C) for approximately two to three weeks, or at higher temperatures for shorter periods, allowing natural tenderization. Surface spoilage or drying sometimes occurs during aging, necessitating excessive trimming.

**Microbiology. Spoilage.** The kinds and numbers of micro-organisms present on meat surfaces or within the meat are influenced by the pretreatment of the product, including: (1) kind and extent of contamination and previous opportunities for growth of certain kinds of organisms; and (2) physical properties of the meat, including the amount of exposed area. When meat is ground, the surface area is greatly increased, releasing moisture and distributing organisms throughout the meat, thereby encouraging microbial growth.

Chemical properties, such as moisture content, pH, and meat composition, affect the kind and number of organisms. Moisture content is one factor determining which organisms will predominate. When moisture is limited, molds will grow and become the dominant organism; yeasts require more moisture; bacteria growth requires even greater amounts of water. Therefore, relative humidity of the storage area is important. Since temperature is the most important factor influencing the kind of organism growth and type of spoilage occurring, meat should be stored at temperatures not far above freezing, allowing only low-temperature organism growth.

Meat discoloration and bacterial spoilage may be initiated during handling and packaging of meat for merchandising, when greater surface areas are exposed to possible juice loss and bacterial contamination. Increased handling and fluctuating temperature reduce keeping qualities. Harmful bacteria include *Pseudomonas*, *Achromobacter*, *Micrococcus*, *Streptococcus*, *Lactobacillus*, and *Clostridium*. Meat is an ideal culture medium because it is high in moisture, rich in nitrogenous foods, plentifully supplied with minerals and accessory growth factors, and usually has some fermentable carbohydrates and favorable pH for most micro-organisms.

Harmful bacteria

**Specific spoilage considerations.** Molds, generally appearing dry and fuzzy to the human eye, are commonly white, green, or black, although numerous colours are possible. Molds give a musty flavour to the meat in the vicinity of their growth. The chief molds affecting meat are *Cladosporium*, *Mucor*, and *Alternaria* genera.

Slimes, not as readily recognized as molds, are slippery or greasy appearing in their early stages, and may be mistaken for a film of fat on the product. The early stage of sliming may be diagnosed by drawing a knife blade across the meat surface. If slime is present, a soft, creamy material will be gathered on the blade, consisting almost entirely of cells of micro-organisms that have grown extensively to produce spoilage.

Spoilage caused by pigmented bacteria appears as various coloured spots, usually red, yellow, and blue, on the meat surface. Greenish-blue to brownish-black spots, found on stored beef, are also caused by pigmented bacteria. Purple “stamping ink” discoloration of surface fat is caused by yellow pigmented cocci and rods; when the fat becomes rancid, the yellow colour changes to a greenish shade, later becoming purplish to blue.

Off odours and tastes in meat, resulting from growth of

bacteria on the surface, are often evident before other spoilage signs.

Souring, putrefaction, and taint are common types of spoilage under anaerobic conditions (without presence of air). Souring can result from the action of the meat's own enzymes during aging; from production of fatty acids or lactic acid by bacterial action; or from protein decomposition, sometimes called "stinking sour fermentation." Putrefaction, anaerobic decomposition of protein, produces such foul-smelling compounds as ammonia, hydrogen sulfide, and mercaptans. The terms bone taint or bone sour usually refer to putrefaction, and sometimes to souring, near the bone. This condition occurs commonly near the joints in hams.

**Meat preservation.** Preservation is concerned with preventing development of undesirable micro-organisms, especially harmful bacteria causing spoilage or decomposition and decay. The economy of the meat industry is highly influenced by meat perishability. Most of the edible tissues of healthy pigs, beef, veal, and lambs are sterile, or contain very low micro-organism population levels. The slaughtering process, by severing the vascular system, introduces the first major contamination. Selection of a preservation method is influenced by the effect on quality, health hazards, marketing, and actual cost.

**Refrigeration and freezing.** Refrigeration is the most widely used method of preserving fresh meat. Low temperatures retard microbial growth and inhibit enzymatic and chemical reaction. The shelf life of fresh meat at temperatures between 28° and 32° F (−2° and 0° C) is largely influenced by the amount of contamination that the meat has previously encountered.

When meat temperature is reduced below 28° F (−2° C), the meat will freeze, undergoing physical change and alteration of the chemical changes which occur. Fresh meat, properly prepared and frozen and stored below 0° F (−18° C), can be preserved for several months with little loss in original palatability. In meat frozen without proper wrapping, however, the surface will undergo "freezer burn," developing serious deterioration and becoming bleached and unattractive in appearance. The major problem in frozen meat is oxidation of the fat, causing a change in aroma after a long storage period. This problem is greatest in pork, which has a higher percentage of the more easily oxidized unsaturated fatty acids than found in beef, veal, or lamb.

For maximum eating quality, frozen meat should not be thawed and refrozen or stored frozen beyond a certain number of months. Refreezing produces crystal enlargement and a greater amount of ice formation and tissue damage, resulting in increased drip loss during subsequent thawing and greater cooking loss. When frozen meat is thawed and held in a thawed condition, rapidity of microbial growth and damage will be influenced by the amount of contamination present before freezing. The occurrence of fluctuating temperatures during frozen storage increases ice crystal size and, subsequently, the amount of drip loss upon thawing.

**Curing.** Frozen storage has replaced curing as the major meat preservation method. Curing is now primarily used to provide flavour and a cured meat colour that is retained during cooking.

In the preservation of meat by curing, the addition of curing salts creates a selective bacteriological medium limiting the kinds of micro-organisms capable of the rapid growth that encourages spoilage. Although smoke and heat, both usually applied to cured products, reduce surface bacterial population, smoke does not play an important role in retarding meat-product spoilage.

**Freeze-drying.** Meat freeze-dried by conventional methods remains frozen throughout the drying cycle, permitting moisture content reduction to less than 2 percent without appreciable alteration in form. Portions must be thin to be readily rehydratable, and this requirement somewhat limits the preservation technique. Another limitation is the need to hold the product in the absence of air and moisture.

**Canning.** Meat is cooked thoroughly in preparation for canning, then packed in hermetically sealed cans,

either as a single product, or in combination with other food products, forming luncheon meats. Acceptance of canned meats has increased, and highly trimmed quality cuts are now available in canned form.

#### MEAT TYPES

Meat quality refers to a combination of traits producing an edible product with minimum loss of constituents; without undesirable characteristics after processing and storage; remaining attractive in appearance; and appetizing, nutritious, and palatable after cooking. Meat quantity, referring to the amount of muscle in relation to bone and fat covering, is also a factor in judging meats.

Governments often establish meat quality standards based upon such highly variable properties as marbling and maturing and also upon such factors as colour, firmness, and texture. The Codex Alimentarius Commission, sponsored by the Food and Agriculture Organization and the World Health Organization, was established in 1961 to consider uniform international food standards. In the early 1970s the Codex Committee on Meat and Meat Products was working on a classification and grading system for carcasses and cuts of beef, lamb, mutton, pork, and veal and was also considering hygiene standards for fresh meat.

**Beef and veal.** Beef animals ranging in weight from 1,000 to 1,200 pounds (450 to 545 kilograms) are usually preferred, although considerable variation exists among beef-consuming countries. The carcass weight of a beef animal ready for market will be about 55–60 percent of its live weight. Thickness of the body wall and degree of fatness influence yield, with old cows yielding only 45 percent of their live weight as carcass, and overly fat, adequately muscled animals yielding close to 70 percent of their weight. Beef carcasses and wholesale cuts have the greatest value when they meet high quality standards and have a high yield of preferred retail cuts, with minimum waste in the form of fat or bone.

Beef quality attributes include (1) maturity, (2) marbling, (3) texture of the lean, (4) lean and fat firmness, and (5) lean and fat colour.

In youthful beef carcasses, the split spinous processes of the vertebrae are soft, red, porous, and tipped with large amounts of soft, pearly white cartilage. Cartilage ossifies as the animal matures, and in very mature cows, all of the cartilage is completely ossified. Within wide limits, muscle colour changes as the animal matures. Texture of lean refers to the prominence of muscle bundles: all other factors being satisfactory, if the muscle bundles are fine, the muscle is likely to be tender. Firmness is important because it reflects to some extent the ability of muscle to hold its juices during cooking. Beef cuts showing coarse, soft muscle and excessive weepage are undesirable for retail marketing.

Moderate amounts of finely and uniformly dispersed marbling (intramuscular fat) in firm red muscle, from a relatively young animal, is considered ideal. Excessive marbling is not desirable, but extremely limited marbling makes beef less palatable than beef with adequate marbling. Beef from old animals is usually less tender than beef from young animals. The range in certain other muscle characteristics considered responsible for eating quality is also variable.

Beef colour varies from pale pink to the extremely dark colour, called "dark-cutting," and the average consumer cannot distinguish between dark cutting beef and beef from old animals or beef held under adverse conditions. Fat should be firm, free from greasy or oily appearance, and white to creamy white in colour. Yellow fat, sometimes appearing on beef and lamb carcasses and on the carcasses of certain breeds of dairy cows, results from concentration of fat-soluble carotinoid pigments.

Quality veal is dry, grayish-pink in colour, and firm in structure. The variety of methods normally utilized in cooking veal makes visible quality features less significant than in beef. Age and nutrition, however, greatly influence veal colour and firmness, and intramuscular fat is rarely visible. Consumers often avoid veal that is too red because of its resemblance to calf or beef.

Meat quality

Carcass weight

"Freezer burn"

Marbling

Beef carcass standards often provide maturity groups ranging from the most youthful through the most advanced maturity grade, having hard, white china bones, with wide, flat rib bones, and musculature dark red and coarse in texture. Yield grades identify carcasses according to differences in yield of boneless, closely trimmed retail cuts from the round, loin, rib, and chuck.

Figure 1 shows the beef carcass with its wholesale cuts

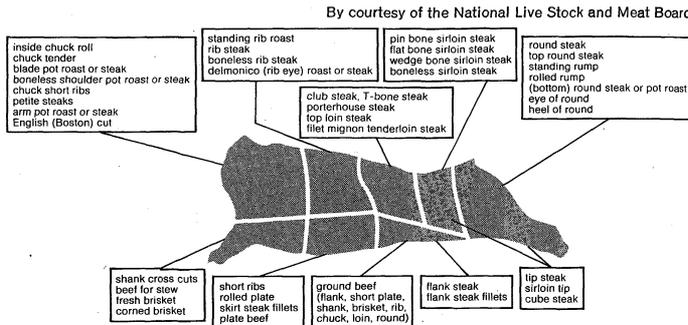

Figure 1: Wholesale and retail cuts of beef (see text).

and lists the names given to the retail cuts commonly made from each of the wholesale cuts. A beef carcass is normally split into two sides, with each side shipped and cut separately.

Figure 2 shows wholesale veal cuts and lists the retail cuts commonly made from each. Cutting is normally accomplished at the retail sales location, and the carcasses are not usually split into sides prior to retail fabrication. The practice of centralized cutting at the packing plant or wholesale-dealer level is, however, becoming increasingly common.

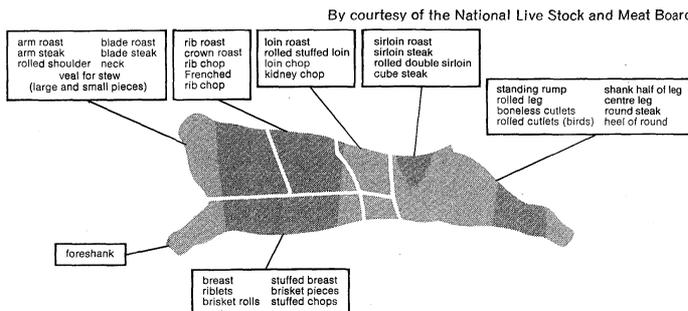

Figure 2: Wholesale and retail cuts of veal (see text).

Carcass length

**Pork.** Market pigs weigh approximately 200–300 pounds (90–135 kilograms) and yield carcasses weighing 70–74 percent of their live weight. Average back-fat thickness and area of the cross section of the longissimus muscle at the tenth rib are among the measurements used to describe quantitative carcass characteristics. These measures are intended to be estimates of the four lean cuts: ham, loin, shoulder, and butt. Yields are expressed as a percentage of the carcass weight.

Barrow (castrated male) and gilt (young female) carcasses represent the bulk of pigs slaughtered; sows (females having raised young) and boars (uncastrated males) are also marketed. The characteristic boar odour decreases desirability of boar carcasses.

The second factor in pork carcass evaluation is the quality of the lean muscle, judged by firmness of fat and lean, colour, marbling, and texture of the lean. The most desirable pork has a firm, dry surface, pinkish red in colour. The quality indicating characteristics evident on the cut surface of a major muscle, in addition to marbling, include firmness, colour, and exudation, and range in description from pale, soft, exudative (PSE) pork, to dark, firm, dry (DFD) pork.

Pork grades are primarily based on anticipated yields of the four lean cuts. Carcasses differ in lean cut yields because of differences in both degree of fatness and degree of muscling (thickness of muscling in relation to skeletal size), and these factors are considered in relation to car-

ness weight as the basis for assigning numbered grades. Figure 3 shows the pork carcass form with its wholesale cuts and lists the common retail cuts made from each of them.

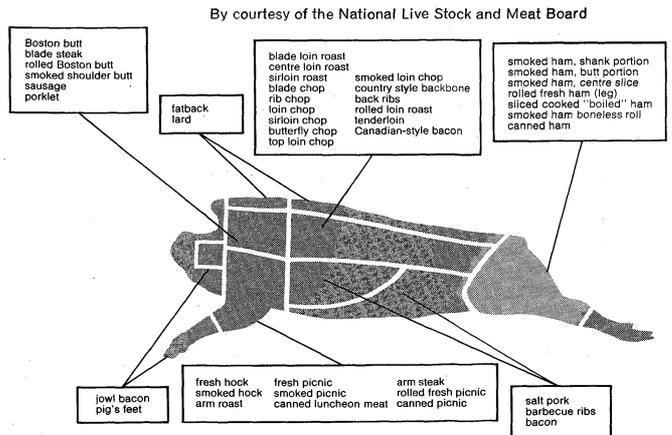

Figure 3: Wholesale and retail cuts of pork (see text).

**Lamb.** Lambs (wethers, castrated males; ewes, females) ready for market usually weigh between 100 and 150 pounds (45 and 65 kilograms). Regional or national preferences affect desirability. Traits associated with carcass desirability, cutability, and quality reflect the proportionate yield of preferred retail cuts and consumer acceptance, including palatability. Greater consideration is generally given to cutability, or proportion of carcass weight salable at retail level, than to quality. Desirable carcasses have a high percentage of weight in the preferred leg, loin, rack, and shoulder cuts. The internal fat of the pelvic cavity and around the kidney is extremely variable and must be estimated carefully. Ideal lamb carcass fat covering is approximately 0.1 inch (2.5 millimetres) over the centre of the rib eye.

Quality in lamb, as in other species, refers to factors influencing acceptability and palatability. Quality lamb muscle has a firm, dry surface, modest marbling, and varies in colour from light to dark pink. Dark muscle colour and yellow fat both suggest mutton-like properties and, where lamb is preferred, may be considered detrimental. Specific ages are usually defined for slaughter lambs, yearlings, and mature mutton. Estimates of maturity are based on ossification and shape of bones and colour and texture of lean. Youthful lambs have pinkish lean, and their shanks are separated at the break joints; mutton carcasses have dark-red lean and spool joints on their front shanks; yearling mutton carcasses are between these two extremes. The spool joint (round) is on the lower end of the metacarpal when the foot is removed at the ankle (next to the metacarpal bone). The break joint is located immediately above the spool joint at the zone of bone growth, the junction of the epiphysis and diaphysis. Growth in this zone stops when cartilage regeneration ceases; then the bones can no longer be separated at the break joint. Since this ossification of the break joint occurs physiologically at an age of about one year, the condition of this joint can be used to distinguish between lamb and yearling carcasses. Mutton terminology is applied to lambs two years of age or older.

Quality factors in lamb

Lamb carcass grades are usually based on maturity, feathering (meaning the fat streaking in muscle between the ribs), fat streaking on the inside of the flank muscles, and firmness of the fat and lean.

Yield grades for lamb and mutton carcasses are concerned with differences in cutability or expected yield of boneless, closely trimmed, major retail cuts from the leg, loin, rack, and shoulder. Yield grades are determined by considering the amount of external fat, amount of kidney and pelvic fat, and conformation grade of the legs. External fat is measured over the 12th and 13th ribs, whereas kidney and pelvic fat must be estimated. Figure 4 shows wholesale lamb cuts and the retail cuts obtained from them.

Although the charts shown are based on U.S. wholesale and retail cuts and exact cuts and terminology may vary among countries, methods are generally similar. Increased international trade and future acceptance of standards prepared for the Codex Alimentarius may be expected to result in greater standardization.

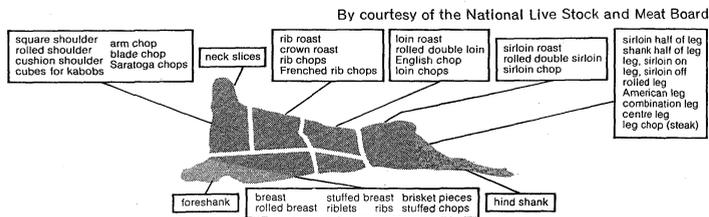

Figure 4: Wholesale and retail cuts of lamb (see text).

**Sausage and ready-prepared meats.** The art of sausage making pre-dates recorded history. The word sausage is derived from the Latin *salsus*, meaning salted or preserved. Salami is mentioned frequently in the pre-Christian period and may be associated with the Greek city of Salamis in Cyprus. The popularity of sausage spread, and by the Middle Ages, sausage making was widely practiced commercially. Sausage makers developed individual spicing formulas, their products taking on the name of the region or city in which they originated. From Frankfurt, Germany, came the frankfurter; from Bologna, Italy, bologna; and so on. Italy's warm climate encouraged development of such dry sausage varieties as genoa; the cooler German climate led to development of such fresh and cooked sausages as bratwurst, head cheese, and blood sausage.

Many European sausage makers eventually emigrated to the United States, where over 200 different sausage varieties are produced by nearly 3,000 meat processors. The wiener and frankfurter—the hot dog—has become the most popular sausage in the United States, where some 16,000,000,000 are consumed each year—about 80 per capita.

Sausages and prepared meats are popular throughout the world, consumed not only in Europe and the U.S. but also in Africa, Asia, and Latin America.

**Sausage types and standards of identity.** Sausage types are classified according to processing methods. Major classifications include fresh sausage, uncooked smoked sausage, cooked smoked sausage, cooked sausage, cooked meat specialties, and dry and semidry sausage.

Fresh sausage, made from uncured pork trimmings and sometimes beef, is delicately seasoned. It is sold in links, patties, or bulk, requires refrigeration, and must be thoroughly cooked before serving. Pork sausage and bratwurst are popular varieties.

The meat materials in uncooked smoked sausage are usually cured and smoked, but not cooked. Sausages must be refrigerated and require cooking. Mettwurst and Polish sausage are examples of this classification.

Cooked smoked sausage is usually made from cured meats. These sausages are chopped, seasoned, stuffed, smoked, and then cooked. They are usually warmed before serving. Popular examples include frankfurters and bologna.

Cooked sausage, prepared from fresh, uncured meats, is cooked and ready to serve. Liver sausage, a popular variety, is a mildly seasoned mixture of livers and pork jowls.

Cooked meat specialties, cooked or baked and ready to serve, are often prepared according to the individual manufacturer's formula and may be extended with such protein materials as soy-protein concentrate. They include spiced luncheon meat, meat loaf, deviled ham, jellied corned beef, and other similar products.

The dry and semi-dry sausage group includes "summer style" products, originally made in winter for summer consumption. They are dried and then fermented with lactic acid bacteria to produce the characteristic tangy flavour. In addition to summer sausages, this group includes pepperoni, landjaeger, and mortadella.

**Commercial production.** Manufacturers consider consumer preference in determining the type and quality of sausage to be produced. Modern equipment provides automated mass economical production; and scientific research has led to an understanding of essential processing steps and elimination of any nonessential steps. In some wiener production, for example, computers select raw material sources daily, and these materials are fed into continuous wiener processing machines. Neither the materials nor the finished product are handled by human hands. This processing method provides for the ultimate in quality control, and a process formerly taking 9 hours is now completed in 45 minutes.

**Cured and smoked meats.** Curing, until the last century used for preservation, is now employed primarily for flavour and colour development. Salt-penetration rate influences the time required for curing, and the method of administration and muscle qualities will also influence the required time. Formerly, dry-salt curing mixtures were rubbed into the meat, which was then aged in curing cellars for prolonged periods. Subsequent methods have included stitch pumping, the injection of brine at different points in the muscle; artery pumping, using the arterial system to circulate the brine; and the modern injecto-cure, employing automatic, multi-needled equipment to inject the curing solution into large meat cuts.

The classic meat-curing agent is a mixture of sodium chloride, either sodium nitrite or sodium nitrate or both, and sugar. Salt inhibits microbial growth by increasing osmotic pressure and lowering water activity. The good keeping qualities of the old "country cured" hams resulted from the relatively low moisture-salt ratio. Because salts accelerate rancidity development when frozen, curing and freezing are not normally combined. Sugar is added to aid in establishing reducing conditions, and nitrate or nitrite is added to obtain colour fixation. During curing, holding, and cooking, changes occurring in the state of the myoglobin, under both desirable and undesirable conditions, include reduction of nitrate and nitrite by bacteria and reducing conditions; the breakdown of the nitrite into a simple compound of nitrogen and oxygen, called nitric oxide; and the combination of nitric oxide with myoglobin, forming nitrosomyoglobin, which becomes nitroshemochrome, pink in colour, when heated. Pork is the most commonly cured meat, although corned beef is cured beef brisket.

Acceptance of artificial ham, chicken, and hamburger, simulated from soy-protein sources, is increasing. In the U.S., "hamburger" implies ground beef with about 20 percent fat and with no pork content. The Codex Committee on Processed Meat Products has been working to establish standards for various processed meat products.

#### MEAT QUALITY

The ideal level of meat quality combines the capacity to retain high nutritive value in cooked form with capacity to satisfy numerous functional roles in the fabrication and processing of acceptable products.

**Measurement of quality.** *Colour and juiciness.* Muscle colour varies with species, beef being the darkest, lamb intermediate, and pork the lightest. Muscle colour intensity also increases with the age of the animal; differences are easily detectable between veal, market-weight beef, and old cows. This difference partially results from myoglobin concentration, generally increasing with age. Red muscles contain a majority of red (pigmented) fibres, although certain muscles have some portions which are red and other portions which are white (low in red-fibre content). The colour of fresh meat is also influenced by the state of the surface myoglobin, or the relative proportions and distributions of the three meat pigments: purple reduced myoglobin, red oxyomyoglobin, and brown metmyoglobin.

Colour is also influenced by muscle texture. Muscle having an alkaline rigor has a closed structure; the proteins are associated with large quantities of water, appearing swollen and tightly packed. This muscle scatters little

Salting

National types of sausage

Influence of muscle texture on colour

incident light and will appear dark. The other extreme is pale, soft, exudative muscle, in which the proteins are highly denatured and the structure is "open." These muscles lose large quantities of juice when cooked, and because of the association between colour and water binding, colour is indirectly related to palatability.

**Tenderness.** Meat tenderness is influenced by either the contractile state of the muscle (tough if the fibres have shortened) or by the amount of cross-linking in the collagen (tough if cross-linking is excessive, as in some older animals). The physiological condition of the animal influences, to some extent, the amount of post-mortem shortening that will occur. The temperature at which the carcass is held is also a factor, as well as excision or cutting, which relieves physical restraint on the muscle. The chronological age and the physiological condition of the animal also influence the alterations in the connective tissue. The amount of juice retained during cooking has an indirect influence on tenderness.

**Aroma and flavour.** Flavours, varying with species and chronological age, are usually enhanced in older animals. The amount of time that carcasses are aged in coolers also influences flavour and aroma, and prolonged aging tends to impart an "aged flavour" to the meat.

The sex of the animal only appears to influence flavour of meat when comparing barrow and gilt (pork) meat with boar meat (uncastrated male). In some boars, the characteristic odour may be quite prominent.

**Factors influencing meat quality.** The quality of fresh meat is influenced by a number of factors, which include firmness, marbling, connective tissue condition, and texture.

**Firmness.** High quality muscle has a rigid structure. Soft muscle results from the same factors contributing to low juice retention and is therefore even more objectionable than it would be on the basis of its lack of firmness alone. For processing, fabricating, slicing, and displaying, the meat firmness is an important attribute of quality, and any tendency toward softness reduces desirability. Firmness is also influenced by the nature and firmness of the fat itself, as well as by the variation in the muscle's fat content. In pigs, soft, oily fat usually results from the diet, which tends to deposit fats as consumed. Unsaturated fats are softer at a given temperature and are more susceptible to oxidative rancidity than are saturated fats.

**Intramuscular fat (marbling).** Marbling is the fat present within the boundaries of a muscle and can be visibly detected as the muscle cross-sectioned surface is exposed. Fine, evenly distributed marbling apparently reduces likelihood of dissatisfaction with the cooked product. A moderate quantity of marbling appears adequate to lubricate the muscle fibres, providing a juicy and flavourful cooked product. Large, coarse strands of marbling, unevenly dispersed throughout a muscle, are unsatisfactory because they do not provide sufficient fat distribution in the entire muscle area.

**Connective tissue.** The proportion of connective tissue in meat varies with its anatomical origin. The distal portions of the limbs, such as the shank, illustrate the converging of several locomotion muscles, each with an increasing proportion of epimysium blending into tendons attached to the skeleton. This cut would be less tender than the posture-control muscles located in other parts of the carcass.

**Texture and fibre size.** The size of fibre is somewhat influenced by the contractile state and influences the size of the fibre bundle. Size of muscle bundles is positively associated with visible coarseness of a cross-sectioned area of the muscle and is related to eating quality. Increased bundle size is associated with reduced tenderness.

The qualities of the fresh meat have an influence on its response during freezing and during storage in the frozen state. Meat should be frozen as rapidly as possible and stored at a temperature well below 0° F (-18° C). Freezing cannot improve quality. Low quality meat, frozen or cured under the best conditions possible, will still be low quality when consumed. High quality meat, however, can deteriorate if not frozen, stored, or cured under proper conditions.

**Factors influencing grade.** Carcass maturity is a significant factor influencing beef- and lamb-carcass grades. Advances in maturity are reflected by calcification of cartilagenous tips on the spinous processes and by calcification of cartilage in the sacral region. In lamb, the calcification of the break joint makes it impossible to remove the foot at this joint. A widening of the costal bones (ribs) also occurs with advancing maturity.

Coarseness and marbling distribution are major factors affecting grade. A moderate amount of fine, evenly dispersed marbling is highly desirable, and coarseness is undesirable. With advancing maturity, a higher degree of marbling is required to equal the grading of a more youthful carcass.

Dark-coloured muscle, if objectionably dark, cannot be distinguished from muscle of very old animals or from muscle which has partially spoiled and is therefore unpopular.

Yellowish, soft, oily fat is undesirable and, if present in quantity, adversely affects the grade of pork carcasses.

Muscling is a major factor affecting pork-carcass grades and is a compensating factor in establishing the final grade for beef and lamb. Excessive fat has a major influence on pork-carcass grade and on yield grade of lamb and beef.

#### MEAT-PACKING INDUSTRY

**History.** Early commercial meat-packing operations, relying on ice for refrigeration, had to restrict slaughter to winter seasons. It was not until the late 19th century that mechanical refrigeration turned the meat-processing industry into a year-round operation. About 1900, mechanized disassembly procedures and conveyor procedures were being incorporated into regular operations.

During the 1950s, major progress was made in both plant sanitation and packaging technology, increasing shelf life significantly and contributing to the expansion of self-service retailing. During the 1960s, the meat-packing industry achieved major advances in research and development.

**Slaughtering methods and equipment.** *Humane slaughter.* In both the United States and Europe the desirability of stunning was recognized before the end of the 19th century, and mechanical equipment for this was developed.

As other countries have become increasingly industrialized, similar practices have been applied. Cattle may be stunned by means of a captive-bolt pistol or a pneumatic gun. Sheep and pigs may be stunned by pistol, by electric shock, or by anesthetizing in a carbon dioxide chamber. After World War II, compressed-air stunners were commonly used for cattle and gas chambers for smaller animals.

In addition to stunning devices, large modern abattoirs use a wide variety of mechanical, electrical, and pneumatic equipment for the various slaughtering and carcass dressing and processing operations. The moving chain-conveyor production-line system is widely used where the scale of operations warrants it. Special provision may be made for "ritual slaughter," or for other slaughter under the requirements of special faiths.

*Hog slaughter.* After stunning, pigs are bled by severing one of the large veins, the anterior vena cava, and then submerged in a scalding tank, with water temperatures between 130° and 142° F (55° and 61° C) for four to six minutes to loosen the hair. They are next subjected to a dehairer that brushes the loosened hair from the skin. The hog is then suspended vertically from a rail and shaved and singed.

The carcasses are opened by a straight cut in the centre of the belly. The viscera, including liver, heart, lungs, large and small intestines, pancreas, spleen, stomach, and bladder, are then easily removed. The intestines may be thoroughly cleaned and washed to serve as casings for specialized sausage products. The kidneys and the fat surrounding them (leaf fat) are also removed. The carcasses are then split down the centre of the backbone and, after washing, are ready to move into the cooler.

Early methods

In modern slaughter plants, each pig is tattooed (producer identification) before slaughter. As the carcasses move into the cooler, a grader records the producer's identification number and the weight and grade for each, using a tape that is fed into a computer, making the information available for proper decisions.

**Cattle slaughter.** After stunning, the carcass is vertically suspended by one or both hindlegs, and the carotid arteries and jugular veins are severed. The carcass is then skinned with an air-operated or electrically operated skinning knife. In old or small operations this is accomplished with the aid of a "stationary bed" on which a pointed stick helps hold the carcass on its back on the floor. Large modern plants use "rail dressing," employing platforms and hide pullers.

Evisceration and splitting are similar to methods used in hog slaughter. Shrouding, performed on many beef carcasses, involves soaking a muslin cloth in warm water and stretching it tightly over the outside surface, securing it with metal pins. The carcasses are then placed in the cooler; and, after 24 hours, the shrouds are removed, and the carcass fat remains smooth and trim.

**Veal slaughter.** Veal slaughter is similar to beef slaughter, but the hides are frequently left on during chilling, as veal carcasses have very little fat. If the hides were removed during chilling, the carcasses would undergo excessive shrinkage.

**Lamb slaughter.** Lambs are slaughtered much like veal, except that the pelts (wool) are removed. The carcasses, however, are not split, but are immediately chilled in the cooler.

**Processing methods and product compositions.** *Wholesale cuts.* In some countries pork carcasses are cut on an assembly line. In the future much of the cutting may be performed electronically.

Beef is primarily cut on the rail, and the cuts are then resuspended. The preparation of both portion-controlled and vacuum-packed cuts at the packer level is increasing.

Government establishment of meat-product-composition controls is becoming increasingly important throughout the world. Many countries establish meat-product-composition controls dealing with such factors as minimum meat content and the use and acceptable quantities of such fillers as cereals, dry milk or other milk products, soybean, corn syrup, and other nonmeat ingredients. In addition to its meat content, sausage may contain other additives, which must be listed on the package. These may include salt; beet or cane sugar; maple, dextrose, or invert sugars; honey; corn-syrup solids; wood smoke; flavourings; vinegar; spices; sodium nitrite; potassium nitrite; and sodium nitrate or potassium nitrate (saltpetre). Total allowable added water is usually greater in uncooked sausage than in cooked sausage.

The allowable weight increase in hams for canning may be limited by government regulation. Such factors as the proportion of nitrite and nitrate; the ascorbic acid content of the brine; and the use of phosphates in sausage, hams, and products such as chopped ham may also be subject to government standards.

Hams may be removed, cured, boned, cooked, cooled, dipped into gelatin, inserted into casings, and sealed, or they may be pressure stuffed into casings.

A body or substance is absolutely sterile only when no vegetative micro-organisms or spores are present, either because there were none originally or because all have been killed. Since the use of sterile raw material in meat canning is not practical, the sterilization process follows as rapidly as possible the hermetic sealing of the cans.

**Labelling.** In various countries where modern food processing techniques are common, governments may specify the required features of a label, such as product name; ingredients, usually in decreasing order by amount; name and place of person for whom product is prepared; statement of weight; and an inspection legend. In 1970 the Codex Committee on Food Labelling submitted a general standard for labelling prepackaged foods to be considered by the member governments.

**Emulsification.** A meat emulsion has characteristics similar to an oil-in-water emulsion. The process is in-

fluenced by type of protein, temperature, speed of blender, and protein-water ratio. Meat from hot carcasses is usually preferred because it has not been affected by a decreasing pH (increased acidity) and is more easily increased in solubility by salt application. Mutton is restricted to 15 percent of any meat formula. If meats must be held, they are held in a frozen state. Many varieties of meats are used, including tongues, livers, hearts, kidneys, and tripe (stomach).

**Manufactured casings.** Cellulosic casings are manufactured from cotton. Casings made from regenerated collagen have the advantage of being consistently uniform in size and thickness.

**Equipment.** A meat grinder permits the worming of meat along a cylinder with sharp-edged ribs and through perforated plates, and as the meat is extruded, it is cut by revolving knives. Commercial operations employ vacuum mixers to combine the various ingredients. Cutters and emulsion mills are used as comminutors, reducing the ingredients of the mixture to minute particles, and stuffers force the mixtures into casings. Computers are major equipment in modern sausage formulation and selection of raw-materials sources.

**Continuous automatic wiener process.** In this process, meats are ground separately, blended with seasonings, and pumped into a final chopper. The mixture is "stuffed" under pressure, linked, and conveyed to "smoking" chambers. The wieners are then cooked, chilled, stripped of cellulose casings, and packaged. Under this process wieners are commonly produced at a rate of 36,000 per hour.

**Packaging methods and equipment.** Packaging is intended to protect the product and to maintain a state of freshness throughout the merchandising cycle. Factors in package-material selection include moisture and gas permeability, strength, sealability, visibility, and cost.

Cellophane, polyester, polyamide, polyolefine, and polystyrene are a few of the materials that may be used. Many packages are vacuum sealed, and most packaging processes are automated.

**Packaging-plant inspection.** *Kosher inspection.* In kosher inspection, a member of the Jewish faith, called a "schachter," cuts the throat of the beef animal by severing the carotid arteries and jugular veins perpendicular to the axis of the neck, immediately behind the jawbone. The beef animals are not stunned before bleeding. After bleeding, the schachter examines the lungs for abnormalities. If any are present the beef is not approved and is called "trepha."

**Meat inspection.** Modern meat inspection is usually concerned with the state of health of the animal; the physical plant, facilities, and equipment; the use of food additives; and the use of proper labels. Inspection is frequently supervised or carried out by licensed veterinarians.

On the basis of antemortem inspection, an animal may be passed for slaughter, considered suspect, or condemned. When passed, the animal proceeds through normal processing and is subjected to routine subsequent inspection procedures. Condemnation may result when an animal plainly shows evidence of disease or a condition that obviously would result in condemnation of the carcass and its parts. If its condition is questionable, the animal may be labeled "suspect." A routine inspection of all body parts is usually conducted as the animal is slaughtered, and an inspector's mark is stamped on. In the U.S. the inspection responsibility is shared by federal and state governments.

Governments are becoming increasingly involved in meat inspection, and it may be expected that meat inspection practices throughout the world will be affected by the recommendations of the various Codex Committees concerned with establishing standards for meat and meat products, food hygiene, food labelling, and analysis and sampling.

**Meat-packing industry by-products.** By-products, the nonmeat materials obtained in meat processing, are used in a wide range of products.

Edible fats are used as lard or in shortenings and cooking oils; inedible fats are used in soap and candles and in

various greases for industrial use. Lanolin, the fat removed from wool, is used in ointments and cosmetics. Gelatin, obtained from collagen, is used in such food products as confections and jellies and in pharmaceuticals. Sausage casings are made from intestines and from regenerated collagen, which is also being developed for use in various leather-like products. Gland extracts are used in such pharmaceuticals as insulin and cortisone.

Wool of slaughtered animals is used like any other, for yarns and textiles; hides and skins are made into leather; and hair is used in brushes, felt, and upholstery products. Bone is used principally in animal feeds and fertilizers and in glue. Blood is also used in animal feeds and fertilizers and in pharmaceuticals.

(E.J.B.)

## Mecca

The holiest of Muslim cities, Mecca (in Arabic Makkah) was the birthplace of Muḥammad, the founder of Islām. Located in the Širāt Mountains inland from the Red Sea coast of Saudi Arabia, it is a religious centre to which all Muslims attempt a pilgrimage, or *hajj*, during their lifetime. Mecca is also the second most populous city of Saudi Arabia, after the national capital of Riyadh. Its early 1970s population of about 300,000 occupied an area of about 10 square miles (26 square kilometres). During the month of pilgrimage, however, the city is swollen with about 1,000,000 worshippers from other parts of the country and from other Muslim nations.

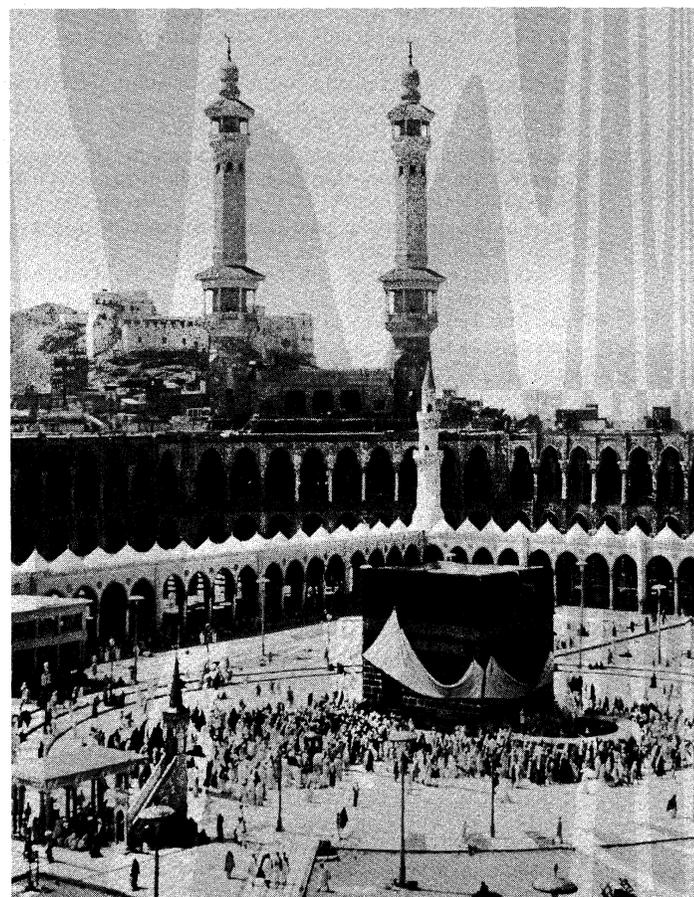

An historic city closely tied to tradition, Mecca has benefited from the Saudi Arabian oil economy of the 20th century, although income from the pilgrimage is still important. In recent decades the city has undergone vast improvements. The area around the religious shrines has been cleared, the mosque has been greatly enlarged, housing and sanitation have been improved, and transportation facilities have been greatly enhanced. As a result, Mecca can accommodate an increasing number of pilgrims, the numbers of which continually increase. (For related articles see ISLAM; ISLAM, HISTORY OF; ISLAMIC MYTH AND LEGEND; and MUHAMMAD.)

**History.** Ancient Mecca was an oasis on the old caravan trade route that linked the Mediterranean world with South Arabia, East Africa, and South Asia. Located about midway between Ma'rib in the south and Petra in the north, the town gradually developed by Roman and Byzantine times into an important trade and religious centre. It was known to Ptolemy as Macoraba.

According to Islāmic tradition, Abraham and Ishmael, his son by Hagar, built the Ka'bah as a replica of God's house in heaven. The central point of pilgrimage in Mecca before the advent of Islām in the 7th century, the cube-shaped stone building has been destroyed and rebuilt several times. During biblical times, the city was ruled by a series of Yemeni tribes. Under the Quraysh, it became a type of city-state, with strong commercial links to the rest of Arabia, Ethiopia, and Europe. Mecca became a place for trade, for pilgrimage, and for poetry festivals.

The city gained its religious importance with the birth of Muḥammad about 570. Forced to flee from Mecca in 622, the prophet returned eight years later and took control of the city. He purged Mecca of idols, declared it a centre of Muslim pilgrimage, and dedicated it to Allāh. Since then, the city has remained the major religious centre of Islām. As the ancient caravan route fell into decline, Mecca lost its commercial significance and has since lived mainly on the annual pilgrimages and the gifts of Muslim rulers.

Camera Press—Pix

The central courtyard of al-Haram mosque. In the centre is the Ka'bah, the holiest shrine of Islām.

Mecca remained virtually independent, although it acknowledged the power of Damascus and later of the 'Ab-bāsīd caliphate of Baghdad, Iraq. In 1269 it came under the control of the Egyptian Mamlūk sultans. In 1517 dominion over the holy city passed to the Ottoman Turks in Constantinople (now Istanbul). The local city rulers were chosen from the *sharīfs*, or descendants of Muḥammad, who retained a strong hold on the surrounding area. With the fall of Turkish power after World War I, control of Mecca was contested between the *sharīfs* and the Wāhhābīs of central Arabia. The Wāhhābī king Ibn Sa'ūd entered the city in 1925, and it became part of the Kingdom of Saudi Arabia, and the capital of Makkah *manāṭiq idāriyah* (province).

Under the Wāhhābīs, a puritanical moral code and law and order were enforced, and the facilities for pilgrims

The period of foreign control

The ancient city

were improved. With the exploitation of Saudi Arabia's oil resources since World War II, Mecca has experienced a high level of economic development.

**The contemporary city.** *The city site.* Mecca is situated at an elevation of 909 feet (277 metres) above sea level in the dry beds of the Wādī Ibrāhīm and several of its short tributaries. It is surrounded by the Širāt Mountains the peaks of which include Jabal Ajjad, which rises to 1,332 feet (406 metres), and Jabal Abū Qubays, which attains 1,220 feet (372 metres), to the east and Jabal Qu'ayq'an, which reaches 1,401 feet (427 metres), to the west. Jabal Hirā' rises to 2,080 feet (634 metres) on the northeast and contains a cave in which Muḥammad sought isolation and visions before he became a prophet. It was also in this cave that he received the first verse (*sūrah*) of the holy Qur'ān. South of the city, Jabal Thawr (2,490 feet [759 meters]) contains the cave in which the prophet hid from the people of Mecca before he moved to Medina.

Entrance to the city is gained through four gaps in the surrounding mountains. The passes lead from the northeast to Minā, 'Arafāt, and aṭ-Ṭā'if; from the northwest to Medina; from the west to Jidda; and from the south to Yemen (Šan'ā'). The gaps have also defined the direction of the contemporary expansion of the city.

Because of its relatively low-lying location, Mecca is threatened by seasonal flash floods despite the low amount of annual precipitation. There are less than five inches of rainfall during the year, mainly in the winter months. Temperatures are high throughout the year and in summer may reach 113° F (45° C). Vegetation and animal life are scarce and consist of species that can withstand the high degree of aridity and heat.

Natural vegetation is sparse, and includes tamarisks and various types of acacia. Wild animals include wild cats, wolves, hyenas, foxes, mongooses, and kangaroo rats (jerboas).

*The city plan.* The city centres upon the al-Haram mosque and the sacred well of Zamzam, located inside the mosque. The compact built-up area around the mosque comprises the old city, which stretches to the north and southwest but is limited on the east and west by the nearby mountains. The main avenues are al-Mudda'ah and Sūq al-Layl to the north of the mosque and as-Sūq as-Saghīr to the south.

Since World War II, Mecca has expanded along the roads through the mountain gaps to the north, northwest, and west. Among the new residential areas are Al-'Azīziyah and al-Faysaliyah along the road to Minā and az-Zāhir, az-Zahra'a, and Shāri' al-Manšūr along the roads to Jidda and Medina. Expansion has been accompanied by the construction of new streets in the old city and by the transformation of Mecca into a modern city, with fountains, built since the 1950s, in its four main squares. The square mosque is magnificent in its size and architecture. Enlarged from 313,520 to 1,724,032 square feet (29,127 to 160,168 square metres), it can accommodate more than 300,000 worshippers at one time. Houses near the mosque have been razed, and it is now surrounded by open spaces and wide streets, which can be crossed through underground walkways, built to ease traffic.

Mecca's more than 35,000 houses are more compacted in the old city than in the newly developed residential areas. Traditional buildings of two or three stories are built of local rock. The villas in the new areas are constructed of concrete. Slum conditions can still be found in various parts of the city; the slum inhabitants are mainly poor pilgrims who remained in Mecca after arriving on pilgrimage in past years.

*The people.* The population of about 300,000 lives in an area of about 10 square miles (26 square kilometres). The average population density is about 30,000 persons per square mile (12,000 persons per square kilometre); most of the people are concentrated in the old city, while densities in the new residential areas may drop to only 7,300 per square mile (2,800 per square kilometre). There are slightly more males than females. About one-third of the population is under 10 years of age, and about two-thirds are under 30 years of age.

Residence in Mecca is permitted only to followers of Islām. It is, however, one of the most cosmopolitan cities in the world, containing people from the various Islāmic countries in Asia and Africa. People of the same national origin tend to live together in certain parts of the city. There is, however, no racial discrimination.

*The economy.* Arable land and water are scarce, and food must be imported. Vegetables and fruits are brought in daily from the surrounding *wadis*, such as Wādī Fātimah, from the Ṭā'if area to the east-southeast, and from the southern agricultural areas, such as Bilād Ghāmid and Bilād Zahrān. Foodstuffs are imported from abroad mainly through the port of Jidda, 45 miles to the west on the Red Sea.

Industry is limited (it includes the manufacture of textiles, furniture, and utensils), and the overall urban economy is commercial. The number of commercial establishments grew from almost 2,300 in 1959 to about 7,000 in 1969. Transportation and facilities related to the pilgrimage are the main service industries.

Mecca has no airport nor water or rail services. It is well served, however, by the Jidda seaport and airport and by truck, bus, and taxi services. Asphalt roads link Mecca with the main cities of Saudi Arabia and neighbouring countries.

Because of the improvement of services, the number of foreign pilgrims increased from 61,000 in 1946 to about 480,000 in 1972. There is also a similar number of Saudi pilgrims. This annual influx brings a good income to the city, but it also results in a population of about 1,000,000, all of whom need accommodations, food, water, electricity, transportation, and medical services. In a normal month Mecca consumes about 173,000,000 gallons of water, but, in the month of Dhū al-Ḥijjah (the month of pilgrimage), the amount of water consumed rises to 552,000,000 gallons.

The main problem is transportation. In accordance with the prescribed route, all pilgrims have to be transported from Mecca to 'Arafāt, a distance of about 12 miles (19 kilometres), during the early morning of the 9th day of the month of Dhū al-Ḥijjah. During the night of the same day, they must travel to Minā, which is almost two miles from Mecca; after three days, all are returned to Mecca. This problem has been met by the construction of a good road network, an adequate supply of vehicles, and traffic control.

*Administration and social conditions.* The governor of the city is the amir of Makkah *manātiq idāriyah*, who is responsible for the maintenance of law and order in both the city and the *manātiq*; appointed by the king, he is immediately responsible to the Minister of the Interior. The municipal council is responsible for the functioning of the municipality; the council was formed after World War II, and has 14 members, who are locally elected and are then approved by the Minister of the Interior. Mecca is also the capital of Makkah *manātiq idāriyah* which includes the cities of Jidda and aṭ-Ṭā'if.

Free education is provided for both girls and boys from primary to university level. There are two university-level colleges—the Sharī'ah College of Islamic Jurisprudence, and the College of Education (a teacher training college).

Health services and medical care are free and adequate. There are more than 800 hospital beds and about 70 physicians. Police and fire service is modern and effective. A major sewer project was under construction in the early 1970s. Despite careful checking at points of entry into Saudi Arabia, pilgrims may bring various illnesses, particularly cholera, smallpox, and cerebro-spinal infections, into the city; the health services, however, have been able to keep such problems under control.

Mecca depends upon the surrounding *wadis* for drinking water. The waters of 'Ayn Zubaydah (Zubaydah Spring), built in the 8th century, flow through tunnels from Wādī Nu'mān, about 20 miles (30 kilometres) to the southwest. 'Ayn al-'Azīziyah sends its waters through pipelines from Wādī ash-Shāmiyah, about 60 miles (100 kilometres) to the northeast. Water and electricity have reached almost all houses. Electricity is generated at an oil-fuelled power station located on the road to Medina.

The problems of the pilgrimage

Mecca's religious shrines

Education services

*Cultural life.* Mecca has a number of cultural and sporting clubs and public libraries. In summer, its residents travel to the nearby resort of at-Ta'if, 50 miles (80 kilometres) to the southeast.

Daily newspapers are available in Arabic, and there is a daily English newsletter. Radio and television programs are broadcast from Jidda.

**BIBLIOGRAPHY.** Literature about Mecca is available mainly in Arabic. For pre-Islamic and early Islamic times, see M.A.A. AL-AZRAQI, *Akhbar Makkah*, written in the 9th century (1875, reprinted 1969); and A.I. AL-SHARIF, *Makkah wa-al-Madinah* (1965). For the Middle Ages, see IBN JUBAYR, *Travels . . . (1183-1185 A.D.)*, written in the 12th century, trans. by R.J.C. BROADHURST (1952); and IBN BATUTA, *Travels, A.D. 1325-1354*, written in the 14th century, trans. by H.A.R. GIBB (1958). Other English-language accounts include JOHN L. BURCKHARDT, *Travels in Arabia* (1829); JOHN F. KEANE, *Six Months in Meccah* (1881); C. SNOUCK HURGRONJE, *Mekka*, 2 vol. (1888-89); Eng. trans. of vol. 2, *Mekka in the Latter Part of the 19th Century: Daily Life, Customs and Learning* (1931); SIR RICHARD BURTON, *Personal Narrative of a Pilgrimage to El-Medinah and Meccah*, 5th ed., 3 vol. (1906); ARTHUR WAVELL, *A Modern Pilgrim in Mecca and a Siege in Sanaa* (1912); ELDON RUTTER, *The Holy Cities of Arabia* (1928); and J.B. PHILBY, *A Pilgrim in Arabia* (1946). For statistics, see the *Statistical Yearbook* (annual), published by the Central Department of Statistics, Riyadh, Saudi Arabia.

## Mechanical Engineering

Mechanical engineering is the branch of engineering that deals with machines and the production of power. It is particularly concerned with forces and motion.

**History.** The invention of the steam engine in the latter part of the 18th century, providing a key source of power for the Industrial Revolution, gave an enormous impetus to the development of machinery of all types. As a result a new major classification of engineering, separate from civil engineering and dealing with tools and machines, developed, receiving formal recognition in 1847 in the founding of the Institution of Mechanical Engineers in Birmingham, England.

Mechanical engineering has evolved from the practice by the mechanic of an art based largely on trial and error to the application by the professional engineer of the scientific method in research, design, and production.

The demand for increased efficiency, in the widest sense, is continually raising the quality of work expected from a mechanical engineer and requiring of him a higher degree of education and training. Not only must machines run more economically but capital costs also must be minimized.

**Fields of mechanical engineering.** *Development of machines for the production of goods.* The high material standard of living in the developed countries owes much to the machinery made possible by mechanical engineering. The mechanical engineer continually invents machines to produce goods and develops machine tools of increasing accuracy and complexity to build the machines.

The principal lines of development of machinery have been an increase in the speed of operation to obtain high rates of production, improvement in accuracy to obtain quality and economy in the product, and minimization of operating costs. These three requirements have led to the evolution of complex control systems.

The most successful production machinery is that in which the mechanical design of the machine is closely integrated with the control system, whether the latter is mechanical or electrical in nature. A modern transfer (conveyor) line for the manufacture of automobile engines is a good example of the mechanization of a complex series of manufacturing processes. Developments are in hand to automate production machinery further, using computers to store and process the vast amount of data required for manufacturing a variety of components with a small number of versatile machine tools. One aim is a completely automated machine shop for batch production, operating on a three-shift basis but attended by a staff for only one shift per day.

*Development of machines for the production of power.* Production machinery presupposes an ample supply of power. The steam engine provided the first practical means of generating power from heat to augment the old sources of power from muscle, wind, and water. One of the first challenges to the new profession of mechanical engineering was to increase thermal efficiencies and power; this was done principally by the development of the steam turbine and associated large steam boilers. The 20th century has witnessed a continued rapid growth in the power output of turbines for driving electric generators, together with a steady increase in thermal efficiency and reduction in capital cost per kilowatt of large power stations. Finally, mechanical engineers acquired the resource of nuclear energy, whose application has demanded an exceptional standard of reliability and safety involving the solution of entirely new problems. The control systems of large power plants and complete nuclear power stations have become highly sophisticated networks of electronic, fluidic, electric, hydraulic, and mechanical components, all of these involving the province of the mechanical engineer.

The mechanical engineer is also responsible for the much smaller internal combustion engines, both reciprocating (gasoline and diesel) and rotary (gas-turbine and Wankel) engines, with their widespread transport applications. In the transportation field generally, in air and space as well as on land and sea, the mechanical engineer has created the equipment and the power plant, collaborating increasingly with the electrical engineer, especially in the development of suitable control systems.

*Development of military weapons.* The skills applied to war by the mechanical engineer are similar to those required in civilian applications, though the purpose is to enhance destructive power rather than to raise creative efficiency. The demands of war have channelled huge resources into technical fields, however, and led to developments that have profound benefits in peace. Jet aircraft and nuclear reactors are notable examples.

*Bioengineering.* Bioengineering is a relatively new and distinct field of mechanical engineering that includes the provision of machines to replace or augment the functions of the human body and of equipment for use in medical treatment. Artificial limbs have been developed incorporating such lifelike functions as powered motion and touch feedback. Development is rapid in the direction of artificial spare-part surgery. Sophisticated heart-lung machines and similar equipment permit operations of increasing complexity and permit the vital functions in seriously injured or diseased patients to be maintained.

*Environmental control.* Some of the earliest efforts of mechanical engineers were aimed at controlling man's environment by pumping water to drain or irrigate land and by ventilating mines. The ubiquitous refrigerating and air-conditioning plants of the modern age are based on a reversed heat engine, where the supply of power "pumps" heat from the cold region to the warmer exterior.

Many of the products of mechanical engineering, together with technological developments in other fields, have side effects on the environment and give rise to noise, the pollution of water and air, and the dereliction of land and scenery. The rate of production, both of goods and power, is rising so rapidly that regeneration by natural forces can no longer keep pace. A rapidly growing field for mechanical engineers and others is environmental control, comprising the development of machines and processes that will produce fewer pollutants and of new equipment and techniques that can reduce or remove the pollution already generated.

**Mechanical engineering functions.** Four functions of the mechanical engineer, common to all the fields mentioned, can be cited. The first is the understanding of and dealing with the bases of mechanical science. These include dynamics, concerning the relation between forces and motion, such as in vibration; automatic control; thermodynamics, dealing with the relations among the various forms of heat, energy, and power; fluid flow; heat transfer; lubrication; and properties of materials.

Complex  
control  
systems

Second is the sequence of research, design, and development. This function attempts to bring about the changes necessary to meet present and future needs. Such work requires not only a clear understanding of mechanical science and an ability to analyze a complex system into its basic factors, but also the originality to synthesize and invent.

Third is production of products and power, which embraces planning, operation, and maintenance. The goal is to produce the maximum value with the minimum investment and cost while maintaining or enhancing longer term viability and reputation of the enterprise or the institution.

Fourth is the coordinating function of the mechanical engineer, including management, consulting, and, in some cases, marketing.

In all of these functions there is a long continuing trend toward the use of scientific instead of traditional or intuitive methods, an aspect of the ever-growing professionalism of mechanical engineering. Operations research, value engineering, and PABLA (problem analysis by logical approach) are typical titles of such new rationalized approaches. Creativity, however, cannot be rationalized. The ability to take the important and unexpected step that opens up new solutions remains in mechanical engineering, as elsewhere, largely a personal and spontaneous characteristic.

**Education and professional societies.** Education in engineering has also reflected the growing professionalism of the practice. Until World War II, most universities in Europe and the U.S. had curricula involving a considerable degree of specialization into mechanical, electrical, or other engineering. With the rapid growth of these fields of technology, students were becoming more and more specialized. At the same time, the increasing complexity of technical projects required from the professional engineer not only a knowledge of his own specialty but an understanding of the other branches of engineering. Widespread revision of university curricula has more recently aimed at providing a broad, fundamental knowledge of engineering science, leaving the specialized training to industry.

Another approach, considered more practical and less intellectual, is the sandwich, or cooperative, system of education, comprising alternating periods of six months spent in industry and at college. British engineering schools have been prominent in pioneering this arrangement.

In the Soviet Union, university courses in mechanical engineering last about five and one-half years, of which the first three are applied to the fundamentals of the subject with a strong mathematical content, while the remaining period provides a wide choice of specialist training. Similarly, in most of the countries of Continental Europe and Japan, engineering courses run for five years and, while of a general nature for the first two years or so, become specialized and practical thereafter. The student is expected to obtain experience in industry during his vacation, so that, after graduation, he is able to take a professional post of responsibility without further training.

The professional societies have been the main instrument in raising the status of mechanical engineering to that of an important profession grounded in a lengthy training in mechanical science.

For the various grades of membership of the major societies it is necessary to attain specified academic qualifications, practical experience, and defined levels of responsibility. In the British Institution of Mechanical Engineers a member of either of the two most senior grades, "Fellow" and "Member," is designated "Chartered Engineer"—a title denied by law to those who have not achieved the necessary qualifications and membership.

Although in the majority of Western countries it is not necessary to attain formal registration before practicing as an engineer, the achievement of a senior grade of membership of a professional society is generally important in seeking a responsible engineering post.

The growth of membership of the Institution of Mechanical Engineers has been almost uniform over 120 years. The mean rate of increase has been 5.2 percent per year, a figure that indicates the rapid and continuing increase in the size and importance of the mechanical engineering profession. The growth rate of the American Society of Mechanical Engineers has been similar.

Societies of professional mechanical engineers have long been established in European countries; in Japan (1897), in India (1920), in China (1951), and in most other countries that have significant strength in this field. The primary function of these societies is to promote mechanical engineering by publishing technical papers and arranging conferences. Unlike the British Institution, however, they do not in general regulate, by their conditions of membership, the qualifications and status of professional engineers.

With the broadening and changing content of mechanical engineering, specialized groups have been organized within the national societies—e.g., groups concerned with automatic control, combustion engines, heat transfer, and lubrication technology.

National societies are also often subdivided on a geographical basis and have links with similar societies in other countries and with their fellow societies in other fields of engineering and science.

**The future of mechanical engineering.** The number of mechanical engineers continues to grow as rapidly as ever, while the duration and quality of their training increases. There is a growing awareness, however, among engineers and in the community at large that the exponential increase in population and living standards is raising formidable problems in pollution of the environment and the exhaustion of natural resources; this clearly heightens the need for all of the technical professions to consider the long-term social effects of discoveries and developments. There will be an increasing demand for mechanical engineering skills to provide for man's needs while reducing to a minimum the consumption of scarce raw materials and maintaining a satisfactory environment.

**BIBLIOGRAPHY.** For general reading, see *Engineering Heritage: Highlights from the History of Mechanical Engineering*, 2 vol. (1963-66), issued by the INSTITUTION OF MECHANICAL ENGINEERS. The history of this society is given in R.H. PARSONS, *A History of the Institution of Mechanical Engineers, 1847-1947* (1947). For information on educational requirements, see the *Britannica Review of Developments in Engineering Education*, ed. by NEWMAN A. HALL (1970- ); and for salaries, the ENGINEERING MANPOWER COMMISSION OF THE ENGINEERS JOINT COUNCIL (New York), *Professional Income of Engineers, 1968-1969* (1969); and the *Survey of Professional Engineers 1968* (HMSO, 1970). Machine-tool trends are discussed in W.H.P. LESLIE (ed.), *Numerical Control Users' Handbook* (1970).

(J.F.Br./P.McG.R.)

## Mechanics, Celestial

Celestial mechanics is a branch of astronomy pertaining to the motion of natural and artificial bodies in space. The application of mathematics to the motion of artificial satellites, space crafts, space probes, rockets, even missiles, is often called astrodynamics, and is considered a branch of astronautics. Dynamical astronomy deals with the forces and motions of celestial bodies and includes stellar and planetary dynamics. The terminology of these scientific areas is not well defined, and there is an undesirable and restrictive traditional association of celestial mechanics with the dynamical study of the solar system. In this article, a systematic treatment of the pertinent dynamical and mathematical principles is applied to the motion of bodies in space, regardless of their origin.

The laws of dynamics are described by differential equations and an understanding of these laws is fundamental to the study of celestial mechanics. The close relation between dynamics and celestial mechanics suggests that Sir Isaac Newton may be the founder of celestial mechanics because his laws of motion, which express the principles of mechanics, are applicable to any force field. His universal law of gravitation is one example of how his formulation and application of the

Growth of membership in engineering societies

calculus to dynamical problems permits an orderly and scientific treatment of the behaviour of celestial bodies. In fact, this is the only known language for treating problems in celestial mechanics, and without it the computation of orbits of space vehicles would not be possible (see MECHANICS, CLASSICAL).

A century before Newton, Johannes Kepler (1571–1630) obtained his three laws of planetary motion empirically, but they may be derived from Newton's laws of motion and gravitation; the brilliant contributions to celestial mechanics of Nicolaus Copernicus (1473–1543), Tycho Brahe (1546–1601), and Galileo (1564–1642) also include special cases of Newton's results, anticipating Newton, though it was he who comprehended and formulated the abstract laws.

Operational processes of celestial mechanics

The operational processes of celestial mechanics use as input either observations or, in the case of space vehicles, certain mission requirements. Next, the equations are formulated and solved. The output may be the time dependence of the position of a satellite, a set of initial conditions applicable to firing tables, the prediction of the orbit of a comet, or the location of a planet at any given time. In 3000 BC the Babylonian priest-astrologers made naked eye observations of what was then considered to be the planetary motions (the five visible planets, the Moon, and the Sun were all considered to be planets of the Earth) in order to keep nations and kings out of trouble, to regulate the calendar, and to aid travellers. Modern preparation of lunar and planetary ephemerides (listings of locations of celestial bodies for regular time intervals), of nautical almanacs, of guidance and firing tables, of refined relativity corrections is fundamentally the same kind of output that Mesopotamia requested from its high priests of celestial mechanics. The computations they performed might be considered clumsy today, but even the modern—but precomputer—use of E.W. Brown's (1866–1938) lunar theory allowed hardly enough time for prediction of the Moon's motion. Two men were fully occupied in establishing one new position of the Moon every 12 hours. The balance between observations and computations has always been precarious, and today the enormous number of radar observations and their high precision may overload the most advanced electronic computers.

**Historical review.** Early celestial mechanics concentrated attention on the behaviour of the major members of the solar system. Observations were relatively crude, and even completely erroneous dynamical ideas, or models devoid of dynamics, could offer fairly satisfactory predictions—at least for short times. This situation has a counterpart today: inadequate knowledge of the gravitational field of the Moon prevents long-term predictions of the orbits of lunar satellites.

The early Babylonian priest-astrologers were mainly observers. They invented the signs of the Zodiac and recognized the precession of the vernal equinox, but there seems to be no evidence that either they or the early Egyptian astronomers established a consistent theory of planetary motions. The Greek period (from about 400 BC) of celestial mechanics is of more interest to philosophers than to astronomers. Plato's problem regarding the representation of the motion of celestial bodies by combining uniform circular motions had, at that time, two philosophical solutions: one culminating in Aristotle's 55 spheres, and the other in the Ptolemaic system. Plato's problem is now seen as one of Fourier analysis, which, using trigonometric series as approximations, is today still the basic tool in treating planetary and lunar theories. The concept of the rotating celestial sphere with the Earth at its centre (even now, occasionally, a useful convention) and the concept of concentric shells used by Aristotle (384–322 BC) were attempts to represent planetary as well as stellar motion relative to the Earth. The model was intended to describe the geometry of the motion without reference to causes. Hipparchus (approximately 130 BC), inventor of spherical trigonometry, emphasized the importance of observations and made Claudius Ptolemaeus' (c. AD 200) system feasible. The Ptolemaic system was still a purely kinematic approach to celestial mechanics, being devoid of dynamical concepts. The Ptolemaic

representation of the apparent planetary motions by epicycles centred at the Earth is approximate and somewhat complicated since the motions of the planets actually centre around the Sun.

Arguments favouring a heliocentric system were mentioned by some early Greek astronomers, notably Aristarchus (c. 270 BC), but the first consistent theory with the Sun placed centrally in the solar system was accomplished in the 16th century by Nicolaus Copernicus. Tycho Brahe later proposed the somewhat irrelevant view that the Sun and Moon moved on circles centered at the Earth, all other planets revolving around the Sun; nevertheless Brahe's excellent observations were fundamental to Kepler's (1571–1630) work.

Kepler's contributions may be considered the last of purely kinematic significance in celestial mechanics. His laws describe the motions of the planets without reference to the governing forces. His original three laws, formulated in 1609, were the ones numbered (1) and (2) below, together with a statement according to which the planes of motion of the planets pass through the Sun. His original fourth law, proposed in 1618, is shown as (3) below. The laws are as follows: (1) the orbit of each planet is an ellipse, with the Sun at one focus of the ellipse; (2) the line joining the Sun to the planet sweeps through equal areas in equal times; (3) the squares of the periods of revolution of any two planets are in the same proportion as the cubes of their mean distances from the Sun.

The first and second laws are true only if perturbations (that is, disturbances caused by additional forces) of the two-body problems are neglected. The third law is only approximately true even when perturbations are not present since it assumes that the masses of the planets may be neglected as compared to the mass of the Sun.

The ellipse of the first law (Figure 1) is a plane curve such that for any point, G, on the ellipse, the sum  $GS + GS'$  is the same. In fact,  $S'G + SG = AP$ . The point P on the orbit closest to the Sun, S, is called the perihelion. The furthest, A, is the aphelion. The foci are S and S'. The semimajor axis of the ellipse is half the distance between A and P; that is, AC or CP, usually denoted by  $a$ ; C is the centre of the ellipse. The eccentricity of the ellipse,  $e$ , is the focal length CS divided by the semimajor axis CP. The *line of apsides* is defined by the major axis. The *mean distance* of a planet from the Sun is the length of its semimajor axis.

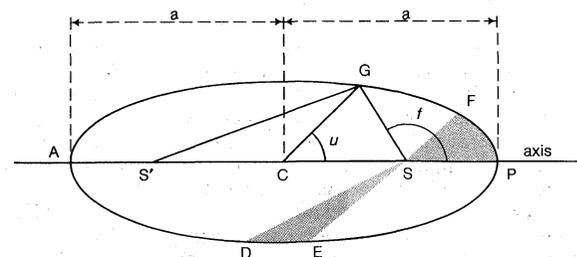

Figure 1: Orbital element in plane (see text).

The second law reveals empirically that the shaded areas on Figure 1 are equal, provided the same time has elapsed between corresponding locations of the planet. In other words, consider a planet located at perihelion P and a month later at point F. Now, if the planet is (at a later time) at point D and one month later at E, then the areas of the sectors SPF and SDE are equal. Inasmuch as points F and P are closer to S than D and E, it can be concluded that the velocity of the planet is greater at perihelion than anywhere else. (Aphelion passage is the slowest and perihelion the fastest.) The angular velocity of the planet (rate of change of its angular position) varies on its orbit; the average angular velocity is called the mean motion of the planet.

The third law relates the semimajor axes of the planets to their mean motions or periods of revolution around the Sun. Once the period of revolution of a planet is known, its mean distance from the Sun can be computed relative to another planet's mean distance. The Earth's mean distance, the astronomical unit (A.U.), is used as

Kepler's laws

the scale of the solar system. Consequently, any planet's mean distance in astronomical units may be obtained by computing the  $\frac{2}{3}$  power of its period of revolution expressed in years. Thus, Jupiter's orbital period is approximately 11.86 years, the  $\frac{2}{3}$  power of which is 5.2. The mean distance of Jupiter from the Sun (its semimajor axis) is 5.2 times that of Earth.

Kepler's contemporary, Galileo (1564–1642), well-known for his observations, which included the discovery of four of Jupiter's satellites, made his major contribution by introducing concepts of modern dynamics. Newton's first two laws of motion were anticipated by Galileo, whose observations uncovered the fact that bodies maintain uniform motion (or are at rest) when no force is acting on them. To demolish the Aristotelian myth that rest was a "natural state" and motion per se required force were major steps made by Galileo before Newton's discoveries.

Newton's laws

Newton's three laws of motion are concerned with the effect of force on motion. They are: (1) every body continues in its state of rest, or of uniform motion in a straight line, unless compelled by a force to change that state; (2) the rate of change of momentum (velocity  $\times$  mass) is proportional to and along the line of the force; (3) to every action corresponds an equal and opposite reaction. The first law may be considered a corollary of the second. The force acting on a body is proportional to the rate of change of momentum; consequently, if there is no force, the body's momentum is constant.

Newton's law of universal gravitation states that two bodies attract each other with a force that is along the line connecting the bodies, is proportional to the product of the masses of the bodies, and is inversely proportional to the square of the distance between the bodies. The law is universal since it is applicable to the motion of a planet around the Sun as well as to the falling of a stone (or apple). The law of gravitation speaks about two bodies, the Sun and a planet, or the Earth and the stone, but the law is valid for computing the interactions of any number of bodies. The motion of two (isolated) bodies subject to mutual gravitational forces can be computed by solving the pertinent differential equations. The solution in the planetary case is an ellipse on which the motion takes place according to Kepler's laws. But this result is no longer empirical; it does not follow from observations as in Kepler's case, but it is obtained by analytical tools using the force as input. In fact, the motion of double stars, of comets, or of satellites might be computed by carefully evaluating the forces and solving the appropriate differential equations. If there are only two bodies participating (called the problem of two bodies), the solution is known to be either an ellipse, hyperbola, or parabola, but such general statements about the solution of problems in which more than two bodies participate cannot be made. The celebrated unsolved problem of celestial mechanics is the problem of three bodies; that is, when three bodies interact gravitationally with each other (see below).

Progress in celestial mechanics after Newton's work was rapid, since the basic force law, as well as the equations to be solved, were now ready for application. Powerful analytic methods have been developed in the last two centuries.

The Newtonian approach to dynamics is to solve the equations of motion by finding *explicit expressions* of the positions of the bodies as functions of the time, but such satisfying and luxuriously elegant results can be obtained only for the simplest problems of celestial mechanics. In practice, one must resort to successive approximations and *series solutions*, since the simple closed-form solutions are not available. Often these series represent solutions valid only for a short interval of time or, in the language of mathematics, the series are either not convergent or have a small radius of convergence. The other fundamental difficulty of series solutions is that they are unable to furnish the properties of the general solution. Nevertheless, the success of classical series solutions in obtaining approximate representations of the motion is unquestionable.

The next step in the development of dynamics was the

application of *qualitative methods*. The unsurpassed master of such methods was H. Poincaré (1854–1912), who revolutionized the fundamental concepts of celestial mechanics. The qualitative approach does not furnish numerical descriptions of the motion; consequently, Poincaré's contributions—and those of G.D. Birkhoff (1884–1944), A. Wintner (1903–58), and A.N. Kolmogorov (1903– )—were of more theoretical than of immediate practical or observational interest.

Qualitative methods of Poincaré

**Modern method.** The qualitative, quantitative, and formalistic methods of celestial mechanics have clearly defined places in the aforementioned development of dynamics. The most powerful mathematical methods belong to the modern qualitative approach, and the use of computers permits the full utilization of the quantitative and formalistic approaches. The formalistic approach is the classical series solution of problems of celestial mechanics used by the great mathematicians from L. Euler (1707–83) to D. Brouwer (1902–66). The capability of high-speed computers to perform algebraic manipulations, series expansions, multiplications of series (in addition to numerical work) makes the classical formalistic approach once again fashionable, since high order expansions may be obtained with high reliability and with great speed. The quantitative approach is popular with astronomers and space engineers because often a particular solution of a problem is sought rather than the general behaviour of the dynamical system. Examples are planetary ephemerides, representing particular solutions of the astronomers'  $n$ -body problems (when any number,  $n$ , of bodies interact) and lunar trajectories, representing particular solutions of the engineers' problem.

The recent popularity and importance of celestial mechanics are due not only to the great advances made in the development of electronic computers but also to successful launching of space probes and satellites. Computers perform computations that some years ago would have taken lifetimes of hard labour with desk calculators. The concept of experimentation in its original and numerical sense has entered celestial mechanics. Physical experimentation in classical astronomy was not possible; the universe could be observed only. But it is now possible to launch satellites on orbits designed to obtain information regarding the Earth's gravitational field, and this is an experiment in astronomy. Modern computers permit *numerical* experiments also. From the point of view of dynamics, it is essential to survey the totality of possible motions and thereby to establish information about the future behaviour of a system of interest. For instance, a stone thrown with various initial velocities will have different orbits. Once a method is established whereby the orbit can be predicted from the direction and speed with which the stone was thrown, the possible motions that result can be surveyed. In space research this concept may assume the greatest interest, as the following example demonstrates.

Space missions as experiments

The orbit of an Apollo space vehicle is designed so that the astronauts may land on the Moon and safely return. There are many possible ways to do this; in other words, there are many possible orbits satisfying the mission requirements (hitting a can with a stone and a target with a missile are similar types of "missions"). Knowing the totality of such orbits permits selection of the optimum path: the shortest flight time, minimum amount of fuel used, largest payload delivered, etc. So, from theoretical and practical viewpoints, comprehension of all possible orbits is essential. The computer furnishes just such information when analytical methods fail.

The problem of three bodies (Earth, Moon, space vehicle) is an unsolved one in celestial mechanics; that is, there are no closed-form formulas describing the orbit of the space probe, but computers offer numerical solutions and help to find the totality of orbits. The dynamical system (in the case of an Apollo flight) consists of the three bodies, the motions of two of which are known since the orbits of the Earth and of the Moon are available from precomputed ephemerides. The motion of the space vehicle may be numerically integrated (*i.e.*, the differential equations may be solved) for any specific set of

initial conditions knowing the firing date, the location, and the direction and magnitude of the initial velocity. Thousands of such trajectories can be calculated in minutes on a computer, and the "best" may be chosen.

In fact, it is possible to experiment numerically to see which planetary or satellite orbits are stable, what initial conditions result in orbits that repeat themselves (periodic orbits), or under what conditions a triple-star system will break up into a binary and an escaping star. The last example refers to the case when two of three stars form a two-body system, revolving around each other, while the third star departs from this binary.

*Orbits with close approaches.* New developments in computational techniques are necessary to satisfy the operational requirements imposed by attempts to solve new problems. An outstanding new problem resulting from space-probe activities is related to the accurate computation of orbits with *close approaches*. Close approaches are common occurrences—in fact, often they are operational requirements—for space probes, while natural celestial bodies seldom have close approaches. The consequence is far-reaching, and it can be comprehended when the structure of the Newtonian gravitational force field is considered. The force acting between two bodies becomes large when their mutual distance decreases. The relative velocities and accelerations also become large, and computational inaccuracies might occur just at the time when increased accuracy is usually mandatory. When the space probe is in the immediate vicinity of a target planet, the accuracy of the orbit prediction must be great; while it is coasting between centres of gravitation, the preciseness of its orbit is not critical. Close approaches may occur sometimes with asteroids or with comets, and ingenious ad hoc methods have been devised for accurate orbit computations by modifying the classical methods. Hansen's (1795–1874) *method of partial anomalies*, one such technique, splits the orbit into segments, and the motion is described by different variables on each segment. Changes of relative distances between bodies in the solar system are not as great as in the case of space probes. The Newtonian force field shows a "singular" behaviour when the participating bodies are close, in that the force becomes large and the slightest computational errors are amplified. Such a singularity may be eliminated in most problems in celestial mechanics by using properly selected variables to describe the motion. This process of mathematical regularization was investigated by T. Levi-Civita (1873–1941), H. Poincaré, and K.F. Sundman (1873–1942).

These mathematical methods were not used much in classical celestial mechanics until the peculiar orbit requirements of space exploration made their applications essential. The theory of regularization, or smoothing of the singular behaviour of the force field, has now become a characteristic approach to celestial mechanics. It stabilizes computational processes, speeds up computer solutions, and simultaneously reduces computational errors. In a special form, the method was already known to Kepler, who made use of the eccentric anomaly (see the angle  $GCS = u$  in Figure 1), in addition to the true anomaly (BSP =  $f$ ) and to the mean anomaly. (This latter is the angular measurement of time expressed in radians along the orbit, so that after the planet completes one orbit around the Sun, its mean anomaly increases by  $2\pi$ .) Introducing the eccentric anomaly as a variable (instead of the time) to describe the motion is the basic method of regularization. Sophisticated regularization techniques may be considered generalizations of the use of the eccentric anomaly and consist of the introduction of new dependent as well as independent variables. These methods have been applied with considerable success to calculations of lunar trajectories as well as to other problems in modern space dynamics.

**The problem of two bodies and perturbations.** The orbits of two gravitationally attracting bodies are ellipses, hyperbolas, or parabolas, depending on the initial conditions of the motion. The orbits of natural and artificial planets and satellites would be ellipses if perturbations did not influence these orbits; any effects that result in devia-

tions from the elliptic orbits are called perturbations. The gravitational effect of Jupiter, for instance, on the motion of the Earth around the Sun is a perturbation; because if the Earth's motion were only under the Sun's influence, its orbit would be an ellipse. One of the classical triumphs of celestial mechanics was the discovery of the planet Neptune in 1846 from perturbations of Uranus (see NEPTUNE).
