Deviations from elliptic orbits may be caused by effects other than that of a third body. The orbit of an Earth satellite is a perturbed ellipse because the Earth does not consist of homogeneous, concentric, spherical shells, and its mass distribution is distorted. Such *oblateness* perturbations on the elliptic orbits of natural and artificial satellites can be evaluated today without difficulty, and it is known that the orbits are not stationary ellipses. Another perturbation on the orbits of close Earth satellites is caused by the atmosphere. Atmospheric effects tend to circularize elliptic orbits and progressively reduce the satellite's altitude until it hits the surface of the Earth, or is destroyed by heat upon re-entering the lower atmosphere. Solar radiation pressure is another perturbation that may become important for large, light, balloon-type satellites. An originally circular orbit is distorted by the radiation effect into an ellipse with decreasing perigee distance until the satellite is destroyed.

In order to describe the effects of perturbations, it is necessary to introduce the conventional parameters describing a satellite orbit in space (see Figures 1 and 2). In

Calculating perturbations

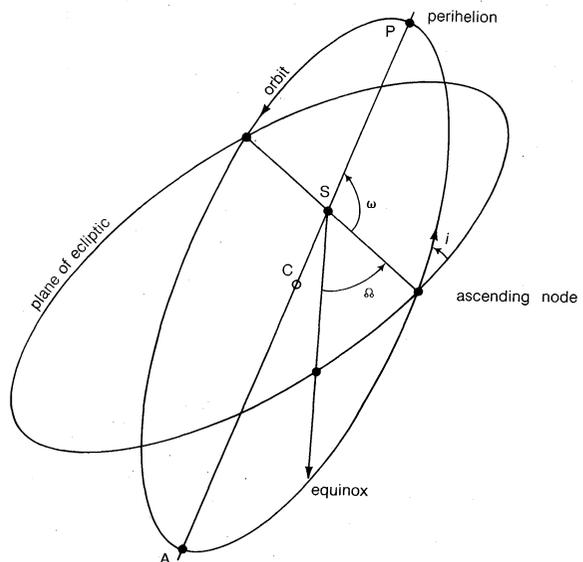

Figure 2: Orbital elements in space (see text).

addition to the previously mentioned orbital elements, the semimajor axis ( $a$ ) and the eccentricity ( $e$ ), which together determine the shape and size of the elliptic orbit, four more quantities (also called parameters) are needed. The inclination ( $i$ ) of the orbital plane to a fixed plane such as the equatorial or the ecliptic plane (in which the Earth moves) and the location of the ascending node  $\Omega$  on the ecliptic define the plane of the orbit. The fifth orbital element,  $\omega$ , determines the orientation of the ellipse in its plane by the location of the pericentre, the point of the orbit closest to the centre of attraction. The last parameter specifies the location of the body on its orbit by the time,  $T$ , of its perihelion (or perigee, etc.) passage or the time when any other position along the orbit is occupied. The ascending node  $\Omega$  is the point where the body in orbit passes from north to south of the ecliptic plane, and it is described by its angular position measured from a point on the ecliptic plane, such as the vernal equinox, at a given time. The six quantities  $a$ ,  $e$ ,  $i$ ,  $\Omega$ ,  $\omega$ , and  $T$ , or any equivalent set, define the unperturbed orbit of a planet around the Sun or of a satellite around a planet. Perturbations will result in changes in these orbital parameters. At any instant one may think of the body moving on a specially varying ellipse called the osculating ellipse

that stimulates the actual momentary path quite closely. If the perturbations suddenly stopped, the body would then continue travelling on the same ellipse.

Those changes in the shape and position of the two-body orbit that progress always in the same direction with time are called *secular*, while certain others, varying in intensity and direction, are called *periodic*. Secular effects are of great importance as they accumulate with time. The term secular in astronomy refers to effects continuing through centuries and ages.

The principal effects of the oblateness of a planet on the motion of its satellites are a backward motion of the node  $\Omega$  and a motion of the apsidal line  $\omega$ . Hence, by carefully measuring satellite orbits, the gravitational field of planets can be determined. Especially designed satellites are observed to obtain information about the internal mass distribution of the Earth. This procedure is called satellite geodesy.

A few numerical results concerning an artificial Earth satellite may be of interest. Consider an orbit inclined at  $30^\circ$  to the Earth's equatorial plane, with perigee altitude of 100 miles and with apogee altitude of 520 miles. The eccentricity is 0.05 and the semimajor axis is 4,273 miles. The orbital period of this satellite is 92 minutes; therefore, it performs 15.7 revolutions per day. The angle of the ascending node changes  $7^\circ$  per day (*i.e.*, the nodal line regresses by  $7^\circ$  per day), or in 51.4 days the orbital plane precesses  $360^\circ$  (*i.e.*, it makes a complete revolution). The argument of the perigee changes  $11^\circ$  per day.

An interesting special case occurs when a satellite is placed in a *synchronous* orbit in the plane of the Equator. The period is 24 hours and consequently without perturbations the satellite is stationary relative to the rotating Earth. But the slight ellipticity of the Equator causes a resonance effect between the Earth and the satellite that might result in instability of the satellite's orbit under certain conditions. If the satellite is placed on the line that is the extension of the minor axis of the Equator, it is stable. At other locations the satellite will drift away from its stationary position. The ellipticity of the Equator measured by the difference between the major and minor semiaxes is 210 feet. The major axis of the ellipse is oriented approximately at  $36^\circ$  west.

*The stability of the solar system.* Perturbations vary the orbital elements of the motion of celestial bodies. These variations may be computed using Lagrange's equations expressing the time rate of change of the orbital elements. These differential equations are solved numerically on a computer or analytically by successive approximations. The equations are exact, but both the numerical and the analytical methods provide only approximate solutions and present fascinating and important unsolved dilemmas regarding the long-time future of the solar system. If, from such approximate calculations, for instance, the eccentricity of the Earth's orbit is shown to increase proportionally with time, the calculations will predict that the orbit eventually will change so much that the Earth may depart from the solar system or fall into the Sun. But when higher order approximations are computed, an opposite or compensating trend may be seen. It is essential to realize the limitations of the analytical methods, as well as the restricted applicability of computers when long-time effects are to be evaluated. At present, questions that are related to the long-time stability of the solar system cannot be answered either analytically or computationally.

These questions involved the fundamental unsolved problem of celestial mechanics, and also of dynamics: whether or not some characteristics of unperturbed, highly idealized elliptic orbits will survive slight perturbations that last for a long time. Recent mathematical results (1954) allow an approach, in principle, to the stability problem for long-time periods in an entirely different manner, according to which the quasi-periodic behaviour of the solar system will prevail. Very small perturbations will not disturb its stability provided that conditions excluding certain resonances in the system are satisfied. Unfortunately, the application of this principle to celestial mechanics encounters two serious difficul-

ties. First, the theory contains certain assumptions whose validity for the solar system is questionable. Second, Newtonian gravitational forces are not the only effects influencing the orbits of the members of the solar system. Atmospheric drag, radiation pressure, relativity effects, and others must be considered also. These forces are negligible at any instant, but their cumulative actions for several times  $10^9$  years may influence planetary motions significantly. In addition, there may be unknown effects and perturbations; these naturally cannot be expressed or represented in the equations, and it must be emphasized that such unknown factors can have only very small instantaneous effects; that is, practically speaking they cannot be detected.

**The classical problem of three bodies.** Because of its historical, dynamical, astronomical, and astronomical significance, the problem of three bodies, the "most celebrated of all dynamical problems" (E.T. Whittaker, 1904), is described separately. This is a strikingly simple problem to state, but its solution is still not available. Three bodies attract each other according to the Newtonian gravitational law. The bodies are thought of as point masses; that is, their gravitational fields correspond to those of the concentric homogeneous spheres mentioned previously. These bodies are free to move in space and are initially supposed to be moving in any given manner. The problem is to determine their subsequent motion. The solution cannot yet be expressed mathematically in finite terms. The number of articles and memoirs published on this problem is well over 1,000 and includes contributions of the greatest mathematicians from Newton to the present. The motion of the Moon in the field of the Sun and the Earth is a classical example. The motion of a planet around the Sun as perturbed by Jupiter, the motions of the satellites of the planets perturbed by the Sun, and, in astronautics, the orbits of space vehicles to the Moon as affected by the Moon and the Earth are others.

A version of the three-body problem of practical importance occurs when one of the three participating bodies is much less massive than the other two. The approximate ratios of the masses of the Sun, Earth, and Moon are 300,000:1:0.01. The mass ratios of the Earth, Moon, and a space vehicle are about 100:1:10<sup>-10</sup>; that is, the mass of a six-ton space vehicle is represented in this ratio by 18 zeroes and a one following a decimal point. When one of the participating bodies has such a small mass, its effect on the other two bodies may be neglected. In this way, the problem is split into a two-body problem (which is solvable) and the problem of determining the motion of the third (small) body. Once the first problem is solved, the third body is introduced into the known and moving (time dependent) gravitational fields of the two large bodies, often called primaries, and an attempt is made to determine the motion of this single small body. The motions of the primaries will not be measurably influenced by the small body; the motion of the small body is governed entirely by the primaries. This problem, originated by L. Euler in the 18th century is known as the *restricted three-body problem*, but even in this simplified form, the problem is not solved.

Unsolved problems in dynamics may have certain characteristics, which, even though the complete solutions are unknown, will promote the understanding of the behaviour of the system. Such characteristics are usually either qualitative or are given in closed form mathematical expressions, representing *some* relations between the variables involved. For instance, in the gravitational problem of any number of bodies, the total energy (the sum of the kinetic and potential energies) is constant, for there is no dissipation of energy. This is the principle of the conservation of energy, and its mathematical expression is known as the integral of energy. The kinetic energy is proportional to the masses and to the squares of the velocities of the participating bodies; the potential energy is related to the relative positions of the bodies. Therefore, the conservation of energy principle can be expressed by an equation relating the velocities to the positions of the participating bodies at any instant. While it does not represent the

Influences  
on orbits

Conserva-  
tion of  
energy

solution of the problem, it does contribute to the understanding of the behaviour of the bodies. Using such an expression, G. Hill arrived at the conclusion that the Moon will never depart from the Earth, provided the assumptions of the restricted problem of three bodies are valid. Regions limiting possible motions of the bodies may be established in this way without solving the problem.

An interesting application of the three-body problem is Lagrange's prediction (1772) of the existence and location of the *Trojan planets*, which, 134 years later, were actually observed. These minor planets are found around the triangular (equilibrium) points of a three-body system, Jupiter and the Sun occupying the other corners of an equilateral triangle. At the points, there are no resultant forces acting on the asteroids, so they are in equilibrium.

The configuration is shown schematically in Figure 3. The line of syzygies is  $L_1L_3$ , connecting the primaries ( $m_1 = \text{Sun}$  and  $m_2 = \text{Jupiter}$ ). Point C is the fixed centre of

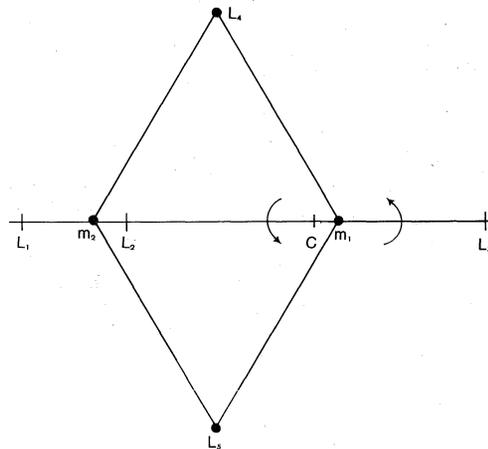

Figure 3: The Lagrangean Points  $L_1$ - $L_5$ .  $L_1L_2L_3$  is a straight line.  $L_4m_1m_2$  and  $L_5m_1m_2$  are equilateral triangles (see text).

mass around which the Sun and Jupiter revolve approximately in circles. As a consequence, the rigid triangles  $m_1L_4m_2$  and  $m_1L_5m_2$  also revolve, and  $L_4$  and  $L_5$  also describe circles. The minor planets "librate" (oscillate) around  $L_4$  and  $L_5$  in stable orbits. Lagrange also showed that if the third particle is placed at any of the three collinear points ( $L_1$ ,  $L_2$ ,  $L_3$ ), the ever-present perturbations will eject it; in other words, these points represent unstable solutions. The stability of  $L_4$  and  $L_5$  when  $m_1 = \text{Earth}$  and  $m_2 = \text{Moon}$  is influenced by the Sun, among other perturbing effects. Mathematical and observational evidence for the possible existence of material particles around the Earth-Moon triangular libration points is still lacking.

Other famous special solutions of the problem of three bodies are *periodic solutions*, in which the three bodies periodically return to their original position with their original velocities and repeat their motion. Poincaré's unproved conjecture in celestial mechanics states that all solutions may be approximated by periodic solutions. This lends considerable importance to the numerical and analytical investigation of periodic orbits. The planetary, lunar, and satellite theories are all based on the idea of using trigonometric functions and periodic solutions as reference orbits, which, when improved, may represent the actual solutions.

When such periodic terms are used in the solution, they introduce small divisors resulting in large amplitude motions. This phenomenon, described by Laplace in 1780, is related to resonance, and one of the most famous examples is "the great inequality" in the motion of Jupiter and Saturn. These planets are nearly in resonance since their mean motions are approximately in the ratio of 5:2.

Another important problem of celestial mechanics is connected with the possibility of *capture*. This formidable mathematical problem may be stated in a variety of ways depending on the orientation of interest. A practical appli-

cation is the origin of the Earth-Moon system. From the point of view of celestial mechanics, it is essential to know if the Moon could have been captured by the Earth, being originally an independent planet with an orbit around the Sun close to the orbit of the Earth. If the assumptions of the restricted problem are valid, this could not have happened, but with tidal effects or dissipative mechanisms operating, the answer could be affirmative.

The systematic numerical survey of the totality of possible solutions in the restricted problem began in 1913 by E. Strömberg at the Copenhagen Observatory. The corresponding survey for the much greater variety of possible motions in the general three-body problem was made possible only by the use of high-speed electronic computers, and it is in progress at the present time.

**The problem of  $n$  bodies.** This is a generalization of the three-body problem for the case when the number of bodies ( $n$ ) is larger than three. All participating bodies attract each other according to the Newtonian law of gravitation and are free to move in space. Initially all bodies have arbitrary positions and velocities. The problem is to find their subsequent motions.

Equations like the integral of energy are again available to establish certain properties of the motion. Nevertheless, the mathematical complications limit the possibility of finding explicit solutions analytically and once again numerical solutions become of considerable interest. Elaborate electronic computers have been used to attack the problem when  $n = 10, 25, 50$  and up to several hundred. The complexity of these programs is revealed when it is realized that for 100 bodies the simultaneous solution of 600 first order differential equations is required. At every step of the computation almost 5,000 mutual distances and the corresponding inverse squares must be computed. Any time two or more of the participating bodies perform close approaches, the accuracy of the computational process is jeopardized. Such computations could not have been performed before the use of electronic computers.

Depending on the number of bodies and on the initial conditions, the  $n$ -body problem corresponds to various physical systems. The solar system has been modelled in this way, and planetary ephemerides have been obtained for thousands of years. If  $n$  is sufficiently large (the order of a hundred), the problem corresponds to the motion of stars in a globular cluster. Computations have shown the dynamical formation of binaries and the phenomenon of escaping stars. Trends regarding the stability of the system also are indicated. It is known that, due to close approaches, a large inherent instability is present in the calculations that makes the results of the numerical integrations questionable.

## Mechanics, Classical

Classical mechanics is the physical science that deals with the motions of material bodies of ordinary size moving at speeds that are small compared with the speed of light. It differs from quantum mechanics, which describes the behaviour of atoms and subatomic particles, and from relativistic mechanics, which deals with high-speed phenomena. In the 1970s classical mechanics applies to the behaviour of supersonic jet planes and artificial satellites.

Classical mechanics, also known as Newtonian mechanics, is a basic part of physics and astronomy and the foundation of most branches of engineering; all rational procedures for the design of machines and structures are based on the laws of classical mechanics. The subject is also of interest to mathematicians because some basic mathematical procedures, such as the differential calculus, were invented for solving mechanical problems.

The bodies dealt with in classical mechanics are assumed to be so stiff that their deformations have no effect on their motions. The effects of deformations are treated in the mechanics of deformable bodies or elasticity; fluid mechanics deals with liquids and gases.

Classical mechanics is usually subdivided into statics, which deals with bodies at rest, and dynamics, which deals with bodies in motion. Dynamics is further subdivided into kinematics, which treats of motions without considering the forces involved, and kinetics, which seeks the relation between the forces and the motions.

Classical mechanics is the oldest of the physical sciences. It grew out of man's search for an explanation of natural physical phenomena and his curiosity regarding the conditions necessary for a state of rest or of motion. Another motivating factor was the urge to create more effective tools and mechanical devices.

## I. The origins and foundations of mechanics

### HISTORY

The foundations of statics were laid in the 3rd century BC by the Greek mathematician Archimedes, who derived formulas for the equilibrium of simple levers and centres of gravity. These derivations were restricted to parallel forces, which were only slightly more difficult to deal with than collinear forces. The treatment of nonparallel forces presented difficulties that were not overcome until force was conceived as a vector quantity, having both magnitude and direction, and describable by a directed line segment (arrow). About 2,000 years after the death of Archimedes, the Dutch mathematician and inventor Simon Stevin, who flourished in the 16th century, solved the lever problem with nonparallel forces and by observation and intuition alone demonstrated the equilibrium of bodies on a double inclined plane; he showed how to add force vectors by constructing a parallelogram using the force vectors as the sides.

In his writings, Stevin makes the statement that what a simple machine gains in force it loses in distance, a clear indication that he understood the principle of virtual work, which was formally enunciated by the Swiss John Bernoulli in the 18th century. The work of Stevin gave a new impetus to the study of statics, which previously had only the theory of the lever as a working principle.

Although the pre-Christian Greeks, particularly Aristotle, tried to explain the behaviour of moving bodies, they were unsuccessful. There were two reasons for their failures: in the first place, they had no satisfactory means for measuring distance or time and, consequently, were unable to check their formulas experimentally; in the second place, they laboured under the false assumption that force was necessary to maintain motion rather than to change its direction or magnitude. It was left for Galileo early in the 17th century to lay the foundation of the science of dynamics, by a combination of analytical and experimental procedures that is characteristic of the best scientific work.

One of Galileo's contributions deals with the motion of falling bodies; he disproved the Aristotelian theory that heavy bodies fall faster than light bodies. To verify his theory that the height fallen would be proportional to the square of the time and independent of the weight, he experimented with a smooth ball rolling down an inclined plane; he measured the time of the motion by weighing the water that flowed through a small hole at the bottom of a large tank filled with water.

Galileo developed the equation of motion of a projectile and showed that, neglecting the air resistance, the curved path was the result of two independent motions, namely, a horizontal motion at a constant speed and a vertical motion at a varying speed under the action of the force of gravity. In this case he utilized the principle of compounding motions in accordance with the parallelogram law for force vectors introduced by Stevin.

Galileo anticipated the law of inertia, formulated by the English physicist Isaac Newton at a later date, when he stated that a body in motion and free from external influences would keep on moving at a constant speed in a straight line; he was the first to recognize that it was acceleration (the rate of change of velocity) and neither velocity nor position that was determined by the external forces.

Following Galileo in the 17th century, the next important contributor to the science of dynamics was the Dutch physicist Christiaan Huygens, who developed the equations of motion of the pendulum and invented the pendulum clock. He was the first to obtain the acceleration of gravity by pendulum observations and the first to encounter the term now known as the moment of inertia—that is, the measure of the inertia of a body in rotary motion.

Isaac Newton was born the year Galileo died, and, apart from his important discoveries of the law of universal gravitation, the mathematics of the calculus, and his work in optics, he introduced the concepts of force and mass and formulated the three laws of motion that summarize, clarify, and extend the principles introduced by

Forces as vectors

The effects of forces

Galileo. The magnitude of his contributions is reflected in the fact that "Newtonian" and "classical" are synonymous terms in the field of mechanics.

Newton's second law equates the force acting on a body to the product of the mass of the body and the acceleration; because the latter is the time rate of change of the velocity, the resulting equations of motion are differential equations and require mathematical techniques for their solution. When possible, Newton used geometrical methods, believing that they would be more easily understood by readers. The Swiss mathematician Leonhard Euler in the 18th century wrote a series of textbooks on mechanics in which he used the analytical methods of the calculus to solve the differential equations of motion. Euler also showed that any motion of a rigid body can be separated into a translation followed by a rotation about a chosen point, and he extended Newton's second law, which applies to bodies with mass but negligible dimensions (particles), to rigid bodies.

The French mathematician Jean Le Rond d'Alembert was the author in the same century of a famous textbook on mechanics and the discoverer of a principle that bears his name. This was an entirely new and original method of solving problems in dynamics by applying the principles of statics. When a body is being accelerated, the forces acting on it are unbalanced, but by Newton's second law they are equal to the product of the mass and the acceleration of the body. By the simple expedient of reversing the mass-acceleration terms, the body is placed in equilibrium, and unknown forces can be determined by the equations that apply to bodies at rest.

One hundred years after the publication of Newton's laws, the French mathematician Joseph-Louis Lagrange developed a formula for deriving the equations of motion that is more universal in its application and for certain types of problems easier to use than Newton's equations. Lagrange's equation is a differential equation that deals with energy rather than force, and with velocity rather than acceleration; the resulting equations of motion are the same as those derived by Newton's second law. Equations of a similar type were developed by the Irish mathematician Sir William Rowan Hamilton in the 19th century. Both Lagrange's and Hamilton's equations have proved invaluable in the more advanced and theoretical treatments of dynamics.

#### THE FUNDAMENTAL CONCEPTS AND QUANTITIES OF MECHANICS

The descriptions of the states of rest or of motion of bodies that Newton's laws provide are inherently mathematical, and, consequently, the quantities appearing in the equations require explanation and in some cases precise definition.

A description of motion requires a frame of reference and means for locating bodies in the frame. The reference frames used in mechanics are known as coordinate systems, with mutually perpendicular axes (lines) emanating from a point known as the origin; for motion parallel to a fixed plane two axes are required, while for motion in space three are required. Strictly speaking, Newton's laws of motion are valid only in a coordinate system with origin at the centre of the solar system; this is known as a Newtonian, or inertial, reference, frame. Although it rotates, the Earth can be considered an inertial reference frame in most cases.

The principal units of length used to describe the position of bodies are the metre in the International System (SI) and the foot in the engineering (English) system. With time measured in seconds, the derived units of velocity (directed speed) are metres per second and feet per second. Acceleration, which is the time rate of change of velocity, is expressed as metres per second per second or feet per second per second.

The mass of a body is a measure of its inertia, or the resistance that it offers to having its speed changed; as an illustration of the difference between mass and weight, consider the following example. If a smooth, heavy body were resting on a flat sheet of ice, the mass of the body would influence the time taken to bring it up to a

given speed by pushing it and also the time taken to stop it; the greater is the mass, the longer is the time. On the other hand, the weight of the body would influence the effort required to lift it.

Newton's second law states that the acceleration  $a$  imparted to a body by a given force is equal to the force  $F$  divided by the mass  $m$ ; *i.e.*,  $a = F/m$ . This means that, because acceleration has the dimensions distance per second per second, the quotient  $F/m$  must have the same dimensions; either  $F$  or  $m$  can be chosen as the fundamental unit, and the other will be the derived unit.

The SI system is known as an absolute system, and mass in kilograms is the fundamental unit; the derived unit of force is known as a newton, and from the expression for  $a$  it is the force that acting on a one-kilogram mass will produce an acceleration of one metre per second per second.

The engineering system is known as a gravitational system, and force in pounds is the fundamental unit; the derived unit of mass is known as a slug, and it is that mass that, when acted on by a one-pound force, will have an acceleration of one foot per second per second.

The relation between mass and weight can be obtained by applying Newton's equation to a falling body. The force acting on the body is  $W$ , the weight, and the average value of the acceleration of gravity  $g$  on the surface of the Earth is 9.81 metres per second per second in the SI system and 32.2 feet per second per second in the engineering system. Then, in the SI system  $W/m = 9.81$ , which means that a kilogram weighs 9.81 newtons; in the engineering system  $W/m = 32.2$ , which means that a slug weighs 32.2 pounds.

The SI and the engineering systems are related in the following way; one pound force equals 4.4 newtons, and one slug mass equals 14.59 kilograms.

The acceleration of gravity varies slightly from place to place on the surface of the Earth, and in interstellar space it may approach zero. Thus, whereas the mass of a body at the speeds considered in classical mechanics is a constant, the weight of a body will vary with its position relative to the centre of the Earth. At the same place, the masses of bodies are proportional to their weights so that weighing is a convenient means of measuring masses.

Newton's equations of motion deal with the gross motion of a body; *i.e.*, the motion of the body as a whole. There is one point in a body the motion of which is characteristic of the gross motion; it is called the centre of mass. If the body rotates, the rotation can always be referred to the centre of mass, and additional equations must be deduced to deal with the rotation. When the gross motion of a body is more significant than its rotary motion, the body may be treated as a particle. The Earth, for example, can be treated as a particle when describing its motion around the Sun; it cannot be treated as a particle when dealing with terrestrial problems.

## II. Statics

The forces in the members of a machine or structure must be known before the dimensions required to carry them can be calculated; thus, methods for determining such forces are of extreme importance to all designers of mechanical devices. Assuming that the main loads that a machine or structure is expected to carry are specified, the forces acting in the connected elements of the machine and the reactions from the supports can be determined by various analytical and graphical procedures. When a machine or structure is in a state of equilibrium (at rest), the science of statics provides the means for calculating a limited number of the unknown forces.

The science of statics assumes that the bodies with which it deals are perfectly rigid and asserts that when at rest the resultant (sum) of all the forces acting on a body must be zero and that there must be no tendency for the forces to turn the body about any axis. These conditions are independent of one another, and their expression in mathematical form constitutes the equations of equilibrium. When all the forces lie in the same plane there are only three equations so that only three unknown forces can be calculated. If there are more than three unknown

Dynamics  
reduced to  
statics

The  
concept  
of mass

forces, it signifies either that there are more restraints than are necessary to keep the body from moving or that there are more members (as in a structure) than are necessary to support the applied loads; the unnecessary restraints and members are said to be redundant. In such cases, the rigid-body assumption must be discarded, and the elastic properties of the members must be considered. Although the procedures for finding the forces in structures with redundant members are strictly static rather than dynamic in nature, it is customary to designate such structures as statically indeterminate. Unless otherwise noted, the following material deals with rigid-body statics only.

**FORCE**

In statics a force may be defined as any action that tends to maintain or alter the position of a body or to distort it. There are many kinds of forces, such as a push or a pull, gravity (which is manifested as weight), steam or gas pressure in an engine cylinder, atmospheric pressure, wind pressure on a building, resistance to motion in air or water, magnetic and electrostatic attraction, nuclear attraction, and pressure and friction between contacting bodies.

The effect of a force on a body is determined by its point of application, its direction, and its magnitude. Because it has direction as well as magnitude, force is a vector quantity and can be shown graphically as a directed line segment; *i.e.*, a line with a length equal to the magnitude of the force, to some scale (such as one inch equals 100 pounds), inclined at the proper angle, and with an arrowhead at one end to indicate sense (one of two opposite directions). When it is necessary to emphasize the vectorial nature of a quantity it will be indicated in boldface type.

The representation of forces by vectors implies that they are concentrated at a single point or along a single line. Physically this is impossible; even when two metallic spheres are pressed together, the contacting surfaces flatten, and the force is distributed over a small area. On a loaded member of a machine or structure, the force produces an internal force or stress that is distributed, in some manner, over the cross section of the member. The force of gravity is distributed throughout the volume of a body. Nevertheless, when the equilibrium of a body is the main consideration, it is usually valid as well as convenient to assume that the forces are concentrated at a point. In the case of the gravity force, the total weight of a body is assumed to be concentrated at its centre of gravity.

**Basic principles.** There are three main principles or axioms that facilitate the solution of problems in statics, namely, the parallelogram of forces, action and reaction, and the transmissibility of a force.

The parallelogram of forces, formulated by Stevin in 1586, states that, if two forces whose lines of action intersect are acting on a body, their action is equivalent to the action of a single force whose vector representation is the diagonal of the parallelogram of which the two original force vectors are sides.

In Figure 1A the flexible cords *AB* and *BC* are attached to a ring at point *B* from which the weight *W* is suspended by the cord *BD*. The forces acting on the ring are the tension in the cord *BD* (acting down and equal to the weight *W*) and the tensions *T*<sub>1</sub> and *T*<sub>2</sub> in the cords *AB* and *BC*, respectively. Because it is in equilibrium, the resultant force acting on the ring—*i.e.*, the sum of *W*, *T*<sub>1</sub>, and *T*<sub>2</sub>—must be zero. This requirement enables *T*<sub>1</sub> and *T*<sub>2</sub> to be determined as functions (*i.e.*, in terms of) of *W*. In Figure 1B the vector *W* is drawn to any convenient length to represent the tension in the cord *BD*; to complete the triangle of forces, *T*<sub>1</sub> and *T*<sub>2</sub> are drawn parallel to *AB* and *BC*, respectively. When vectors are added, they are placed tail to tip so that knowing the sense of *W* the arrowheads can be placed on *T*<sub>1</sub> and *T*<sub>2</sub> to satisfy this requirement.

In Figure 1A the vector *BE*, acting upward, is the diagonal of the parallelogram formed by *T*<sub>1</sub> and the parallel side *GE* and *T*<sub>2</sub> and the parallel side *FE*. Because triangle *BEF* is similar to the triangle of forces in Figure 1B, the

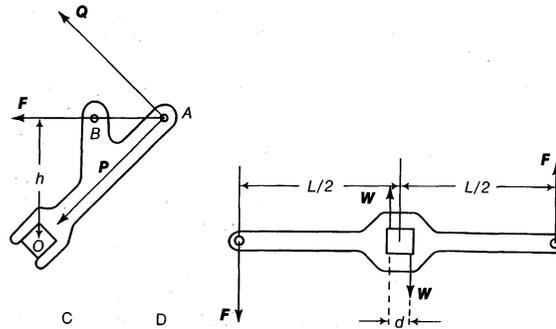

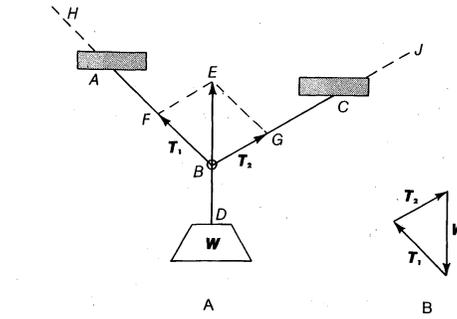

Figure 1: Equilibrium of forces and their turning effects. (A) Parallelogram of forces, (B) triangle of forces, (C) moments, (D) couples (see text).

vector *BE* must be equal in magnitude to *W*. It is shown acting upward to indicate that it is the resultant of *T*<sub>1</sub> and *T*<sub>2</sub> and could serve as their replacement as far as their effects on the ring at *B* are concerned. The ring would then be in equilibrium under the action of two forces, namely, *W* acting upward and *W* acting down.

The principle of action and reaction, which is also known as Newton's third law of motion, states that, when one body exerts a force on another body, the second body exerts a force on the first body; the two forces are collinear (act along the same line), equal in magnitude but opposite in sense.

The weight *W* in Figure 1A pulls down on the ring *B* while the ring pulls up on the weight with an equal and opposite force. Contact forces between bodies always occur in pairs; a book resting on a table pushes down on the table with a force that is equal and opposite to the upward force of the table on the book. The principle is also true for some of the forces that act at a distance, such as gravitational attraction; a flying airplane pulls up on the Earth with a force equal and opposite to its weight.

The principle of transmissibility states that the equilibrium of a body is not altered when the point of application of a force is moved to some other point on its line of action; *i.e.*, the line along which the force acts. In Figure 1A the position of the weight *W* would be unaltered if the cord *BD* were lengthened and attached to *W* at its centre or if *A* and *C* were moved to points such as *H* and *J* or *F* and *G*.

**Moment of a force and a couple.** The concept of moment, or torque, as it is used in mechanics is the tendency of a force to rotate the body to which it is applied about a point or axis. Of the three forces of equal magnitude applied to the wrench in Figure 1C, the force *Q*, which acts at right angles to *OA*, is clearly the most effective in tending to turn the square bolt head to which the wrench is applied about the point *O*; force *P* is completely ineffective. The moment of a force about a point *O* is equal to the product of the magnitude of the force and the length of a line from *O* at right angles to the line of action of the force. Thus the moment of the force *F* in Figure 1C is equal to *Fh*, and from the principle of

Internal forces

The principle of transmissibility

transmissibility  $F$  would have the same effect if applied at either point  $A$  or point  $B$ .

A more effective wrench than the one in Figure 1C is shown in Figure 1D. If the forces  $F$  are equal, they constitute a "couple," and the turning effect, or moment, of the couple is  $FL$ . To keep this wrench in equilibrium, another couple,  $Wd$ , the reaction from the bolt head, must be acting and must be equal to  $FL$ . On the other hand, because the torque is applied to the wrench in Figure 1C by a force, there must be a force equal and opposite to  $F$  (or  $Q$ ) acting on the wrench in addition to a balancing couple.

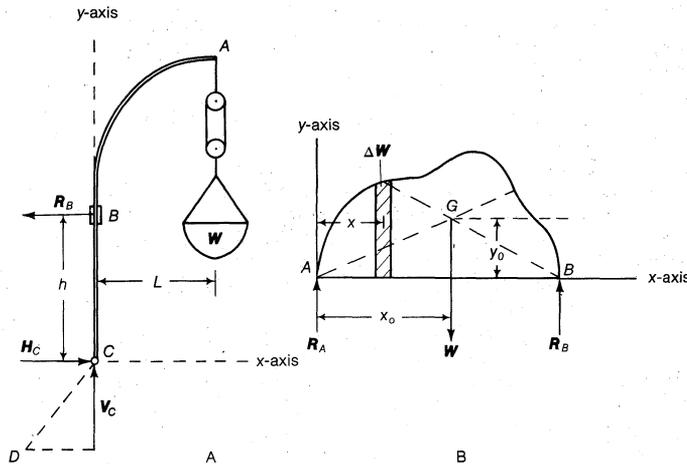

Figure 2: Supporting reactions on stationary bodies. (A) Lifeboat davit, (B) flat plate (see text).

**Application of equilibrium equations.** Figure 2A shows one of the two davits used to suspend a lifeboat. The load applied to the davit at  $A$  by the boat is  $W$ , the reaction  $R_B$  at  $B$  is assumed to be horizontal because the support is frictionless, and the support at  $C$  is a ball-and-socket joint that can carry both horizontal and vertical reactions, such as  $H_C$  and  $V_C$ . It is required to find the reactions as functions of  $W$ ,  $h$ , and  $L$ .

When applying the condition that when a body is in equilibrium the resultant force acting on the body must be zero, it is usually convenient to resolve (separate) the forces into sets of orthogonal (mutually perpendicular) components and assert that the summation of the forces in each orthogonal direction must be zero. Because the direction of a vector involves both inclination and sense, a vector or the component of a vector along or parallel to any fixed line, such as the axis of a coordinate system, has a fixed inclination and can be described by a number, either positive or negative, to indicate its magnitude and whether it points in one or the other of two opposite directions (sense). Consequently, such vectors, although they are shown as directed lines, can be considered as scalars; *i.e.*, quantities that require only a number for their specification. In the following examples, force components along chosen directions will be taken as scalars and be added, subtracted, multiplied, and divided like ordinary numbers.

For the davit, using the  $x$  and  $y$  coordinate axes as convenient directions,  $\Sigma$  for summation,  $F$  as a general term for forces, and  $F_x$  and  $F_y$  for the forces acting along  $x$  and  $y$ , the two force equations of equilibrium would be  $\Sigma F_x = 0$  and  $\Sigma F_y = 0$ . An additional moment equation, expressing the requirement that the davit must not rotate about any chosen point in the plane of the forces, must be written; choosing point  $C$  and using  $M$  to designate moment, the moment equation would be  $\Sigma M_C = 0$ . In Figure 2A the reaction  $R_B$  and the two components of the reaction at  $C$ , namely,  $H_C$  and  $V_C$ , are shown acting in assumed directions; the correctness of these assumptions will be verified later. Because positive directions for  $x$  and  $y$  are to the right and up, respectively,  $R_B$  is negative, while  $H_C$  and  $V_C$  are positive. Clockwise moments will be considered positive.

From  $\Sigma F_y = 0 = V_C - W$  it follows that  $V_C = W$ ;

from  $\Sigma M_C = 0 = WL - R_B h = 0$  it follows that  $R_B = WL/h$ ; and from  $\Sigma F_x = 0 = H_C - R_B$  it follows that  $H_C = R_B = WL/h$ . Because all three unknown forces came out positive, it proves that the assumed directions were correct; if  $H_C$ , for example, had been assumed in the negative  $x$  direction, it would have come out negative in  $\Sigma F_x = 0$ . The total force at  $C$ , which is the resultant of  $V_C$  and  $H_C$ , is a vector  $DC$ , pointing up and to the right.

**Centre of gravity.** Figure 2B shows a plate of weight  $W$  resting on horizontal supports at  $A$  and  $B$ . If the reactions  $R_A$  and  $R_B$  were required, the summation of vertical forces  $F_V$  would yield only  $\Sigma F_V = R_A + R_B - W = 0$ ; to find  $R_A$  and  $R_B$  it would be necessary to write a moment equation about either  $A$  or  $B$  that would include the moment of the weight of the plate. The moment of the plate about  $A$  could be obtained by adding up the moments of a large number of small slices of the plate, symbolized by  $\Delta W$  (delta  $W$ ), whose moment arms  $x$  are taken at the centre lines of the slices. It would be more convenient if a point such as  $G$ , the centre of gravity, could be found at which the entire weight of the plate could be concentrated. The distance  $x_0$  from  $A$  to the line of action of  $W$  can be found by equating the moment  $Wx_0$  to the sum of the moments obtained by the slicing method; this gives  $Wx_0 = \Sigma(\Delta W)x$ , in which the summation is taken over the whole body. Solving this equation for  $x_0$  yields  $x_0 = \Sigma(\Delta W)x/W$ . The vertical coordinate  $y_0$  of  $G$  can be obtained by slicing the plate parallel to  $AB$ . The coordinate of  $G$  perpendicular to the plane of the paper would be half the thickness of the plate from either surface of the plate.

If the upper surface of the plate were a curve that could be described by a mathematical equation, the coordinates of  $G$  could be obtained by the integral calculus. The summation sign  $\Sigma$  becomes an integral sign  $\int$ , the slices become infinitesimally thin, and the calculated value of  $x_0$  is exact. For a plate of any shape the centre of gravity can be obtained by suspension. If the plate in Figure 2B were suspended from  $A$ , the line  $AG$  would be vertical, while if suspended from  $B$  the line  $BG$  would be vertical; point  $G$  is at the intersection of these two lines.

For bodies with three planes of symmetry, such as a sphere or a circular cylinder, the centre of gravity is at the geometric centre of the body. For bodies with geometric shapes, such as cones, segments of a circle, and triangles, formulas for the centre of gravity are to be found in handbooks.

#### FRICITION

Friction is of considerable importance in everyday life as well as in mechanics. Without friction, walking would be impossible, no ladder would stand against a wall, an automobile could not be driven or stopped.

Between two bodies in direct contact there is always some friction, which tends to hinder, or even prevent, the sliding of one body on the other. Consider the steel block resting on the steel table in Figure 3A. The weight  $W$ , acting down, and the reaction  $N$  from the table, acting up, must be equal and opposite. If a small horizontal force  $P$  is applied to the block and the block does not move, there must be a friction force  $F$ , equal and opposite to  $P$  at the surface of contact between the block and the table. If the force  $P$  is increased, it will eventually cause the block to slide on the table.

Experiments show that when slipping impends, the value of  $F$  is always a fixed ratio of the normal force  $N$  and that this ratio depends on the materials and the roughness of the contacting surfaces. Thus, when slipping impends,  $F = fN$ , in which  $f$  is the coefficient of static friction. For dry steel on steel the value of  $f$  is given as 0.15 in some handbooks, but it varies greatly with surface roughness and whether or not surface films such as oxides are present.

The value of  $f$  can be determined experimentally by means of an adjustable inclined plane, as in Figure 3B. The angle  $\theta$  (theta) is slowly increased until the block starts to slide down the plane. There are two forces acting on the block: the weight  $W$  and the reaction  $R$  from the plane, both of which must pass through the centre of

Centre of gravity by suspension

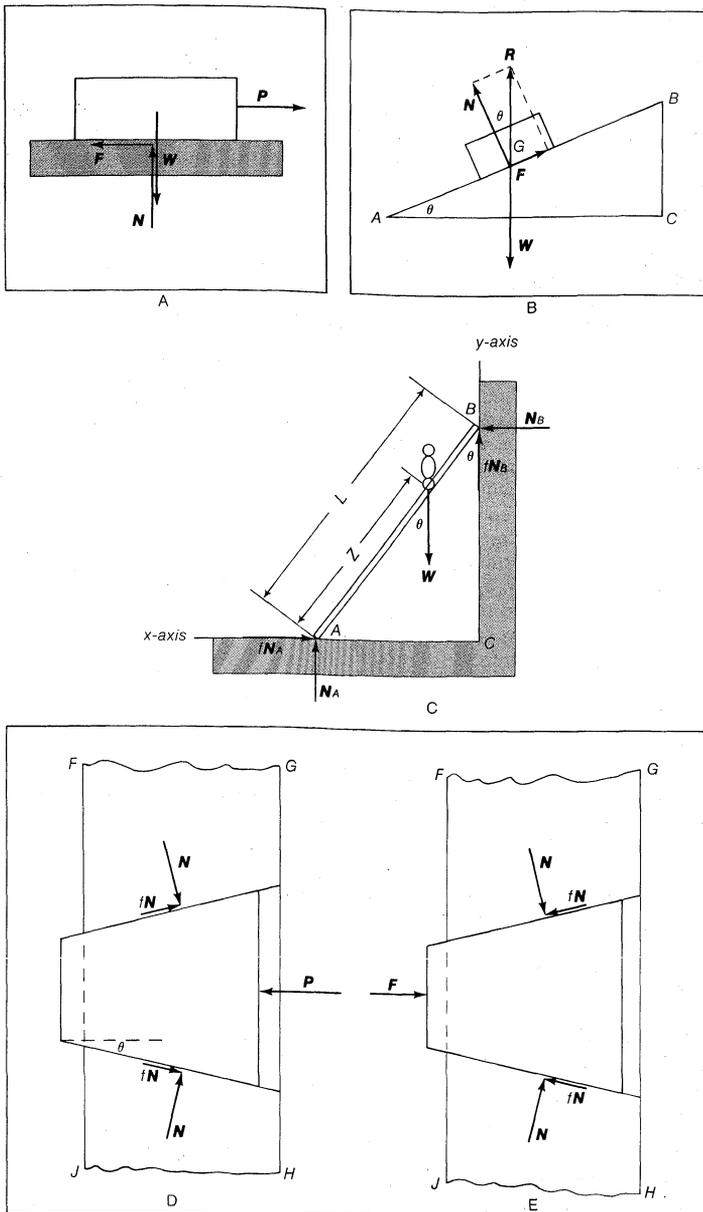

Figure 3: Friction forces and their effects. (A) Sliding block, (B) the angle of repose, (C) a sliding ladder, (D,E) a wedge (see text).

gravity  $G$ . Resolving  $R$  into the components  $N$  and  $F$  and noting that triangle  $ABC$  and the triangle formed by  $R$ ,  $N$ , and  $F$  are similar,  $BC/AC = F/N = \tan \theta$ , which by definition is equal to  $f$ ; the angle  $\theta$  is known as the angle of repose.

Between a rubber tire and a dry concrete road  $f$  could reach a value of 1.00 so that  $F = N$ , and in Figure 3B,  $BC$  would equal  $AC$  and  $\theta$  would equal  $45^\circ$ . This means that an automobile with locked brakes could stand on an incline of  $45^\circ$ , but for greater angles it would slide downhill.

The first complete investigation of dry friction was made by the French physicist Charles-Augustin Coulomb in 1781; he discovered that the total amount of friction that can be developed between two contacting bodies is proportional to the normal pressure and independent of the area of contact. If a brick is pulled along a table, the frictional force is the same whether the brick is lying flat, on its side, or on its end. Coulomb also found that after slipping has started, the frictional force is less than the friction when slipping impends. Later experiments indicate that at extremely high pressures abrasion may alter the surface conditions and cause  $f$  to reach unpredictable values. Dry friction is usually called Coulomb

friction, to distinguish it from viscous friction, which occurs in oil films.

In the operation of machines, friction may be either a useful agent or the cause of lost power. The operation of brakes and clutches, the grip of belts on pulleys, and the tractive effort of wheels on rails are all applications in which the maximum amount of friction is desired. In bearings and sliding connectors the friction, which causes heat and loss of power, is reduced to a minimum by the addition of lubricants whose main function is to minimize metal-to-metal contact.

**The ladder.** A ladder  $AB$  of length  $L$  in Figure 3C rests on a horizontal floor at  $A$  and a vertical wall at  $B$ . It is required to find the maximum distance  $Z$  that a man of weight  $W$  can climb up the ladder before slipping occurs at  $A$ ; the weight of the ladder, being small compared with the man's weight, is to be neglected.

In addition to the man's weight, there is a force  $N_A$  normal (at right angles) to the floor at  $A$  and a force  $N_B$  normal to the wall at  $B$ . There must also be a friction force  $fN_A$  at  $A$  to balance  $N_B$ ; the friction force  $fN_B$  at  $B$  is not necessary to maintain equilibrium, but it appears because the wall is assumed to be rough. To simplify calculation, it is assumed that the coefficient of friction  $f$  is the same between the floor and the ladder as between the wall and the ladder.

To determine  $N_A$  and  $N_B$  in terms of  $W$ , it is necessary only to equate the sum of the forces in the vertical ( $y$ ) direction and in the horizontal ( $x$ ) direction to zero. To obtain a relation between  $Z$ ,  $L$ ,  $\theta$ ,  $f$ , and the forces, however, it will be necessary to write a moment equation about a convenient point such as  $A$ . Then:

$$\begin{aligned}\Sigma F_y &= N_A + fN_B - W = 0, \\ \Sigma F_x &= N_B - fN_A = 0.\end{aligned}$$

The summation of moments is given by:

$$\Sigma M_A = WZ \sin \theta - N_B L \cos \theta - fN_B L \sin \theta = 0$$

( $\sin$ ,  $\cos$ ,  $\tan$ , and  $\cot$  are ratios of the various sides of a right-angled triangle). Solving these equations yields the following:

$$\frac{Z}{L} = \frac{f \cot \theta + f^2}{1 + f^2}.$$

As long as  $f \cot \theta$  is equal to or greater than one,  $Z/L$  will be equal to or greater than one, and the man can climb to the top of the ladder without fear of the ladder slipping. When slipping impends,  $f \cot \theta = 1$  or  $f = 1/\cot \theta = \tan \theta$ . From Figure 3C,  $\tan \theta = AC/BC$  so that as long as  $AC/BC$  is less than  $f$  the ladder will not slip. For timber on stone  $f$  is approximately 0.40, which corresponds to an angle  $\theta$  of  $21^\circ 48'$ ; if  $\theta$  is greater than this, the ladder will slip. On rough ground  $f$  could be 1.0, which corresponds to a safe angle  $\theta$  of  $45^\circ$ . It is worth noting that  $\theta$  is the same as the angle of repose, in Figure 3B, at which friction just holds the block from sliding down.

**The wedge.** In Figure 3D a tapered plug is being driven into a matching hole in the member  $FGHJ$  by a force  $P$ ; the progress of the plug is opposed by the two normal (at right angles) reactions  $N$  and the two friction forces  $fN$ . The summation of forces in the horizontal direction yields the equation  $P - 2N \sin \theta - 2fN \cos \theta = 0$ , which, solved for  $N/P$ , gives

$$\frac{N}{P} = \frac{1}{2(\sin \theta + f \cos \theta)}.$$

The ratio  $N/P$  is the mechanical advantage, a measure of the force-amplifying property of a wedge. The magnitude of the ratio increases as the denominator of the previous equation decreases. The magnitude of the denominator depends on both the angle  $\theta$  and the coefficient of friction  $f$ ; the smaller is the angle and the smaller is the friction coefficient, the smaller is the denominator. As  $\theta$  approaches zero,  $\sin \theta$  approaches zero and  $\cos \theta$  approaches unity. This means that no matter how small  $\theta$  becomes, the term  $f \cos \theta$  can only be reduced by lowering  $f$ .

If the plug in Figure 3D is to be pulled out, the force

The angle of repose

$P$  (now labelled  $F$ ) and the frictional forces will be reversed, as shown in Figure 3E. For this case it can be shown that  $F = 2N(f \cos \theta - \sin \theta)$ .

When  $f \cos \theta = \sin \theta$ , or  $f = \tan \theta$ , the magnitude of  $F$  is zero. This means that the plug will fall out of its own accord when  $P$  is removed. For all angles for which  $\tan \theta$  is less than  $f$ , the taper is a "sticking" one, and  $F$  in the previous equation will be greater than zero. Sticking tapers are used for holding such cutting tools as drills and reamers in machine-tool spindles.

Wedges  
that stick

### III. Dynamics

#### KINEMATICS

**The position vector and motion.** Motion is change of position, and to describe the motion of a body  $A$ , for example, relative to another body  $B$ , it is necessary to establish a reference frame on body  $B$  and means for describing the position of any point in body  $A$  in this frame. A convenient frame is a system of rectangular coordinate axes; *i.e.*, graduated lines emanating from a point called the origin and at right angles to one another. For three-dimensional (space) motion three axes are necessary, for two-dimensional (plane) motion two are required, while for one-dimensional (line) motion only one axis is necessary.

In Figure 4A the position of point  $P$  on its path in the  $OXY$  coordinate system can be described either by the coordinates  $x$  and  $y$  or the length of the vector  $S$  and the angle  $\theta$ . Like all vectors,  $S$  has both magnitude, as given by its length, and direction, which is a combination of inclination and sense (one of two opposite directions). When a vector, such as  $S$ , is used to describe the position of a point, it is known as a position vector.

As the point moves on its path, the head of vector  $S$  will move with it, and the magnitude and direction of  $S$  will change. These changes are the only two that a vector can experience. The coordinates  $x$  and  $y$  will change in magnitude as the point moves and serve as orthogonal components of the vector  $S$ .

**Velocity.** The speed of the point  $P$  is the time rate at which the point moves along the path; the velocity of the point is a vector quantity and as such has both magnitude, which is equal to the speed, and direction, which, as shown in Figure 4A by the vector  $v$ , is tangent to the path and pointing in the direction in which the point is moving.

By definition, the velocity of point  $P$  can be expressed either as the time rate of change of the vector  $S$  or the vector sum of the changes in  $x$  and  $y$ . Because  $S$  changes in both magnitude and direction, the velocity  $v$  must be the vector sum of these changes. As will be shown below, changes in the magnitude of a vector are always collinear with the vector, whereas changes in direction are at right angles to the vector.

The vector  $v_M$  in Figure 4A represents the rate at which the magnitude of  $S$  is changing and  $v_D$  the rate at which its direction is changing. Both of these changes are functions of  $S$ ; *i.e.*, they are expressed mathematically in terms of  $S$ .

The coordinates  $x$  and  $y$  are quantities that have magnitude and sense only; they are positive when they lie above and to the right of the origin  $O$  and negative when they lie below or to the left of  $O$ . Because they do not rotate and change in magnitude only,  $x$  and  $y$  can be considered as scalars or directed lines or one-dimensional position vectors. The velocities resulting from their rates of change are usually called the scalar components of  $v$ . Velocities obtained from scalar quantities, or the magnitude of a velocity vector, are usually indicated by  $v$ . Then  $v_x$  and  $v_y$  are the velocities resulting from the changes in  $x$  and  $y$  and their resultant is the vector  $v$ .

**Acceleration.** Being a vector, the velocity  $v$  may change in both magnitude and direction as the point moves, and the vector sum of these changes is defined as the acceleration  $a$  of  $P$ . The acceleration can also be defined in terms of the sum of the changes in  $v_D$  and  $v_M$ , or the changes in  $v_x$  and  $v_y$ . Because  $v_D$  and  $v_M$  move with  $S$ , they may change in both magnitude and direction, and the acceleration vector will have four components if they are used, and they will all be functions of  $S$ ; if  $v_x$  and  $v_y$  are used,

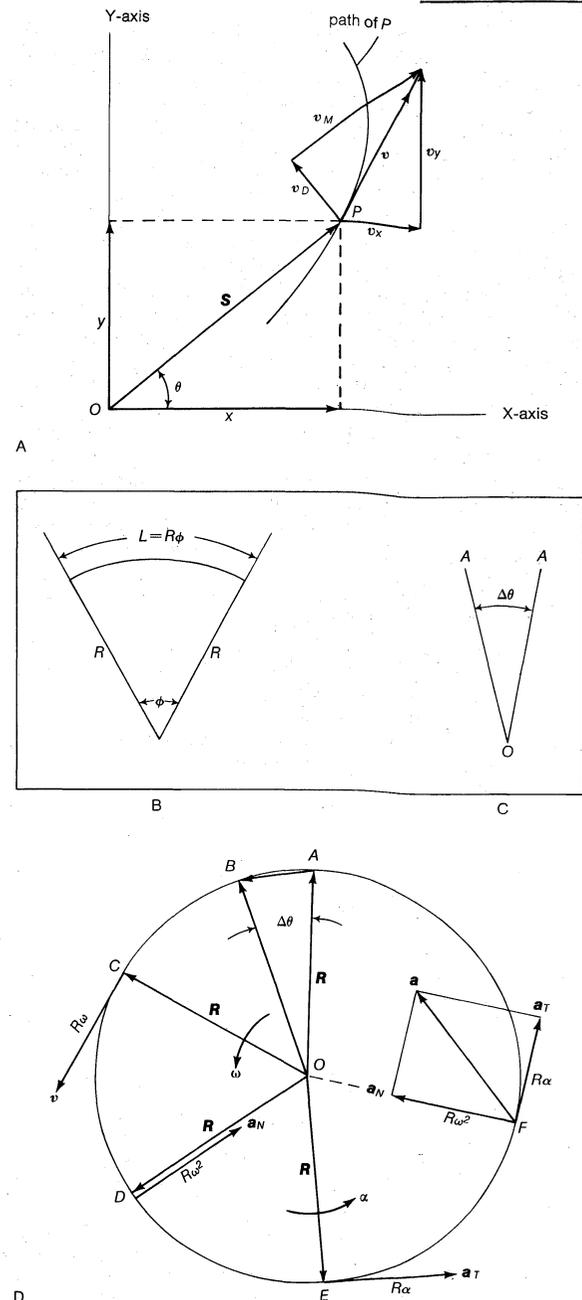

Figure 4: Motion of a point on a plane (flat) curve. (A) Position and velocity vectors, (B) radian measure, (C) rotary motion, (D) motion on a circle.

there will be only two components, parallel to the  $X$  and  $Y$  axes, and functions of  $x$  and  $y$ . These scalar components, like the magnitude  $a$  of  $a$ , are written as  $a_x$  and  $a_y$ . If a point moves on a curved path, the direction of its velocity must change, and its acceleration can never be zero, even if the speed is constant.

Because the coordinate system in Figure 4A can be located in any position relative to the path, there are an infinite number of coordinates and position vectors that can be used to describe the position of the point; the choice must be made by the analyst. For a straight path, a directed line lying in the path and changing only in magnitude is obviously the best choice. For a point moving on a circle, a position vector with its tail at the centre of the circle and changing only in direction is most suitable. The use of position vectors that change in both magnitude and direction is to be avoided, if possible.

**Rotation about a fixed axis.** When a body rotates about a fixed axis, the angular position of any line on the body

Scalar  
compo-  
nents of  
accelera-  
tion

passing through and perpendicular to the axis changes with respect to time, and the time rate at which the line sweeps out angles is known as the angular velocity of the body.

Because it permits a simple mathematical relationship between the length  $L$  of the arc of a circle (i.e., segment of the circumference) and the angle subtended (enclosed) at the axis by the arc, measurement of angles in classical mechanics is expressed in radians, as explained below. In Figure 4B if  $\phi$  (phi) is measured in radians, the arc length  $L$  is given by  $L = R\phi$ . This means that, when the length of the arc equals the radius, or  $L = R$ ,  $\phi$  is one radian, or the angle at the centre of a circle subtended by an arc equal to the radius is one radian. In one revolution the arc length is equal to the circumference so that  $L = 2\pi R$ , and thus  $2\pi R = R\phi$  or  $\phi = 2\pi$  radians; this means that in one revolution there are  $2\pi$  (i.e., approximately 6.28) radians.

If the line  $OA$  in Figure 4C is on a body rotating about a fixed axis  $O$  perpendicular to the page and sweeps out an angle  $\Delta\theta$  in a time interval  $\Delta t$ , the average angular velocity  $\omega$  (omega) during the interval is  $\omega = \Delta\theta/\Delta t$  radians per second. As the time interval  $\Delta t$  is reduced, the average velocity approaches the instantaneous velocity. The limiting value of  $\Delta\theta/\Delta t$  as  $\Delta t$  approaches zero is defined in the differential calculus as the instantaneous angular velocity, and the equation is written  $\omega = d\theta/dt$ . If  $\theta$  is expressed as a function of  $t$ , exact values of  $\omega$  can be obtained by procedures developed in the calculus. If the angular velocity changes by an amount  $\Delta\omega$  in time  $\Delta t$ , the average angular acceleration  $\alpha$  (alpha) is given by  $\alpha = \Delta\omega/\Delta t$ , and the instantaneous acceleration, in calculus notation, is  $\alpha = d\omega/dt$ . Because  $\alpha$  is the rate of change of  $\omega$ , which is itself the rate of change of  $\theta$ ,  $\alpha$  can also be described as the second derivative of  $\theta$  and written as  $\alpha = d^2\theta/dt^2$ .

**Motion on a circular path.** To describe the motion of a point on a circular path, a position vector coinciding with the radius and changing only in direction is the best choice.

In Figure 4D, when the point moves from position  $A$  to position  $B$  on the circle of radius  $OA = R$ , the vector  $R$  of magnitude  $R$  changes by the amount  $AB$ ; i.e.,  $AB$  is the vector that must be added vectorially to  $R$  to obtain the vector  $OB$ . If  $\Delta\theta$  is measured in radians, the length of the arc  $AB$  equals  $R\Delta\theta$ , and it is approximately equal to the length of the vector  $AB$ , which is the chord of the arc, and also the magnitude of the change in the vector  $R$  because of its rotation through the angle  $\Delta\theta$ . If  $\Delta\theta$  takes place in time  $\Delta t$  then  $R(\Delta\theta/\Delta t)$  is approximately the magnitude of the average time rate at which the vector  $R$  is changing. As  $\Delta\theta$  decreases, the lengths of the chord and the arc  $AB$  approach one another and the angle between  $R$  and  $AB$  approaches  $90^\circ$ . In the limit, as  $\Delta t$  approaches zero,  $\Delta\theta/\Delta t$  (using the notation of the calculus) becomes  $d\theta/dt$ , which is recognizable as  $\omega$ , the angular velocity of  $R$  in radians per second. Then  $R\omega$  is the magnitude of the vector that represents the instantaneous time rate of change of  $R$ ; this is the magnitude of the velocity, or the speed, of the moving point and is written as  $v = R\omega$ . The velocity vector  $v$  is inclined at  $90^\circ$  to  $R$ , with a sense compatible with the direction of  $\omega$ . At point  $C$  in Figure 4D, a position vector  $R$  rotating in a counterclockwise direction and the corresponding velocity vector  $v$  of magnitude  $R\omega$ , are shown in the proper relationship. As shown below, this relationship can be described in a more convenient way.

When a vector rotates, its time rate of change resulting from the rotation is a vector whose magnitude is equal to the product of the magnitude of the rotating vector and its angular velocity; the direction of the vector is found by turning the rotating vector through  $90^\circ$  in the direction of the angular velocity. This procedure applies to all rotating vectors regardless of the kinematic property that they represent. As shown below it can be used to find the acceleration resulting from the rotation of  $v$ .

The vector  $v$  in Figure 4D must always change in direction, and because it is always at right angles to  $R$  its angular velocity is  $\omega$ . The vector that represents the rate at which its direction changes will have a magnitude equal

to  $R\omega \times \omega$  or  $R\omega^2$  and its direction will be obtained by turning  $v$  through  $90^\circ$  in the direction of  $\omega$ . As shown at  $D$  in Figure 4D, this vector, labelled  $a_N$  and with magnitude  $a_N = R\omega^2$ , is collinear with  $R$  but with the opposite (inward) sense. If  $R$  rotated clockwise,  $v$  would point up at point  $C$  and when rotated clockwise it would point toward the centre of the circle, just like  $a_N$  at point  $D$ .

The vector  $a_N$  always points toward the centre when a point moves on a circular path. The subscript  $N$  signifies that the vector lies along the normal (at right angles) to the tangent to the path;  $a_N$  is also known as the centripetal acceleration.

The relation  $v = R\omega$  when solved for  $\omega$  yields  $\omega = v/R$ , and, if this is substituted for  $\omega$  in  $R\omega^2$ , the magnitude of the normal acceleration can be written as  $v^2/R$ . When a point moves on a curved but noncircular path, the normal component of acceleration has a magnitude  $v^2/\rho$ , in which  $\rho$  (rho) is the radius of curvature of the path; i.e., the radius of the circle that matches the curve at the point.

Any changes in the speed of the point in its orbit about  $O$  must come from changes in  $\omega$ , which are measured by the angular acceleration  $\alpha$  of  $R$ . Consequently, the magnitude of the other component of the acceleration of the point is  $a_T = R\alpha$ , because it represents a change in the magnitude of  $v$ , it must be collinear with  $v$ ; i.e., tangent to the path and with a sense compatible with the direction of  $\alpha$ , as shown by  $a_T$  at point  $E$  in Figure 4D. The resultant (total) acceleration  $a$  of the point, as shown at  $F$ , is the vector sum of  $a_N$  and  $a_T$ .

**Simple harmonic motion.** The device shown in Figure 5A is a Scotch yoke; it consists of a T-shaped yoke with

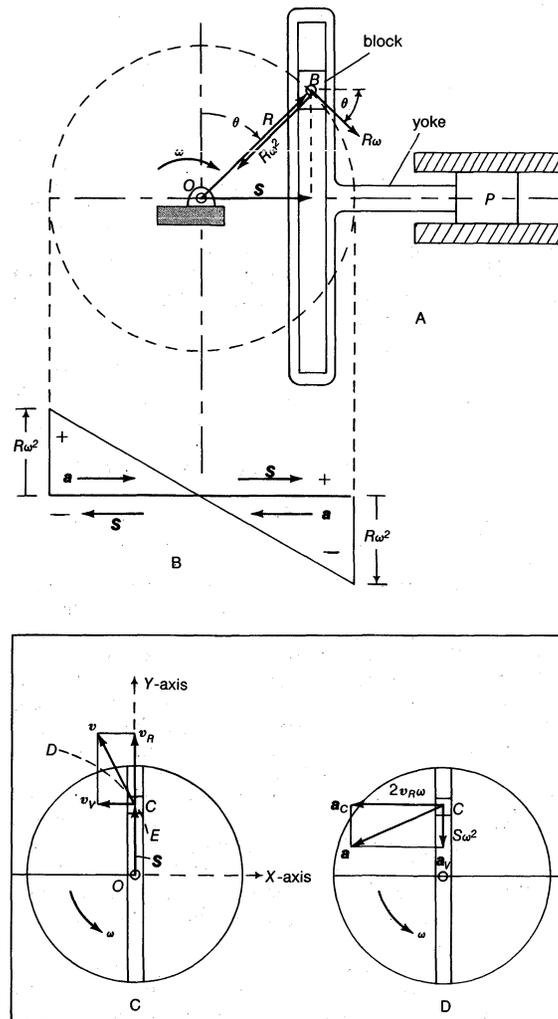

Figure 5: Harmonic and relative motion. (A) Scotch yoke, (B) harmonic motion, (C) relative velocity, (D) relative acceleration.

Vectors that rotate

a slot in which the block can slide and an integral piston  $P$  that slides in a cylinder in the frame, which is shown crosshatched. The crank of radius  $R$  is pivoted to the frame at  $O$  and to the block at  $B$ . Rotation of the crank about  $O$  with an angular velocity  $\omega$  causes the block to slide up and down in the slot and the yoke to move back and forth (left and right in the Figure) with a translatory motion while guided by the piston.

The directed line  $S$ , with its tail at  $O$  and head at the centre of the slot, is convenient for describing the position of the yoke on its straight path. From the Figure it is clear that the length of  $S$  measured from  $O$  depends on the length of  $R$  and the angle  $\theta$  and that  $S$  will point to the left when  $\theta$  exceeds  $180^\circ$ ; to distinguish between the directions of  $S$  it will be assumed that  $S$  is positive (+) when it points to the right and negative (−) when it points to the left.

From trigonometry the relation between  $S$ ,  $R$ , and  $\theta$  is given by  $S = R \sin \theta$ . When  $\theta$  is zero and  $180^\circ$ ,  $\sin \theta$  and  $S$  are zero; when  $\theta = 90^\circ$ ,  $\sin \theta = 1$  and  $S = R$ ; when  $\theta$  is between  $180^\circ$  and  $360^\circ$ ,  $\sin \theta$  is negative. Consequently, the magnitude and direction of  $S$  are taken care of automatically by  $\sin \theta$ .

Because the vector  $S$  does not rotate, its time rate of change, which is the velocity of the yoke, can be obtained from the calculus by taking the derivative of  $S = R \sin \theta$  with respect to time. The velocity can also be obtained by utilizing the relationships shown in Figure 4D for a point moving on a circular path. Point  $B$  in Figure 5A moves on a circular path of radius  $R$ , and its velocity, of magnitude  $R\omega$ , is perpendicular to  $R$  and pointing down. The velocity of the yoke is the horizontal component of  $R\omega$ , namely,  $v = R\omega \cos \theta$ , pointing to the right in the position shown and collinear with  $S$ .

If  $\omega$  is constant, the acceleration of  $B$  has a magnitude  $R\omega^2$  and is collinear with  $R$  and pointing toward  $O$ . The acceleration of the yoke is the horizontal component of  $R\omega^2$ , namely,  $a = -R\omega^2 \sin \theta$ , pointing to the left in the position shown and collinear with  $S$ .

Because  $S = R \sin \theta$ , the horizontal component of the acceleration can be expressed in terms of  $S$ , as  $a = -S\omega^2$ . This important relationship is illustrated in Figure 5B. The motion of the yoke, which is known as a simple harmonic motion, can be described in words as follows: if the displacement ( $S$ ) of a reciprocating point is measured from the centre of its path and the acceleration is proportional to the displacement and in the opposite sense, then the motion is called simple harmonic. In Figure 5B, when the displacement  $S$  is to the right (+) the acceleration is to the left (−), and when  $S$  is to the left (−) the acceleration is to the right (+).

Simple harmonic motion is an important form of periodic motion; it is the motion of a point on the prong of a tuning fork, the bob of a simple pendulum swinging on a small arc, and a weight hung from a spring and vibrating vertically.

The period, or time required for one complete to-and-fro motion of a body executing simple harmonic motion, is equal to the time required for one revolution of the crank in Figure 5A. Because there are  $2\pi$  radians in one revolution, the speed of the crank in revolutions per second is  $\omega/2\pi$  and the time for one revolution  $T = 2\pi/\omega$  seconds. Then, from  $a = -S\omega^2$ ,  $\omega = \sqrt{-(a/S)}$  and  $T = 2\pi/\sqrt{-(a/S)}$  or  $T = 2\pi\sqrt{-(S/a)}$ . Because  $S$  and  $a$  are always of opposite sign, the quantity under the radical is always numerically positive.

**Relative motion.** Although all motion is relative, the term is usually reserved for motion on a moving path or, in other words, relative to a moving coordinate system. In Figure 5C, a large horizontal table rotating at a constant (nonvarying) speed  $\omega$  about a vertical axis  $O$  carries a radial track on which a car  $C$  is moving away from the axis at a constant speed. The track is a moving path, and the  $OXY$  axes attached to the table form a moving coordinate system. Because the car is being carried around counterclockwise by the table as it moves outward along the radial track, the path that it traces in space will be a spiral curve, like  $ED$ . The motion of the car on its space path—i.e., its absolute motion—can be described as the

sum of its motion relative to the table and the motion of the table, and for this purpose the position vector  $S$  is convenient. Relative to the table,  $S$  changes only in magnitude at a time rate appropriately designated as the relative velocity  $v_R$ . Because it rotates with the table,  $S$  also changes in direction at a rate that, as shown previously, is given by a vector, of magnitude  $S\omega$ , perpendicular to  $S$  and pointing to the left because of the direction of  $\omega$ . All points on the table have circular space paths, and their speeds are equal to the products of their distances from the centre of the table and the angular velocity  $\omega$ . Consequently,  $S\omega$  can be interpreted as the speed of the point on the table that coincides with  $C$  at the instant considered; the corresponding vector is called the vehicle velocity  $v_V$ , the table being the vehicle. The absolute velocity  $v$  of the car is equal to the vector sum of  $v_R$  and  $v_V$ , and, as shown in Figure 5C, it is tangent to the space path.

Because the car is moving at a constant speed there is no relative acceleration, and, consequently,  $v_R$  remains constant in magnitude; it does change in direction, however, because it rotates with the table at an angular velocity  $\omega$ . The vector  $v_V$  also changes in direction, but, in addition, it changes in magnitude because  $S$  is increasing in magnitude. Thus the acceleration of the car is the sum of the three changes in the components of the velocity, namely, the changes in the direction and magnitude of  $v_V$  and the change in the direction of  $v_R$ .

The directional change in  $v_V$  is obtained by turning  $v_V$  through  $90^\circ$  in the direction of  $\omega$ ; because  $v_V = S\omega$  its magnitude is  $S\omega \times \omega = S\omega^2$  and it is collinear with  $S$  and in the opposite sense; because of its similarity to  $a_N$  in Figure 4D, it can be interpreted as the acceleration of the point in the table coinciding with  $C$  at the instant considered; this is the vehicle acceleration  $a_V$ .

Because  $v_V = S\omega$  and  $\omega$  is constant, the change in the magnitude of  $v_V$  is the result of the change in the magnitude of  $S$ , which has already been shown to be  $v_R$ . Consequently, the magnitude of this change in  $v_V$  is  $v_R\omega$  and it is collinear with and has the same sense as  $v_V$  because  $S$  is increasing.

The directional change in  $v_R$  is obtained by turning  $v_R$  through  $90^\circ$  in the direction of  $\omega$ ; its magnitude is  $v_R\omega$  and it will coincide with  $v_V$  in Figure 5C. It can be shown that the two vectors of magnitude  $v_R\omega$ , one resulting from the change in magnitude of  $v_V$  and the other from the change in direction of  $v_R$  will always coincide. The sum of these two components is the Coriolis component of acceleration  $a_C$ , and its magnitude is  $2v_R\omega$ . In Figure 5D the absolute acceleration of the car  $a$  is shown as the vector sum of  $a_V$  and  $a_C$ . If the car were moving at a variable speed, there would be a relative acceleration vector, collinear with  $S$  and pointing in the same direction as  $S$  if the relative velocity were increasing. If the table were being accelerated, there would be another component of vehicle acceleration, perpendicular to  $S$  and of magnitude  $S\alpha$ , in which  $\alpha$  is the angular acceleration of the table.

Summarizing, the absolute velocity is always equal to the sum of the relative and vehicle velocities. The absolute acceleration is the sum of the relative and vehicle accelerations, and, if the vehicle rotates, there is an added term, the Coriolis component (discovered in 1835 by the French mathematician Gustave-Gaspard Coriolis).

In the case considered, it is clearly convenient to describe the absolute motion in terms of the relative motion and the vehicle motion. To find  $v$  and  $a$  using absolute quantities, it would have been necessary to know the precise nature of the absolute (space) path. There are many applications, particularly in the analysis of machinery, for which either absolute or relative quantities can be used. In some cases absolute quantities provide the simpler solution.

#### KINETICS

**Newton's laws of motion.** Newton's three laws are the basic postulates (self-evident truths) governing the relations between the forces acting on a body and the motion of the body. Although they were formulated for the first time in usable form by Isaac Newton, they had been

Motion of a tuning fork

Coriolis component of acceleration

discovered experimentally by Galileo about four years before Newton was born. The laws cover only the overall motion of a body—*i.e.*, the motion of its centre of mass—and not any rigid-body motion such as a rotation. This is equivalent to assuming that the body is a particle.

**The law of inertia.** The first law states that, if a particle is at rest or moving at a constant speed in a straight line, it will remain at rest or keep moving at a constant speed in a straight line unless it is acted upon by a force. This postulate is known as the law of inertia, and it is basically a description of one of the properties of a force, namely, that it can change rest into motion or motion into rest or one kind of motion into another kind.

Before Galileo's time it was thought that bodies could move only as long as a force acted on them and that a body free from external influences would come to rest. Those who sought to find the forces that kept the planets moving did not realize that no force was necessary to keep them moving at a practically uniform rate in their orbits; gravitational force was necessary only to change the direction of motion.

The most common impediment to steady motion is friction. A power-driven vessel is quickly brought to rest by fluid friction when the driving engine is stopped; after being struck, a hockey puck will keep on moving for a longer time on smooth ice than on a rough road. No moving body is entirely free from the effects of friction, but it seems reasonable to assume that, if a moving body were free from all external influences, it would move at a constant speed in a straight line. When a body is at rest the forces acting on it form a balanced system; *i.e.*, the net or resultant force is zero.

**The law of force.** Newton's second law is a quantitative statement of the changes that a force can produce in the motion of a particle. It states that the time rate of change of the velocity—*i.e.*, the acceleration—is directly proportional to the force and inversely proportional to the mass of the particle. The larger the force ( $F$ ) is, the larger is the acceleration ( $a$ ), and the larger the mass ( $m$ ) is, the smaller is the acceleration; thus  $a = F/m$ .

Both force and acceleration are vector quantities and as such have both magnitude and direction. The acceleration produced by a force is in the same direction as the force; if several forces act on a body, it is their resultant (sum), obtained by adding the vectors tail to tip, that produces the acceleration.

The mathematical expression of the second law can be established by considering the results of Galileo's experiments with falling bodies; he found that the force of gravity  $W$ , acting alone on a body, produces a constant acceleration equal to  $g$ . If a force  $F$  acts on the same body instead of  $W$  and produces an acceleration equal to  $a$ , it follows from the second law that the ratio of  $a$  to  $g$  is the same as the ratio of  $F$  to  $W$ ; *i.e.*,  $a/g = F/W$ , from which  $a = F/(W/g)$ . The quantity  $W/g$  is equal to  $m$ , the mass of the particle, and a measure of its inertia or reluctance to having its speed changed. As stated in the law, the larger the mass is, the smaller is the acceleration produced by a given force. The second law is usually expressed in the form

$$F = ma. \quad (1)$$

If the force acting on a body is resolved into components along coordinate axes, each component force equals the mass multiplied by the corresponding component of the acceleration.

**The law of action and reaction.** Newton's third law, frequently referred to as the law of action and reaction, asserts that forces, being the result of interactions of two bodies, always appear as equal and opposite pairs. For bodies in direct contact with one another the proposition seems obvious; it is also true for some forces that act at a distance, such as gravitational attraction. As noted previously, the property of forces expressed by the third law is particularly useful in statics.

**Motion under a constant force.** According to Newton's second law—namely,  $F = ma$ —if the force acting on a body passes through the body's centre of mass and remains constant in magnitude and direction, the body will

move in a straight line with a constant acceleration. This means that the body will acquire equal increments of velocity in equal time intervals. Figure 6A shows how the velocity of the body increases from zero at the beginning of a time interval  $t$  to  $v$  at the end of the interval.

Because the line  $odf$  is straight, the ratios  $cd/oc$  and  $ef/oe$ , which represent the slope of the line, are equal, and either may be used to find the acceleration, which is the rate of increase of velocity per unit of time, or  $v/t$ . Using  $ef/oe$ ,  $a = v/t$ ; solving this equation for  $v$  yields  $v = at$ , which states that, if the velocity is zero at the beginning—*i.e.*, when  $t = 0$ —the velocity at the end of any time interval  $t$  is equal to the acceleration multiplied by the time.

The distance travelled in a given time by a body moving at a constant velocity is equal to the velocity multiplied by the time. When the speed varies, it is equal to the product of the average velocity and the time. In Figure 6A the average velocity is  $v/2 = at/2$  so that the distance  $S$  travelled during the interval is the average velocity times the time:  $S = at/2 \times t = \frac{1}{2}at^2$ , which is half the product of the acceleration and the square of the time; it is also equal to the area of the triangle in Figure 6A.

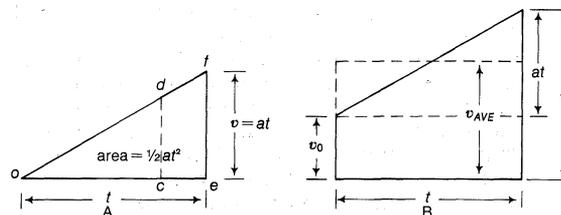

Figure 6: Uniformly accelerated motion.

(A) Initial velocity zero, (B) initial velocity  $v_0$  (see text).

If the body were moving with an initial velocity  $v_0$  before the force were applied to it, the relation between velocity and time—*i.e.*, the velocity-time ( $v, t$ ) curve—would look like Figure 6B. In this case  $v$  is equal to the initial velocity  $v_0$  plus the added part  $at$ ; *i.e.*,  $v = v_0 + at$ . The distance travelled,  $S$ , is the area under the curve, which is the sum of the rectangle  $v_0 t$  and the triangular piece, which is the same as the one in Figure 6A, namely,  $\frac{1}{2}at^2$ . The distance travelled can also be expressed as the average velocity  $v_{AVE} = (v_0 + v)/2$  multiplied by  $t$ . Summarizing:

$$v = v_0 + at \quad (2)$$

$$S = v_0 t + \frac{1}{2}at^2 \quad (3)$$

$$S = \left( \frac{v_0 + v}{2} \right) t. \quad (4)$$

If air resistance is neglected, these equations are valid for a falling or a rising body that is sufficiently close to the Earth that the acceleration of gravity  $g$  may be taken as a constant. For a body falling from rest,  $v_0 = 0$  and  $a = g$ ; for a body projected vertically upward with an initial velocity  $v_0$ ,

$$v = v_0 - gt \quad (5)$$

$$S = v_0 t - \frac{1}{2}gt^2. \quad (6)$$

At the top of the rise  $v = 0$ , and setting  $v = 0$  in equation (5) and solving for  $t$  yields the corresponding time

$$t = \frac{v_0}{g}. \quad (7)$$

Substituting this value of  $t$  in equation (6) gives  $S = v_0^2/2g$ , which is the height to which the body will rise.

**Motion of a projectile.** Consider a projectile of mass  $m$  fired from a gun with an initial velocity  $v_1$  at an angle  $\theta$  to the horizontal (Figure 7A). The projectile's motion may be considered as consisting of a horizontal part and a vertical part, the initial horizontal component of velocity being  $v_H = v_1 \cos \theta$  and the initial vertical component  $v_V = v_1 \sin \theta$ . If air resistance is neglected, the only force on the projectile after firing is its weight,  $W$ , acting downward; there is no force in the horizontal direction. Consequently, the horizontal component of velocity will remain

Bodies  
at rest

Forces  
in pairs

Falling or  
rising  
bodies

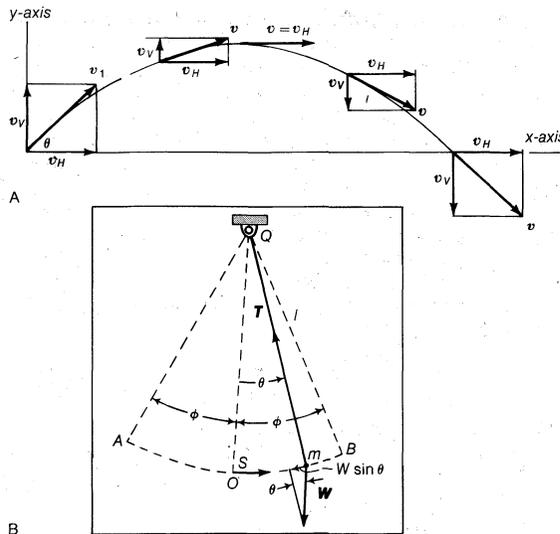

Figure 7: Motion of a projectile and a pendulum. (A) Projectile, (B) simple pendulum.

unaltered throughout the motion, while the vertical component will change because of the force of gravity; *i.e.*, the weight.

It is clear that the projectile will rise and then fall back to Earth after describing a curved path. During its travel the velocity  $v$  will remain tangent to the path, while  $v_H$  will remain constant, and  $v_V$  will vary as shown in Figure 7A.

The distance covered in a given time by a body moving with a constant velocity is equal to the velocity multiplied by the elapsed time. Therefore  $x$ , the horizontal distance traversed in time  $t$  by the projectile, is given by  $x = (v_1 \cos \theta)t$ .

The vertical motion of the projectile is governed by the action of gravity and is entirely independent of the horizontal motion. It is an example of a body projected vertically upward with a velocity  $v_1 \sin \theta$ , and, consequently, equations (5) and (6) will apply. Letting  $S = y$ ,  $v = v_V$ , and  $v_0 = v_1 \sin \theta$

$$v_V = v_1 \sin \theta - gt \tag{8}$$

$$y = (v_1 \sin \theta)t - \frac{1}{2}gt^2. \tag{9}$$

From equation (8) it may be seen that the projectile will have reached its greatest height when  $v_V = 0$  and  $t = (v_1 \sin \theta)/g$  and returned to Earth when  $t = (2v_1 \sin \theta)/g$ . Substituting this value of  $t$  in the equation for  $x$  gives  $x = (2v_1^2 \sin \theta \cos \theta)/g$ , which can be written  $x = v^2 \sin 2\theta/g$ .

Because  $\sin 2\theta$  has its maximum value of unity when  $2\theta = 90^\circ$ —that is, when  $\theta = 45^\circ$ —it follows that the greatest horizontal range for a given initial velocity is obtained when  $\theta = 45^\circ$ .

Ballistic calculations such as the foregoing are of little practical value when the initial velocities and the ranges are large. A precise calculation of the trajectory of a long-range projectile or guided missile must take into account air resistance, the variation in the value of  $g$ , the rotation of the Earth, and any spin of the projectile.

Long-range projectile motion

**Simple pendulum.** A simple pendulum (Figure 7B) consists of a small, heavy body of mass  $m$  called the bob, suspended from a fixed point  $Q$  by a cord of length  $l$  and of mass so small compared with  $m$  that it can be neglected.

If the bob is raised to position  $A$  in Figure 7B and let go, it will oscillate (swing back and forth) in a vertical plane through the angle  $\phi$  on each side of the equilibrium position  $OQ$ . The forces acting on the bob are the tension  $T$  in the cord, acting upward, and the weight of the bob  $W$ , acting down. The cord tension keeps the bob on its circular-arc path  $AB$ , and the resulting centripetal acceleration  $a_N$ , which is a consequence of the changing direction of the velocity of the bob, is directed toward  $Q$ . The tangential component of the acceleration  $a_T$ , which results from changes in the magnitude of the velocity, is

produced by the component of the weight of the bob acting tangent to the path.

In Figure 7B the bob is shown in an intermediate position defined by the angle  $\theta$  in radians, measured, for convenience, from the midposition  $OQ$ ; the corresponding displacement  $S$  along the arc is given by  $S = l\theta$ , and it is arbitrarily considered positive when pointing to the right.

From Newton's second law, the summation of forces along the cord yields  $T - W \cos \theta = ma_N$ ; from this equation the cord tension  $T$  can be calculated, but only after  $a_N$  has been determined by other means. Along the tangent the only force acting is the component  $-W \sin \theta$  of  $W$ , which is negative because it points to the left; then, from Newton's second law,  $-W \sin \theta = ma_T$ . Now  $a_T$  can be expressed as a function of  $\theta$ , namely, the second derivative of  $\theta$  with respect to time, as described above under *Rotation about a fixed axis*. If this replacement for  $a_T$  is made, the previous equation becomes a differential equation; it is difficult to solve, but, if the oscillation of the pendulum is restricted to small angles, which it usually is, a simple solution can be obtained by replacing  $\sin \theta$  by the angle  $\theta$  in radians. On pendulum clocks the half oscillation  $\phi$  is usually less than  $10^\circ$ , and for that angle the difference between  $\sin \theta$  and  $\theta$  in radians is never more than one-half of 1 percent.

Because  $S = l\theta$  in Figure 7B, then  $\theta = S/l$ , and, if this is substituted for  $\sin \theta$  in the previous equation and  $m$  is expressed as  $W/g$ , the weight  $W$ , being on both sides of the equation, will cancel out, and the equation will reduce to  $-S/l = a_T/g$  or  $a_T = -(g/l)S$ .

The term  $g/l$  is a constant; *i.e.*, it does not vary during the motion. Thus the tangential acceleration of the bob is proportional to its displacement ( $S$ ) from the midposition and in the opposite sense. By definition, this is a simple harmonic motion, and the formula for the period (time for a complete cycle of two swings) of such a motion, previously derived for a Scotch yoke, is applicable. For the Scotch yoke  $T = 2\pi \sqrt{-S/a_T}$ ; for the pendulum  $S/a_T = -l/g$  so that  $T = 2\pi \sqrt{l/g}$ .

A seconds pendulum is one that takes one second to make one swing (one-half cycle); then  $T = 2$  seconds or  $l = g/\pi^2$ . Because  $g$  varies slightly on the surface of the Earth, the length of a seconds pendulum will be different at the North Pole than at the Equator. An average value for  $l$  for a seconds pendulum is slightly more than 39 inches, or about one metre. By measuring the length and period of a pendulum the value of  $g$  can be calculated; this is one of the most accurate methods of determining  $g$  at any place on the surface of the Earth.

The seconds pendulum

**Force required for motion on a circle.** When a particle moves on a circular path with a velocity that is changing in both magnitude and direction, it is convenient to treat these effects separately when seeking the forces that are their causes.

In Figure 8A, a particle of mass  $m$  in the form of a

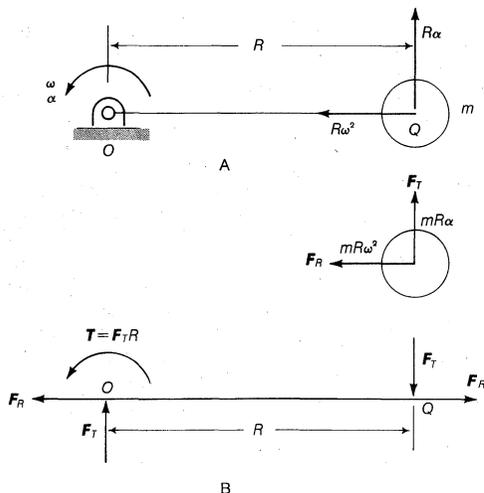

Figure 8: Forces required for motion in a circle. (A) The acceleration, (B) the forces.

circular plate is attached at  $Q$  to a rigid bar of length  $R$  that rotates about a fixed axis at  $O$  with an angular velocity  $\omega$  and an angular acceleration  $\alpha$ . The mass of the bar is assumed to be so small compared with the mass of the particle that it can be neglected, while the total mass of the particle is assumed to be concentrated at  $Q$ . From Figure 4D the two components of the acceleration of the particle are  $R\omega^2$ , the centripetal or radial component directed inward along the bar, and  $R\alpha$ , the tangential component at right angles to the bar and with a sense compatible with a counterclockwise  $\alpha$  (Figure 8A).

To determine the forces that are acting on the particle and on the bar, it will be convenient to draw free-body diagrams. A free-body diagram is a sketch showing a body isolated from all adjacent bodies and with all the forces acting on it that are significant to the problem under consideration.

From Newton's second law the components of the acceleration of the particle are caused by the forces  $F_R = mR\omega^2$  and  $F_T = mR\alpha$ ; in Figure 8B these forces are shown acting on a free-body diagram of the particle.

From Newton's third law, action and reaction are equal and opposite. The forces  $F_R$  and  $F_T$  are exerted by the bar on the particle, and, consequently, the particle must exert equal and opposite forces on the bar; they are shown at point  $Q$  on a free-body diagram of the bar in Figure 8B. Because the mass of the bar is to be neglected, there are no inertial effects, and the forces on the bar must balance. The force  $F_R$  at  $Q$  is easily balanced by an equal and opposite force at  $O$ . To balance  $F_T$  there must be an equal and opposite force at  $O$ , but, because these forces are equal, opposite, and separated by a distance  $R$ , they constitute a clockwise couple that, for balance, requires that a counterclockwise couple or torque,  $T = F_T R$ , be applied (by some means) to the bar at  $O$ . Because  $F_T = mR\alpha$ , the torque can be expressed as  $T = mR^2\alpha$ .

If another particle of mass  $m$  were located diametrically opposite to the first particle on a bar at the same distance  $R$  from  $O$ , the forces created at  $O$  would be equal and opposite to those shown in Figure 8B, and they would cancel each other. The torque  $T$ , however, would be twice as much, namely,  $2mR^2\alpha$ .

The quantity  $mR^2$  is a measure of the rotational inertia of a particle, in the same way that  $m$  is a measure of its translatory inertia. Each particle in a rigid body has rotational inertia about any chosen axis, and the sum of all these inertias is called the moment of inertia,  $I$ , of the body.

For a rigid body  $I = \sum mR^2$ , or, using the calculus notation,  $I = \int r^2 dm$ , which means that every particle in the body is to be multiplied by the square of its distance from the chosen axis and the products added together. For a rigid body rotating about a fixed axis, for which its moment of inertia is  $I$ , the relation between the torque  $T$  and the resulting angular acceleration is given by

$$T = I\alpha \quad (10)$$

This equation is analogous to  $F = ma$  for translatory motion. For a circular cylinder of radius  $A$  and mass  $m$ , the moment of inertia, obtained most easily by means of the integral calculus, is equal to  $mA^2/2$ . It is a common and convenient practice to express the moment of inertia of a body as  $I = mK^2$ , in which  $K$  is the radius of gyration of the body with respect to the chosen axis; for the circular cylinder,  $K^2 = A^2/2$ .

**Kinetics of general plane motion.** As originally formulated, Newton's second law,  $F = ma$ , deals with the motion of particles. The law is valid also for the motion of the centre of mass of all bodies; *i.e.*, for a point in a body that is equivalent to the centre of gravity for the bodies and the motions dealt with in classical mechanics. When a body rotates, the causes and effects of the rotations must be treated separately from the motion of the centre of mass; Newton's law can be extended to take care of rotations.

If the resultant of all the forces acting on a body passes through the centre of mass of the body, it will not cause

the body to rotate. In the most general case, the resultant force does not pass through the centre of mass, and, consequently, it will cause the body to rotate. By applying Newton's second law to each particle of the body, it can be shown that in all cases the centre of mass behaves as if the resultant force passed through it (whether it does or does not), while the moment, or torque, of the resultant force about the centre of mass is equal to the moment of inertia of the body about an axis through the centre of mass multiplied by the angular acceleration of the body.

If  $G$  is the centre of mass and  $a_G$  its acceleration,  $I_G$  the moment of inertia of the body about  $G$ ,  $T_G$  the torque of the resultant force about  $G$ , and  $\alpha$  the angular acceleration of the body, then

$$F = ma_G \quad (11)$$

$$T_G = I_G\alpha \quad (12)$$

Forces and torques are the basic causes in mechanics,

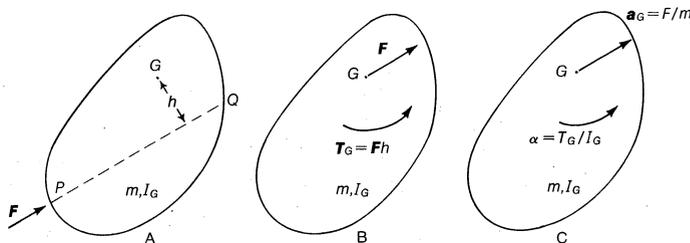

Figure 9: Causes and effects in plane motion. (A) Prime cause, (B) resulting cause, (C) effects.

while accelerations are their effects. In Figure 9A, the resultant force  $F$  acting along the line  $PQ$  on the body of mass  $m$  creates a torque,  $T_G = Fh$ , about the centre of mass  $G$ . The equivalent force and torque system are shown in Figure 9B, whereas the effects are shown in Figure 9C. It should be noted that, while equations (11) and (12) express relationships that exist at any instant during the plane motion of a rigid body, the magnitudes and directions of  $a_G$  and  $\alpha$  may be changing continuously on account of changes in  $F$ .

Since the position of point  $P$  relative to  $G$  in Figure 9A affects the magnitude and direction of  $T_G$  and  $\alpha$  but not the magnitude and direction of  $a_G$ , it follows that the motion of the centre of mass of a body is entirely independent of any rotation of the body. This means that the centre of mass moves as if it were a particle with the mass of the entire body and acted upon by the resultant force. Neglecting air resistance, any rotational motion of a projectile, for example, will not affect the motion of its centre of mass. Even after the projectile explodes, the centre of mass of the fragments will continue moving on the same path the shell was travelling before the explosion.

Equations (11) and (12) were derived by specifying the instantaneous acceleration of one point in a body and the angular velocity and acceleration of the body and then determining the resultant of the force system required to produce the accelerations. A similar procedure is necessary when making a dynamic analysis of the mechanism of a machine.

#### PRINCIPLES OF MOMENTUM AND ENERGY

Newton's second law,  $F = ma$ , describes the relation between the acceleration of a particle and the force acting on it. This equation works both ways; *i.e.*, if the acceleration is known, the force required to produce it can be calculated, while if the force is known, the acceleration that it produces can be calculated. The relationship defined by the equation is a causal one between the force, which is the cause, and the acceleration, which is the effect.

Although the acceleration  $a$  of a particle at any instant can be calculated directly from the formula if  $F$  and the mass of the particle are known, this instantaneous value of acceleration gives no information regarding the velocity of the particle. To obtain an adequate description of a particle's motion—*i.e.*, its velocity and displacement (position)—the manner in which  $F$  varies must be known. In

Rotational inertia

Motion of centre of mass

general,  $F$  may vary with the elapsed time or with the distance that it moves or with its velocity.

If  $F$  is known as a mathematical function of  $t$ ,  $S$  (distance), or  $v$ , it may be possible to integrate the equation  $F = ma$  (which is basically a differential equation) by the methods of the integral calculus and so obtain equations for the displacement and velocity of the particle. When the force is constant (nonvarying), the velocity and displacement can be found without using the calculus; when the force varies with time or distance, the results of the integration are embodied in two important and useful relations. One of the relations, known as the principle of impulse and momentum, describes what a force can do in a given time; the other, the principle of work and energy, describes what a force can do in a given distance. Both of these principles are extensions of Newton's second law, and they can be derived in a fairly satisfactory manner without using the calculus.

**Impulse and momentum.** When a constant force is applied for a time  $t$  to a particle moving with a velocity  $v_0$ , the velocity of the particle increases to some value  $v$ , as shown in Figure 6B. From this figure, if  $a$  is the acceleration of the particle,  $v - v_0 = at$ . From Newton's second law,  $F = ma$  or  $a = F/m$ . Substituting  $F/m$  for  $a$  in the previous equation gives  $v - v_0 = (F/m)t$ , which can be written  $Ft = m(v - v_0)$ . The term  $Ft$ , which is the product of the force and the time during which it acts, is called the impulse of the force. The product of the mass of a particle and its velocity is known as the momentum of the particle so that  $m(v - v_0)$  is the change in momentum. Hence, the impulse of a force equals the change in momentum produced by it; this is the principle of impulse and momentum, and it simplifies the solution of many problems that would be difficult to solve by  $F = ma$ .

The impulse  $Ft$  can be visualized as the area of a rectangle  $t$  units of time long and  $F$  units of force high. When the force  $F$  is not constant, the impulse is the average force during the time interval multiplied by the time interval; this average is the imaginary (constant) force whose impulse equals the impulse of the real (varying)

The impulse of a force

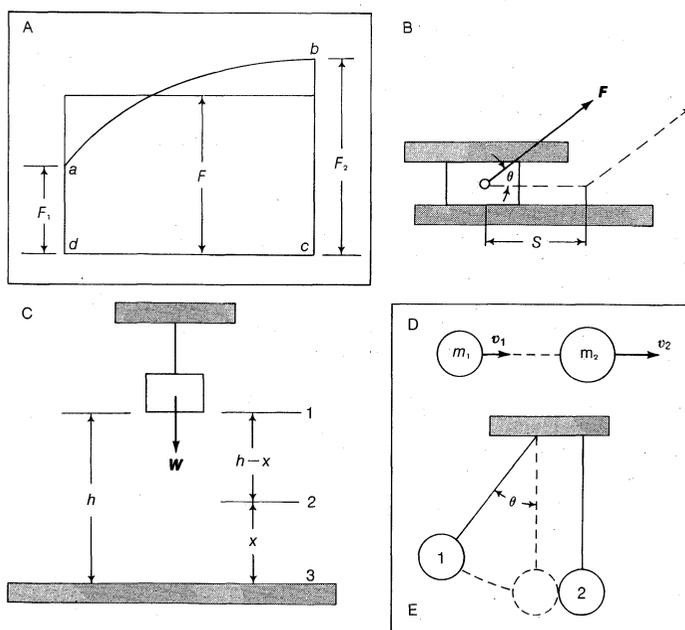

Figure 10: Work, energy, and impact. (A) Average force  $F$ , (B) work done by a force, (C) potential energy, (D,E) impact, or collision.

force. In Figure 10A, the force varies from  $F_1$  at the beginning of the time interval  $dc$  to  $F_2$  at the end of the interval. The average force  $F$  is the force that when multiplied by  $dc$  gives the area enclosed by  $abcd$ . Consequently, the impulse of a force is the area under the force-time ( $F, t$ ) curve.

The impulse-momentum equation is especially useful

in dealing with the interactions between pairs of particles since in such cases it may not be necessary to calculate the impulse. As an example, consider a projectile of weight  $W_1$  and a gun of weight  $W_2$ , which is free to recoil. During the short interval of the explosion, the equal and opposite forces  $F$  acting on the gun and projectile, produced by the gas pressure, vary in an unknown manner, and it would be difficult to calculate the impulses of these forces. Because the forces and the times are equal, however, the impulses on gun and projectile must be equal and opposite. Thus, if the initial velocities are zero and the final velocities  $v_1$  and  $v_2$  for the projectile and gun, respectively, then  $Ft = (W_1/g)v_1 = (W_2/g)v_2$ , from which  $v_1/v_2 = W_2/W_1$ . Thus the velocities of the projectile and gun after firing are in opposite directions and inversely proportional to their weights.

The projectile and the gun can be thought of as a system of two particles on which no external force acts; the forces  $F$  are internal forces. In general, when no external force is applied to a system of particles, the momentum of the system remains unchanged. This is known as the principle of conservation of momentum; the solar system furnishes an illustration of this principle. Because the nearest stars exert no appreciable attractions, the members of the system move under the action of their mutual attractions only, and the momentum of the system does not change. Consequently, the mass centre of the system moves in a straight line with a uniform velocity, just like a particle with a mass equal to the sum of the masses of the Sun and planets.

**Work and energy.** When a force moves a body through a given distance in the direction in which it acts, the changes in the velocity of the body that result from this action are easily calculated if the force is constant. From equation (4),  $S = \frac{1}{2}(v + v_0)t$ ; solving this equation for  $t$  yields  $t = 2S/(v + v_0)$ . If this value of  $t$  is substituted in the impulse-momentum equation,  $Ft = m(v - v_0)$ , the result is  $FS = \frac{1}{2}m(v^2 - v_0^2)$ .

The quantity  $FS$  is the work done by the force. One-half the product of the mass of a body and the square of its velocity is called the kinetic energy of the body, or K.E.  $= \frac{1}{2}mv^2$ . The quantity of  $\frac{1}{2}m(v^2 - v_0^2)$  is, therefore, the gain in kinetic energy of the body, and, from the previous equation, the work done on a body is equal to the gain in kinetic energy; this is the principle of work and energy, and it simplifies the solution of many problems difficult to solve by  $F = ma$ .

The work  $FS$  can be visualized as the area of a rectangle  $S$  units of distance long and  $F$  units of force high. If the force  $F$  varies, the work is the average force for the distance multiplied by the distance moved; this average is the imaginary (constant) force that would do the same work as the real (varying) force. In Figure 10A, the force varies from  $F_1$  at the beginning of the displacement  $dc$  to  $F_2$  at the end of the movement. The average force  $F$  is the force that when multiplied by  $dc$  gives the area enclosed by  $abcd$ . Consequently, the work done by a force is the area under the force-distance ( $F, S$ ) curve.

When a force does not act in the same direction in which it moves, it is only the component of the force in the direction of the motion that performs work. In Figure 10B, work  $= FS \cos \theta$ . If a force moves in a direction opposite to that in which it acts, it does negative work.

In the treatment of impulse and momentum, it was shown that the momenta of a projectile and gun are equal and opposite because they are acted upon by equal and opposite forces for the same length of time. Because the mass of the gun greatly exceeds the mass of the projectile, however, the final velocity of the gun will be considerably less than that of the projectile. This means that the distance that the gun moves during recoil will be less than the distance that the projectile moves during the firing period. Consequently, the force, acting for a longer distance on the projectile than on the gun, will do more work on it, and the kinetic energy of the projectile will be greater than that of the gun.

A particle that is in such a state that it can do work is said to possess energy; this energy may be kinetic and the

The work done by a force

result of the particle's motion or it may be the result of other circumstances, such as position above the Earth's surface or elastic deformation.

Consider, for example, the weight of mass  $m$  and weight  $W$  suspended by a cord at a height  $h$  above the ground (Figure 10C). If the cord were cut, the weight would fall to the ground, and the gravity force would do work. Thus, by virtue of its position above the ground, the weight has the capacity for doing work. This is known as its potential energy relative to the ground.

The work done by gravity on the weight must be equal to the kinetic energy of the weight just before it strikes the ground. If, as shown in Figure 10C, the initial position of the suspended weight is designated by 1, an intermediate position by 2, and the final position by 3, then  $Wh = \frac{1}{2}mv_3^2$ .

It is worth noting that the previous equation provides the most direct method of determining the final velocity of a freely falling body in terms of the initial height. Substituting  $W/g$  for  $m$ ,  $Wh = \frac{1}{2}(W/g)v_3^2$  and solving for  $v_3$  yields

$$v_3 = \sqrt{2gh}. \quad (13)$$

In position 2 in Figure 10C, the weight will have a potential energy of  $Wx$  relative to the ground and kinetic energy of  $\frac{1}{2}mv_2^2$ , which must be equal to the work done by gravity as the weight fell from position 1 to position 2, namely,  $W(h - x)$ . If  $E$  represents the total energy,  $P$  potential energy, and  $U$  kinetic energy, then at position 2,

$$E_2 = P_2 + U_2 = Wx + W(h - x) = Wh.$$

Now  $E_1 = Wh$  and  $E_3 = \frac{1}{2}mv_3^2 = Wh$ , so that in all three positions of the weight its total energy is the same. In position 1 the energy is all potential, in position 2 it is partly potential and partly kinetic, while in position 3 it is all kinetic. A system of particles in which the sum of the potential and kinetic energies remains constant is said to be a conservative system and to satisfy the law of conservation of mechanical energy; the forces involved are said to be conservative forces. When the motion of a body is opposed by friction, mechanical energy is lost; because the energy is not conserved, the force of friction is said to be a nonconservative force.

The work-energy equation can be used to approximate the force required to stop a moving particle or the "force" of a blow. If a wooden pile is being driven into the ground by successive blows of a hammer of weight  $W$  falling from a height  $h$  on the head of the pile, the "force" of the blow will depend on the nature of the ground and the amount that the pile penetrates the ground on each blow. If the penetration  $d$  is small compared with the height  $h$  and the weight of the pile is small compared with the weight of the hammer, then the average "force" of the blow, or resistance to penetration  $R$ , will be obtained by equating the kinetic energy of the hammer to the work done by the force  $R$  during the penetration. The kinetic energy of the hammer when it strikes the pile is equal to its potential energy at the height  $h$ , namely,  $Wh$ , and the work done on the pile is  $Rd$ . Then  $Wh = Rd$ , from which  $R = Wh/d$ . This result shows that for given values of  $W$  and  $h$  the force  $R$  depends on  $d$ , which depends on the nature of the ground; the harder it is to penetrate the ground, the larger the value of  $R$ . If the ground acted like a compressed coil spring, the maximum force would be doubled.

**Momentum and energy in rotary motion.** Because it is applicable only to the motion of particles or the centres of mass of bodies, the equation  $Ft = m(v - v_0)$  is known as the linear impulse-momentum equation. In much the same way that  $F = ma$  for particles was shown to become  $T = I\alpha$  when applied to the rotary motion of bodies, the linear impulse-momentum equation can be adapted to rotating bodies. In order to do this in a simple way, it will be expedient to utilize the perfect analogy between the mathematical description of motion on a straight path and rotation about a fixed axis.

If the position of a particle on a straight path is described by a position vector that lies in the path, the vec-

tor will change only in magnitude as the particle moves, the first time rate of change being the velocity and the second the acceleration of the particle; all vectors will lie in the path.

The angular position, relative to a fixed radial line, of a line on a body rotating about a fixed axis can be described by a vector that lies along the axis and points in a direction that a right-hand screw would advance in a fixed nut if it were attached to and rotated with the body. As the body rotates the vector will change in length, the first rate of change being the angular velocity of the body and the second change the angular acceleration, just like the vectors for a point moving on a straight path.

As a consequence of the similarity of their vector representation,  $\theta$  (in radians) in rotary motion is analogous to  $S$  in linear motion,  $\omega$  is analogous to  $v$ , and  $\alpha$  to  $a$ . The diagrams in Figure 6 can be adapted for rotation by a constant torque by changing  $v$  to  $\omega$  and  $a$  to  $\alpha$ . From equations (11) and (12),  $T$  is analogous to  $F$  and  $I$  to  $m$ .

Using these relationships, the angular impulse-momentum equation can be written as  $Tt = I(\omega - \omega_0)$ . If the angular impulse  $Tt$  imparted to a rotating body for an interval of time is zero, then the angular momentum of the body must remain constant during the interval. This is known as the conservation of angular momentum. A figure skater may start to revolve slowly at a speed  $\omega_1$  and a moment of inertia  $I_1$  with arms extended. By drawing the arms in close, the moment of inertia is reduced to  $I_2$  and the speed increased to  $\omega_2$ . From the previous equation, with zero impulse  $I_1\omega_1 = I_2\omega_2$  or  $\omega_2 = (I_1/I_2)\omega_1$ .

The dimensions of linear impulse are force multiplied by time, and those of angular impulse, moment multiplied by time. Consequently, the linear momentum and the angular momentum of a body cannot be added.

The equation for work and kinetic energy of rotation can be written down at once by using the analogies; it is  $T\theta = \frac{1}{2}I(\omega^2 - \omega_0^2)$ . The work done by a torque is equal to the torque multiplied by the angle that it turns through in radians. Because  $\theta$  is dimensionless,  $T\theta$  has the same dimension as  $FS$ , and the kinetic energy of rotation can be added to the kinetic energy of translation.

#### IV. Other topics in mechanics

##### MECHANICS OF NONRIGID BODIES

**Impact, or collision.** When two moving bodies collide, the magnitude of the forces created at the region of contact and the resulting changes in the velocities of the bodies depend on the shapes of the bodies, their masses, their elastic properties, and their initial velocities. The fundamental theory of impact can be developed by means of the two spheres of the same material in Figure 10D, of masses  $m_1$  and  $m_2$  and moving in a straight line with velocities  $v_1$  and  $v_2$ .

If  $v_1$  is greater than  $v_2$  the spheres will collide, and after collision  $v_2'$ , the final velocity of sphere 2, will be greater than  $v_1'$ , the final velocity of sphere 1.

During the short period of contact the forces on the spheres will be equal and opposite, and, because they act for the same length of time, their impulses will produce equal and opposite changes in the momentum of the spheres. Hence, the law of conservation of momentum applies, and the total momentum after impact equals the total momentum before impact, or

$$m_1v_1' + m_2v_2' = m_1v_1 + m_2v_2. \quad (14)$$

In order to determine the velocities after impact, the energies of the spheres must be considered. At the moment of impact the energy is all kinetic; during impact some of this energy is lost as a result of permanent deformation of the spheres and the generation of vibrations and sound waves. If there are no losses, it can be shown that the velocity difference of approach ( $v_1 - v_2$ ) is equal to the velocity difference of separation ( $v_2' - v_1'$ ). By experiment, Isaac Newton discovered that ( $v_2' - v_1'$ ) is always less than ( $v_1 - v_2$ ) and that the relation between these velocity differences is given by

$$v_2' - v_1' = e(v_1 - v_2), \quad (15)$$

Potential energy

The "force" of a blow

The conservation of momentum

The coefficient of restitution

in which the numerical factor  $e$ , the coefficient of restitution, has values between zero and unity that depend only on the material of the bodies and not on their masses or velocities. Knowing  $v_1$ ,  $v_2$ , and  $e$ , the final velocities  $v_1'$  and  $v_2'$  can be calculated from equations (14) and (15).

If the spheres were lead, putty, or some other soft material,  $e$  would be almost zero, and from equation (15),  $v_2' = v_1'$ , which means that after impact the spheres would move on together with a common speed that can be calculated by equation (14). This is known as inelastic impact.

For the special case of equal masses and purely elastic impact—*i.e.*,  $e = 1$ —it can be shown, by solving equations (14) and (15) simultaneously for  $v_1'$  and  $v_2'$ , that  $v_1' = v_2$  and  $v_2' = v_1$ , which means that the spheres will exchange velocities after impact. If sphere 2 is stationary when sphere 1 strikes it—*i.e.*, if  $v_2 = 0$ —then  $v_1' = 0$ , and sphere 1 will stop dead on impact, while sphere 2 will move on with the speed of sphere 1 before impact. This effect can be demonstrated by suspending the spheres on cords, as shown in Figure 10E. If sphere 1 is moved through the angle  $\theta$  and let go, it will stop dead when it collides with sphere 2, which instantaneously will acquire the velocity of sphere 1 and swing up through an angle slightly less than  $\theta$  on account of energy losses. Isaac Newton is reported to have used this apparatus with cords 10 feet long to confirm his third law.

If a small ball is dropped on the horizontal surface of a large mass of the same material, the coefficient of restitution can be calculated by comparing the height  $h$  to which the ball bounces with the height  $H$  from which it is dropped. Assuming that the large mass is stationary before and after impact, then  $v_2$  and  $v_2'$  are both zero, and from equation (15)  $-v_1' = ev_1$  or  $e = -v_1'/v_1$ .

From equation (13)  $v_1 = +\sqrt{2gH}$  in a downward (assumed positive) direction, and  $v_1' = -\sqrt{2gh}$  in an upward (assumed negative) direction; then  $e = \sqrt{h/H}$ .

**Mechanics of elastic bodies.** There are several reasons, even in a treatment of classical mechanics, which deals largely with so-called rigid bodies, for considering the deformations of these bodies. It has already been pointed out that the number of unknown forces in the members of a machine or structure that can be determined by the equations of rigid-body statics is limited and that the elastic properties of the members must be taken into account if the forces in redundant members or supports are to be found.

Most structural members may be classified as either bars or beams; bars are usually subjected to longitudinal (axial) loads that tend to stretch or shorten them, while beams usually support transverse loads that bend them. In machine construction, shafts are usually bent by transverse loads and twisted by torques. The type of stress (internal force) and the deformations that these three types of forces produce form the subject matter of "strength of materials" and "theory of elasticity," but, to the extent that the nature of these stresses and deformations influences the reactions on the members, their consideration in this article is justified.

The tension in a flexible cable (rope or chain) hanging freely between two horizontal supports and the shape of the curve assumed by the cable can be found by the equations of statics, but only under the assumption that the cable cannot offer any resistance to bending.

The mechanical oscillations of bodies and the vibration of strings and membranes are all maintained by interchanges in kinetic energy and elastic strain energy; *i.e.*, the energy stored in an elastic body when it is deformed.

When the shape of a solid body is changed by the application of a force, the body may be elastic and assume its original shape when the force is removed or be plastic and retain much or all of its loaded shape when unloaded. Most metallic bodies are elastic if the load to which they are subjected does not exceed a limiting value.

The simplest loaded state, and the one to which all other loaded states are referred when the limiting loads in these states are being investigated, is the state of simple tension; a wire fixed at one end and supporting a weight hung on the other end is in this state.

If the load is applied to a suspended wire by attaching a container to the free end and gradually filling it with water, there will be a measurable relation between the stretch of the wire and the weight of the water in the container. In order to make the results of such measurements applicable to all wires of the same material regardless of their length and cross-sectional area, it is convenient to designate the stretch of the wire as a fraction of its original length and the load as the weight of the water divided by cross-sectional area of the wire.

If  $L$  is the original length of the wire,  $A$  its area, and  $L'$  the length under a load  $P$ , then  $(L' - L)/L = \epsilon$  is known as the unit strain corresponding to the stress  $\sigma = P/A$ . If the wire is made of steel, the relation between  $\sigma$  and  $\epsilon$  will remain constant as long as the limiting value of  $\sigma$  (the elastic limit) is not exceeded. This relationship is known as Hooke's law and is given by  $\sigma = E\epsilon$ , in which  $E$  is the modulus of elasticity (a measure of a material's resistance to being stretched) of steel. Materials such as steel, which obey Hooke's law up to the elastic limit, are said to be linearly elastic; *i.e.*, if the stress is doubled, the strain is doubled. It should be noted that strain is a measurable quantity, while stress is a concept and is not directly measurable.

A useful form of Hooke's law can be derived by noting that  $L' - L = \Delta$  is the deflection at the loaded end of the wire, so that  $\epsilon = \Delta/L$ . Substituting  $\Delta/L$  for  $\epsilon$  and  $P/A$  for  $\sigma$  in the equation defining Hooke's law yields  $\Delta = PL/AE$ .

**Stiffness.** In addition to being strong enough to carry the imposed loads without failure, a structure or a machine component must also satisfy certain requirements regarding deflections. In most cases a structure should be rigid, whereas a spring should be flexible. Stiffness is also important in all forms of mechanical vibration.

Within the limits of elastic behaviour the deformations of solid metallic bodies are extremely small. For unhardened steel, for example, the allowable unit tensile strain  $\epsilon$  is about 0.001 inch per inch, or centimetre per centimetre, or metre per metre. This means that a bar one inch long could be stretched to no more than 1.001 inches, or one centimetre to 1.001 centimetres, and so on. To obtain the flexibility that is characteristic of a spring from a bar stressed in simple tension, it would be necessary to use a very long bar. By loading the bar in a different way, however, or by changing its geometry—*i.e.*, by making its axis curved instead of straight—the flexibility of the bar can be increased and its stiffness reduced.

The deflection ( $\Delta$ ) of an axially loaded wire or bar has been shown to be  $\Delta = PL/AE$ , which, solved for  $P/\Delta$ , given  $P/\Delta = AE/L$ . The quantity  $P/\Delta$  is the ratio of the load to the corresponding deflection, while  $AE/L$  depends only on the dimensions of the bar and its material; these equivalent quantities, expressed in different ways but having the same dimension, namely, load per unit of deflection, are measures of the stiffness of an axially loaded bar. The stiffness of any elastic body or structure depends on the way in which it is loaded—*i.e.*, on whether it is pulled, bent, or twisted—but it is always equal to the load divided by the corresponding deflection. If the structure is complex, the stiffness may have to be determined experimentally by simultaneous measurements of load and deflection. The stiffness is usually designated by  $K$ , which has the dimension pounds per inch, or newtons per metre, or any other load-deflection ratio.

For simple structures or bodies loaded in a simple way, such as an axially loaded bar, the stiffness can usually be obtained analytically and expressed by a formula as a function of the dimensions of the structure and the modulus of elasticity of the material.

If a bar of length  $L$ , a circular cross section of diameter  $D$ , and an area  $A$  were fixed at one end in a horizontal position and loaded at the free end like a cantilever beam with a transverse load  $P$ , its stiffness would be  $K = (AE/L)(3D^2/16L^2)$ . Comparing this formula with that for an axially loaded bar, it is seen that the fraction  $3D^2/16L^2$  is a measure of the reduction in stiffness obtained by using the bar as a cantilever beam; for  $L = 12D$  the reduction is  $1/768$ . Because of the way in which it is

Hooke's law

Interchanges of energy

loaded, the bending stress in the cantilever bar would be almost 100 times greater than the tensile stress in the axially loaded bar for the same load  $P$ . This means that the limiting elastic load on the cantilever bar would be about one-hundredth of that for the axially loaded bar. Nevertheless, as long as the limiting load is not exceeded, the cantilever bar will satisfy Hooke's law—*i.e.*, the deflection under the load will be proportional to the load. In some cases Hooke's law may not be valid for certain configurations of elastic components; this is usually the result of changes in the geometry of the assemblage as the load is increased.

#### INERTIA FORCES AND THE CORIOLIS FORCE

It was pointed out by Jean Le Rond d'Alembert that Newton's second law could be interpreted in a different way by writing it in the form  $F + (-ma) = 0$  and treating the term  $(-ma)$  as if it were a force. In this form  $(-ma)$  is called an inertia force to distinguish it from such real forces as the force of gravity or the force exerted by one body on another by direct contact. The inertia-force concept makes it possible to reduce a problem in dynamics to a problem in statics by writing the second law in the form  $\Sigma F = 0$  and including the inertia forces in the summation. The term  $(-ma)$  is sometimes called a reversed effective force and also a fictitious force.

Fictitious forces

When a particle is moving on a curved path at a constant speed, the force and the centripetal acceleration are both directed toward the centre of curvature of the path. The corresponding outward inertia force, equal in magnitude to the centripetal acceleration, is called the centrifugal force. Neglecting gravity, a stone whirling in a circle in a horizontal plane at the end of a string has only one real force acting on it, namely, the tension in the string. The string tension keeps the stone on its circular path, and, because it continually alters the direction of the velocity of the stone, it creates the centripetal acceleration. Using the inertia-force viewpoint, the stone is in equilibrium—*i.e.*, has zero acceleration—under the influence of the inward string tension and the outward centrifugal force. A real force, however, equal to the centrifugal force in both magnitude and direction, is acting on the member at the centre of the circle to which the string is attached.

When a body is at rest, the external forces (loads and reactions) acting on it are in equilibrium. If the body is assumed to be cut in a region that is stretched, bent, or twisted, the stresses acting on the cut cross section must balance the external forces on the portions of the body on either side of the cross section. When a machine or structural member is being accelerated, the external forces are not in equilibrium, and the stresses on any cross section do not balance the loads and reactions. By employing d'Alembert's principle this difficulty can be overcome, and a problem in dynamics becomes a problem in statics, for which the equations of equilibrium can be used.

D'Alembert's principle is particularly useful in deriving the equations for the stresses in bodies rotating about fixed axes. On a disk rotating at a constant speed, for example, each cubical element of the disk is assumed to be in equilibrium under the action of the stresses acting on its sides and the outwardly directed centrifugal (inertia) force. To a person standing on it, the particles of the disk do appear to be in equilibrium because they do not move relative to the disk. In the theory of elasticity (*q.v.*), inertia forces and gravitational forces are classified as body forces; in the rotating disk, the centrifugal forces, because they vary with the distance of the element from the axis, have the same effect on the stresses as varying gravitational forces. From a similar point of view, a centrifuge or a cream separator is a system in equilibrium to an observer rotating with it and can be more easily explained in terms of centrifugal force than in terms of centripetal force.

In the treatment of relative motion in Figure 5D, the absolute acceleration  $a$  is shown as the resultant of the Coriolis component  $2v_R\omega$  and the centripetal component  $a_v = S\omega^2$ , in which  $S$  is the magnitude of the vector  $S$ . If  $m$  is the mass of the car, the track must be exerting a force on the car equal to  $m2v_R\omega$ , collinear with the accel-

ation vector and in the same direction; this is the Coriolis force. There must also be a centripetal force  $ma_v$ , collinear with  $a_v$  and in the same direction, generated by the mechanism that drives the car on the track.

The Coriolis force is always present when a particle moves on a rotating body or when a body rotates about an axis that is fixed on another rotating body. The torque in a fluid coupling or converter is created by the Coriolis forces that result from the relative motion of the fluid; on an automobile making a turn to the right, elements in the upper half of the rotating flywheel experience a Coriolis acceleration forward and those in the lower half an acceleration backward. The Coriolis forces corresponding to these accelerations are produced in the crankshaft bearings; they are known as gyroscopic couples. The behaviour of gyroscopes can be explained in terms of Coriolis forces.

Because of its rotation about an axis joining the poles, the Earth is a rotating frame of reference, and the Coriolis and centripetal components will appear in the acceleration equations for particles moving in certain directions and in certain locations on and near the Earth's surface. Because the Earth rotates at only 0.000694 revolution per minute (0.0000729 radian per second), the forces associated with these accelerations are small and can usually be neglected; they do have some geophysical importance, however.

Like the expansion of a rotating disk caused by the centrifugal forces, the centrifugal forces on the Earth's crust are responsible for the equatorial bulge; the forces are greatest at the Equator because the centrifugal force ( $-mR\omega^2$ ) depends on the distance  $R$  from the polar axis.

The Earth's equatorial bulge

In Figure 5D, the real Coriolis force from the track is pushing to the left on the car; the inertia force from the car is pushing to the right against the track, and if the track were not there the car would slide to the right. This deviation is known as the Coriolis drift, and it has a marked effect on the paths of long-range projectiles and the direction of trade winds and ocean currents.

To complete the treatment of relative motion and the corresponding forces, it will be helpful to re-examine the implications and validity of Newton's second law,  $F = ma$ . As stated, the law applies to the absolute motions of particles—*i.e.*, their motions in a reference frame or coordinate system attached to the fixed stars. This is called either a Newtonian frame or an inertial frame. If the motion of the particle is described in terms of a moving coordinate system—*i.e.*, one attached to a moving vehicle—it may be necessary to modify Newton's equation.

In general, when a particle moves on a nonrotating vehicle, its absolute acceleration can be expressed as the vector sum of the absolute acceleration of the point on the vehicle coinciding with the particle at the instant considered ( $a_v$ ) and the acceleration of the particle relative to the vehicle ( $a_R$ ). Thus  $a = a_v + a_R$ , it being understood that the plus sign signifies a vector addition. Then Newton's second law takes the form  $F = m(a_v + a_R)$ .

If the vehicle is moving with a uniform velocity—*i.e.*, on a straight line at a constant speed—then  $a_v = 0$  and  $F = ma_R$ . This means that Newton's law applies without correction to, for example, motions relative to a train moving on a straight track at a constant speed.

If the vehicle is accelerating, then  $a_v$  is the same for all points in the vehicle and can be added vectorially to  $a_R$  to obtain the absolute acceleration  $a$ . Newton's equation, however, can be written as  $F - ma_v = ma_R$ ; in this form it signifies that the law applies to accelerations relative to an accelerating nonrotating vehicle, provided an inertia force of magnitude  $-ma_v$  is added to the left side of the equation.

If the vehicle rotates, the Coriolis component  $a_c$  appears, and the absolute acceleration  $a = a_v + a_R + a_c$ . When Newton's law is written in the form  $F - ma_v - ma_c = ma_R$ , it signifies that the law applies to acceleration relative to a rotating vehicle, provided the inertia forces  $-ma_v$  and  $-ma_c$  are added to the left side of the equation.

In Figure 5D, there is no relative acceleration  $a_R$ , and the vehicle acceleration  $a_v$  is simply the centripetal accel-

eration  $S\omega^2$ ; if the vehicle were being accelerated, there would be another component  $S\alpha$ . Consequently,  $F - ma_v - ma_c = 0$ , and to an observer on the table the inertia forces  $-ma_v$  and  $-ma_c$  balance the two components of  $F$ , one from the bottom of the track and one from the side of the track; *i.e.*, the car is in relative equilibrium.

On the surface of the Earth  $-ma_v$ , the centrifugal force, and  $-ma_c$ , the reversed Coriolis force, are both small and can usually be neglected. Then  $F = ma_n$ , and Newton's second law can be applied, without correction, to motions relative to the Earth.

#### MECHANICS OF COMPLEX SYSTEMS

**The principle of virtual work.** The solution of problems in statics by the equations of equilibrium—*i.e.*, by force and moment summations—can become tedious for complex structures and mechanisms. To determine forces by the equilibrium method it is usually necessary to dismember the structure and treat each component separately; when the number of components is large, many equations must be solved. In addition, even if only one or two unknown forces are to be found, in moving from one component to the next, many unwanted forces may appear and require evaluation. The method of virtual work is an alternate approach to statics problems that is well suited for complex systems and for cases in which only a few unknown forces are to be found. It can also be used for the dynamic analysis of mechanisms, provided the inertia-force concept of d'Alembert is utilized to create a state of equilibrium in each component.

The principle of virtual work, formulated by Johann Bernoulli in 1717, states that, if a rigid body or a system of connected rigid bodies is in equilibrium, then the total virtual work of the external forces acting on the body or system of bodies is zero for any arbitrary virtual displacement of the body or the system consistent with the constraints.

When the force  $F$  moves a very short distance,  $\Delta S$ , in the direction in which it is acting, the mechanical work done is  $F\Delta S$ . The displacement  $\Delta S$  is "virtual" if it is not actually experienced but merely imagined in the course of an analysis; it is usually assumed to be infinitesimal in order that the geometry of the system be maintained and that  $F$  and  $\Delta S$  be always in the same direction. The product of  $F$  and a virtual displacement is virtual work. The principle can be illustrated by means of the simple lever in Figure 11A.

Virtual  
displace-  
ments

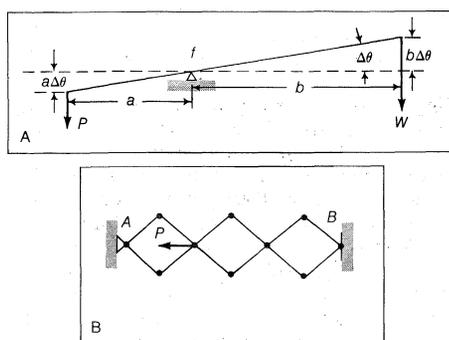

Figure 11: Applications of virtual-work principle. (A) Simple lever, (B) linked structure.

For the lever, a virtual displacement consistent with the constraints is a rotation through a small angle  $\Delta\theta$ , in radians, about the fulcrum  $f$ . The virtual displacements of  $P$  and  $W$  are  $a\Delta\theta$  and  $b\Delta\theta$ , respectively. Because  $P$  goes down during the displacement, its virtual work is positive; the work of  $W$  is negative because  $W$  and  $b\Delta\theta$  are in opposite directions. The sum of the virtual works is thus given by  $P(a\Delta\theta) - W(b\Delta\theta) = 0$ , from which  $P/W = b/a$ . In this case, the principle of virtual work offers no real advantage; it seldom does for a single rigid body.

The device in Figure 11B consists of eight weightless pin-connected bars that are held at  $A$  and  $B$  and subjected to a load  $P$ ; the reactions at  $A$  and  $B$  are required. When

point  $B$  is displaced a distance  $\Delta$  to the right by a force  $Q$ , the displacement will be consistent with the restraint at  $A$ . Then, from the nature of the device, the corresponding displacement of  $P$  will be  $\Delta/3$  to the right. The sum of virtual works is  $Q\Delta - P\Delta/3 = 0$ , from which  $Q = P/3$ , pointing to the right. By similar means the reaction at  $A$  can be shown to be  $2P/3$ , pointing to the right. This problem would be more difficult to solve by any other means.

The principle of virtual work, or, as it is sometimes called, the principle of virtual displacements, was originally known as the principle of virtual velocities. Because all of the displacements are simultaneous, their relative magnitudes are unaltered if divided by equal time intervals; the resulting quotients are average velocities that become instantaneous velocities when the time interval approaches zero. The use of instantaneous velocities instead of displacements has many advantages when the principle is applied to machine mechanisms and leads to a basic velocity-force-power relationship in machines.

If a virtual displacement  $\Delta S$  takes place in a time interval  $\Delta t$ , then  $F(\Delta S/\Delta t)$  is the average time rate at which the work is being done—or the average power—while  $\Delta S/\Delta t$  is the average velocity of the force. In the limit, as  $\Delta t$  approaches zero,  $\Delta S/\Delta t$  becomes  $v$ , the instantaneous velocity, and  $Fv$  the instantaneous power.

On such simple machines as the lever, the wheel and axle, and the screw, the ratio of the load (output force) to the effort (input force) is called the mechanical advantage (MA). The ratio of the motion of the effort to the motion of the load is known as the velocity ratio (VR). If friction is neglected, the mechanical advantage is the reciprocal of the velocity ratio. Because of friction, the mechanical advantage is always less than the velocity ratio, and the ratio MA/VR is the mechanical efficiency of the machine. The efficiency of machines that rotate continuously is most easily obtained by measuring the instantaneous output and input powers and dividing the output by the input.

The principle of virtual work can also be applied to rotating bodies; it is only necessary to replace the force  $F$  by the torque  $T$  and  $\Delta S$  by  $\Delta\theta$  (in radians). Then the virtual work is  $T(\Delta\theta)$ , and instantaneous power becomes  $T\omega$ . In the case of the lever in Figure 11A, the torques are  $Pa$  and  $Wb$ , in which  $a$  and  $b$  are the lever arms, so that  $(Pa)(\Delta\theta) - (Wb)(\Delta\theta) = 0$ , which leads to the same result as before.

**Spinning tops and gyroscopes.** In the previous sections the force systems and the motions of the particles and bodies were confined to parallel planes. There were two reasons for restricting the treatment to two dimensions; in the first place, most of the problems of interest to physicists and engineers can be solved by the equations of plane mechanics; in the second place, solutions to spatial (three-dimensional) problems in statics can be effected most easily by the formalized procedures of vector analysis, while some of the problems in spatial dynamics are so complicated that solutions have not yet been obtained.

In three-dimensional space, as in two-dimensional space, the centre of mass of a body moves as if it were a particle with the resultant of the external forces acting on it. In plane motion the sum of the torques about the centre of mass equals  $I_G\alpha$ , which is equivalent to assuming that the body rotates about an axis passing through the centre of mass and perpendicular to the plane of motion. In space motion there are three planes and three axes through the centre of mass about which the body may be rotating simultaneously; this is the reason for the complexity of space motion. In special cases, such as the motion of spinning tops and gyroscopes, satisfactory explanations of dynamic behaviour can be obtained by making simplifying assumptions.

It has been shown that when a body rotates about a fixed axis the torque impulse  $Tt$  is equal to the change in the angular momentum  $I(\omega - \omega_0)$ . Because  $t$  is the time interval during which the torque acts, it may be written as  $\Delta t$ , and, because  $I(\omega - \omega_0) = I\omega - I\omega_0$  is the corresponding change in the angular momentum, it may be written as  $\Delta(I\omega)$ . Then  $T(\Delta t) = \Delta(I\omega)$ , from which

Mechanical  
advantage

$T = \Delta(I\omega)/\Delta t$ , or the torque is the time rate of change of the angular momentum. When a body rotates about a fixed point, a similar equation applies; in this case,  $T$  is replaced by  $M$ , the moment of the external forces about the point, and  $I\omega$  is the resultant angular momentum of the body. Then, in the limit, as  $\Delta t$  approaches zero,  $M = d(I\omega)/dt$ .

In Figure 12A, a top in the form of a disk of weight  $W$ , mounted on a shaft with a pointed end, is held in a frictionless support at  $O$  in the frame. The shaft rotates at a high speed  $\omega$  in a clockwise direction viewed from  $O$ . If the top were stationary, the moment of the weight  $W$ , which is  $M = WC \sin \alpha$ , would cause it to fall. Because the top rotates, however, the spin axis  $OS$  sweeps out the surface of a cone as the line  $QS$  (which is at right angles to  $OQ$ ) rotates at an angular speed  $\Omega$  in a counterclockwise direction, viewed from above, about point  $Q$ .

Precession  
of a  
top

The right-angled triangle  $OQS$  forms a plane that sweeps out the volume of the cone at the speed  $\Omega$ , which is called the angular velocity of precession of the top.

The angular momentum  $I\omega$  of the top is represented by the vector  $OS$ , coinciding with the axis of the top and pointing in the direction that a right-handed screw would advance if it were attached to the rotating axis. The vector  $OS$  of magnitude  $I\omega$ , is changing in direction only, and, because its rate of change must equal the velocity  $v_s$  of point  $S$  on the circular path, it is also equal to the rate of change of  $QS$ , of magnitude  $I\omega \sin \alpha$ . Then  $v_s = QS\Omega = (I\omega \sin \alpha)\Omega$  is the time rate of change of  $I\omega$ .

As the top rotates about its axis, the axis also rotates, and  $I\omega$  is not the total angular momentum of the top; there are two other components of the momentum, and they would have to be considered for a complete description of the motion. If  $\omega$  is very large compared with  $\Omega$ , however, a satisfactory explanation of the motion can be obtained by assuming that  $I\omega$  is the resultant momentum.

Using the right-hand screw rule, the moment  $M$ , of magnitude  $WC \sin \alpha$ , is a vector acting through  $O$ , at right angles to the plane  $OQS$  and, therefore, parallel to  $v_s$ . Then, equating the moment to the rate of change of momentum,  $WC \sin \alpha = (I\omega \sin \alpha)\Omega$ , from which  $WC = I\omega\Omega$ . This result shows that the velocity of precession is the same for all values of  $\alpha$ . Because of the attraction of the Sun and the Moon on the Earth's equatorial bulge, the Earth's axis has a small velocity of precession. It requires 26,000 years for a complete revolution and was first explained by Isaac Newton.

A gyroscope is a small, accurately made flywheel that is usually supported in encircling rings known as gimbals in such a way that it can rotate freely about any axis. This is equivalent to mounting it at its centre of mass so that the distance  $C$  in Figure 12A is zero and the axis of spin remains immovable (theoretically) in space.

In Figure 12B a circular disk of moment of inertia  $I$ , rotating at a high angular velocity  $\omega$ , is supported in bearings at  $A$  and  $B$  in the U-shaped frame. The frame is rotating about a vertical axis at  $C$  with a clockwise

(viewed from above) angular velocity  $\Omega$ , indicated, according to the right-hand rule, by a vector pointing down. This is a forced precession, and the change in the angular momentum vector  $I\omega$ , like the change in any vector caused by rotation, will be perpendicular to  $I\omega$  and pointing into the paper for the given direction of  $\Omega$ . The magnitude of the change in  $I\omega$  is  $I\omega\Omega$ , and the moment  $M$  that produced the change must have the same magnitude and direction; it is shown by the vector  $M$  in Figure 12B. The additional loads on the bearings, the equal and opposite forces  $P$  that create the moment  $M$ , are obtained from  $PL = I\omega\Omega$ . Note that the spin, precession, and moment axes are mutually perpendicular and that the spin axis, when precessing, always rotates toward the moment axis.

On some ships the controlled precession of a large gyroscope is used to produce a moment to counteract the rolling of the ship at sea. There are many other applications of the gyroscope.

**Lagrange's and Hamilton's equations.** As the complexity of the problems in classical dynamics increases, it becomes more and more difficult either to formulate the equations of motion or to solve them. In many cases, the forces acting on the particles may be difficult to ascertain, and Newton's second law, which expresses a causal relationship between force and acceleration, may be difficult to formulate. Among the more powerful and more universal methods that have been developed for deriving the equations of motion for these more complicated situations, the equations of Lagrange and Hamilton are the most generally useful. These equations do not represent new theories, but only new ways of looking at dynamics, and the resulting equations of motion are the same as those derived by Newton's law.

Because it emphasizes the vectorial characteristic of the quantities involved, Newtonian dynamics is largely geometric; Lagrangian and Hamiltonian dynamics, on the other hand, require only analytical operations and deal with scalar (nonvectorial) quantities that require no geometric representation.

In Newtonian dynamics force and acceleration are the basic components, and in the coordinate systems only lengths and angles are used to describe the position of particles. In the Lagrange and Hamilton equations, the components are kinetic and potential energy, and the coordinates are generalized; *i.e.*, they are not restricted to lengths and angles but may be any quantities that describe the state of a mechanical system and can be varied independently of one another. In some cases, areas or combinations of lengths and angles may be used. It is common practice to represent the generalized coordinates by  $q_1, q_2, q_3, \dots, q_n$ .

General-  
ized  
coordinates

Corresponding to each  $q$  there is a generalized velocity that is simply the derivative (rate of change) of  $q$  with respect to time, namely,  $dq/dt$ , and it is written as  $\dot{q}$ . If  $q$  represents a length, then  $\dot{q}$  is a real linear velocity, while if  $q$  represents an angle, then  $\dot{q}$  is an angular velocity. If  $q$  is neither a length nor an angle,  $\dot{q}$  is not a real velocity but a defined one.

The derivation of Lagrange's equations is a lengthy, abstract mathematical exercise in differential calculus; the basic equations take several forms, depending on the nature of the loads acting on the system. For conservative systems—*i.e.*, systems for which the law of conservation of energy is valid—the following equation holds for each generalized coordinate  $q$ :

$$\frac{d}{dt} \left( \frac{\partial L}{\partial \dot{q}} \right) - \frac{\partial L}{\partial q} = 0.$$

The quantity  $L = (T - V)$ , in which  $T$  is the kinetic energy and  $V$  the potential energy of the system in generalized coordinates, is called the Lagrangian function. The term  $\partial L / \partial \dot{q}$  is the derivative (rate of change) of  $L$  with respect to  $\dot{q}$  when all other variables in the expression for  $L$  are held constant; it is called a partial derivative and written with  $\partial$  instead of  $d$ , to distinguish it from  $dq/dt = \dot{q}$ , which is called an ordinary derivative.

When  $\partial L / \partial \dot{q}$  has been evaluated, the first term in Lagrange's equation is obtained by taking its derivative

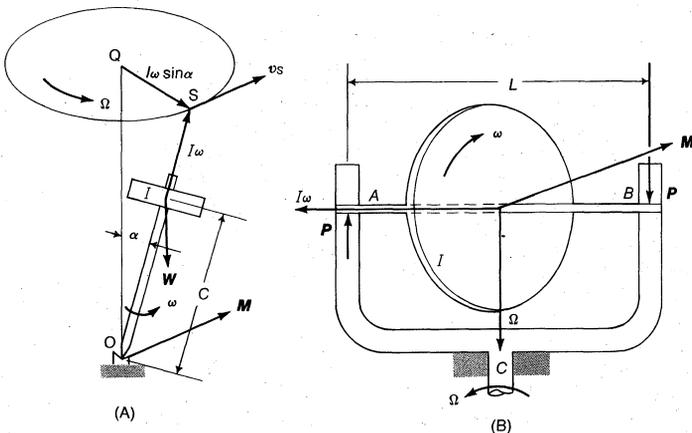

Figure 12: Gyroscopic action.  
(A) Spinning top, (B) forced precession.

with respect to time. The terms  $\partial/\partial q$  and  $d/dt$  can be thought of as operators that are to be applied to  $L$  and  $\frac{\partial L}{\partial \dot{q}}$  respectively. If the position of a point moving on a straight path is described by its distance  $s$  from a fixed point on the path then  $ds/dt$  is the velocity of the point. In general,  $dy/dx$ , the derivative of  $y$  with respect to  $x$ , can be applied to any function of  $x$  such as, for example,  $y = x^n$ , in which  $n$  is any number such as 0.5, 1, 2, and so on, but the physical interpretation of the derivative depends on the nature of the function.

There are simple algebraic rules for taking derivatives; for the power function  $y = x^n$ , the derivative  $dy/dx = nx^{n-1}$  so that, if  $y = x^2$ , then  $dy/dx = 2x$ . Since  $dy/dx$  is also a function of  $x$ , the derivative of  $dy/dx$  with respect to  $x$ , namely,  $d^2y/dx^2$ , is equal to 2; this is the second derivative of  $y$  with respect to  $x$ .

As an example of the application of Lagrange's equation, consider a freely falling body of weight  $W$  and mass  $m$  at a height  $y$  above the ground and assume that the differential equation of motion is required; i.e., an equation containing the second derivative of  $y$  with respect to time, namely,  $\ddot{y}$ .

The velocity of the body is given by  $\dot{y}$  and the kinetic energy  $T$  by  $\frac{1}{2}m\dot{y}^2$ ; the potential energy  $V$  is  $Wy$  and  $L = T - V = \frac{1}{2}m\dot{y}^2 - Wy$ . The obvious generalized coordinate is  $q = y$ ,  $\partial L/\partial y = -W$ ,  $\partial L/\partial \dot{y} = m\dot{y}$ , and  $d(m\dot{y})/dt = m\ddot{y}$ . Substituting these values in Lagrange's equation gives  $m\ddot{y} + W = 0$ , from which  $\ddot{y} = -W/m$  and since  $m = W/g$  this reduces to  $\ddot{y} = -g$ . This is the differential equation of motion for a falling body, which may be written as  $d^2y/dt^2 = -g$  and expresses the acceleration of the body in terms in the second derivative of  $y$  with respect to time. The velocity equation,  $v = \frac{dy}{dt}$ ,

is the function of time that when differentiated will yield the acceleration. This process is known as integration, and it is the inverse of differentiation. It is easy to see that  $v = \frac{dy}{dt} = -gt + v_0$ , in which  $v_0$  is the velocity of the body when  $t = 0$ ; because  $v_0$  is a constant, its derivative is zero. Integrating the velocity equation yields  $y = -\frac{1}{2}gt^2 + v_0t + y_0$ , in which  $y_0$  is the position of the body when  $t = 0$ . This is the complete equation for a falling body, which was obtained previously by more elementary methods; differentiating it twice yields  $d^2y/dt^2 = -g$ .

When using Lagrange's equations the differential equations of motion are derived in the same way for each generalized coordinate. Because kinetic energy involves velocities only, accelerations do not have to be considered; in addition, the velocity terms are squared so that the kinetic energy is always positive, and difficulties with algebraic signs are avoided.

Lagrange's equations are particularly useful when the number of generalized coordinates is two or more or, in other words, when the number of degrees of freedom—i.e., the ways in which the system can move—is two or more. The differential equations of motion for vibrating systems with multiple masses and springs are most easily obtained by Lagrange's equations.

The equations of Hamilton contain another generalized quantity, namely, generalized momentum  $p$  and the Hamiltonian function  $H$ . The generalized momentum  $p$  associated with the generalized coordinate  $q$  is defined as  $p = \partial L/\partial \dot{q}$ . If  $q$  is a length, then  $p = m\dot{q}$ , which has the dimensions of linear momentum,  $mv$ ; if  $q$  is not a length, it does not have this dimension, and the generalized momentum is strictly a mathematical definition. The function  $H$  is defined as  $H = \sum p\dot{q} - L$ , in which  $\sum p\dot{q}$  is the sum of the  $p\dot{q}$  terms for all generalized coordinates in the system and  $L$  is the Lagrangian function. For each generalized coordinate, Hamilton's canonical equations are

$$\dot{q} = \frac{\partial H}{\partial p}, \quad \dot{p} = -\frac{\partial H}{\partial q}.$$

Because Hamilton's equations utilize both generalized coordinates and momenta, whereas Lagrange's equations

use only generalized coordinates, there is more freedom in choosing the variable when Hamilton's equations are used.

It should be noted that, although Lagrange's equations are useful for finding the differential equation of motion of a dynamic system, Newton's equations are still unrivalled when the forces acting on the system are required.

**BIBLIOGRAPHY.** The PHYSICAL SCIENCE STUDY COMMITTEE, *Physics* (1960); and SIDNEY ROSEN, ROBERT SIEGFRIED, and JOHN M. DENNISON, *Concepts in Physical Science* (1965), contain well-illustrated elementary treatments of the principles of mechanics suitable for a beginner; they are the only books in this list that do not utilize calculus. JAMES L. MERIAM, *Mechanics*, 2nd ed., 2 vol. (1971); and JACOB P. DEN HARTOG, *Mechanics* (1948), are both designed for undergraduate engineering students and contain a large number of worked and exercise problems dealing with machine and structural components. SIR CHARLES INGLIS, *Applied Mechanics for Engineers* (1951), is noteworthy in both style and content and is based on lectures given by the author to students working for honour degrees in engineering at the University of Cambridge, England; it assumes some knowledge of the principles of mechanics. JAMES H. JEANS, *An Elementary Treatise on Theoretical Mechanics* (1907, reprinted 1967); and WILLIAM F. OSGOOD, *Mechanics* (1937, reprinted 1965), are paperbacks that are more theoretical in their approach than the previous three books and cover more advanced topics. JOHN L. SYNGE and BYRON A. GRIFFITH, *Principles of Mechanics*, 3rd ed. (1959); HERBERT GOLDSTEIN, *Classical Mechanics* (1950); GEORGE W. HOUSNER and DONALD E. HUDSON, *Applied Mechanics*, 2nd ed., 2 vol. (1959-61); JAMES W. BROXON, *Mechanics* (1960); KEITH R. SYMON, *Mechanics*, 3rd ed. (1971); LAWRENCE E. GOODMAN and WILLIAM H. WARNER, *Dynamics* (1963); and JERRY B. MARION, *Classical Dynamics of Particles and Systems*, 2nd ed. (1970), are all of an intermediate level and, in keeping with the modern trend, utilize algebraic rather than geometric methods in the treatment of vectors. In most cases an introductory chapter on vector analysis is included. F.P. BEER and E.R. JOHNSTON, JR., *Vector Mechanics for Engineers*, 2 vol. (1970), like practically all modern texts for undergraduate engineering students, employs the full vector treatment and contains a large number of practical problems. EDMUND T. WHITTAKER, *Treatise on the Analytical Dynamics of Particles and Rigid Bodies*, 4th ed. (1959), is a well-known classic that presents an exhaustive and strictly analytical treatment of dynamics. It does not, however, use vector notation, and the scarcity of diagrams makes it difficult to follow. ROBERT B. LINDSAY and HENRY MARGENAU, *Foundations to Physics* (1936), is a work that contains a concise treatment of the foundations of classical mechanics. A.G. WEBSTER, *The Dynamics of Particles . . .* (1904), is a classic work containing an extensive treatment of the dynamics of rigid bodies.

## Mechanics, Fluid

Fluid mechanics, one of the engineering sciences, is concerned with gases and liquids at rest or in motion. A fluid is any gas or liquid, and, as such, a mass the shape of which yields to pressure (a more formal definition will be given below in the section *Properties of ideal and actual fluids*). Fluid mechanics deals with the forces exerted on a fluid to hold it at rest, as well as with the interplay of forces between a fluid and boundaries that cause motion of the fluid. It uses methods of analysis that have evolved from the application of basic principles, concepts, and laws such as: Isaac Newton's law of motion and viscosity (the resistance to flow); the first and second laws of thermodynamics; the principle of conservation of mass; and equations of state relating fluid properties of pressure, temperature, and density, all of which will be elaborated on below.

Fluid mechanics is important in that it supplies the theoretical foundation for many disciplines: meteorology, the global study of the atmosphere, which takes into account the dynamics of its motion caused by heating and cooling effects and changes in the amount of water content; hydrology, which deals with the processes governing the depletion and replenishment of water resources of the land areas of the Earth and which is also concerned with rainfall, consumptive uses of water, and runoff of water in rivers and through the ground; hydraulics, the

The importance of fluid mechanics

Degrees of freedom

technology dealing with flow of fluids in pipes, rivers and channels, and the confinement of fluids by dams and tanks; aerodynamics, the study of the flow of gases and its application to design of objects acted upon by the force of air and wind, such as aircraft, rockets, automobiles, ships, bridges, and tall buildings; magneto-hydrodynamics, the science dealing with relationships between magnetic fields and plasmas (a state of matter in which single electrons and positive particles, in about equal proportions, form a gas); and cryogenics, the physics of low temperatures, which includes the study of superfluids (*e.g.*, the flow of liquid helium at high velocity through tiny holes and capillaries impervious to the flow of ordinary liquids).

This article is divided into the following sections:

- Properties of ideal and actual fluids
  - The mechanical properties of fluids
    - Fluid pressure and solubility of gases
    - Density-related terms
    - Compressibility and elasticity
    - Surface tension and capillarity
  - The thermodynamic properties of fluids
    - Temperature, heat content, and work
    - The first and second laws of thermodynamics
    - The perfect gas law
    - Flow processes
- Fluid statics and equilibrium
  - Basic equation of fluid statics
  - Fluid forces on planes and curved surfaces
    - Pressure measurement: manometers
    - Analysis of fluid forces
    - Buoyant force
    - Stability of floating and submerged bodies
- Fluids in motion: hydrodynamics and aerodynamics
  - Frictionless one-dimensional fluid flow
  - Flow in pipes
    - Laminar flow: the Poiseuille equation
    - Turbulent flow
    - Special types of flow
  - General two- and three-dimensional flow
    - Mathematical conditions
    - Vorticity
    - Boundary layers
    - Drag
  - Compressible fluid flow
    - The equations of gas dynamics
    - Isentropic (reversible-adiabatic) flow
    - Shock waves

*Studies before the 20th century.* The control of water has been practiced by man from prehistoric times. He has constructed irrigation works including dams, canals, and other control structures and has been able to take advantage of wind and water by the use of windmills and sailing vessels.

Archimedes, who studied under the disciples of Euclid in Alexandria, Egypt, in the 3rd century BC, was the first to develop the principles of buoyancy and flotation. He derived the following three basic theorems of hydrostatics: (1) Any solid lighter than a liquid of equal volume will be immersed to such an extent that the weight of the solid is equal to the weight of displaced liquid. (2) If a solid lighter than a liquid of equal volume be immersed in it, the fluid will exert a force upward on the solid equal to the weight of displaced fluid. (3) A solid heavier than a fluid of equal volume will descend to the bottom of the fluid if immersed in it. When weighed in the fluid, it will be lighter by the weight of displaced fluid.

These findings are as relevant now as they were in the time of Archimedes, and they form the basis for flotation and stability analysis with substantially no change up to the present time. Archimedes is also credited with inventing a pump known as Archimedes' screw, which consists of a pipe wound around an inclined shaft with the lower end open and submerged in water. Rotation of the shaft causes water to be picked up and carried to the upper end of the pipe, from which it is discharged into a trough.

The Romans made use of the hydraulics of both pipes and open channels for water supply and transport of sewage, although the laws associated with the resistance of pipes and channels to the flow of liquids were completely unknown at that time.

In the 15th and 16th centuries Leonardo da Vinci of Italy was aware of the earlier accomplishments of fluid flow engineering and referred to them in his copious notes. He strongly urged that observation and experiments be performed before trying to analyze the problem and discover the basic laws. He wrote on the following subjects of fluid mechanics: water waves, eddies, floating bodies, falling water, flow in pipes, destructive force of water, efflux, and mills and hydraulic machinery. He was the first to propose the parachute, the anemometer (which measures wind speed), and the centrifugal pump. He recognized and stated the principle of continuity (discussed below) and also the principle of force involved in the hydraulic press.

Simon Stevin, a Dutch mathematician of the 16th and 17th centuries, apparently unaware of Leonardo da Vinci's work, also wrote a book on hydrostatics, in which he developed the correct analysis for forces on plane surfaces and so proved that pressure is a function of distance below the free surface of a liquid. Evangelista Torricelli, who occupied Galileo's chair of mathematics at Florence later in the 17th century, stated the hypothesis that liquid issuing from an outlet in a tank would have the same speed as if it were dropped from the free surface to the outlet; this hypothesis is now known as Torricelli's theorem. He is credited with the discovery of the barometer as well.

Blaise Pascal, 17th-century French mathematician and scientist who influenced the development of the calculus, is best known in hydraulics for the axiom that for fluids at rest, pressure is transmitted equally in all directions, now known as Pascal's law. An English contemporary, Isaac Newton, recognized the nature of resistance to fluid flow and developed his law of viscosity relating shear force or stress, viscosity, and relative motion of one layer of fluid adjacent to another layer.

Henri Pitot, who practiced civil engineering in southern France in the 18th century, building bridges and aqueducts and providing flood protection for his district, is remembered today primarily for the invention of a velocity-measuring device for fluids that is now called the Pitot tube. By determining the impact of the pressure of flowing water, as measured by the height the column would rise in a vertical tube, Pitot was able to calculate the water's velocity.

Daniel Bernoulli and Leonhard Euler, Swiss mathematicians of the 18th century, contributed greatly to the formulation of hydrodynamics. Bernoulli is best known for his development of energy principles, and Euler developed the general nonviscous equations of motion in terms of the acceleration components of a fluid particle. Euler also developed the equations for analysis of the reaction turbine. In the 18th and 19th centuries Joseph-Louis Lagrange of France contributed to hydrodynamic theory by introducing the concepts of velocity potential and stream function. In the 18th and 19th centuries Pierre-Simon Laplace of France worked with waves and tides but is best known for his mathematical operator, called the Laplacian operator, symbolized by  $\nabla^2$ , a partial differential operator of calculus that expresses how a mathematical or physical variable (*e.g.*, curvature or pressure) changes with respect to spatial coordinates. It represents one of the most important relationships in theoretical fluid mechanics.

In the 18th and 19th centuries Giovanni Battista Venturi, an Italian physicist who studied the flow of fluids through conical reducing tubes and through expanding tubes, for the purpose of reducing the turbulence and losses caused by such velocity changes, devised the venturi meter, a device that allows computation of flow volume by a measurement of the pressure drop through a conical reducing section. Claude-Louis-Marie Navier, a 19th-century French engineer who was primarily a builder of bridges, made a major contribution to hydrodynamics by extending the Euler equations to include the attraction of adjacent molecules.

The French engineer Adhémar-Jean-Claude Barré de Saint-Venant in the 19th century developed the equations of motion of a fluid particle in terms of the shear and

Pascal's  
law

Archi-  
medes'  
theorems

normal (perpendicular) forces exerted on it. Sir George Gabriel Stokes, a 19th-century English physicist, made the final derivation of the equations of motion in terms of the coefficient of viscosity, now called the Navier–Stokes equations.

*Developments during the 20th century.* Fluid mechanics is based today on the experimental approach of hydraulics over the past 200 years plus the mathematical developments over the same period. These two approaches did not converge until the 20th century. Valuable contributions to the experimental approach to understanding were made by Jean-Louis-Marie Poiseuille, a 19th-century French physiologist interested in blood flow, who determined the equation for laminar flow (flow without turbulence) through capillary tubes. A 19th-century German engineer, Julius Weisbach, included hydraulics in a treatise on engineering mechanics; he also made contributions to the knowledge of flow over weirs (dams) and of losses caused by sudden contractions in a pipeline. Osborn Reynolds, a 19th-century British physicist, made important advances both analytically and through experimentation, notably his development of the dimensionless parameter, now called the Reynolds number, that distinguishes the type of flow, laminar or turbulent, in a closed conduit. He also expressed the Navier–Stokes equations in a form introducing the concepts of turbulent shear stress.

The  
Reynolds  
number

Important contributions to vortex (whirling) motion, free streamlines, and dynamic similarity were made by a 19th-century German physicist, Hermann von Helmholtz, and studies of vortex motion, irrotational flow, and open-channel waves were made by the 19th-century British physicist Lord Kelvin. The first correct analysis of the water-hammer effect, a pressure wave that travels the water with the speed of sound, was made by the 19th- and 20th-century Russian aerodynamicist Nikolay Yegorovich Zhukovsky, who made a thorough, large-scale experimental confirmation of the effect in 1897. The 19th- and 20th-century English mathematician and physicist Sir Horace Lamb's six editions of *Hydrodynamics* (1895–1932) made available a great amount of work on fluid motion.

Ludwig Prandtl, a German physicist, by statement of his boundary-layer hypothesis in 1904, was able to bridge the gap between empirical hydraulics and hydrodynamics. His hypothesis holds that for fluids of low viscosity, the effects of viscosity may be considered to be limited to a narrow region surrounding the boundaries of the flow. Outside this region, irrotational (nonrotatory) flow exists (practically). Through his great insight into the mechanics of fluid flow and his ability to perform pertinent simple experiments, he contributed greatly to understanding of the boundary layer, turbulent velocity distributions, and separation of flow at boundaries. Theodore von Kármán, a student of Prandtl, made important advances in the knowledge of velocity distributions, open channel flow, and aerodynamics and jet propulsion. The British meteorologist and physicist Geoffrey Ingram Taylor, through his ingenious experiments and profound insight into flow phenomena, has contributed strongly to understanding of fluid turbulence and to diffusion caused by turbulence.

During the first three quarters of the 20th century, the number of investigators in fluid mechanics multiplied and the fields of research broadened.

#### Properties of ideal and actual fluids

A fluid is a substance, the parts of which cannot remain at rest relative to one another when subjected to a shear force, no matter how small that force may be. A shear force is defined as a force exerted along a direction parallel to an area, and it is distinguished from a compressive force exerted at right angles to an area. Thus a shear force—or, simply, shear—can produce a sliding motion of one block on another, whereas a compressive force only squeezes them together. A plastic substance does not, however, satisfy the definition of a fluid; it needs a definite shear exerted on it to exceed what is known as its yield strength and produce the movement of one layer

Shear  
force

with respect to another, and hence the shear force is not infinitesimally small. Similarly, a granular material cannot fit the definition of a fluid because it requires a finite force to overcome Coulomb (dry) friction between its parts.

When a fluid is placed between two closely spaced parallel plates, with one in motion at a velocity relative to the other and at a fixed distance from it, the fluid will be subjected to shear by the plate motion. If the shear force as measured is proportional to the relative velocity of the plates, then the fluid is defined as a Newtonian fluid. All other fluids are known as non-Newtonian fluids, and their study is known as rheology. Most gases and thin liquids tend to be Newtonian fluids. If the shear force exerted on the fluid varies with the amount of prior motion of the plates (*i.e.*, prior work done on the fluid by a shear force), then the fluid is said to be thixotropic. Printer's ink and thick paints are well-known examples of thixotropic fluids.

Both gas and liquid flow study are included in fluid mechanics. Gas flow regimes (behaviours) may be classified by the ratio of average distance that gas molecules travel between collisions to a characteristic length for a confining body or conduit. For small values of the ratio, the flow regime is called gas dynamics; the next regime is called slip flow; and for large values of the ratio it is called free molecule flow. The properties of fluids are treated below in two categories, mechanical properties and thermodynamic properties.

#### THE MECHANICAL PROPERTIES OF FLUIDS

**Fluid pressure and solubility of gases.** Average pressure of a static, or resting, fluid in contact with a plane area is defined as the normal, or perpendicular, force exerted against the area divided by the area. The pressure at a point is the limit of the normal force divided by the area as the area approaches zero size at the point. The pressure is the same in all directions at a point within a static fluid at rest.

The pressure and temperature of a liquid affect its ability to hold gases in solution. The greater the external pressure on a liquid, the more gas may be held in solution; and the lower the temperature, the more gas may be held in solution. Changes in pressure and temperature of a flowing liquid may affect its compressibility and acoustic behaviour (sound-conducting property), as a result of gases coming out of solution and being carried along as fine bubbles.

Changes  
in  
acoustic  
behaviour

Liquids may sustain extremely high pressures without much change in volume. In general, they cannot sustain tensile forces, forces that extend them, unless they are indeed pure, for otherwise vapour bubbles will form and rupture the liquid.

**Density-related terms.** The density, symbolized by the Greek letter rho,  $\rho$ , of a fluid is the ratio of the mass of a portion of the fluid to the volume of that portion. Density at a point is the limit of the ratio as the mass and volume shrink to zero (mathematically) at the point. Density in SI (International System) units is expressed in kilograms per cubic metre; in the English system it is expressed either in pounds mass per cubic foot or in slugs (32.174 pounds mass) per cubic foot. The specific weight, symbolized by the Greek letter gamma,  $\gamma$ , of a fluid is the weight of a unit volume of the fluid. In the SI system it is newtons per cubic metre; in the English system it is pounds force per cubic foot.

The specific volume of a fluid ( $V_s$ ) is the reciprocal of its mass density; *i.e.*, its volume per unit mass  $V_s = 1/\rho$ . The specific gravity of a substance is the ratio of its weight to the weight of an equal volume of water at standard conditions.

**Compressibility and elasticity.** The compressibility of a liquid is usually expressed by the value of its bulk modulus of elasticity. If a volume ( $V$ ) of liquid is subjected to an additional increment of pressure ( $\Delta p$ ; an incremental change in a variable hereafter will be represented by the delta symbols  $\Delta$  and  $\delta$ ), its volume will be reduced by an amount  $-\Delta V$ . The ratio of pressure change to volume change per unit volume is the bulk

modulus of elasticity  $K$ , which is equivalent in the case when the volume shrinks to zero to the density ( $\rho$ ) times the rate of change of pressure with density, expressed as the differential  $dp/d\rho$ . Thus, as noted below, the equation can be written as:

$$K = - \frac{\Delta p}{(\Delta V/V)} = \frac{\rho dp}{d\rho}$$

As the ratio  $\Delta V/V$  is dimensionless (*i.e.*, is not expressed in terms of physical units), the bulk modulus of elasticity ( $K$ ) has the units of pressure. Water has a value for the bulk modulus of about  $2 \times 10^9$  newtons per square metre (300,000 pounds per square inch [psi]) for ordinary pressures and temperatures. As the pressure increases, the bulk modulus of elasticity of water increases. At about 50,000 atmospheres pressure, the value of  $K$  will be doubled. Although the compressibility of gases may be expressed by use of the bulk modulus, it is considered customary to use the perfect gas law to express the relations among temperature, pressure and specific volume, or density. The perfect gas law is examined below under the main heading of *The thermodynamic properties of fluids*.

**Surface tension and capillarity.** A quasi-film forms at a liquid-gas or liquid-liquid interface because of the mutual attraction of liquid molecules near that region. The formation of a film at an interface may be considered from the basis of surface energy, or the work per unit area required to bring the interior molecules to the interface (or surface in a liquid-gas system). The film has a resistance to tension (that is, to having its area increased), called the surface tension of the liquid. The surface tension of a water-air interface may be demonstrated in a simple manner by floating a steel needle on the surface of water.

The surface tension of water varies from 0.073 newton per metre (0.005 pound force per foot) at 20° C (68° F) to 0.059 newton per metre (0.004 pound force per foot) at 100° C (212° F). Surface tension is the same phenomenon that causes small liquid droplets to tend to be spherical, because a sphere has the least area per unit volume of any closed shape.

The action of surface tension of a liquid that partially fills a vertical tube is to draw the liquid up into the tube if the liquid wets the tube, and to depress the liquid surface (meniscus) if it does not wet the tube. This effect is called capillarity. The adhesion of water to glass at an air-water-glass interface is greater than the cohesion of water, and hence water is said to wet the glass. On the other hand, at an air-mercury-glass interface, the cohesion of mercury is greater than its adhesion to glass and it does not wet the glass. Hence a mercury column is seen to be depressed.

The height to which a liquid column rises in an open tube is used as a measure of pressure at the base of the tube. For small diameter tubes (less than a centimetre [0.4 inch] in diameter) the effects of capillarity should be taken into account.

#### THE THERMODYNAMIC PROPERTIES OF FLUIDS

Thermodynamic relations of particular value in fluid flow situations include the concepts of temperature, work, and thermal energy, as well as the first and second laws of thermodynamics.

**Temperature, heat content, and work.** The temperature of a substance is a measure of its molecular activity. In dealing with gases, absolute temperature scales are used, because molecular activity approaches zero as the absolute temperature approaches zero. The internal energy of a substance is the sum of its potential and kinetic energies, plus its intrinsic energy ( $u$ ), which is related to its molecular spacing and forces. The relation between intrinsic energy and temperature is given by a partial derivative (denoted by the symbol  $\partial$ , which means that all variables except one are held constant) stating that the rate of change of the intrinsic energy with absolute temperature, the volume of the substance being held constant, is equal to a constant known as the specific heat at constant volume; *i.e.*, is given by  $c_v = (\partial u/\partial T)_v$ , in

which  $c_v$  is the specific heat at constant volume and  $T$  is the absolute temperature. In other words, if a unit mass of a pure substance held at constant volume has its temperature raised one degree by addition of thermal energy (*e.g.*, heat transfer across its boundaries), the amount of thermal energy addition is its specific heat  $c_v$ .

Another kind of specific heat is  $c_p$ , the amount of thermal energy per unit mass added to cause the temperature to rise one degree when the substance is held at constant pressure. Specific heat depends on the enthalpy per unit mass, which is a property of the substance defined as the sum of the intrinsic energy and the ratio of pressure to density; *i.e.*,  $h = u + p/\rho$ . In equation form, specific heat at constant pressure is equal to the partial of the enthalpy per unit mass ( $h$ ) with respect to absolute temperature, the pressure remaining constant, or  $c_p = (\partial h/\partial T)_p$ .

Many of the common gases, such as air, oxygen, hydrogen, and water vapour, have specific heat values,  $c_v$  and  $c_p$ , that are substantially constant over a wide temperature range. They may be taken as constants in solving practical problems. The specific heat at constant pressure is always greater than the specific heat at constant volume because of the work done by the gas in expanding its boundaries at constant pressure.

The term system refers to a definite mass of material and distinguishes it from all other material, referred to as its surroundings. A system is said to do work on its surroundings when the sole effect on the surroundings is equivalent to the lifting of a weight. Work or energy is measured in joules in the SI system and in foot-pounds in the English system.

**The first and second laws of thermodynamics.** According to the first law of thermodynamics, a statement of the conservation of energy, the heat added to a system, minus the work done by the system, depends only upon the initial and final energy states of the system. The difference in the initial and final states of the system, being independent of the path (the means by which it changes) from initial to final state, must be a property of the system and is called the internal energy ( $E$ ) of the system (the internal energy per unit mass is represented by a quantity  $e$ ). In equation form, the heat added to a system minus the work done by a system is equal to the difference in energy between the final and initial states, or,  $Q_H - W = E_f - E_i$ , in which  $Q_H$  is the heat added,  $W$  is the work done by the system, and  $E_f$  and  $E_i$  are the final and initial internal energies.

The first law of thermodynamics may also be written for a control volume; *i.e.*, a fixed volume in space through which fluid may flow. The heat ( $\delta Q_H$ ) added to the control volume ( $V$ ) per unit time ( $\delta t$ ) minus the shear work ( $\delta W_s$ ) done by the fluid within the control volume on its surroundings per unit time must just equal the time rate of increase of internal energy per unit mass ( $e$ ) in the control volume plus the work done by the boundaries and the efflux of internal energy across the boundaries. By shear work one means the export of work from the control volume, as by a rotating turbine shaft or by electric power leaving the control volume. In equation form, the first law states:

$$\frac{\delta Q_H}{\delta t} - \frac{\delta W_s}{\delta t} = \frac{dE}{dt} = \frac{\partial}{\partial t} \int \rho e dV + \int \left( \frac{p}{\rho} + e \right) \rho v \cdot dA,$$

in which  $dV$  is an element of volume within the control volume, and the density ( $\rho$ ) times the scalar product of the vectors  $v$  and  $dA$ , or,  $\rho v \cdot dA$ , is the mass per unit time flowing with velocity  $v$  out of an element  $\delta A$  of the control surface comprising the boundary. The first integral is throughout the volume and the second integral is over the boundary surface.

Before developing relationships pertaining to the second law of thermodynamics, some definitions are needed. A process is known as a succession of states through which a system passes, such as changes in temperature, pressure, density, and elevation. When a process takes place in such a manner that it can be reversed (that is, return to its original state without a change in the surroundings) the process is called reversible. Any actual process is irrever-

Definition  
of  
system

Capillarity

sible. The difference in the amount of work a process can accomplish and the amount of reversible work is called the irreversibility of the process. This irreversibility of the process is also called the losses, the loss of ability to do work. Losses do not refer to lost energy but to a transformation of energy to a form not available to do work directly.

An important thermodynamic property is entropy, defined for a reversible process as the ratio of the heat added to a system to the absolute temperature, that is, in differential form,

$$ds = \left( \frac{dq_H}{T} \right)_{rev}, \quad (1)$$

in which  $ds$  is the change in entropy per unit mass caused by the addition of  $dq_H$  units of heat per unit mass at absolute temperature  $T$ .

The first law of thermodynamics, in the absence of shear work, may be expressed as: heat added is equal to the sum of two terms, the first being the product of the pressure and the change in specific volume, and the second, the change in intrinsic energy:

$$dq_H = pd\left(\frac{1}{\rho}\right) + du. \quad (2)$$

The first term on the right is work done by the fluid on its boundaries. For a reversible process, the heat term  $dq_H$  may be completely eliminated in the above equations (1) and (2), thus giving the relationship that the change in entropy per unit mass times the absolute temperature is equal to the work done by the fluid plus the change in intrinsic energy, or

$$Tds = pd\left(\frac{1}{\rho}\right) + du. \quad (3)$$

Equation (3) is a well-known and important version of the second law of thermodynamics; although it was primarily developed for reversible processes, because every term is a property, it must also hold for real, or irreversible, processes.

The Clausius inequality

The Clausius inequality (so called for the 19th-century German physicist Rudolf Clausius) states that the entropy change per unit mass is equal to or greater than the heat change divided by the absolute temperature; *i.e.*,  $ds \geq dq_H/T$ , or  $Tds \geq dq_H$ . The equality of the two terms applies only for reversible processes. By defining losses in terms of an inequality of the two terms, that is, the losses being equal to the absolute temperature times the entropy change per unit mass, minus the amount of heat added to the system, or

$$d(\text{losses}) = Tds - dq_H, \quad (4)$$

it is an important fact that losses are zero for the reversible case. It is also to be remembered that, in the absence of heat transfer out of a process, the entropy of a system cannot decrease, and with processes in real systems it can only increase.

Equation (3) is one form of the second law of thermodynamics. In the section on compressible fluid flow below, it will be extended to other useful forms.

**The perfect gas law.** Any fluid that substantially obeys the law that its pressure is proportional to its mass density and the absolute temperature, or

$$p = \rho RT, \quad (5)$$

in which  $R$  is known as the gas constant, is called a perfect gas and the formula is the perfect gas law. Here,  $p$  is the absolute pressure; *i.e.*, pressure measured from absolute zero, such as that of a complete vacuum. The mass density, symbolized by the Greek letter rho ( $\rho$ ), may be written as the ratio of the mass of gas ( $m$ ) to its volume ( $V$ )—that is,  $m/V$ —with the result that the pressure times volume of a gas is equal to its mass, times the gas constant, times the absolute temperature:  $pV = mRT$ . In this form the relations among pressure, volume, and temperature are exposed. The formula contains both Boyle's law and Charles's law. Boyle's law is an isothermal (constant temperature) law and states that at constant temperature the volume of a given mass of gas

varies inversely as the pressure. Charles's law states that for constant pressure the volume of a given mass of gas varies directly with the absolute temperature. The gas constant ( $R$ ) depends upon the molecular weight ( $M$ ) of the gas and upon the units of pressure, temperature, volume, and mass used in the formula. In the International System of Units it is  $R = 8.31434$  joules per degree Kelvin per mole.

**Flow processes.** Real flow processes are generally complicated, involving the effects of many kinds of forces caused by gravity, viscosity, surface tension, compressibility, pressure, and shear, and the effects of heat transfer and friction. To analyze and design systems, one usually tries to simplify the interaction of forces by neglecting those forces that have a minor effect upon the process. Other assumptions may be made to simplify the analysis; then practical corrections must be made to improve the accuracy of the final result. Some of the flow processes used are:

**Isothermal flow.** The flow is assumed to take place with no change in its temperature; this condition requires heat transfer to take place if the pressure is changing. An example of such a flow process is the transmission of natural gas through pipelines.

**Adiabatic flow.** In insulated pipes, for instance, or in flow systems in which heat transfer is minimized, the system may be analyzed as if no heat transfer (adiabatic condition) takes place. However, during rapid changes in properties, as through a flow nozzle, when little time is available for heat transfer, the flow is assumed to be adiabatic.

**Isentropic flow.** When flow of a fluid may be assumed to take place without heat transfer and by neglecting frictional effects (reversible-adiabatic), it is said to be isentropic flow. Flow through the test section of a wind tunnel (in the absence of shock waves) is an example of isentropic flow.

**Polytropic flow.** An actual flow process with little frictional loss that obeys the relation, pressure divided by density raised to some power  $n$  is equal to a constant ( $P/\rho^n = \text{constant}$ ), is called a reversible-polytropic process. The air in an air chamber on the discharge side of a reciprocating pump would approximately obey the equation for a power of  $n = 1.2$ . In general, heat transfer takes place during a polytropic process.

## Fluid statics and equilibrium

### BASIC EQUATION OF FLUID STATICS

By consideration of the fluid forces acting on a small element of fluid, as in Figure 1, with gravity acting in the vertical, or  $-y$  direction, equations for rate of change of pressure in the coordinate directions are obtained. The pressure is  $p$  at the centre of the element and is assumed to vary continuously in any direction. The equation for the sum of forces acting on the element in the  $x$ -direction,  $\Sigma f_x = 0$ , has only the two forces, the pressure forces on the faces normal (perpendicular) to  $x$ , which must then be equal and opposite, yielding the partial derivative of pressure with respect to distance  $x$  equals zero,  $\partial p/\partial x = 0$ . Similarly for the  $z$ -direction,  $\partial p/\partial z = 0$ . For the vertical direction, however, the body force, or weight, of the element must be included, resulting in the partial derivative of pressure with respect to vertical distance ( $y$ ) equals minus the specific weight, or  $\partial p/\partial y = -\gamma$ .

The partial derivative expressions,  $\partial p/\partial x$ ,  $\partial p/\partial z$ , equal to zero, are one of several forms of Pascal's law, which state that two points at the same elevation in the same continuous mass of fluid at rest have the same identical pressure.

Inasmuch as the pressure is a function of the vertical direction only, then the partial derivative becomes a total derivative of pressure with respect to vertical distance; *i.e.*,

$$\frac{dp}{dy} = -\gamma, \quad (6)$$

which is the relation for determination of pressure variation in a static fluid, liquid, or gas.

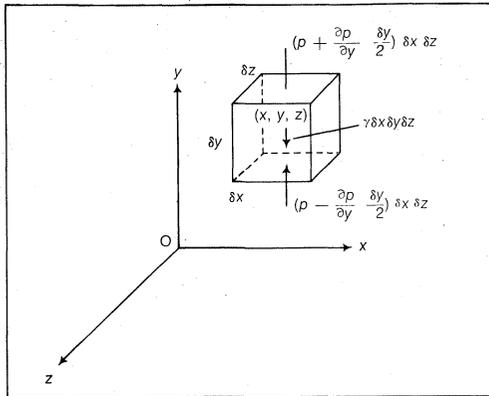

Figure 1: Fluid forces acting on a rectangular parallelepiped element of fluid at rest at point  $(x, y, z)$  (see text).  
From V.L. Streeter, *Fluid Mechanics*, copyright 1971; used with permission of McGraw-Hill Book Co.

For a liquid, the specific weight may usually be considered to be constant, and so integration of equation (6) gives the relationship that pressure equals minus specific weight times vertical distance, plus a constant of integration:

$$p = -\gamma y + \text{constant.}$$

This equation states that the pressure increases linearly with depth, or  $-y$ . If  $y = 0$  is taken at the free liquid surface at atmospheric pressure (gauge pressure zero,  $p = 0$ ) and  $h$  is measured vertically downward from the free surface, then the pressure is equal to specific weight, symbolized by a Greek gamma,  $\gamma$ , times depth, or

$$p = \gamma h, \quad (7)$$

a simple form of the fluid static law for liquids. Under ordinary conditions the specific weight for water is about 9,800 newtons per cubic metre (62.4 pounds per cubic foot). The pressure variation for perfect gases requires that the specific weight be expressed in terms of the perfect gas law, equation (5). From the relation density is equal to specific weight divided by  $g$ , the acceleration of gravity ( $\rho = \gamma/g$ ;  $g$  is approximately 9.8 metres, or 32.2 feet, per second per second), it follows that the specific weight is equal to pressure times the acceleration of gravity, divided by the gas constant times absolute temperature,  $\gamma = pg/RT$ ; then from equation (6), the total derivative of the pressure with respect to vertical distance is equal to minus pressure times acceleration of gravity, divided by the gas constant times absolute temperature, or

$$\frac{dp}{dy} = \frac{-pg}{RT}. \quad (8)$$

If the gas is at constant temperature (*i.e.*,  $T = \text{constant}$ ), the isothermal case, the equation may be integrated as the natural logarithm ( $\ln$ ) of pressure equals minus a quantity, acceleration of gravity times the vertical distance ( $y$ ), divided by the gas constant times absolute temperature, plus a constant of integration ( $C$ ), namely,

$$\ln p = \frac{-gy}{RT} + C.$$

If the pressure is  $p_0$  at a vertical distance  $y = 0$ , the equation becomes: pressure equals the pressure at zero vertical distance times the exponential constant ( $e = 2.718$ ) raised to a negative power of acceleration of gravity times vertical distance divided by the gas constant times absolute temperature, or

$$p = p_0 e^{-gy/RT}, \quad (9)$$

showing that the gas pressure reduces exponentially with vertical distance in the isothermal case.

The atmosphere near the Earth's surface, called the troposphere, experiences a drop in temperature with elevation, on the average, which may be expressed as minus beta,  $\beta$ , per unit distance ( $-\beta/\text{metre}$ ,  $-\beta/\text{foot}$ ). The constant  $\beta$  is called the temperature lapse rate. Hence,

measured from sea level, the absolute temperature ( $T$ ) is equal to the absolute temperature at sea level ( $T_0$ ) minus the temperature lapse rate times elevation (vertical distance); that is,  $T = T_0 - \beta y$ . By substituting this relation in equation (8), the total derivative of pressure with respect to elevation is equal to minus the pressure times the acceleration of gravity divided by the quantity, gas constant times the difference between the absolute temperature at sea level and the temperature lapse rate times elevation, or

$$dp/dy = -pg/R(T_0 - \beta y).$$

This equation may be integrated for constant  $\beta$ , yielding the variation of pressure with elevation for a gas with a constant temperature gradient, that is, the pressure is equal to the pressure at sea level times a quantity, one minus the temperature lapse rate times elevation divided by the absolute temperature at sea level, all raised to the power: acceleration of gravity divided by the gas constant times the temperature lapse rate, or

$$p = p_0 \left(1 - \frac{\beta y}{T_0}\right)^{g/R\beta}. \quad (10)$$

Equation (10), together with the isothermal equation (9), may be used to calculate pressure and density relations in the stratosphere. For the defined standard atmosphere,  $\beta = 0.0065^\circ \text{C per metre}$  ( $\beta = 0.0036^\circ \text{F per foot}$ ).

#### FLUID FORCES ON PLANES AND CURVED SURFACES

**Pressure measurement: manometers.** Local atmospheric pressure is the datum for gauge pressures. It varies from one location to another and from one time to another. The barometer measures the local atmospheric pressure in terms of its difference from absolute zero pressure, a complete vacuum. A standard atmosphere is the average sea level pressure, about  $1.01 \times 10^6$  dynes per square centimetre, or  $1.01 \times 10^5$  newtons per square metre (14.7 pounds force per square inch). As equivalents, it will support a column of mercury of a height of 760 millimetres (30 inches) or a column of water of a height of 10.3 metres (33.8 feet). A bourdon gauge, which measures gauge pressures, consists of a closed hollow curved member with its inside exposed to the pressure to be measured. Pressure causes the member to tend to straighten, thereby actuating a pointer that moves along a calibrated dial. The gauge is adjusted so that its reading is zero when exposed to the same pressure inside and outside the curved member. Common gauge pressure units in the metric system are the barye, one dyne per square centimetre, or 0.1 newtons per square metre; the megabarye, also called the bar,  $10^6$  dynes per square centimetre, or  $10^5$  newtons per square metre; and millimetre of mercury (in the English system, the units are pounds per square inch, inches of mercury, and feet of water). When a pressure is negative, called suction or vacuum, it is measured from the gauge pressure zero datum and is less than local atmospheric pressure. By adding the barometric pressure, in the proper units, to a gauge pressure, the absolute pressure is easily obtained. The standard atmosphere is considered to be a unit of absolute pressure only and is always measured from an absolute vacuum.

The simple manometer (Figure 2) is used to measure gauge pressures. It generally is composed of a transparent tube containing liquid, with one end connected to the pressure source and the other end, known as the meniscus, open to the local atmosphere. By use of equation (7), the hydrostatic law for liquids, the pressure change from the known zero gauge pressure to the unknown pressure is given by the product of the vertical distance ( $h$ ) and the specific weight ( $\gamma$ ). In some cases, two or more liquid columns may be used; then the algebraic sum of the pressure changes caused by the liquid columns is calculated to determine the unknown pressure.

In certain situations, as with rate measuring instruments such as a venturi meter, a difference in pressure between two points of unknown pressure is needed. Figure 3 illustrates the differential manometer used to measure pres-

sure differences. It also utilizes equation (7) as the measure of pressure change from one meniscus to another. For example, in Figure 3A, the difference in liquid pressures between bulbs B and A, ( $p_A - p_B$ ), in terms of specific weight times vertical distance, is  $p_A - p_B = \gamma_1 h_1 + \gamma_2 h_2 - \gamma_3 h_3$ . There are many kinds of manometers, such as inclined manometers and micromanometers, but all use the same basic concepts in determining pressure differences.

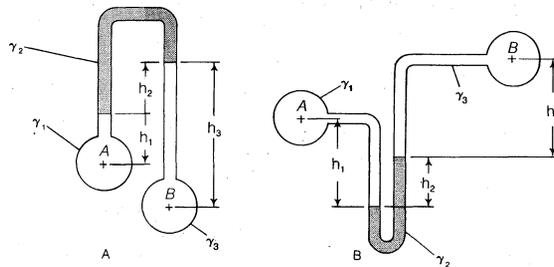

Figure 3: Differential manometers (see text).

**Analysis of fluid forces.** By Pascal's law, pressure ( $p$ ) is constant over a horizontal area submerged in a static fluid. The force ( $F$ ) on such a surface would then be equal to pressure times surface area ( $A$ ) or  $F = pA$ . For an inclined plane area submerged in a liquid, the pressure changes linearly with elevation, and a simple expression can be obtained for magnitude of the force by summing up the product  $p\delta A$  over the surface by the calculus method of integration. With reference to Figure 4A using the strip element of area  $\delta A$  of width  $\delta y$ , the elemental force  $\delta F$  on the strip is  $\gamma h\delta A$ , or specific weight times depth times element of area, or  $\gamma y \sin \theta \delta A$ , in which  $h = y \sin \theta$ . The angle symbolized by the Greek letter theta,  $\theta$ , that the plane B'A' makes with the horizontal, and the specific weight are constant. The force is therefore given by the specific weight times sine of the slope angle times the integral of  $y\delta A$  taken over the total area ( $A$ ); as shown by

$$F = \gamma \sin \theta \int_A y \delta A = \gamma \sin \theta \bar{y} A = \gamma \bar{h} A = p_{cg} A, \quad (11)$$

in which  $\bar{y}$  is the distance from the axis  $Ox$  of the area and  $\bar{h}$  is the vertical distance from the centroid of the area to the liquid free surface. The last form of the expression, equation (11), is particularly convenient in that  $p_{cg}$ , the pressure at the centroid (centre of mass) of the area, may be found by any available means and does not, in fact, imply a free surface.

The force  $F$ , however, does not act at the centroid if it is to be equivalent to the distributed force and replace its action. Because it must be an equivalent force, it has the same moment of force (torque) about any axis, say the

$Ox$  axis. Then the product  $y_p F$  is equal to the integral, taken over the area  $A$ , of the elemental force  $dF$  times the distance  $y$  ( $dF = \gamma \sin \theta y dA$ ), or

$$y_p F = \int_A y dF,$$

in which  $y_p$ , the distance in the  $y$ -direction from  $Ox$  to the line of action of the resultant force, is sought. Similarly, to find the location of the line of action of  $F$  in the  $x$ -direction, the moment equation about  $Oy$  is

$$x_p F = \int_A x dF.$$

These equations may be solved for the two distances  $x_p$  and  $y_p$ ; then by placing the force  $F$  at this  $x_p, y_p$  location, called the pressure centre, the action of the distributed liquid force on the area has been replaced with  $F$ , its resultant force.

Pressure centre

If the action of liquid pressure on a submerged curved surface is desired, it is convenient to decompose the liquid forces into horizontal and vertical components at right angles, then combine them as vectors. (Vectors are quantities that may be symbolized by arrows to show their magnitude and direction.) The horizontal component of force in the  $x$ -direction on a curved surface, Figure 4B, may be shown to be equal to the force on a projection of the curved surface onto a plane normal to  $x$ . The force on a small area element exerted by pressure  $p$  on an elemental area  $\delta A$  is  $p\delta A$ , and the  $x$ -component of this elemental force is  $p\delta A \cos \theta$ . The quantity  $\delta A \cos \theta$ , however, is the projection of the area element onto the normal plane. By summing up all such elemental forces it is noted to be equivalent to finding the force on the projected vertical plane area. The pressure centre for the projected area gives the location of line of action of this component. By taking the horizontal axis at right angles to  $x$ , the force component is found in magnitude and location in the same way. After combining these two forces as vectors the resultant horizontal component of force on the curved surface has been determined.

The vertical component of force on a curved surface is found in a rather similar manner, Figure 4C, by considering the force element  $p\delta A$  and taking its vertical component  $p\delta A \cos \theta$ . The quantity  $\delta A \cos \theta$  is the projection of the elemental area  $\delta A$  onto a horizontal plane and is the area of the base of the liquid prism of height  $h$  (for which  $h = p/\gamma$ ) extending up to the free surface. By summing up all such volume elements the vertical component of force on the curved surface equals the weight of liquid vertically above the curved surface. For situations in which there is no free surface, an imaginary free surface may be constructed such that it would yield the same pressure at each point on the curved surface. It may be shown that the line of action of the resultant vertical force acts through the centroid of the liquid volume (real or imaginary) above the curved surface. By adding the vertical component force to the horizontal resultant vector, the single force replacing the distributed liquid force on the curved area is found.

Determination of the vertical component of force

A body submerged or floating in a static liquid can have no horizontal component of force exerted on it due to the fact that the projection on a vertical plane is always zero.

**Buoyant force.** The resultant force exerted by static liquid on a body floating or submerged in it is called the buoyant force. It must be vertical (that is, acting in a direction opposite to the force of gravity), and its magnitude can be found by application of the relations for finding the vertical component of force on a curved surface, applied to its lower and upper surfaces. This operation results in the simple relationship that the buoyant force is equal to the weight of fluid displaced by the body ( $\gamma V$ ), and its line of action is through the centroid of the displaced volume. In equation form,  $F_B = \gamma V$ , in which  $F_B$  is the buoyant force and  $V$  the displaced volume of fluid. This equation is a statement of Archimedes' principle.

The hydrometer uses this principle in determining the specific gravity of a liquid. The less the specific weight of a liquid, the farther downward a floating object sinks before equilibrium is reached. Marks on the body may be

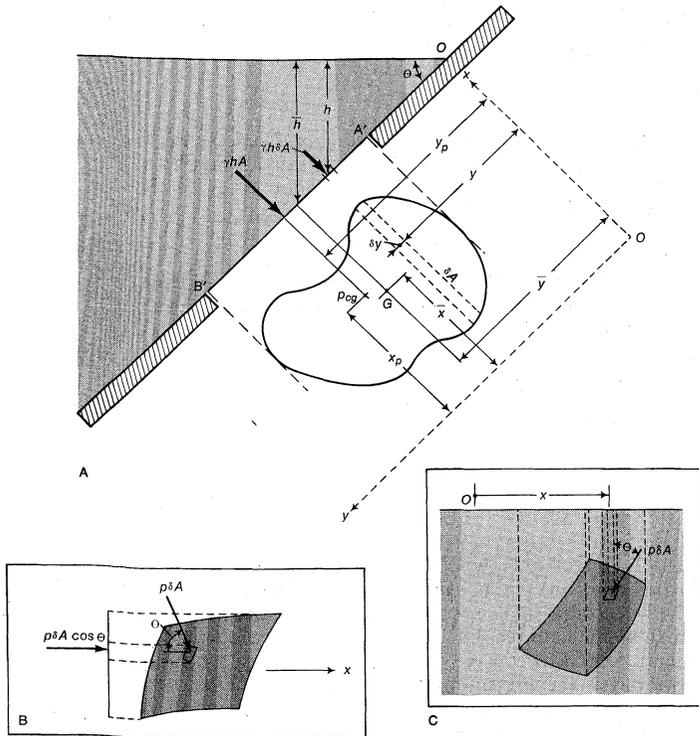

Figure 4: Three aspects of liquid force. (A) On one side of a plane inclined area. (B) Horizontal component of force on a curved surface. (C) Vertical component of force on a curved surface (see text).

made at the liquid contact line designating the specific gravity of the liquid.

**Stability of floating and submerged bodies.** A body floating in a liquid has vertical stability. Any tendency for it to become further submerged results in a greater buoyant force that returns it to its equilibrium position, and any tendency for it to rise higher causes a reduction in the buoyant force so that the weight of the body returns it to its original position.

The centre of buoyancy is the centroid of the displaced liquid volume, and the buoyant force always acts vertically through the centre of buoyancy. The weight of a body acts vertically downward through its centre of gravity. A body has rotational stability if any rotational displacement sets up a rotational force, called a couple, tending to return the body to its original position. If a couple tends to increase the displacement, then the body is unstable, and if no couple is set up it is said to have neutral equilibrium. In Figure 5A a light piece of wood has a weight attached to one end; it is stable as shown. Figure 5B shows unstable equilibrium and Figure 5C is a case of neutral stability.

Any submerged body must have the centre of gravity vertically below the centre of buoyancy to be in stable rotational equilibrium. In the case of floating bodies, however, such is not the case. When a floating body is rotated slightly there is a shift in the centre of buoyancy toward the portion of the object moving deeper into the liquid. In effect, a wedge-shaped volume of fluid is displaced on the low side, and an equal volume wedge-shaped portion on the high side is removed from below the liquid surface. If the centre of buoyancy is below the

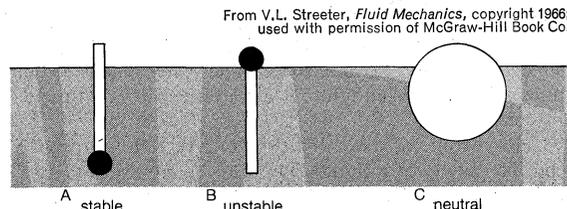

Figure 5: Examples of equilibria (see text).

From V.L. Streeter, *Fluid Mechanics*, copyright 1966; used with permission of McGraw-Hill Book Co.

centre of gravity of the object, but the centre of buoyancy shifts enough so that the vertical line through the new centre of buoyancy intersects the original vertical line (equilibrium) above the centre of gravity, the body has stable equilibrium with respect to that rotation. The intersection of the two lines is called the metacentre, and the distance of the intersection above the centre of gravity is called the metacentric height. The greater the metacentric height, the more stable the body.

In Figure 6 the shift in centre of buoyancy is from the point  $B_0$  of Figure 6 (left) to the point  $B'$  in Figure 6 (right), caused by the rotation  $\theta$  shown. Point  $B'$  is the centroid of the trapezoidal area submerged for this prismatic case. The vertical through  $B'$  intersects the centre line  $PG$  at  $M$ , which is above the centre of gravity at  $G$ . If the metacentre is at  $G$ , neutral stability is indicated; and if the metacentre is below  $G$ , the body is unstable and will not remain in a vertical position.  $MG$  is the metacentric height.

From V.L. Streeter, *Fluid Mechanics*, copyright 1966; used with permission of McGraw-Hill Book Co.

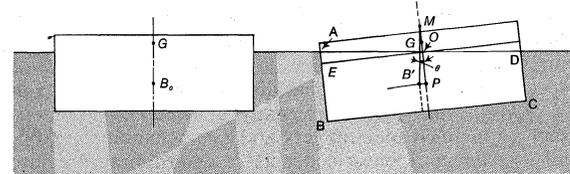

Figure 6: Stability of prismatic body. (Left) A cross section of a body with all other parallel cross sections identical. (Right) When the body is tipped, the centre of buoyancy is at the centroid  $B'$  of the trapezoid ABCD. The buoyant force acts upward through  $B'$ , and the weight acts downward through  $G$ , the centre of gravity of the body.

**Fluids in motion: hydrodynamics and aerodynamics**

Flow of liquids and gases through closed conduits and open channels may be treated as one-dimensional flow; *i.e.*, flow in which pressure and velocity are dependent upon distance along the length of the conduit only. The variations in a transverse direction are neglected, the average velocity over the cross section being used in place of the actual velocity at the centre line. A great majority of engineering applications of fluid flow to design may be carried out using the one-dimensional analysis. Compressible flow is considered in a separate section. The flow in general is assumed to be steady; *i.e.*, not to vary with time at any point.

**FRICTIONLESS ONE-DIMENSIONAL FLUID FLOW**

Many frictionless flow problems may be analyzed by use of three equations: the continuity equation, Euler's equation, and Bernoulli's equation. The continuity equation, one of the most fundamental equations of fluid dynamics, is derived for one-dimensional flow from the general law of conservation of mass, whereas the Euler equation and the Bernoulli equation are consequences of applying Newton's second law of motion to a fluid particle. A few definitions are needed before the following equations can be stated.

A streamline is a line drawn through a fluid in such a manner that it has the direction of the fluid velocity at every point. If the flow is steady, the streamline is fixed in space and is the path a fluid particle would follow. If all the streamlines through a small closed curve were constructed for a steady flow, these streamlines would form a stream tube, fixed in space that completely separates the flow inside the tube from the flow outside the tube. Obviously, no flow can take place through the wall of the tube.

*The continuity equation.* For a steady stream tube (Figure 7A), the mass flow rate through section 1 must just equal the mass flow rate through section 2. If this were not so, some fluid would be added to storage or taken out of storage between the two sections, and this change would require a change in conditions (density) with time that contradicts the assumption of steady flow. If a stream tube, Figure 7A, has end sections of elemental area  $\delta A_1$  and  $\delta A_2$ , then the mass flow per unit time at section 1 is equal to its density ( $\rho$ ) times flow velocity

Equations used in frictionless flow problems

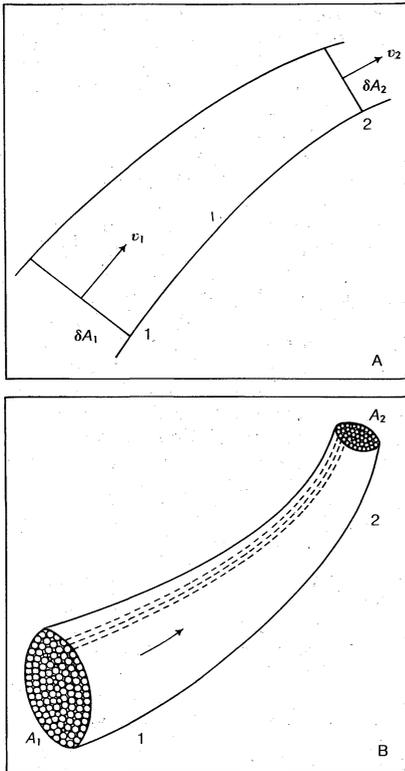

Figure 7: Steady flow. (A) Through a stream tube. (B) A collection of stream tubes between fixed boundaries (see text). From V.L. Streeter, *Fluid Mechanics*, copyright 1966; used with permission of McGraw-Hill Book Co.

( $v_1$ ) times sectional area ( $\delta A_1$ ), and similarly at section 2; or in equation form, which is the continuity equation for the stream tube of elemental area,  $\delta A$ ,  $\rho_1 v_1 \delta A_1 = \rho_2 v_2 \delta A_2$ . If all the stream tubes comprising a flow situation, such as those shown in Figure 7B, are summed up, the continuity equation states that the product of density, velocity, and cross-sectional area ( $A$ ) is the same at ends 1 and 2, or  $\rho_1 v_1 A_1 = \rho_2 v_2 A_2$ , in which  $\rho_1$  and  $v_1$  are the average density and velocity over cross section  $A_1$ , and similarly over cross section  $A_2$ . For the incompressible flow case, with  $\rho_1 = \rho_2$ , the equation reduces to a simpler form such that  $Q$ , the discharge rate (volume per unit time) passing any cross section in the collection of stream tubes comprising the flow, is equal to the velocity of the fluid times the cross-sectional area, or  $Q = v_1 A_1 = v_2 A_2$ .

**Euler's equation.** By applying Newton's second law, the equation of motion, to a fluid particle in the direction along a streamline in steady, incompressible, frictionless flow, a differential equation is obtained, called Euler's equation. In Figure 8, a particle having an elemental area  $\delta A$  and length  $\delta s$  is acted on by three forces along the path indicated by  $s$ : a force acting uphill, equal to pressure times area, or  $p \delta A$ ; a force acting downhill equal to minus the pressure, which has changed by the increment  $\frac{\partial p}{\partial s} \delta s$ ,

or  $(p + \frac{\partial p}{\partial s} \delta s) \delta A$ ; and a second force acting downhill, the component of weight  $\rho(\delta s \delta A) g$ , or  $-\rho g \delta A \delta s \cos \theta$ . The sum of these forces, according to Newton's second law, is equal to the mass of the particle times its acceleration ( $a_s$ ) along path  $s$ , giving  $p \delta A - (p + \frac{\partial p}{\partial s} \delta s) \delta A - \rho g \delta A \delta s \cos \theta = \rho \delta A \delta s a_s$ . Because  $\cos \theta$  may be expressed as the ratio  $\delta z / \delta s$ , in which  $z$  is measured vertically upward, the equation reduces to: the change in pressure divided by the density, plus the acceleration of gravity times change along vertical direction, plus the particle acceleration times change of path length along path, equals zero, or  $\frac{dp}{\rho} + g dz + a_s ds = 0$ . The ac-

celeration component, being the change of velocity with time ( $dv/dt$ ), may be written as the product of the change of velocity with distance along the path ( $dv/ds$ ) and the velocity along the path ( $v = ds/dt$ ), or  $a_s = (dv/dt) \times (ds/dt) = v (dv/ds)$ .

Substituting  $v (dv/ds)$  for  $a_s$  in the preceding equation yields a relationship such that the sum of three terms is zero, namely, change of pressure divided by density, acceleration of gravity times change in vertical distance, and velocity times change in velocity, or  $dp/\rho + g dz + v dv = 0$ , which is the Euler equation.

**Bernoulli's equation.** Euler's equation may be integrated, for constant density, yielding the Bernoulli equation: pressure divided by density, plus acceleration of gravity times total vertical distance moved along the path, plus one-half the velocity squared, equals a constant, or

$$p/\rho + gz + v^2/2 = \text{constant.}$$

By dividing each term by the acceleration of gravity it takes the form: pressure divided by specific weight plus vertical distance, plus one-half the velocity squared divided by the acceleration of gravity, equals a constant, or

$$\frac{p}{\gamma} + z + \frac{v^2}{2g} = \text{constant.} \quad (12)$$

The term  $\rho/\gamma$  may be interpreted as flow work, or as a portion of the potential energy term that the fluid is capable of yielding because of its sustained pressure. The term may also be called the pressure energy;  $z$  is the potential energy, and  $v^2/2g$  is the kinetic energy, each term having the dimensions of a length that is interpreted as energy per unit weight. In the International System of Units each term is in metres, or in joules per newton (in English units feet, or foot-pounds per pound).

From V.L. Streeter, *Fluid Mechanics*, copyright 1971; used with permission of McGraw-Hill Book Co.

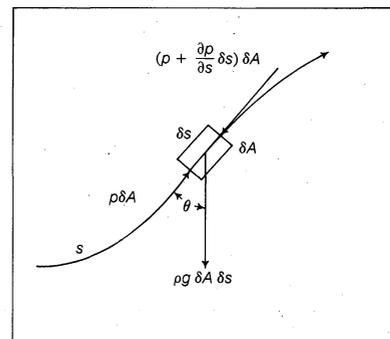

Figure 8: Force components on a fluid particle (see text).

The Bernoulli equation aids in solving problems in which the losses may be neglected or corrected for by application of an experimentally determined coefficient. Three applications of the equation are given:

**Torricelli's theorem.** The Bernoulli equation states that the energy is the same at any two points along a streamline in steady, frictionless, incompressible flow. In the case of a tank of liquid having a nozzle (point 2) on the side at a distance  $H$  below the surface (point 1), one may consider that a streamline connects points 1 and 2, and applying equation (12) to each point,

$$v_1^2/2g + p_1/\gamma + z_1 = v_2^2/2g + p_2/\gamma + z_2.$$

The velocity at the surface of the reservoir is almost nil, in which case  $v_1$  is approximately zero and the pressure is zero ( $p_1 = 0$ ). At point 2 the pressure is substantially zero, neglecting surface tension effects, because the streamlines are parallel and surrounded by zero-pressure air.

The elevation difference is  $z_1 - z_2 = H$ , and therefore the square of the velocity of the liquid issuing from the spout divided by twice the acceleration of gravity is equal to the head, or distance of the liquid level above the spout:  $v^2/2g = H$ , or  $v_2 = \sqrt{2gH}$ . This speed is the same as that attained by a particle in dropping the distance  $H$

Discharge rate

under the acceleration of gravity. This result is known as Torricelli's theorem.

**The venturi meter.** The venturi meter shown in Figure 9A is used to measure the rate of flow of a fluid in a closed conduit. It consists of a converging portion from 1 to a throat section at 2, followed by a gradually diverging reach that converts most of the kinetic energy at 2 back into pressure. Pressure connections are attached at sections 1 and 2 so that the pressures may be determined. The Bernoulli equation for points 1 and 2 may be written  $p_1/\gamma + v_1^2/2g = p_2/\gamma + v_2^2/2g$  after eliminating  $z$ ; as  $z_1 = z_2$ . By use of the continuity equation  $v_1A_1 = v_2A_2$ , the equations may be solved for  $v_2A_2$ , equal to the discharge rate ( $Q$ ), which is equal to the product of the two areas times the square root of twice the acceleration of gravity times the difference of the two pressures divided by the specific weight times the difference of the square of the two areas, or

$$Q = v_2A_2 = A_1A_2[2g(p_1 - p_2) / \gamma (A_1^2 - A_2^2)]^{1/2}.$$

This result is a little high, in general, because of the neglect of friction. An experimentally found coefficient may be applied as a multiplier to make the equation yield correct results.

From V.L. Streeter, *Fluid Mechanics*, copyright 1971; used with permission of McGraw-Hill Book Co.

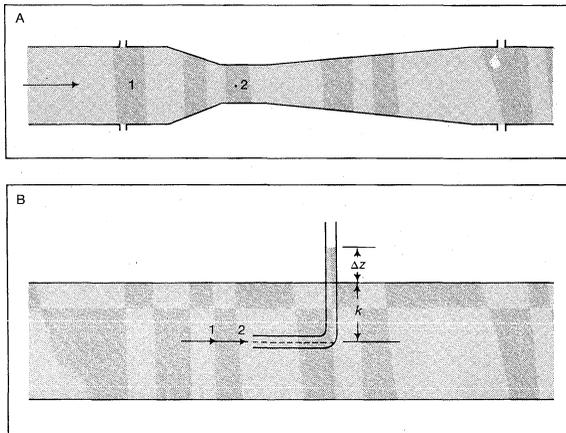

Figure 9: Fluid flow measuring devices. (A) Venturi meter. (B) Pitot tube.

**Pitot tube.** An open tube, bent at right angles and inserted into a flowing stream of liquid with one end open and facing upstream and one leg vertical, as in Figure 9B, is a form of pitot tube and may be used to measure the velocity of a flowing stream. At point 2, the liquid is forced into the open end until the impact of the flow is just balanced by the column height ( $\Delta z + k$ ) in the tube. Point 2 is a stagnation point, at which the velocity is zero ( $v_2 = 0$ ). By writing Bernoulli's equation from point 1, an undisturbed point having velocity  $v$ , there results  $v^2/2g + p_1/\gamma = p_2/\gamma = p_1/\gamma + \Delta z$ , using manometer principles. A solution of this equation gives for the velocity,  $v = \sqrt{2g\Delta z}$ .

**Energy equation.** The energy equation for steady, incompressible, one-dimensional flow takes the form of the Bernoulli equation with a correction term for losses. If section 1 is upstream of section 2, then

$$v_1^2/2g + p_1/\gamma + z_1 = v_2^2/2g + p_2/\gamma + z_2 + \text{losses}_{1-2}.$$

In words, the energy equation, in joules per newton (or foot-pounds per pound) states that the available energy at 1 is equal to the available energy at 2, plus all the losses between the two sections. If a pump were in action between the sections, its total dynamic head would appear in the loss term as a negative quantity. Similarly a turbine would be treated as a loss.

**FLOW IN PIPES AND CHANNELS**

**Laminar flow: the Poiseuille equation.** In laminar flow, fluid particles move in laminas, or layers; e.g., in a pipe, each concentric cylindrical shell of fluid moves faster than its next outer layer, with the fluid at rest at the

pipe wall. Losses are proportional to the first power of the velocity. In turbulent flow in a pipe there are erratic transverse motions of the fluid, which tend to equalize the velocity over a cross section and to produce more shear stress at the wall. Losses tend to vary in proportion to about the 1.85 and 2 power of the average velocity. The nature of flow in a tube may be characterized by the value of the Reynolds number, a dimensionless parameter that is the product of velocity, density, and diameter, divided by the viscosity. When its value is less than 2,000 (in any consistent units) for a straight round tube, the flow is generally laminar. For values greater than 2,000 in ordinary situations for pipes, the flow is usually turbulent. The greater the Reynolds number, the greater the intensity of the transverse turbulent fluctuations. For one-dimensional laminar flow in a fluid of viscosity, symbolized by the Greek letter mu,  $\mu$ , Newton's law of viscosity states that the fluid shear stress symbolized by the Greek letter tau,  $\tau$ , resulting from the motion of one layer adjacent to another layer, is equal to the viscosity times their relative velocity ( $du/dy$ ), or

$$\tau = \mu \left( \frac{du}{dy} \right). \tag{13}$$

The viscosity of the fluid is frequently determined by setting up an experiment so that the shear stress and the relative velocity can be measured. For steady flow through a circular tube of radius  $a$ , as shown in Figure 10, the pressure drop is just balanced by the shear force on a free body of the fluid; i.e., the pressure drop (a negative value) times the end area equals the area of curved cylinder times the shear stress, or  $(-dp/dl)\delta l\pi r^2 = 2\pi r\delta l\tau$ ; or, after simplifying, the shear stress varies directly as the pressure gradient and as the radius of cylinder ( $r$ ), or  $\tau = -(dp/dl)r/2$ , in which the shear stress is considered positive as shown. If equation (13) is written  $\tau = -\mu(du/dr)$  and is substituted into the last equation, then

$$\mu \left( \frac{du}{dr} \right) = \left( \frac{dp}{dl} \right) r/2.$$

The term  $dp/dl$  is not a function of  $r$ , and hence the equation may be integrated so that  $u = 1/4\mu (dp/dl)r^2 + \text{constant}$ . Because the velocity of a real fluid must be zero at a stationary boundary,  $u = 0$  when  $r = a$ ; the constant may thus be determined, yielding  $u = -[(a^2 - r^2)/4\mu] (dp/dl)$ . This equation shows that the velocity is a maximum at the centre line, and varies parabolically to zero at the wall. The maximum velocity is  $u_{max} = -(a^2/4\mu) (dp/dl)$ , and the average velocity is  $u_{av} = -(a^2/8\mu) (dp/dl)$ . The discharge rate  $Q$ , volume per unit time, is the product of the average velocity by the area  $\pi a^2$  of the tube; that is,

$$Q = -\frac{\pi a^4 dp}{8\mu dl} \tag{14}$$

**Poiseuille's equation.** The Poiseuille equation states that the laminar flow through a circular tube varies as the fourth power of the radius, inversely as the viscosity and directly as the pressure drop per unit length; i.e., as given in equation (14). The discharge is independent of the density of the fluid and of the roughness of the tube wall.

The differential  $dp/dl$  is sometimes expressed as  $(p_2 - p_1)/l$ , in which  $p_1$  and  $p_2$  are the pressures at points 1 and 2, and  $l$  is the distance between them.

**Turbulent flow. Prandtl mixing length.** In order to obtain some measure of the turbulent fluctuations and their relation to shear stresses, Prandtl developed the concept of a mixing length  $l$  that a molar fluid particle might move transversely in a turbulent flow before it became identified with the fluid around it. The concept is analogous to the mean free path of a molecule. He obtained an expression ( $y = \text{distance from the boundary}$ ) that the shear stress ( $\tau$ ) equals the product of density ( $\rho$ ), square of the mixing length, and square of the velocity gradient ( $du/dy$ ), or  $\tau = \rho l^2 (du/dy)^2$ .

By further reasoning the mixing length was taken to be proportional to the distance from a pipe wall, which leads to equations for the variation of velocity across a pipe in

Laminar flow through a circular tube

Ber-noulli's equation with losses

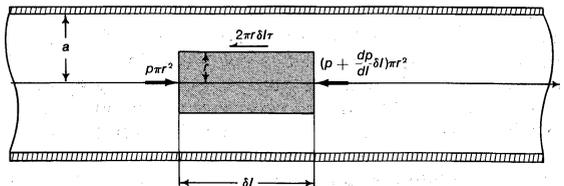

Figure 10: Free-body diagram for steady flow through a round tube.

From V.L. Streeter, *Fluid Mechanics*, copyright 1966; used with permission of McGraw-Hill Book Co.

turbulent flow, and also leads to an expression for energy loss in turbulent flow through pipes.

**The Darcy-Weisbach equation.** Laminar flow through pipes is calculated by the Poiseuille equation, as stated above. For turbulent flow in pipes the Darcy-Weisbach equation is frequently used, which states that the head loss (energy difference between two sections of a pipe) is proportional to the product of length of pipe and the square of the velocity divided by the diameter and by twice the acceleration of gravity, or  $h_f = f L v^2 / 2Dg$ , in which  $h_f$  is the head loss (energy loss in joules per newton, or foot-pounds per pound) for the length  $L$  of pipe of inside diameter  $D$  and average velocity  $v$ . For turbulent flow the dimensionless factor  $f$  is dependent upon the pipe wall roughness and the fluid properties of density and viscosity; it also is a function of the velocity and pipe diameter, because the losses are not always proportional to the square of the velocity and inversely proportional to the diameter.

For closed conduits of other than circular cross section, an equivalent diameter  $D$  may be approximated by four times the cross-sectional area ( $A$ ) divided by the wetted perimeter ( $P$ ), or  $D = 4 A/P$ ; by wetted perimeter is meant the length of the boundary of the cross section in contact with the flowing fluid.

Complex steady flow piping systems may be analyzed by use of the Darcy-Weisbach equation, plus the continuity equation which states the flow into a junction of pipes must equal flow out of the junction. For networks of pipes an additional criterion is needed, namely, that the pressure difference around any closed loop in the network must be zero. These problems are generally too complex for a direct analytical solution and procedures are used that improve the solution with repeated trials.

**Special types of flow.** *Unsteady flow.* Unsteady flow in pipes is much more complicated than steady flow, because conditions may be changing with time at any point within the system. Unsteady flow problems are usually calculated by use of the digital computer. The basic partial differential equations of motion and continuity are converted into algebraic finite difference equations that are applied repeatedly to individual reaches of the conduits making up the flow system. Extremely complex problems may be solved by these methods, such as the calculation of pressures and flows through a network of pipes when power to a pumping station supplying the system is interrupted.

*Flow in open channels and rivers.* Uniform flow occurs when the velocity vector is everywhere the same throughout the flow at an instant. This strict definition is relaxed for real fluids so that when the average velocity at every cross section of the flow is the same at any instant the flow is called uniform. A widely used empirical equation for steady-uniform flow in open channels is the Manning formula in English units,  $v = 1.49 R^{2/3} S^{1/2} / n$ , in which  $v$  is the average velocity in feet per second,  $S$  is the slope of the bottom of the channel,  $R$  is the hydraulic radius, defined as the ratio of the cross-sectional area of the flow to the wetted perimeter (liquid-solid contact line) of the cross section, and  $n$  is an absolute roughness factor. In SI units the constant 1.49 becomes 1.

Because the Manning formula is empirical it is essential that the velocity be in feet per second, the radius in feet, and the slope be dimensionless. The equation may be written in terms of the discharge,  $Q$ , by multiplying both sides by the area  $A$ :  $Q = 1.49 A R^{2/3} S^{1/2} / n$ .

The value of  $n$  for water and concrete is 0.012, and for

water and corrugated metal it is 0.022. These values are reasonably satisfactory for other low viscosity liquids as well.

For natural rivers the flow may be fairly steady for some periods of time, but the flow is never uniform because of the variation of cross-sectional area and the changing direction of the river bed. The flow in a river is usually determined by measuring the velocity at many positions over a cross section, then multiplying the velocity by the appropriate area for each measurement and summing up the resulting discharges for the total area. The flow may be approximated by measuring the cross-sectional area at each end of a fairly uniform reach, and by measuring the slope of water surface and estimating the channel roughness. These values are substituted into the Manning formula to calculate the discharge.

In general, for gradually varying flow in the river with time, the differential equations of continuity and momentum are written, using the Manning formula above as a basis for estimating losses (or wall shear stresses). Solutions to the equations are usually carried out with the aid of a digital computer.

#### GENERAL TWO- AND THREE-DIMENSIONAL FLOW

Two- and three-dimensional flow must be approached from a mathematical viewpoint, resulting in complicated equations not appropriate to this article.

**Mathematical conditions.** The conditions to be satisfied are:

1. Continuity principles, derived from the general law of conservation of mass, which states that the net mass inflow into any small volume must just equal the time rate of increase of mass within the volume. For incompressible fluids this condition guarantees that fluid will not pile up at a point, or that gaps will not occur in a fluid.
2. Newton's second law of motion, which states that the net force acting on any small particles of fluid (mass) will cause it to be accelerated in proportion to the force and in inverse proportion to its mass. For real (viscous) fluids, shear forces must also be taken into account.
3. Boundary conditions, which are statements that the velocity component of a fluid normal to a solid boundary must just equal the velocity of the boundary normal to itself. For real fluids the velocity of a particle of fluid in contact with a boundary has the same velocity as the boundary; e.g., fluid particles in contact with a solid boundary at rest have no velocity.
4. Irrotational (nonrotatory) conditions for nonviscous fluids, which state that a portion of fluid with each particle moving or at rest without rotation cannot be set into rotation. The amount of rotation of a fluid particle about an axis through it is defined as the average of the angular velocities of two line segments mutually at right angles to the axis.

Each of these basic concepts leads to equations that must be satisfied by the flow. This field of study is referred to as hydrodynamics, which was developed primarily during the 19th century.

The irrotational flow concepts lead to the definition of a velocity potential, which is a scalar function of time and space the derivative of which with respect to any direction is the negative of the velocity component in that direction. The combination of the irrotational concept with the continuity equation in frictionless incompressible flow leads to the Laplace equation. When this equation is satisfied by any function of space and time, say a function of the rectangular coordinates  $x, y, z$ , and time  $t$ —i.e.,  $f(x, y, z, t)$ —then this function is the velocity potential for some fluid flow case. The determination of which case this may be requires a detailed examination of the possible boundary conditions that it can satisfy.

By use of the irrotational condition plus Newton's second law of motion (through development of Euler's equations of motion), it is possible to obtain an energy equation that states that in any steady, irrotational flow of a frictionless, incompressible fluid, the energy throughout the fluid must be constant. This equation is known as the Bernoulli equation.

**Vorticity.** By considering that a fluid has particles that have rotation about their axes, another field of study called vortex flow has been evolved. No velocity potential exists for this flow. A single line through a fluid may be

The Manning formula

Hydrodynamics

considered to have vorticity, and this condition affects the motion of fluid around it that may be irrotational.

If a long cylindrical body is rotated in a real fluid, it tends to pull fluid particles around it, thereby setting up some rotation. If a line is drawn in the fluid that contains the cylinder within it, the sum of the products of the velocity component tangent to the line by an element of length of line is called the circulation about the cylinder. It may be shown that when fluid flows across such a cylinder having a circulation, a force at right angles to the approaching flow develops that is called the lift force. It is proportional to the circulation, the approach velocity, and the fluid density. An example of this was an experimental vessel that sailed the Atlantic Ocean, called the Flettner rotorship after its inventor, a German engineer, Anton Flettner. It had two large vertical cylinders mounted on deck that were rotated mechanically, and thus had a thrust at right angles to the wind's directions.

Lift force

Viscous three-dimensional flow theory must take into account the shear stresses exerted on the fluid particles by their angular deformation. The equations of motion are called the Navier–Stokes equations, and are extremely complicated, having been solved only for cases in which great simplifications could be made.

The Navier–Stokes equations apply directly to low Reynolds number flow (laminar flow), such as creeping flow between surfaces or small clearance; e.g., flow through journal bearings (called hydrodynamic lubrication).

The equations may be applied to the steady flow case of two horizontal closely spaced plates, with separation  $a$ , the lower plate being fixed in position and the upper one being free to move parallel to the lower plate at velocity  $U$  in the  $x$ -direction. The pressure of the fluid contained between the two plates may change in the  $x$ -direction because of the conditions at the boundaries (see Figure 11). The  $z$ -axis is vertical,  $z$  being the distance above the fixed plate. For this case the velocity  $u$  for any point is a function of  $z$  only. An equation for the velocity  $u$  may be derived, yielding  $u = U z/a - (dp/dx)(az - z^2)/2\mu$ , in which the Greek letter  $\mu$  symbolizes the viscosity.

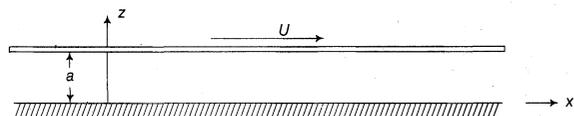

Figure 11: Flow between parallel plates with one plate in motion.

The term  $dp/dx$  is the change in pressure per unit length in the direction of flow. If this pressure gradient  $dp/dx$  is zero, the equation shows the velocity to be zero at the fixed plate, varying linearly with  $z$  to  $U$  at the moving plate. For two fixed plates ( $U = 0$ ) the velocity distribution is parabolic; i.e., the velocity is a parabolic function of the distance  $z$ . The discharge per unit width (measured normal to the page) is given by  $Q = U a/2 - a^3(dp/dx)/12\mu$ . This equation is useful in determining leakage between small clearances, as in a piston pump.

To apply the Navier–Stokes equations to turbulent flow cases, they must be altered to bring in turbulent shear stresses.

Prandtl's hypothesis

**Boundary layers.** In 1904 Prandtl stated his boundary-layer hypothesis: For fluids having relatively small viscosity, the effect of internal friction in a fluid is appreciable only in a narrow region surrounding the fluid boundaries. This statement implies that the flow outside of the narrow region surrounding fluid boundaries may be considered as irrotational (nonrotatory) fluid flow. The boundary-layer hypothesis permitted the vast theory in potential flow to become useful in practical flow situations, joining the empirical approach of hydraulics with the mathematical theory of irrotational flow. The Navier–Stokes equations may be applied to the boundary regions, and the Euler equations to nonboundary regions of flow.

The boundary layer is defined as that portion of the flow that has had its velocity affected by fluid shear at the boundary. If a flat, smooth plate is immersed in a moving

fluid parallel to the flow direction, a boundary layer develops along the plate. At the upstream end of the plate the boundary layer at first has negligible thickness, and there is a large shear at the plate as the velocity gradient  $du/dy$  is large. This shear causes a reduction in fluid velocity near the plate. Farther downstream along the plate the shear is reduced as the velocity gradient reduces, but the continuing action of fluid shear causes growth in the thickness of the fluid layer of reduced velocity in the downstream direction. Near the upstream end of the plate, the layer is called a laminar boundary layer, because the fluid particles move in smooth paths substantially parallel to the plate; as the layer becomes thicker, however, the laminar flow becomes unstable and transverse fluctuations develop within the layer changing the flow to turbulent flow. This portion of the flow is called the turbulent boundary layer. The thickness of laminar boundary layer grows as the square root of distance along the plate, whereas the shear stress varies as the inverse square root of the distance. For the turbulent boundary layer, it grows in thickness proportional to distance to the  $4/5$  power, and the shear stress varies inversely as distance to the  $1/5$  power.

For the case of a flat plate, parallel to the flow, the boundary layer continues to grow in the downstream direction indefinitely. If the flow boundaries are such that the pressure is increasing downstream, as with flow between diverging plates or in a conical diffuser, the action of the pressure is to hasten the growth of the layer and to bring the momentum of the flow in the layer to zero near the boundary. When this occurs, the boundary layer separates from the boundary and a region of backflow, called the wake, develops near the boundary. Separation of the boundary layer and the ensuing wake adds to increased losses in the flow. In flow around airfoil sections, as in airplane wings, and through the vanes of hydraulic machines such as propellers, pumps, or turbines, the separation of boundary-layer flow is the principal factor in poor performance. By altering the shape and thickness of airfoil sections or flow passages, the advent of transition to turbulent boundary layer may be delayed in such a manner as to reduce losses; or in some cases, by causing the turbulent boundary layer to develop before separation occurs, the size of the wake may be reduced and efficiency improved. In some practical cases momentum may be added to the boundary layer, as by drawing off the slow-moving fluid near the boundary, allowing high-momentum fluid from the main flow to replace it, and thus retarding separation.

Flow around airfoils

**Drag.** An object submerged in a flowing fluid is subjected to a fluid force component on it in the direction of the approach velocity, called the drag. The drag force is caused by skin friction drag, which is caused by shear stress components in the flow direction, and by form, or profile, drag, caused by the lower pressure on the downstream side of the object. Drag, in general, must be determined experimentally, and it is convenient to use a drag coefficient  $C_D$ , which depends on the object shape and the fluid viscosity. An equation for drag therefore includes a drag coefficient and is proportional to the area ( $A$ ) presented to the flow and velocity squared; i.e., drag =  $C_D A \frac{\rho}{2} U^2$ , in which  $C_D$  is dimensionless,  $A$  is usually the

Drag coefficient

projected area of the object onto a plane normal to the flow direction, the Greek letter  $\rho$ , symbolizes the mass density, and  $U$  is the velocity of the approaching fluid relative to the object. The drag coefficient for a given body is a function of Reynolds number,  $Ul/\nu$ , in which  $l$  is a characteristic length of the body and the Greek letter  $\nu$ , symbolizes the fluid kinematic viscosity. Figure 12 is a plot of drag coefficients versus the Reynolds number  $R$  (in which  $R = UD/\nu$ ) for spheres and circular disks on a log–log scale. The line marked Stokes is a representation of the Stokes law, drag =  $6\pi a\mu U$ , for a sphere of radius  $a$  in laminar flow. The critical Reynolds number of laminar flow around a sphere is  $UD/\nu = 1$ , with  $D$  the diameter of sphere. The results shown in the plot were determined by experiment. The sudden drop in the drag coefficient for the sphere at  $R = 250,000$  is caused by the

laminar boundary layer changing to a turbulent boundary layer which delays separation and causes a smaller wake. The disk, normal to the flow, has its separation at the edge of the disk, and hence does not have such a sudden reduction in the drag coefficient.

From V.L. Streeter, *Fluid Mechanics*, copyright 1966; used with permission of McGraw-Hill Book Co.

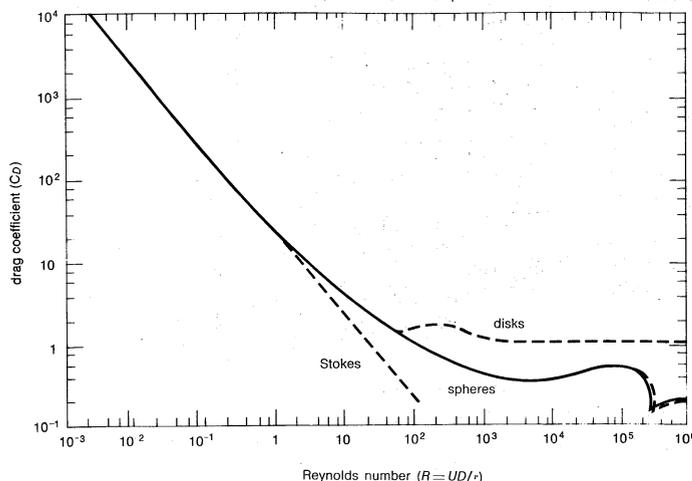

Figure 12: Drag coefficients for spheres and circular disks.

A disk that rotates while submerged in a real fluid has a drag moment, or torque, exerted on it by boundary shear forces. In hydraulic machinery this disk drag contributes to losses. A circular cylinder, rotating while submerged in a real fluid flowing around it at right angles to the cylinder axis, suffers a drag force component as well as the lift force component, known as the Magnus effect.

#### COMPRESSIBLE FLUID FLOW

**The equations of gas dynamics.** The perfect gas law,  $p = \rho RT$ , equation (5), has been defined, as well as the definitions of specific heats  $c_v$  and  $c_p$ . Also, enthalpy has been defined as  $h = u + p/\rho$ . The specific heat ratio  $k$  is given by the ratio of the two specific heats, namely,  $k = c_p/c_v$ . The gas constant  $R$  and  $k$ ,  $c_p$  and  $c_v$  are related by the equations  $c_p = kR/(k - 1)$ ;  $c_v = R/(k - 1)$ , in which consistent heat units or work units must be employed. Equation (3) states:  $Tds = du + pd(1/\rho)$ . By using  $du = c_vdT$  and the perfect gas law, it becomes  $ds = c_v(dT/T) + R\rho d(1/\rho)$ . This equation may be integrated, yielding the difference in entropy per unit mass for the two states, 1 and 2; i.e.,  $s_2 - s_1 = c_v \ln[(p_2/p_1) (\rho_1/\rho_2)^k]$ . These equations are forms of the second law of thermodynamics.

If a process is reversible, the entropy differential  $ds = dq_H/T$ ; furthermore if the process is also adiabatic (no heat transfer), the heat-added differential  $dq_H = 0$ . Thus  $ds = 0$ , for an isentropic, or reversible-adiabatic, process. From the equation, for  $s_2 - s_1 = 0$ , the relation  $p_2/\rho_2^k = p_1/\rho_1^k$  results, which describes the relationship of pressure to density for an isentropic process. The enthalpy change for an isentropic process is

$$h_2 - h_1 = c_p(T_2 - T_1) = c_p T_1 [(p_2/p_1)^{(k-1)/k} - 1].$$

**Isentropic (reversible-adiabatic) flow.** *Speed of a sound wave: Mach number.* The speed of a sound (acoustic) wave in a one-dimensional flow may be determined by use of the continuity and momentum (one form of Newton's second law) equations. The question of the possible conditions that would permit a consideration of small change in velocity, pressure, and density at a fixed position in a prismatic channel in steady flow leads to the following expressions for speed  $c$  of a sound wave:  $c = \sqrt{dp/d\rho} = \sqrt{K/\rho} = \sqrt{k p/\rho} = \sqrt{kRT}$ , in which  $K$  is the bulk modulus of elasticity,  $k$  is the specific heat ratio, and  $R$  is the gas constant. The last two expressions are for isentropic (reversible-adiabatic) conditions. A sound wave through air closely approximates isentropic flow.

The ratio of velocity at a point to the local wave speed

$v/c$ , is called the Mach number  $M$ , a dimensionless number. It is a measure of the importance of compressibility. The acoustic speed in air at sea level and at 20° C (68° F) is 0.343 kilometre (1,125 feet) per second, and the acoustic speed in water at ordinary pressure is 1.442 kilometres (4,730 feet) per second. For an incompressible fluid, the acoustic speed approaches infinity and  $M$  is equal to zero.

*Flow in ducts and nozzles.* Although isentropic (reversible-adiabatic) flow is unattainable with real fluids, it is approached in flow through transitions, nozzles, and venturi meters in which friction effects are small and heat transfer is minor. By use of Euler's equation and the continuity equation, an expression of interest may be derived for duct flow:  $dA/dv = A(M^2 - 1)/v$ , in which  $A$  is the cross-sectional flow area,  $v$  the average velocity, and  $M$  the local Mach number.

This equation is for steady, one-dimensional frictionless flow in the duct of varying cross sectional area. If the Mach number is less than unity (one), the situation for subsonic flow,  $dA/dv$  is always negative, and hence for acceleration of flow the area must reduce. The Mach number can be unity (i.e., sonic flow will prevail) only when  $dA/dv = 0$  (at a throat or minimum section). For Mach numbers greater than unity (supersonic flow)  $dA/dv$  is positive; hence for acceleration of the flow the cross-sectional area must increase. In order for supersonic flow from a reservoir through a duct to occur, the flow is accelerated in the subsonic regions from zero to sonic flow through a converging duct leading to a throat, or minimum cross section. Then the duct must expand in area to accommodate supersonic flow. Whether or not supersonic flow actually occurs depends upon downstream conditions.

Isentropic flow, because it is frictionless and does not allow for heat addition or heat loss, is flow with constant energy. This kind of flow permits the energy, momentum, and continuity equations, as well as the perfect gas law and the constant entropy condition,  $p\rho^{-k} = \text{constant}$ , to be applied to any problem. For flow through a duct of varying cross sections from a reservoir, simple equations may be developed for changes in pressure, density, and temperature,  $p$ ,  $\rho$ , and  $T$ , from their respective values in the reservoir,  $p^0$ ,  $\rho^0$ , and  $T^0$ , all in terms of the local Mach number  $v/c$ . These equations are:

$$\frac{p^0}{p} = \left(1 + \frac{k-1}{2} M^2\right)^{k/(k-1)},$$

$$\frac{\rho^0}{\rho} = \left(1 + \frac{k-1}{2} M^2\right)^{1/(k-1)},$$

$$\frac{T^0}{T} = 1 + \frac{k-1}{2} M^2.$$

For flow with sonic conditions at the throat ( $M = 1$ ) in which the area is  $A^*$ , the value of Mach number at any other cross section  $A$  (for air or diatomic gases having  $k = 1.4$ ), there results

$$\frac{A}{A^*} = \frac{1}{M} \left(\frac{5 + M^2}{6}\right)^3.$$

The area  $A$  must always be greater than the throat area  $A^*$ . The maximum flow rate  $\dot{m}$ , the change of mass per unit time, through a duct system (for  $k = 1.4$ ), is given by  $\dot{m} = 0.685 A^* p_0/\sqrt{RT_0}$ ; i.e., the flow  $\dot{m}$  is directly proportional to the throat area  $A^*$ , to the reservoir pressure  $p_0$ , and inversely proportional to the square root of the temperature in the reservoir.

Figure 13 shows the relations among Mach number, pressure ratio  $p/p_0$ , and area ratio  $A^*/A$  for  $k = 1.4$ . At point  $r$  on the curve the fluid would be at rest with the Mach number  $M = 0$ . As the pressure is reduced, say at point  $t$ , subsonic flow occurs. At the throat, for critical (sonic) flow at point  $t^*$ , the Mach number is unity. Then for supersonic flow in the diverging portion of the tube; say at  $s$ , the area ratio is shown related to pressure ratio and Mach number.

Figure 14 illustrates the various possible flow cases for isentropic flow through a converging-diverging nozzle, including the possibility of a normal shock wave. If the

The Mach number

Supersonic flow

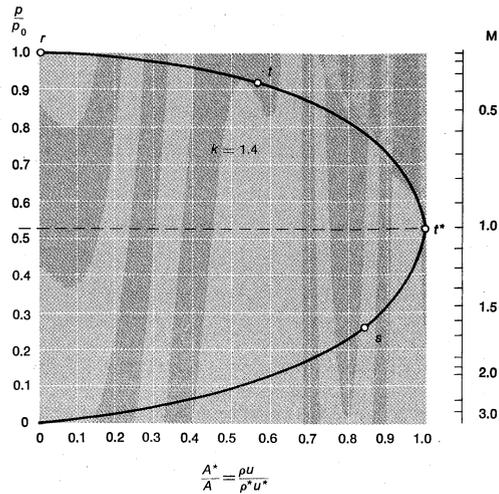

Figure 13: Isentropic relations for a converging-diverging nozzle.

From *Elements of Gas Dynamics* by H. Liepmann and A. Roshko, copyright 1957. By permission of John Wiley & Sons, Inc.

downstream pressure is  $p_c$  or greater, isentropic subsonic flow occurs throughout the duct. If the pressure is at  $j$  on the graph, isentropic flow occurs throughout, with supersonic flow in the diverging portion. For downstream pressure between  $c$  and  $f$ , a normal shock wave occurs within the tube, causing a non-isentropic sudden jump from supersonic to subsonic conditions. For pressure  $p_f$  a normal shock wave occurs at the exit, and for pressures between  $p_f$  and  $p_j$ , oblique shock waves occur at the exit.

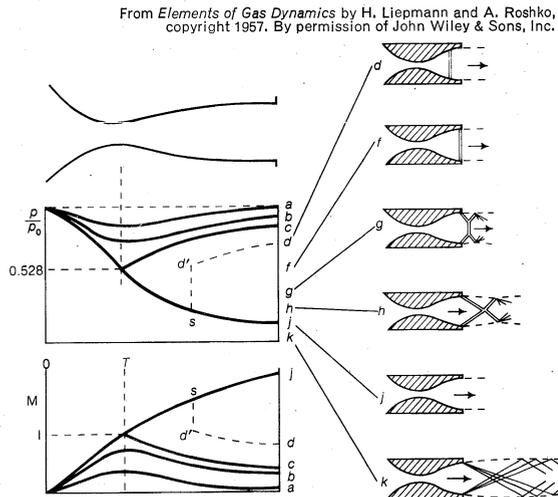

Figure 14: Various pressure and Mach number configurations for flow through a nozzle.

**Shock waves.** The one-dimensional steady shock wave (*i.e.*, the normal shock wave) occurs under certain conditions in a converging-diverging duct. The normal shock wave consists of a sudden change in pressure, density, and velocity, always from supersonic flow to subsonic flow. The thickness of the shock wave is of the order of the molecular mean free path (average distance between collisions of molecules) of the gas, and hence the cross-sectional area on each side may be considered the same. Losses occur in flow through the shock wave. The continuity equation, the energy equation, and the momentum equation must be satisfied.

Figure 15 portrays a normal shock wave. If the conditions of the supersonic flow,  $\rho_1, p_1, v_1$ , are known, by solution of the three equations, the values of  $\rho_2, p_2, v_2$  may be calculated for the shock wave to occur. These values are  $p_2 = [1/(k + 1)] [2\rho_1 v_1^2 - (k - 1)p_1]$ ,  $v_2 = (p_1 - p_2 + \rho_1 v_1^2) / \rho_1 v_1$ , and  $\rho_2 = \rho_1 v_1 / v_2$ .

(In open channel flow, under certain conditions, a hydraulic jump occurs that is analogous to the normal shock

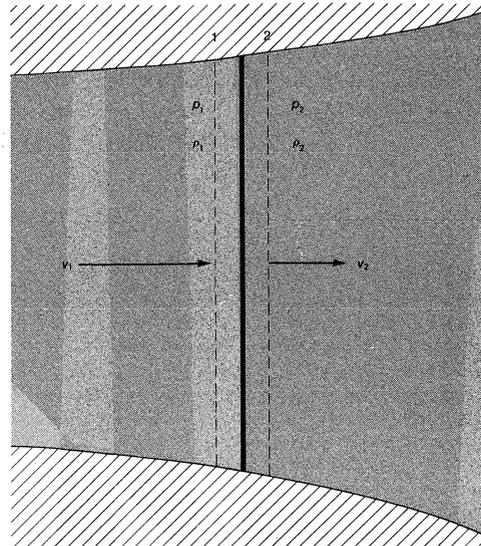

Figure 15: Normal compression shock wave. From V.L. Streeter, *Fluid Mechanics*, copyright 1966; used with permission of McGraw-Hill Book Co.

wave. It is a rather sudden increase in depth of the flowing stream [Figure 16].) Losses occur across a shock wave so the flow is not isentropic; *i.e.*, there is an increase in entropy from 1 to 2 in Figure 15. The velocity always changes from supersonic to subsonic.

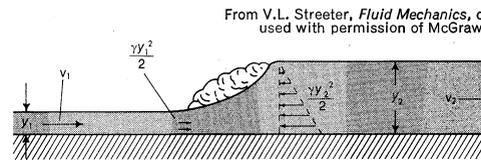

Figure 16: Hydraulic jump in a rectangular channel. A liquid jet stream of specific weight  $\gamma$  that flows in an open channel with depth  $y_1$  and velocity  $v_1$  expands to a slower moving stream (velocity  $v_2$ ) of depth  $y_2$  and the same width, giving steady non-uniform flow.

**Fanno and Rayleigh lines.** The normal shock wave has been analyzed by means of the continuity, energy, and momentum equations applied to a situation of constant area. Valuable conclusions can be obtained by use of the continuity and energy equations only, applied to a constant area situation for steady adiabatic, frictional flow. The line obtained by plotting enthalpy against entropy is called a Fanno line (Figure 17). Similarly, a plot resulting from use of the momentum and continuity equations is called a Rayleigh line. Because neither includes the complete physics of shock wave formation, it is necessary to draw conclusions from both lines.

Shock wave formation

From V.L. Streeter, *Fluid Mechanics*, copyright 1966; used with permission of McGraw-Hill Book Co.

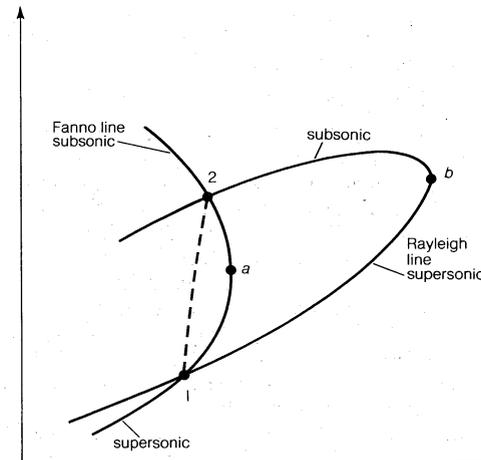

Figure 17: Fanno and Rayleigh lines.

Point *a* on the curve can be shown to be the sonic condition on the Fanno line, and point *b* the sonic condition on the Rayleigh line. The intersection of the Fanno and Rayleigh lines satisfies all three equations for the normal shock wave. Because no heat transfer has taken place, and by the second law of thermodynamics the entropy cannot decrease, the shock wave must occur from the supersonic point 1 to the subsonic point 2.

**Sonic boom.** When an aircraft flies at a speed faster than the speed of sound, it creates shock waves in the air around the plane. Under certain conditions these shock waves reach the ground and are heard and felt as explosions, or sonic booms. The stronger booms are caused by an airplane diving to accelerate through the sonic speed range. As the plane pulls out of its dive the shock waves continue, striking the ground, buildings, or the listener's ears, with one or two explosive booms.

## Mechanics, Quantum

Quantum mechanics is the branch of mathematical physics that deals with the motion of electrons, protons, neutrons, and other subatomic particles in atoms and molecules. The subject is entirely a product of researches made in the 20th century, particularly resulting from major contributions, which are treated in this article, by the physicists Werner Heisenberg, Louis de Broglie, Erwin Schrödinger, Max Born, and Paul A.M. Dirac since 1925. The ideas and methods of quantum mechanics have dominated all progress in atomic, nuclear, and molecular physics and chemistry since that year. In the first quarter of the century the principal initial discoveries were made by Max Planck, Albert Einstein, and Niels Bohr.

Before the principles of quantum mechanics were discovered, physicists had taken for granted that motions at the atomic level should be described in terms of the classical mechanics of Isaac Newton, perhaps with relatively minor modifications. This form of mechanics (see MECHANICS, CLASSICAL) was initially developed in connection with the study of motions of bodies, such as planets and satellites of the solar system, projectiles moving near the Earth's surface, or, in general, bodies of all kinds that are large compared with the atoms of which they are composed. Newtonian mechanics is even found to be applicable with high accuracy to the motion of subatomic particles under certain circumstances, such as the beam of electrons in a cathode-ray tube (e.g., television picture tube) or the beams of protons in cyclotrons or high-energy accelerators.

The use of classical Newtonian mechanics to describe electronic motions within atoms was initiated by Bohr in 1913 and found to have considerable success, proving to be a great stimulus to further developments. But by 1925 this approach had run into difficulties; physicists realized that the principles of quantum mechanics differ drastically from those of Newtonian mechanics, even when used in the relativistic form developed by Einstein in 1905. Despite the great differences in outlook between classical and quantum mechanics, they are, of course, closely related. The relationship is much like that already known from 19th-century optics. Here much of the theory of reflection and refraction as used in optical instruments can be handled by methods of geometrical optics, which

trace rays of light through the instruments as if these are the paths of particles of light. But after the phenomena of interference and diffraction were discovered it was necessary to modify such treatments to obtain greater accuracy by describing light as a propagated wave motion that was recognized in the late 19th century as being electromagnetic in character. Quantum mechanics also recognizes that material particles in motion need a related wave motion for their description, and in consequence the subject is sometimes called wave mechanics.

There is another and deeper sense in which classical and quantum mechanics are related. Science is a human enterprise, carried out by human beings, employing sense organs, muscular structure, and a nervous system, as well as auxiliary tools of manipulation and observation, which are enormously large compared to the atoms of which they consist. When scientists seek to learn details of atomic structure by observation, they are limited to what can be learned through observations made with such large instruments. Some of the features of quantum mechanics have to be understood in terms of this limitation on human observational powers.

This article is divided into the following sections:

- I. Development of quantum theory
  - Classical mechanics
  - Heisenberg uncertainty principle
  - Wave-particle duality
  - De Broglie waves
  - Bohr's theory of atomic spectra
  - Schrödinger's wave mechanics
  - Pauli exclusion principle
- II. Applications of quantum mechanics
  - Molecular structure
  - Nuclear structure and particle physics
  - Other applications

### I. Development of quantum theory

#### CLASSICAL MECHANICS

Because of the close relation between classical and quantum mechanics, concepts employed in the former also occur in the latter, with the same names but often with greatly altered meanings, a fact that can be confusing to the beginner. Space and time are dealt with classically in nonrelativistic forms of the theory, to which attention here is largely confined. Also, particles will be thought of as being subatomic. Space being three-dimensional, three coordinates ( $x, y, z$ ) are needed to specify the location of a point at an instant of time ( $t$ ). Each and every particle has an attribute called its mass ( $m$ ), a measure of its inertia. The velocity and acceleration of a particle each require three components (i.e., their values along the directions of the coordinates  $x$ ,  $y$ , and  $z$ ) for their description: ( $v_x, v_y, v_z$ ) and ( $a_x, a_y, a_z$ ), respectively, in which each component of velocity is the time rate of change of the associated space coordinate, and each component of acceleration is the time rate of change of the corresponding component of the velocity. The product of mass by each component of velocity gives the three components of the momentum ( $p$ ) so that  $p_x = mv_x$ ,  $p_y = mv_y$ , and  $p_z = mv_z$ .

The classical equations of Newton say that each component of the time rate of change of the momentum is equal to the corresponding component of the total force ( $F_x, F_y, F_z$ ) acting on it due to the influences of neighbouring particles. Thus, to describe the motions of planets in the solar system (for which the theory was originally designed), there are three such differential equations of motion for each body, so  $3N$  simultaneous differential equations for a system of  $N$  bodies. The general solution of these describes all possible forms of motion of the system represented. It involves  $6N$  arbitrary constants. To complete the specification of the motion in a particular case it is necessary to determine the particular values of these  $6N$  constants. Usually this is done by choosing them to represent the  $3N$  position coordinates and the  $3N$  velocity coordinates at some initial instant of time. With the particular solution so determined, the exact positions of the bodies at all future times can be in principle exactly calculated.

Thus classical mechanics has a fully deterministic char-

Need  
for  
quantum  
mechanics

The deterministic nature of classical mechanics

acter: given the masses and the forces and the initial positions and velocities exactly, exact predictions of future (and past) behaviour can be found by the method outlined. In complicated cases, the finding of accurate solutions is a matter of great computational difficulty, but when carried out with sufficient care such solutions are always found in large systems to predict the motions in a way agreeing with later observations of the highest precision. Such a procedure receives one of its severest tests in predicting the orbital motions, from Earth to Moon and return, of manned spacecraft that have been made to travel to a specified place on the Moon and return to a specified place on the Earth.

This fully deterministic character has played an important role in the philosophy of determinism and free will. It was particularly stressed by a French mathematician, Pierre Simon de Laplace, in the 18th century (and for this reason is often sometimes called Laplacian determinism) in an oft-quoted passage:

We ought then to regard the present state of the universe as the effect of its antecedent state and the cause of the state that is to follow. An intelligence knowing, at any given instant of time, all forces acting in nature, as well as the momentary positions of all things of which the universe consists, would be able to comprehend the motions of the largest bodies in the world and those of the smallest atoms in one single formula, provided it were sufficiently powerful to subject all data to analysis: to it, nothing would be uncertain, both future and past would be present before its eyes.

The point here is not so much whether or not such an intelligence exists but the supposed attribute of the universe to run on like a machine with no capacity for caprice or free choice in any of its behaviour, including that of the living beings who are also supposed to be subject to Newtonian mechanics.

#### HEISENBERG UNCERTAINTY PRINCIPLE

An essential feature of the classical procedure just outlined is the need to know precisely initial positions and velocities of all the particles in a system in order fully to determine the applicable special solution of the equations of motion. This step requires observation of all the positions over a small time interval to get also the velocities, or momentum components. Ordinarily this could be done by illuminating them and observing them by means of the light that they scatter into the eyes or optical instruments of the observer. The validity of this procedure depends thus on the tacit assumption that the motion of the bodies being observed is not disturbed by the fact of their having scattered the light with which they are observed. The actual success of classical mechanics when applied to large objects is thus an indication of the lack of appreciable disturbances of motion by the light scattering.

The situation is otherwise when this general procedure is applied in an attempt to study motions of electrons within atoms and molecules. It is known that the light from a point source is not brought to a point focus in the image plane of a telescope or microscope. The image is always somewhat blurred by the property called diffraction, and this blurring gives rise to a corresponding uncertainty in the measurement of the direction of the light source from the instrument. Diffraction is an inherent and inescapable feature associated with the wave nature of light, over and above any blurring that may be caused by imperfections of workmanship in making the instrument.

The simplest form of wave motion is sketched in Figure 1. The amplitude  $\Psi$  (the Greek letter psi) is drawn as a function of  $x$ , a coordinate in the direction of wave propagation, as a sinusoidal curve for a particular instant of time,  $t$ . At a time  $t'$  later, the wave will have progressed to the right without change of form by a distance  $ct'$ , in which  $c$  is the wave velocity. This is the speed of travel of some particular feature of the wave, such as one of the crests. The distance from crest to crest is called the wavelength,  $\lambda$ , and its reciprocal,  $1/\lambda$ , or  $\lambda^{-1}$ , is called the wave number, giving the number of crests found in unit length. The number of crests passing a stationary observer in unit time is called the frequency ( $\nu$ ) and is equal to

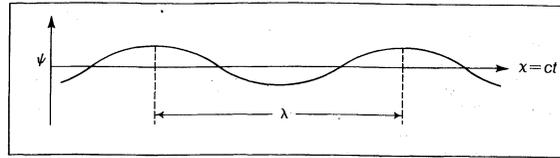

Figure 1: Sinusoidal wave motion at an instant of time  $t$ .  $\Psi$  is a measure of amplitude at any position  $x$  along the curve (see text).

the velocity of the wave (*i.e.*, the crest) times the wave number, or  $\nu = c\lambda^{-1}$ . These relations apply to wave motions of all kinds. In a sound wave,  $\Psi$  is the deviation of the gas pressure from its mean value, and in radio or light waves it is the electric vector,  $E$ , that gives the measure of the electric force exerted by the wave on unit electric charge.

When light from a point source is brought to a focus with a lens of aperture  $A$  as shown in Figure 2 ( $A$  is the angle at the focus subtended by the half-diameter of the lens), the blurred diffraction image gives rise to a positional uncertainty (within the image) of what is commonly regarded as a point image by the amount  $(\lambda/2\pi)/\sin A$ . Thus, to reduce the uncertainty it is desirable to use the shortest wavelength possible and make the lens opening as large as possible. This is done in microscopy by using ultraviolet light instead of visible light and using an objective with a wide aperture. But there is no actual way possible to reduce to zero the blurring of an image. For visible light of the shortest wavelength the uncertainty of position location is necessarily about  $6 \times 10^{-8}$  metre, which is about 600 times the radius of most atoms. Hence visible light is wholly unsuitable for following the details of position changes of electrons within single atoms.

Conditions for accuracy of location

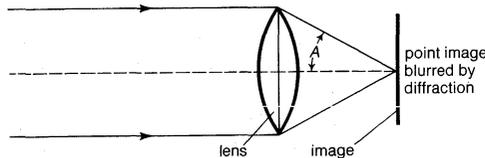

Figure 2: Diffracted image formed by lens of half-diameter  $A$  (see text).

Light has attributes other than those described by regarding it as a wave motion. In interacting with matter (emission, scattering, absorption) it also behaves in some respects like a stream of particles, called light quanta or photons. Each photon carries an amount of energy ( $W$ ) equal to a constant ( $h$ ) times its corresponding frequency ( $\nu$ ), or  $W = h\nu = hc\lambda^{-1}$ , and an amount of momentum ( $p$ ) in the direction of propagation of the light beam, equal to this same constant ( $h$ ) times the wave number, or  $p = h\lambda^{-1}$ . Here  $h$  is called Planck's constant, equal to  $6.625 \times 10^{-34}$  joule second. Planck's constant  $h$  is the fundamental parameter of quantum mechanics, occurring in every quantitative expression relating to quantum phenomena. In the example above it appears in a way that relates the dual aspects of light as a wave motion and as a stream of photons.

When an electron is exposed to a light beam (*i.e.*, stream of photons), there is a fundamental indeterminacy about the light-scattering processes that take place. Some photons go by unaffected. Others are scattered through various angles. Change in direction of motion of a photon so scattered necessarily involves a change in its momentum (Compton effect; see following sections). Because of conservation of momentum, this necessarily involves a change in the momentum of the scattering electron. This alteration occurs in a statistically random way; thus, there is an uncertainty in the electron's momentum after scattering even if there had been none before. This uncertainty in momentum is less with photons of small wave number (long wavelength) observed over a wide range of scattering angles.

Thus, the conditions needed for accuracy in observation of the electron's momentum are in direct conflict with those needed for accuracy in observation of its position.

Importance of knowledge of original positions and velocities

Detailed analysis along these lines shows that the product of the position uncertainty,  $\Delta x$ , and the associated momentum uncertainty,  $\Delta p_x$ , must always be greater than  $h/4\pi$ , and similarly for the other components of position and momentum.

This basic result was first recognized by Heisenberg in 1927. It is known as the Heisenberg uncertainty (or indeterminacy) principle. It provides the fundamental reason why Newtonian mechanics cannot be applied at the atomic level: it is impossible to know both position and momentum with sufficient accuracy at the same time. Thus the Newtonian laws, with their exactly deterministic solutions, must be replaced by different laws of quantum mechanics. These laws of quantum mechanics do not describe detailed orbital motions. They describe alternative possible happenings and give numerical values for the relative probabilities of occurrence of the different alternatives, in much the same way that actuarial tables give the probability of a person's death at each age, without making any assertion about the life span of a particular individual.

#### WAVE-PARTICLE DUALITY

The preceding section considered the dual aspects of the nature of light whereby it exhibits properties of a wave motion in some respects and of a stream of particles (photons) in others. The energy and momentum of photons increase with the frequency so that photons are extremely small for light of long wavelengths, and therefore the wave aspect is most pronounced; photons are large for X-rays and gamma rays, for which wavelength is short, and therefore with these radiations the particle aspect is the more pronounced. In reality, however, both aspects play a role at all frequencies or wavelengths.

Historically this duality was first recognized by Planck in 1900. He was studying the distribution in wavelengths of the radiation from a black body (an ideal solid postulated to absorb all the light falling on it, having zero reflectivity). In colloquial terms this is the problem of quantitatively describing how hot bodies become redder and brighter as their temperature is increased. To explain the observed distribution he had to assume that emission and absorption of radiation occurs in quanta of energy, now called photons, each quantum having an energy ( $W$ ) equal to the constant  $h$  times its frequency, or  $W = h\nu$ . Thus was  $h$ , Planck's constant, first introduced into physics. Planck's reasoning was somewhat complicated, and the concept of quanta was not accepted by physicists at first.

Planck's  
constant

In 1905 Einstein firmly established the photon concept by using it to interpret the photoelectric effect ( $q.v.$ ), which is the ejection of electrons from a metal when illuminated particularly by ultraviolet light or X-rays. He postulated that, when light falls on a metal, the photons are absorbed by individual electrons, giving their energy to them, one by one. Thus the photon energy has to be more than enough to free an electron from the forces binding it to the metal, accounting for the observed fact that light must have more than a threshold frequency to be able to cause emission of electrons. This also accounts for the observed fact that greater intensity of light results in the emission of more electrons, but the energy of each individual electron is not increased with increasing intensity. For this work, not that on the theory of relativity, Einstein received the Nobel Prize for Physics in 1921.

The inverse of the photoelectric effect occurs when X-rays are generated in an X-ray tube. Here a beam of electrons is given energy by applying a high negative voltage (around 10,000 to 1,000,000 volts) to the cathode, a hot filament that emits electrons. These electrons are accelerated toward the anode because of its positive field; they strike and enter the anode, losing their energy in various kinds of collisions with its atoms and electrons, a small fraction of them radiating their energy as X-rays. From the photon view, the maximum energy that could be radiated by an electron would be all that it had gained in the tube. This energy in joules is the product of the voltage ( $V$ ) applied to the tube and the electronic charge

( $e$ ) in coulombs,  $Ve$ . Hence the shortest wavelength ( $\lambda_{min}$ ) of the X-ray photons is given by  $Ve = hc\lambda_{min}^{-1}$ . X-rays of longer wavelength than  $\lambda_{min}$  are also emitted: these come from emission by those electrons that lose part of their energy by other processes before radiating. This short-wave limit of the X-ray spectrum is observed experimentally and accords with what is expected on assuming that X-rays consist of photons.

In 1923 Arthur Holly Compton of the United States studied the scattering of a beam of X-rays by solid matter, using mostly graphite (carbon) because the electrons are less tightly bound to atoms of carbon and other elements with low atomic number than is the case with elements that have medium or high atomic number. Using an incident monochromatic beam of wavelength  $\lambda_0$ , he found that the scattered radiation consists of two wavelengths: unmodified  $\lambda_0$  and modified  $\lambda_1$ , in which  $\lambda_1$  is greater than  $\lambda_0$  by an amount that increases with the angle of scattering  $A$ , as indicated in Figure 3. This indi-

The work  
of A.H.  
Compton

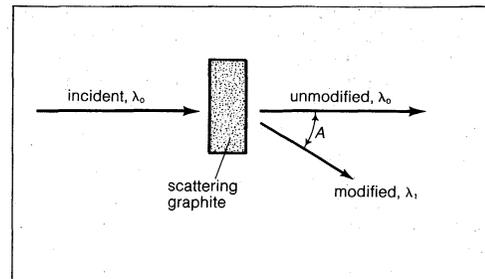

Figure 3: Compton effect in scattering of X-rays. The modified wavelength ( $\lambda_1$ ) is greater than the unmodified ( $\lambda_0$ ) and increases with angle of scattering ( $A$ ).

cates clearly that there are two distinct processes by which X-rays are scattered. The unmodified photons are interpreted as having been scattered by those electrons that are tightly bound to atoms in the graphite. The modified photons are interpreted as arising from the loosely bound electrons, which can be regarded as moving almost freely within the graphite.

To account for the shift of wavelength to larger values and hence to photons of smaller energy, Compton assumed this to be a consequence of the photons having momentum as well as energy, of amount  $p = h\lambda^{-1}$  in their direction of motion. In being scattered through angle  $A$ , the momentum is changed and some of the energy of the scattered photon is transferred to the scattering electron, which recoils because of the momentum given to it. The theory also predicts the direction and speed of the recoil electron for each angle of scattering. These recoil electrons have been studied experimentally and found to have properties expected from the theory.

The photoelectric effect and the Compton effect point to the existence of photons of energy  $W = h\nu$ , and of momentum  $p = h\lambda^{-1}$ . The connecting link between  $W$  and  $p$ , which describe the particle aspect, and  $\nu$  and  $\lambda$ , which describe the wave aspect, is the Planck quantum constant,  $h$ .

#### DE BROGLIE WAVES

In 1924 a suggestion was put forward by de Broglie that the duality shown by light might extend to particles other than photons. In particular, he postulated that the behaviour of electrons is somehow governed by an accompanying wave motion (which later became known as de Broglie waves) of which the wavelength is related to the classical momentum by the same relation,  $p = h\lambda^{-1}$ , that applies to photons.

Because the kinetic energy of an electron accelerated by a voltage  $V$  is  $Ve$ , this postulate gives for the de Broglie wavelength of electrons accelerated through  $V$  the expression

$$\lambda = \frac{h}{\sqrt{2meV}}$$

Substitution of known values for  $h$ ,  $m$ , and  $e$  shows that

an electron for which  $V = 150$  volts has a de Broglie wavelength of  $10^{-10}$  metre, which is of the order of usual X-ray wavelengths and also of the same order as the spacing between atoms in most crystals. This suggested that a beam of electrons when scattered by a crystal would be diffracted by the regularly spaced atoms in the crystal, in much the same way as a German physicist, Max von Laue, observed in 1912 in an experiment that laid the basis for the wave aspect of X-rays and that, as X-ray diffraction, provided a powerful tool for the study of crystallography (*q.v.*). In short, de Broglie's idea led to the prediction of the probable existence of the analogous electron diffraction phenomenon by Walter Elsasser, born in Germany. Experimental proof of the actual existence of electron diffraction by crystals came in 1927.

Subsequently, de Broglie's wave-particle idea was extended to other particles, such as protons, hydrogen and helium atoms, and neutrons, for which diffraction was also found experimentally. The masses of these particles are much greater than that of the electron; so for the same energy their wavelengths are much smaller in fulfilling the basic de Broglie relation,  $\lambda = h/p$ .

In all subsequent work, physicists have regarded all matter as being dually associated with de Broglie waves. For the large bodies of classical mechanics, the wavelengths are too small for their effects to be detectable.

These discoveries confronted physicists with the problem of learning more about these de Broglie waves and of finding the ways in which the waves are related to the particle aspect of the motions that they somehow govern. The solution of this problem, as known today, is the principal content of quantum mechanics.

Principal  
content  
of  
quantum  
mechanics

The revolutionary development of quantum mechanics (of which wave mechanics and matrix mechanics are specialized partial formulations) occurred with breathtaking rapidity in the years 1925–30. It is an essentially mathematical subject that can scarcely be described without using mathematical concepts that are usually unknown to persons whose education is limited to humanistic studies. The far-reaching importance of the results requires, nevertheless, an attempt to give such persons a glimpse of how physicists understand these questions. In doing so some compromise with accuracy must be made: the process is somewhat analogous to an attempt to convey an appreciation of classical literature while making no mention of Greek or Latin and while using only the Anglo-Saxon part of the vocabulary of the English language.

As indicated above, physicists took the radical step of giving up the strict determinism of Newtonian mechanics. Instead they postulated strict deterministic propagation only for the waves involved in the wave aspect of matter. They then introduced a looseness of connection between the waves and the motion of the associated particles, whereby the waves merely tell what may happen among a number of alternatives, together with predictions of the relative probabilities of the various alternatives actually occurring in a particular set of observations.

This loose, or partial, determinism, as contrasted with the strict determinism of classical physics, is now quite generally accepted as fundamental in theoretical physics. But a long struggle preceded this acceptance. The indeterministic probabilistic interpretation is often called the Copenhagen interpretation, because it was largely developed in the school headed by Bohr. This view was not accepted by Einstein, and it has been strongly criticized by experts on quantum theory, notably de Broglie, David Joseph Bohm, and others.

It is important to be clear on the nature of this difference of opinion. Einstein and other critics of the Copenhagen interpretation accept, of course, the positive content of the computational methods of quantum mechanics, including the indeterminisms inherent in present knowledge. Where the two schools differ is in their attitude toward the indeterministic qualities. The Copenhagen view is that these qualities are ultimate and fundamental. The anti-Copenhagen view is that they are evidences of incompleteness of present knowledge that are

likely to be eliminated at some future date by new fundamental discoveries, the nature of which cannot at present be foreseen.

In this sense the dispute is more concerned with feelings about possible future developments in quantum mechanics than with implications of present knowledge. The Copenhagen view leads to seeking detailed knowledge concerning these uncertainties wherever they manifest themselves. The anti-Copenhagen view motivates its adherents to a quest for modifications of present theory so that the elements of strict determinism will be restored.

The following quotation from a 1936 essay by Einstein serves to illustrate his attitude about expectations or preferences in this field. After briefly expounding the orthodox uncertainty principle view, he writes:

But now I ask: Is there really any physicist who believes that we shall never get any inside view of these important alterations in the single systems, in their structure and their causal connections, and this regardless of the fact that these single happenings have been brought so close to us, thanks to the marvelous inventions of the Wilson chamber and the Geiger counter? To believe this is logically possible without contradiction; but it is so very contrary to my scientific instinct that I cannot forego the search for a more complete conception.

This quest for elimination of indeterminacy has been followed diligently but fruitlessly by a minority of physicists for some four decades. Although this failure does not prove the incorrectness of the anti-Copenhagen view, it has tended to make many physicists adhere to the Copenhagen view. If, at some time in the future, discoveries are made that restore strict determinism to quantum mechanics, this will mean a new revolution in physics at least as momentous as that of 1925–30, which introduced indeterminacy into present-day physics.

A possible  
future  
revolution  
in physics

#### BOHR'S THEORY OF ATOMIC SPECTRA

When the light emitted by a gas discharge at low pressure (such as in a neon sign) is analyzed in a spectrograph, it is found to consist of a large number of lines, the frequencies of which can be precisely measured, usually at least to an accuracy of six decimal places. These are called lines because of their appearance in the spectrograph as sharp images of the linear slit in the spectrograph. The ensemble of the lines emitted or absorbed by a particular element, in a particular stage of ionization, is called its spectrum. Thousands of such lines may be involved in the spectrum of each kind of atomic ion, although different elements give rise to spectra of widely differing degrees of complexity. The simplest spectra are those emitted by atomic hydrogen and the alkali elements: lithium, sodium, potassium, rubidium, and cesium.

Experimental study of atomic spectra was well started by 1860, and the first numerical regularities between the frequencies observed were found in the 1880s. Bohr gave the first successful interpretation of atomic spectra in 1913, and the study since of the many lines and their relative intensities has proved by far the richest source of observational material contributing to knowledge of atom structure and guiding the development of quantum mechanics.

Bohr adopted Einstein's idea that light is emitted and absorbed in photons or quanta of energy,  $W = h\nu$ . He also postulated that atoms are capable of existing only in discrete quantized energy levels,  $W_1, W_2, W_3, \dots$ , which are characteristic of the atomic number ( $Z$ , charge on its nucleus) and the total number ( $N$ ) of electrons in the ion, in which  $N = Z$  for the usually neutral atom. He then postulated that a photon of radiation is emitted when an atom makes a transition from a higher initial level,  $W_i$ , to a lower final level,  $W_f$ , the energy difference going into the energy content of the emitted photon, thus giving the relation

$$h\nu = hc\lambda^{-1} = W_i - W_f.$$

An absorption line occurs at the same frequency when an atom picks up a photon to make a transition from a lower energy level to a higher energy level. This picture of the origin of spectral lines is fundamental to all subsequent

developments and applies to spectra of molecules and of nuclei, as well as to that of atoms.

Furthermore, Bohr provided a model of the hydrogen atom in which the single electron, acted on by the electrical (inverse square) attraction of the proton, would go around the proton in circular orbits (later generalized to include elliptic orbits and hyperbolic orbits). According to Newtonian mechanics, orbits of all radii and eccentricities are possible. Bohr had to add a rule of quantization, as an additional postulate, in order to pick out a discrete set of orbits from this continuum of possible orbits to get the discrete energy levels needed to describe the line spectrum of atomic hydrogen.

For the circular orbits he proposed the rule that the orbital angular momentum ( $L$ ) of the electron motion is equal to a number ( $k$ ) of units of  $h/2\pi$ , in which  $h$  is Planck's constant and the angular momentum is equal to the product of the velocity of the electron ( $v$ ) in the circular orbit, its radius ( $r$ ), and its mass ( $m$ ); *i.e.*,

$$L = mvr = k(h/2\pi), \quad k = 1, 2, 3, \dots$$

When elliptic orbits are considered, a slightly more complicated expression for orbital angular momentum is involved, but it is still assumed to be constant and equal to an integral multiple of  $h/2\pi$ . For elliptic orbits, in which the electron moves in and out radially instead of staying always at the same distance from the proton, another rule is needed, as the actual ellipticities are also restricted. This rule introduces another integer,  $n$ , called the principal quantum number, whereas  $k$  is called the azimuthal quantum number. In general, each integer (sometimes half an odd integer) that occurs in labelling a quantum level, which represents a distinctive energy state, is called a quantum number.

Spectral series

The most conspicuous feature in the visible spectrum of hydrogen is the Balmer series, a series of lines that a Swiss physicist, Johann Jakob Balmer, represented by a simple empirical formula as early as 1885,

$$\lambda_n^{-1} = R \left( \frac{1}{2^2} - \frac{1}{n^2} \right), \quad n = 3, 4, 5, \dots,$$

in which  $R$  is called the Rydberg constant and has the observed value of 109,677 waves per centimetre. The observed wave numbers of the Balmer lines agree to high accuracy with the Balmer formula on supposing that these arise from transitions from higher states down to the final  $n = 2$  state. From Bohr's theory one would expect another series of lines lying in the deep ultraviolet, which were not known at the time but were soon found by a United States physicist, Theodore Lyman, and are now known as the Lyman series. These lines correspond to transitions to the final  $n = 1$  state. Similarly, other series of lines corresponding to transitions to final  $n = 3, 4, 5$  states from higher levels lie in the infrared. They too were found experimentally within a few years under the stimulus provided by Bohr's ideas. The various lines of the spectrum of the one-electron ions with  $Z$  greater than unity lie in the deep ultraviolet. These too were soon studied and found to agree with Bohr's theory.

Ordinarily in a gas at room temperature all the atoms are in their state of least energy, called the ground state, or normal state, and therefore cannot radiate, as this would require transitions to still lower levels. When a gas is excited to radiate, this is usually done by having free electrons accelerated in the gas so that they gain enough energy to put the atoms into excited states by collisional exchange of energy. Many experiments were performed to verify the quantum nature of this energy exchange of electrons with atoms in gases, largely under the leadership of the German physicists James Franck and Gustav Ludwig Hertz. This provided a valuable additional triumph for Bohr's ideas, as well as a new tool for the experimental study of atomic structure.

Immediately after the end of World War I, there followed a tumultuous period of extending Bohr's hydrogen theory to other atoms, which brought forth successes and difficulties, and was the principal activity of physicists in the early 1920s.

Bohr's rule of quantization for the circular orbits can be

stated in another way in terms of de Broglie waves, as de Broglie recognized in 1924. For the  $k$ th orbit the relation  $mvr_k = k(h/2\pi)$  can be rewritten

$$2\pi r_k = k(h/mv_k), \quad k = 1, 2, 3, \dots$$

In this form it is recognized as the requirement that the circumference ( $2\pi r$ ) of the allowed orbit be such as to contain an integer ( $k$ ) number of de Broglie wavelengths, ( $h/mv_k$ ).

In this form the rule is suggestive of the kinds of relations involving integers that occur in musical instruments in which vibrations of stretched strings (violin, guitar, etc.) or vibrations of air columns in tubes (flute, clarinet, etc.) are involved. On an indefinitely long stretched string it is possible to have travelling waves of any frequency. But, when the two ends are stopped, as in a violin, the wave is reflected at each end to give a standing wave, and these two waves must be of such a frequency that the length ( $L$ ) of the string between stops is exactly equal to an integer multiple of half wavelengths for the allowed frequencies. This gives the relation,

$$L = m(\lambda_m/2), \quad m = 1, 2, 3, \dots,$$

in which  $m = 1$  is called the fundamental mode of the string, and higher values of  $m$  are called harmonics. More complicated analysis is needed to describe the modes of vibration of a vibrating drumhead, but this case also resembles the stretched string in that there is a discrete set of allowed vibrational patterns that are distinguished by integer labels like the quantum numbers of the Bohr theory.

#### SCHRODINGER'S WAVE MECHANICS

This analogy with acoustic devices led Schrödinger in 1926 to carry the de Broglie wave idea much further than de Broglie had done. Schrödinger postulated the existence of a wave amplitude,  $\Psi(x,y,z,t)$ , varying with position and time for the de Broglie wave associated with a single moving particle. His next task was to postulate a suitable partial differential equation governing  $\Psi$ , reasoning by analogy with the earlier (19th-century) work on the mathematics of wave motion.

Wave amplitude

This procedure has a certain analogy with what had happened earlier in the development of optics. At first, light was supposed to travel in paths given by geometrical optics. Then wave theory was substituted to give a more accurate account of the actual distribution of light intensity as influenced by interference and diffraction. Similarly here, Schrödinger supposed that the motion as given by Newtonian equations is an approximation analogous to that of geometrical optics, to be supplanted by a wave theory of higher accuracy, for the motion of the represented particle.

Most wave theory as it had been developed up to that time was restricted to the case of homogeneous media, in which the wavelength remains the same from point to point, except for the abrupt changes that take place at the boundary between two different homogeneous materials. When a particle moves classically in a force field, its momentum is continually changing, and therefore the de Broglie wavelength changes with position; so the forms of wave propagation involved in such problems as the wave version of the hydrogen atom and others are mathematically more complicated than the cases usually treated in acoustics or wave optics.

For a single particle of mass  $m$ , moving under forces such that its potential energy is  $V(x,y,z)$  at location  $(x,y,z)$ , the relation from classical mechanics between the kinetic energy (equal to  $p^2/2m$ , in which  $p$  is momentum), the potential energy, and the total energy ( $W$ ) is

$$\frac{p^2}{2m} + V(x,y,z) = W.$$

Because kinetic energy is essentially positive, this equation indicates that the particle's motion is confined within a region of space in which  $V(x,y,z)$  is less than the total energy,  $W$ . Schrödinger postulated that this relation could be used to give the value of momentum  $p$  and hence of de Broglie's wavelength  $\lambda = h/p$  at each point in

space, and he used this expression for  $\lambda$  varying with position in an equation for the wave amplitude that was known from classical acoustics.

The result is called Schrödinger's equation and can be written in the following form:

$$-\frac{(h/2\pi)^2}{2m}\left(\frac{\partial^2\Psi}{\partial x^2} + \frac{\partial^2\Psi}{\partial y^2} + \frac{\partial^2\Psi}{\partial z^2}\right) + V\Psi = W\Psi.$$

The properties of this equation are fully discussed in books on quantum mechanics. Here it must suffice to say that in certain cases, with regard to choice of potential energy  $V$ , the equation has solutions for only certain discrete values of the total energy  $W$ . This happens whenever the region of space in which  $V$  is less than  $W$  is finite so that the waves are confined to a finite region, as they are, for example, with a violin string or a vibrating drum-head. The general character of the solution for the amplitude, or wave function,  $\Psi$ , is that it is oscillatory (but more complicated than sinusoidal) inside the region where  $W$  is greater than  $V$  but dies off rapidly (but not abruptly) at places outside this region. Schrödinger postulated that this new procedure gives the allowed energy levels and that the  $\Psi$  associated with any one of the allowed values of  $W$  provides the new wave mechanical description of the particle's orbital motion when it has that energy. This rule replaces the old Bohr rule for quantization of the classical mechanical orbits. The quantized classical orbits of Bohr now are regarded as a historical stepping-stone to the more accurate methods of wave mechanics.

In the hydrogenic atoms (a single electron outside a closed or completed electron shell), the potential energy is a function only of  $r$ , the distance of the electron from the nucleus, varying as the inverse first power because the force varies as the inverse square of the distance. The problem therefore has spherical symmetry with

$$V(r) = -Ze^2/r.$$

The solutions of the wave equation of Schrödinger correspond to the values of the total energy ( $W$ ) derived by Bohr and require three quantum numbers ( $n, l, m$ ) for their specification, in which  $n$  is the total quantum number introduced above. Here  $l = k - 1$  of the Bohr theory and is the measure of resultant orbital angular momentum of the state in units of  $h/2\pi$ , whereas  $m$  in the same unit gives the  $z$  component of the angular momentum. Two angles ( $\theta, \phi$ ) are used to specify the direction in space of the line from nucleus to electron. The wave function has the form of a product of a radial function  $P_{nl}(r)/r$  multiplying into a set of functions  $Y_{lm}(\theta, \phi)$  that specify the dependence of the wave function on direction. These angular functions are called spherical harmonics and occur in nearly all problems of classical mathematical physics that have spherical symmetry.

Schrödinger first supposed that the electron is actually spread out and distributed in space in such a way that the square of the wave function ( $\Psi^2$ ) in his equation gives the fractional density of the total at the place for which it is calculated. This view soon proved untenable and was replaced by Max Born's interpretation, now generally accepted, that  $\Psi^2$  gives the probability of finding the electron in unit volume, the electron itself remaining a tiny charge that is itself much smaller in extent than the region of space over which there is a reasonable probability of finding it. Because of this probability interpretation, the wave function,  $\Psi$ , is often called the probability amplitude. Because of the dependence of the quantity  $\Psi^2$  on the angles  $\theta$  and  $\phi$ , the location of an electron with respect to the nucleus in a hydrogen-like atom is equally probable in any direction only when it is in the quantum state  $l = 0$ . If the atom changes to other values of  $l$ , the probability pattern may take the form of rings, multiple lobes, etc., and thus this atom would not have the simple appearance of a sphere.

Study of the fine structure of atomic spectral lines finally led in 1925 to the realization that an electron requires another coordinate for the description of its motion. This was called spin and can be visualized by supposing that each electron rotates on its axis with an amount

$\frac{1}{2}(h/2\pi)$  of spin angular momentum, which is capable of being oriented either parallel or antiparallel to any direction in space. This discovery was made in The Netherlands by physicists George Uhlenbeck and Samuel Abraham Goudsmit as the culmination of a long and confusing period of study of fine structure by many physicists. Introduction of the spin brings with it the need for the introduction of a fourth quantum number,  $m_s$ , which is restricted to the two values  $\pm \frac{1}{2}$ , so that with a given  $nl$  the number of distinct quantum states is  $2(2l + 1)$ .

For an atom consisting of several, say  $N$ , electrons, the wave function  $\Psi$  becomes a function of the locations and spin of each of them, hence it depends on  $3N$  positional coordinates and  $N$  spin coordinates. In an analogous way, the classical potential energy ( $V$ ), which appears in the Schrödinger equation to represent the electric interactions, becomes a function of all  $3N$  positional coordinates. Likewise, there have to be  $N$  terms, such as the first term in the wave equation representing one particle, to represent the sum of the kinetic energies of each of the electrons.

The resulting wave equation is too complicated to be solved exactly, even for the very next case,  $N = 2$ , the helium-like atoms and ions. (This is also true of those equations governing the planetary orbits in celestial mechanics.) A large part of the subject is therefore concerned with finding techniques for obtaining approximate solutions of such complicated wave equations. Such methods go by the general name of perturbation theory. An attempt is first made to discover a problem that resembles but is simpler than the more complicated one and one that can be solved exactly. Using this simpler solution as a starting point, an attempt is then made to estimate quantitatively the difference between the allowed levels and wave functions of the actual problem and the simpler problem. Most of the actual results that are obtained in quantum mechanics are obtained in this manner, since the relevant problems that can be exactly solved are relatively few in number.

The theory of atomic structure is entirely based on a special case of perturbation theory known as the central field approximation. Each electron in an atom is attracted to the nucleus of charge  $Ze$  in a way described by a potential energy term  $-Ze^2/r$  in which  $r$  is the distance from the electron to the nucleus. Each electron is also repelled by the other  $N - 1$  electrons. These are distributed in a nearly spherically symmetric way around the nucleus. As a result, the repulsion also acts approximately as a central field. The part of the  $N - 1$  electrons at greater distance than  $r$  do not give rise to a net repulsion; so the screening, or weakening, of the nuclear attraction by the presence of the part closer than  $r$  can be taken into account by supposing each electron to be acted on by a central field of the form  $V(r) = -Z(r)e^2/r$ , in which  $Z(r) = Z$  very close to the nucleus and decreases to  $Z(r) = Z - N + 1$ —that is, to 1 for neutral atoms—at distances outside the radius of a sphere in which the  $(N - 1)$  electrons are almost certain to be found. Figure 4 gives as an example some calculated curves of how the effective field decreases for various values of  $Z$  as the distance  $r$  increases. A log-log plot is used in which the logarithm of  $Z(r)$  is the ordinate and the logarithm of  $(r/a)$  the abscissa,  $a$  being the Bohr radius as already defined. These curves were calculated for neutral atoms by what is known as the Thomas-Fermi method and illustrate how the central field  $Z(r)$  decreases to its limiting value of unity in every case for  $r = 3a$ . For large  $Z(r)$ , the more tightly bound are the electrons, especially those of smaller values of the principal quantum number  $n$ . Another effect of the departure from the inverse-square law of effective central force is that now the energy depends on  $l$  as well as on  $n$  by an amount that increases as the atomic number  $Z$  increases, as shown in Figure 5.

The dependence of the effective field  $Z(r)$  on  $r$  is a consequence of the radial distribution of density of the electrons, which in turn is a consequence of the way in which  $Z(r)$  depends on  $r$ ; thus, ways of calculation of  $Z(r)$  have to be devised that are self-consistent, which

Spin  
quantum  
number

Schrödinger's  
equation

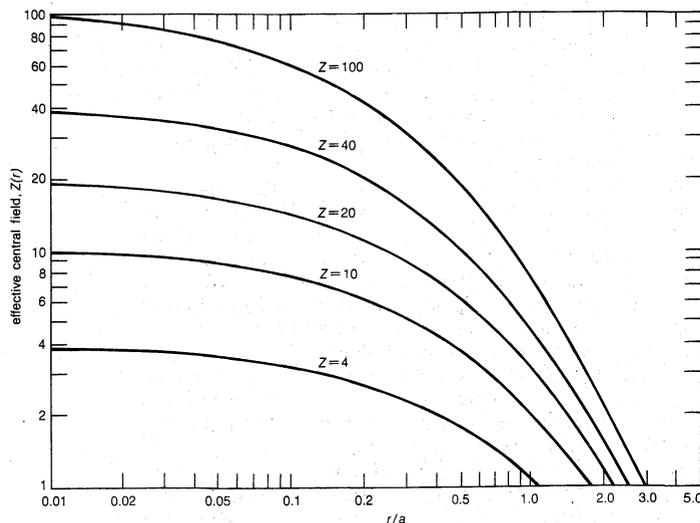

Figure 4: Log-log plot showing variation with  $r/a$  (ratio of separation to Bohr radius) of the effective central field  $Z(r)$  in neutral atoms having various values of  $Z$ .

Radial wave functions means that the  $Z(r)$  leads to radial wave functions that give a density distribution that is consistent with the assumed  $Z(r)$ .

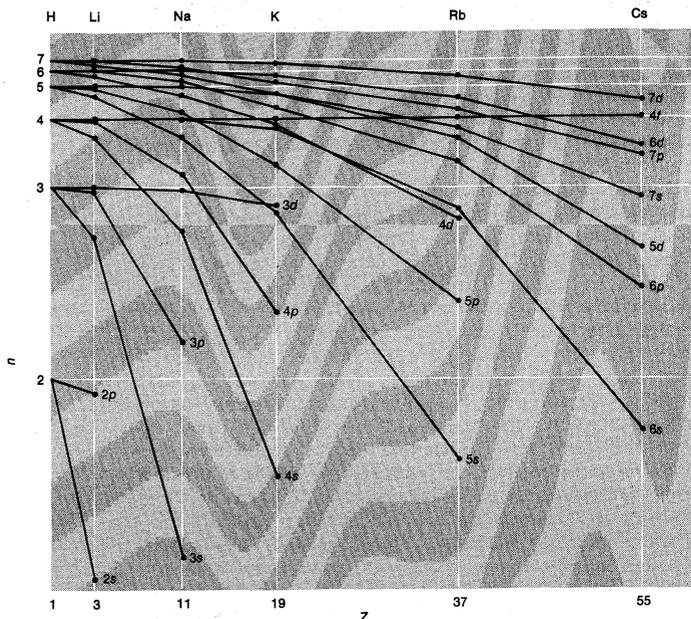

Figure 5: Some observed energy levels (indicated by circles) in hydrogen and in the alkali metals, showing the increasing dependence of  $W_{nl}$  on  $l$  as  $Z$  increases and as the effective central field departs more strongly from the Coulomb field. (The  $W_{1s}$ , not shown, is four times that of  $W_{2s}$ .) Total quantum numbers  $n$  are shown on the ordinate.

Because each electron requires four quantum numbers ( $n, l, m, m_s$ ) to specify its state, an atom or ion containing  $N$  electrons requires  $N$  such sets of four quantum numbers to specify the quantized state of the  $N$  electron system. Starting with a bare nucleus, the electrons are successively captured into the lowest available energy state that determines the quantum numbers of the  $N$  electrons in the normal or ground state.

#### PAULI EXCLUSION PRINCIPLE

Wolfgang Pauli, an Austrian physicist, discovered in 1924 the rule that governs the states that are available to be filled in adding electrons to a nucleus. It is known as the Pauli exclusion principle. At first it was found as an empirical rule; later it was found to be a consequence of the then newly discovered principles of quantum mechanics. The Pauli principle may be stated as the rule that no

two of the  $N$  sets of four quantum numbers can be fully alike. Here the rule is discussed in relation to the isolated atoms of elements. It also plays a role of great importance in controlling the behaviour of electrons in molecules, and hence the energy of chemical bonds, as well as controlling the behaviour of electrons in solid bodies, particularly determining whether the solid in question is a metal, semiconductor, or insulator. (For details of how the exclusion principle is used to build up the periodic system of the elements, see PERIODIC LAW; ATOMIC STRUCTURE; and SPECTROSCOPY, PRINCIPLES OF.)

The basis for the Pauli principle in quantum mechanics is a property of the Schrödinger equation called equivalence degeneracy. This is a consequence of the fact that each of the  $N$  electrons in the atom is exactly alike with respect to mass, charge, and other basic attributes. Therefore, the Schrödinger equation is unaltered by permuting any two of the electrons, say the  $i$ th and the  $j$ th. Consequently, the  $N$  sets of different one-electron quantum numbers can be assigned to the  $N$  electrons in any one of  $N!$  (e.g., if  $N = 4$ ,  $N! = 4 \times 3 \times 2 \times 1 = 24$ ) permuted orders. The wave functions resulting from various linear combinations of the wave functions in different permutations are also solutions of the Schrödinger equation. Among these possibilities there is always one that is totally antisymmetric, which means that it reverses sign everywhere if any two electron indices in the equation are interchanged. Such a wave function vanishes identically when any of the two individual sets of four quantum numbers are alike, and so the empirical fact that Pauli's principle holds indicates that it is the totally antisymmetric wave function that occurs for systems of electrons.

Particles for which the wave function must be totally antisymmetric in the several coordinates are called fermions and are said to obey the Fermi-Dirac statistics (that is, the particles obey the Pauli exclusion principle, which means that no two particles may be in the same energy state). In addition to electrons, the protons and neutrons of which nuclei are composed are also known to be fermions.

## II. Applications of quantum mechanics

### MOLECULAR STRUCTURE

Molecules emit and absorb light by transitions between quantized energy levels to give spectra that are vastly more complicated than those of atoms. When interpreted, these complicated spectra give a great deal of quantitative information about the way in which electrons are shared between atoms to form the chemical bonds by which molecules are held together. This application of quantum mechanics has revolutionized the science of chemistry in the past half century, giving rise to a new borderline science known as chemical physics (see MOLECULAR STRUCTURE; CHEMICAL BONDING).

The richness of molecular spectra arises from the fact that, in addition to possessing quantized electronic energy levels, the molecule as a whole may have quantized amounts of rotational and vibrational motion. Changes in these can occur simultaneously with (or without) changes in the electronic state to give many hundreds of lines associated with a single electronic change. From their spacing it is possible to learn exact distances between atoms in a molecule and also the forces that develop when a chemical bond is stretched and that govern the modes of vibration (see SPECTROSCOPY, PRINCIPLES OF).

The possibility of an analysis in which rotation and vibration of the molecule as a whole are treated somewhat separately from the theory of the electronic states owes its validity to the fact that the masses of the nuclei are thousands of times greater than the mass of each electron. This permits a treatment (known as the Born-Oppenheimer approximation after Max Born and J. Robert Oppenheimer) in which it is first assumed that the nuclei do not move at all. The electronic energy levels of such a system are then found to depend on the assumed distances of separation of the nuclei. The variation with nuclear coordinates of the electronic energy (including electric repulsion of the nuclei) then can be used as the

potential energy function that determines the equilibrium size and shape of the molecule, and hence its rotational energy levels, and also its modes of vibration about this equilibrium shape. The guiding idea here is that the nuclei in fact move so slowly compared to the electrons in a molecule that in the first approximation the dynamical effects of their actual motion can be neglected in analyzing the electronic states.

Thus the problem of molecular structure is effectively separated into two parts: (1) the study of electronic states for quasi-stationary nuclei and (2) the study of the slow nuclear motions that arise from the variations in the energy of the electronic states due to nuclear motions.

The one-electron wave functions of isolated atoms are often called atomic orbitals. As two or more atoms approach each other so closely that there is appreciable "overlap" (a condition in which orbitals of different atoms have appreciable values in a region of space close to both of them), the atomic orbitals become distorted into forms called molecular orbitals. This distortion results from the fact that under these conditions the outer electrons formerly belonging distinctly to a particular atom come under the influence of more than one nucleus and its attendant electrons, thereby affecting, through the Schrödinger equation, the distribution in space of the wave amplitude and also the associated electronic energy level.

The computations involved in using quantum mechanics for molecular structure problems are exceedingly complex. Much use is made of automatic digital computers. But even so, in many cases the results so far have been only semi-quantitative. Nevertheless, the overall result has been to give a theoretical framework for the correlation of many of the known facts of chemistry.

#### NUCLEAR STRUCTURE AND PARTICLE PHYSICS

Nuclear physics as a major discipline is treated more fully elsewhere (see NUCLEUS, ATOMIC); here, only the major connections with quantum mechanics are outlined. Atomic nuclei have radii about  $\frac{1}{10,000}$  of the radii of the atomic orbitals of the electrons—that is, about  $10^{-15}$  metre. Nuclear binding energies are of the order of 1,000,000 times greater than those of the outer atomic electrons. Accurate mass measurements show that the masses of compound nuclei are less than the sum of the masses of the nucleons of which they are composed. This result provided the first direct experimental support for Einstein's famous mass equivalence relation ( $E = mc^2$ ).

The first major application of quantum mechanics to the nucleus was the barrier leakage interpretation of the natural radioactive decay of those elements that emit alpha particles or helium nuclei. This was done in 1928 independently by physicists George Gamow in Germany and R.W. Gurney and Edward Condon in the United States. The theory used a mathematical property of the Schrödinger equation that had been first noticed a few months earlier by Oppenheimer.

In the disintegration of uranium-238, for example, the alpha particle, a helium-4 nucleus, is emitted with a kinetic energy of 4.25 MeV (million electron volts). The instant at which a particular nucleus disintegrates is apparently a matter of pure chance, the statistical disintegration rate in this case being exceedingly slow. Of a given quantity of uranium only half of it disintegrates in  $4.5 \times 10^9$  years.

The fact that an alpha particle can remain in the uranium nucleus for  $10^9$  years shows that when inside it is attracted by strong forces that are effective only over a distance comparable in size to that of the nuclear radius. When the alpha particle is just outside what was the parent uranium-238 nucleus, its two positive charges are strongly repelled by the 90 positive charges in the resulting daughter nucleus, thorium-234. The emitted alpha particle gains its kinetic energy by the action of this electric repulsion. Thus the alpha particle can be inside the nucleus or outside, the two regions being separated by a potential wall. It cannot be inside, according to classical mechanics, for to be there its kinetic energy would have to be negative; in quantum mechanics, however, the de

Broglie waves have a small and calculable probability of penetrating such a barrier, which is totally impenetrable in classical mechanics. Calculations based on this property gave at once (1928) a quantitative understanding of the rate of decay of  $\alpha$ -emitters. It also served at that time greatly to strengthen faith in the then new probability interpretation of  $\Psi^2$ .

Nuclear physics really came into being with a momentous series of discoveries all made in 1932. These were (1) the discovery of the neutron, leading to the realization that nuclei are compounds of protons and neutrons; (2) the discovery of deuterium, or heavy hydrogen, whose nucleus is the simplest compound nucleus, a binary compound of one proton and one neutron; (3) the discovery of the positron, a particle having positive charge numerically equal to the negative charge of the electron and the same mass as the electron; and (4) the production of nuclear transmutations in copious quantities by using artificially accelerated protons.

In 1935 a Japanese physicist, Hideki Yukawa, showed that neutrons and protons, or nucleons, are held together by a newly conceived kind of interaction, called the strong interaction because the force is much stronger than the electrical repulsions between protons at distances corresponding to nuclear radii. These interactions are short-range in character, the forces falling to zero rapidly when the nucleons are separated by distances greater than usual nuclear radii. Among the central problems of nuclear physics in the past three decades have been the devising of theory and experiments for determining the quantitative details of the strong interaction and applying quantum mechanics to the construction of models for all of the observed nuclei.

Nucleons, like electrons, have individual spin angular momenta of  $\hbar/4\pi$  and also require the use of antisymmetric wave functions, and hence there exists in nuclei a controlling influence that is analogous to the Pauli exclusion principle in the outer electronic structure.

Development of nuclear models proved to be much more difficult than the corresponding theory of the outer electronic structure of atoms because of the initial lack of knowledge about the nature of the strong interaction.

Of particular importance was the discovery in 1937 of charge-independence of strong interaction. According to this, the proton-proton, proton-neutron, and neutron-neutron strong interactions are nearly, if not exactly, equal. This not only introduces a great simplification into calculations of nuclear structure but also serves to strengthen the view, which had been suspected earlier, that proton and neutron are different quantum states of a single basic particle, the nucleon. In addition to its three position and one spin coordinates, it is convenient to introduce a fifth coordinate, called isospin, which tells whether the nucleon is in a proton state or in a neutron state. This view, that various seemingly different elementary particles correspond to different quantum states of some other particle, has played an increasingly important role in particle physics in the past two decades.

This view of interconvertibility of proton and neutron found its first fruitful application in the theory of beta radioactivity as developed in 1934, principally by Fermi. When a radioactive atom emits a high-energy electron or positron, the emitted particle must have been created in the emission process, because there are strong grounds for believing that there can be no electrons or positrons in nuclei. This process is analogous to the creation of the emitted photon when light is emitted in radiative transitions, there being no preformed photons in the atom waiting to be emitted. In beta decay, one electronic charge is emitted, and, as total charge is conserved, this is accompanied by the change within the nucleus of one nucleon from the neutron state to the proton state. Conversely, emission of a positron involves the change in the nucleus of one nucleon from a proton state to a neutron state. The total nucleon number  $A$  is unchanged in these processes. With electron emission atomic number  $Z$  changes to  $Z + 1$ , and with positron emission  $Z$  changes to  $Z - 1$ . Writing  $P$  and  $N$ , respectively, for a nucleon in a proton or neutron state, the changes could be written

Barrier  
penetration

Orbitals

As the changed nucleon is part of a compound nucleus, the energy change involved in these transformations is that of the entire nucleus of which the nucleon is a part.

If this were a correct formulation, then the emitted electron or positron, respectively, would come out with a definitely calculable amount of kinetic energy, the energy equivalent of the mass difference of the parent and daughter nuclei involved in the change. It had long been known, however, especially from studies on the naturally beta-active elements, that the emitted electrons are ejected with a broad continuous distribution of kinetic energies, in seeming violation of the principle of conservation of energy. This difficulty was resolved by Pauli in 1933 with the suggestion that the total available energy is divided between two emitted particles, so the preceding equations become

in which  $\nu$  and  $\nu'$  symbolize the new particles that elude detection in the experiments carried out in the usual way. To account for the fact that the new particles, called neutrinos by Fermi, escape detection, they have to be without charge and without rest mass and thus able to pass through solid matter for great distances without interaction.

In 1934 Fermi took the neutrino idea and developed a quantum mechanical theory of beta decay based on it. This used some relatively new mathematical methods for treating processes of creation and destruction of new particles in quantum transitions. This led to the discovery of mathematical forms for processes, now called weak interaction, that describe the overall rate at which beta decay occurs and details concerning the way in which the total available energy is statistically distributed between the emitted particles.

All subsequent work on beta decay is based on extensions of the general pattern of Fermi's theory. The neutrino hypothesis has been experimentally confirmed in many ways, such as measurement of the recoil of the decaying nuclei, detection of the momentum carried off by the elusive neutrino, and direct detection of the neutrinos themselves.

Development of these ideas has opened up a large field of study concerned with the nature of the weak interaction. Whether or not weak interaction is fundamentally connected with the strong interaction between nucleons, in the sense that the existence of one quantity implies the existence of another, remains an open question.

#### OTHER APPLICATIONS

Allusion only is made here to some other topics of great importance in which quantum mechanics plays a role in modern physics but that cannot be treated because of space limitations.

Going beyond the application of quantum mechanics to molecular structure is its application to the theory of matter in the solid state. It is concerned, among other things, with the forces that determine crystal structure, the behaviour of electrons in states that permit motion over large distances in a crystal (metals and semiconductors), and the physical factors that determine magnetic properties. Also of great importance is the quantum mechanical treatment of special interactions of electrons in those metals that give rise to superconductivity.

Quantum mechanics has also been widely applied to the study of electron-atom collision processes; that is, of the details of the mechanisms by which an electron colliding with an atom can raise it to an excited quantum level or even knock free one or more of its electrons (ionization). Atom-atom and molecule-molecule collisions are treated by the quantum mechanics of collision processes to investigate ways in which atoms and molecules dissociate and re-form and the elementary processes that determine the rate at which chemical reactions occur (chemical kinetics).

Quantum mechanical collision theory also finds a wide range of important applications in the analogous treatment of nuclear reactions in which compound nuclei are transformed. Further applications occur in the description of the processes by which electron-positron pairs are created and annihilated and the many analogous processes involving the creation of mesons and strange particles that are studied in high-energy physics.

Another major development is that of quantum electrodynamics. Initially it was assumed that the electromagnetic field could be handled mainly by the classical methods of the British physicist-chemist James Clerk Maxwell. But it was soon realized (initially by Dirac in 1926) that the equations of the electromagnetic field must be reformulated to take explicit account of quantum phenomena. This has led to some important corrections to energy levels not covered by the ordinary treatment and confirmed by experimental observation (Lamb-Retherford shift; see ELECTRON).

Among the most important practical consequences of quantum electrodynamics has been the development of lasers, which permit the generation and study of beams of coherent light. In these, light beams are produced that are millions of times more intense than with any previously known light source. This is a consequence of a feature, first noted by Einstein in 1917, whereby atoms that are exposed to a coherent light beam are stimulated to emission at a greater rate than that of their spontaneous emission. Production of such intense light beams has opened up a large field of study of new optical properties of matter that are manifested when such intense beams go through it (see LASER AND MASER).

**BIBLIOGRAPHY.** For a general descriptive survey, VICTOR GUILLEMIN, *The Story of Quantum Mechanics* (1968), is recommended. Also relatively non-mathematical are WERNER HEISENBERG, *Die physikalischen Prinzipien der Quantentheorie* (1930; Eng. trans., *The Physical Principles of Quantum Theory*, 1930) and *Physics and Philosophy* (1958); HANS REICHENBACH, *Philosophic Foundations of Quantum Mechanics* (1944); and STEPHAN KORNER (ed.), *Observation and Interpretation: A Symposium of Philosophers and Physicists* (1957). Good elementary texts that are more mathematical than this article are V.B. ROJANSKY, *Introductory Quantum Mechanics* (1938); and DAVID BOHM, *Quantum Theory* (1951). More advanced works are P.A.M. DIRAC, *The Principles of Quantum Mechanics*, 4th ed. (1958); and L.D. LANDAU and E.M. LIFSHITZ, *Quantum Mechanics: Nonrelativistic Theory*, 2nd ed. (1965). On the historical side, MAX JAMMER, *The Conceptual Development of Quantum Mechanics* (1966); and TED BASTIN (ed.), *Quantum Theory and Beyond* (1971), are recommended. A relatively elementary introduction to the applications to atomic and molecular structure is UGO and L. FANO, *Basic Physics of Atoms and Molecules* (1959). Basic works on the more advanced phases are E.U. CONDON and G.H. SHORTLEY, *The Theory of Atomic Spectra* (1935); J.C. SLATER, *The Quantum Theory of Atomic Structure*, 2 vol. (1960); C.A. COULSON, *Valence*, 2nd ed. (1961); and LINUS PAULING, *The Nature of the Chemical Bond, and the Structure of Molecules and Crystals*, 3rd ed. (1960). A good general work on application to nuclear structure is R.D. EVANS, *The Atomic Nucleus* (1955). More specialized in this field are M.G. MAYER and J.H.D. JENSEN, *Elementary Theory of Nuclear Shell Structure* (1955); and B.L. COHEN, *Concepts of Nuclear Physics* (1971).

(E.U.C.)

## Mechanoreception

Sensitivity to mechanical stimuli is a common endowment among animals. In addition to mediating the sense of touch, mechanoreception is the function of a number of specialized sense organs, some found only in particular groups of animals. Thus, some mechanoreceptors act to inform the animal of changes in bodily posture, others help detect painful stimuli, and still others serve the sense of hearing (see SOUND RECEPTION).

Slight deformation of any mechanoreceptive nerve cell ending results in electrical changes, called receptor or generator potentials, at the outer surface of the cell; this, in turn, induces the appearance of impulses ("spikes") in the associated nerve fibre. Laboratory devices such as the cathode-ray oscilloscope are used to record and to observe these electrical events in the study of mechano-

The  
neutrino  
hypothesis

Quantum  
electro-  
dynamics

receptors. Beyond this electrophysiological approach, mechanoreceptive functions are also investigated more indirectly—*i.e.*, on the basis of behavioral responses to mechanical stimuli. These responses include bodily movements (*e.g.*, locomotion), changes in respiration or heart-beat, glandular activity, skin-colour changes, and (in the case of man) verbal reports of mechanoreceptive sensations. The behavioral method sometimes is combined with partial or total surgical elimination of the sense organs involved. Not all the electrophysiologically effective mechanical stimuli evoke a behavioral response; the central nervous system (brain and spinal cord) acts to screen or to select nerve impulses from receptor neurons.

Man experiences sharp, localized pain as a result of stimulation of "pain spots" (probably free nerve endings) in the skin, and dull pain, usually difficult to localize, associated with inner organs. The sensory structures of pain spots in the skin differ from other receptors in that they respond to a wide range of harmful (noxious or nociceptive) stimuli. Excessive stimulation of any kind (*e.g.*, mechanical, thermal, or chemical) may produce the human experience of pain. Apart from eliciting this subjective feeling of pain, stimulation of pain receptors in the human skin is objectively characterized by such signs of emotional expression as weeping and by efforts to withdraw from the stimulus. The reflex withdrawal of his hand from a burning stimulus may begin even before the person becomes conscious of the pain sensation (see PAIN, THEORIES OF).

Experience of pain in animals

Judging from objective criteria, responses to painful stimuli also occur in nonhuman animals, but, of course, any subjective experience of pain sensation cannot be directly reported. Still, the question of painful experience among animals is of considerable interest because investigators (*e.g.*, medical researchers) are often obliged to subject laboratory animals to treatments that would elicit complaints of pain from a man. If a cat's tail is accidentally stepped on, the pitiful screeching and efforts to withdraw are so strikingly similar to human reactions that the observer is led to attribute the experience of pain to the animal. If one treads accidentally on an earthworm and observes the animal's apparently desperate struggles to get free, he might again be inclined to suppose that the worm feels pain. This sort of "mind reading," however, is inherently uncertain and may be grossly misleading.

The following observations illustrate some of the difficulties in making judgments of the inner experiences of creatures other than man. After the spinal cord of a fish has been cut, the front part of the animal may respond to gentle touch with lively movements, whereas the trunk, the part behind the incision, remains motionless. A light touch to the back part elicits slight movements of the body or fins behind the cut, but the head does not respond. A more intense ("painful") stimulus, however (for instance, pinching of the tail fin), makes the trunk perform "agonized" contortions, whereas the front part again remains calm. To attribute pain sensation to the "painfully" writhing (but neurally isolated) rear end of a fish would fly in the face of evidence that persons with similarly severed spinal cords report absolutely no feeling (pain, pressure, or whatever) below the point at which their cords were cut.

Aversive responses to noxious stimuli nevertheless have a major adaptive role in avoiding bodily injury. Without them, the animal may even become a predator against itself; bats and rats, for instance, chew on their own feet when their limbs are made insensitive by nerve cutting. Some insects normally show no signs of painful experience at all. A dragonfly, for example, may eat much of its own abdomen if its tail end is brought into the mouthparts. Removal of part of the abdomen of a honeybee does not stop the animal's feeding. If the head of a blow fly (*Phormia*) is cut off, it nevertheless stretches its tubular feeding organ (proboscis) and begins to suck if its chemoreceptors (labellae) are brought in touch with a sugar solution; the ingested solution simply flows out at the severed neck.

At any rate, responsiveness to mechanical deformation is a basic property of living matter; even a one-celled organism such as an amoeba shows withdrawal responses to touch. The evolutionary course of mechanoreception in the development of such complex functions as gravity detection and sound-wave reception leaves much room for speculation and scholarly disagreement.

#### RECEPTION OF EXTERNAL MECHANICAL STIMULI

**The sense of touch.** Sensitivity to direct tactual stimulation—*i.e.*, to contact with relatively solid objects (tangoreception)—is found quite generally, from one-celled organisms up to and including man. Usually the whole body surface is tangoreceptive, except for parts covered by thick, rigid shells (as in mollusks). Mechanical contact locally deforms the body surface; receptors typically are touch spots or free nerve endings within the skin, often associated with such specialized structures as tactile hairs. The skin area served by one nerve fibre (or sensory unit) is called a receptive field, although such fields overlap considerably. Particularly sensitive, exposed body parts are sometimes called organs of touch—*e.g.*, the tentacles of the octopus, the beak of the sand-piper, the snout of the pig, or the human hand.

Stimulation of the human skin with a bristle reveals that touch (pressure) sensation is evoked only from certain spots. These pressure spots, especially those on hairless parts (*e.g.*, palm of the hand, or sole of the foot), are associated with specialized microscopic structures (corpuscles) in the skin. Pressure spots are most densely concentrated on the tip of the human tongue (about 200 of them per square centimetre), roughly twice their concentration at the fingertip. A characteristic feature of many tactile sense organs is their rapid and complete adaptation (*i.e.*, temporary loss of sensitivity) when stimulated. Still, in man a distinction can be made between transient and more prolonged pressure sensations.

Relatively little research has been done with regard to the physiology of individual tangoreceptors in vertebrates. The Pacinian corpuscle of higher vertebrates, however, has been studied in isolation (see SENSORY RECEPTION, HUMAN for illustrations). These corpuscles, found under the skin, are scattered within the body, particularly around muscles and joints. Local pressure exerted at the surface or within the body causes deformation of parts of the corpuscle, a shift of chemical ions (*e.g.*, sodium, potassium), and the appearance of a receptor potential at the nerve ending. This receptor potential, on reaching sufficient (threshold) strength, acts to generate a nerve impulse within the corpuscle. Among insects, movements of tactile hairs have been shown (sometimes specifically) to affect the receptor potential and the impulse frequency in the connected nerve fibre.

Many vertebrates and invertebrates can localize with some precision points of tactual stimulation at the body surface. People typically can still distinguish two sharpened pencil points, or similar pointed stimuli, when the points are separated by as little as about one millimetre at the tip of the tongue. (When moved closer together, the two points are perceived as one.) The human two-point threshold is about two millimetres at the finger tip, reaching six or seven centimetres at the skin of the back. Such tactual ability serves blind people when they read raised type (Braille) with their fingers. Closely related functions include the ability to distinguish between tactile stimuli that differ qualitatively; for example, between a rough and a smooth surface. This ability is even observable in the ciliate *Stylonychia* (a one-celled relative of *Paramecium*).

Sensory contact with the ground below often informs animals about their spatial position. Nocturnal animals (for example, some eels) find shelter during the day by keeping as much of their skin as possible in contact with solid objects in the surroundings (thigmotaxis). Animals that live in running water usually maintain their position as they turn and swim head-on against the current (rheotaxis). Study of rheotactic behaviour reveals that the sensory basis almost exclusively depends on visual or tactile stimuli (or both) arising from the animal's movements

Reading Braille

relative to the solid bottom or surroundings. The long antennae of many arthropods (e.g., crayfish) and the lengthened tactile hairs (vibrissae) on the snouts of nocturnally active mammals (e.g., cat, rat) serve in tactually sensing objects in the vicinity of the animal's body, extending and enriching the adaptive function of the sense of touch.

**Lateral-line organs.** *Mechanoreceptor function.* All of the primarily aquatic vertebrates—cyclostomes (e.g., lampreys), fish, and amphibians—have in their outer skin (epidermis) special mechanoreceptors called lateral-line organs. These organs are sensitive to minute, local water displacements, particularly those produced by other animals moving in the water. In this way, approaching organisms are detected and localized nearby before actual bodily contact takes place. Thus the lateral lines are said to function as receptors for touch at a distance, serving to perceive and locate prey, approaching enemies, or members of the animal's own species (e.g., in sexual-display behaviour).

Each epidermal organ, called a sense-hillock or neuromast (Figure 1C), consists of a cluster of pear-shaped sensory cells surrounded by long, slender supporting

lateral-line organs; only the deeply situated, labyrinthine sense organs persist.

The sensory cell of a neuromast bears one relatively long hair (kinocilium) and about 50 shorter ones (stereocilia). The kinocilium is inserted eccentrically on top of the sense cell; the stereocilia are arranged in parallel rows. In about half of the hair cells of a neuromast, the kinocilium is found on one (and the same) side of the cell; in the remaining hair cells it is found on the opposite side. In most cases these are cranial and caudal side, respectively. In the toad *Xenopus*, each group of hair cells in a neuromast connects to its own nerve fibre; hence there are two fibres per sense organ. The hair cells send a continuous series of neural impulses toward the acoustic tubercle in the absence of adequate external stimulation. A longitudinal water current along the toad's body surface, however, selectively increases or decreases the frequency of impulses from the cranial and caudal cells, depending on whether the flow is from head to tail or vice versa; current directed at right angles to such neuromasts has no effect. The impact of the moving water moves the cupula to deform the sensory hairs. Even minute cupula displacements of less than one thousandth of a millimetre are clearly effective in altering the impulses.

In *Xenopus*, as well as in other animals that have lateral-line organs, there are also some neuromasts with their hair cells asymmetrical at right angles to the head-tail axis. These add directional sensitivity so that other animals moving nearby in the water are well distinguished and localized. The postulated function of the lateral-line organs in the reception of low-frequency propagated pressure waves ("subsonic sound") has not been verified behaviorally. At very short distances, however, a vigorous low-frequency sound source stimulates the lateral-line system on the basis of acoustical near-field effects (water particle displacements), just as does any moving or approaching object.

Cyclostomes, many bony fishes, and all the aquatic amphibians studied have only superficial ("free") neuromasts of the kind described above. In the development of most fish, however, a number of structures called lateral-line canals (Figure 1B) are formed as a secondary specialization. They begin as grooves that develop in the epidermis along the main lateral lines; thus, a number of formerly free neuromasts are taken down to the bottom of each groove. The walls of the grooves then grow together above the neuromasts. Eventually the grown-together walls form canals under the epidermis, containing in their walls a series of canal neuromasts and a chain of openings to the outside (canal pores) along the lateral lines. The cupulae are changed in form, fitting the canal somewhat like swinging doors. The canal is filled with a watery fluid. Stimulation occurs essentially in the same way as with free neuromasts: local, external water displacement is transmitted via one or more canal pores to produce a local shift of the canal fluid to move cupulae. The sense cells in the canal neuromasts are polarized in the direction of the canal.

Canal specialization is particularly well developed in lively species of fish that swim more or less continuously and in bottom dwellers that live in running or tidal waters. Canalization has been interpreted as a case of adaptive evolution, serving to avoid the almost continuous, intense stimulation of free neuromasts by water flowing along the fish body during swimming or, in the case of relatively inactive bottom dwellers, by the external currents. These coarse water displacements probably mask subtly changing stimuli from detection by the lateral-line organs on the surface of the animal's body. Canal neuromasts are shielded in large degree from these masking currents.

The lateral-line organs function mainly in locating nearby moving prey, predators, and sexual partners. Usually these objects must be much closer than one length of the animal's body to be detected in this way; even intense stimuli are hardly ever detected beyond five body lengths away. Lateral-line function in rheotactic orientation against currents is restricted mainly to inhabitants of

Detection of water currents

cells. The sense hairs on top of the sensory cells project into a jellylike substance (the cupula) that bends in response to water displacement. The cupula stands freely in the surrounding water, grows continuously (e.g., as a human fingernail), and wears away at the top. Sense organs of this type are distributed along definite lateral lines on the head and body of the animals (Figure 1A), developing in the outer layer of cells (ectoderm) of the embryo from a thickening called the lateral placode. From the central part of the same placode the sensory cells of inner-ear structures (the labyrinth) arise. The common embryologic origin and structural similarities of mature neuromasts and labyrinthine cell groups have led to the designation of all of these organs as the acoustico-lateralis system. The nerves to all the sense organs of the system arise from a common neural centre (called the acoustic tubercle in the wall of the brain's medulla oblongata). Among such amphibians as frogs, lateral-line organs and their neural connections disappear during the metamorphosis of tadpoles; as adults they no longer need to feed under water. The higher land-inhabiting vertebrates—reptiles, birds, and mammals—do not possess the

small currents such as mountain brooks, where marked differences of water-flow velocity affecting the fish body locally are likely to occur. Compared to their use of other sensory functions (e.g., vision) the animals depend little on ability to sense extremely close, resting objects (obstacles) through the lateral lines. Obstacle detection of this kind does not arise from reflection of water waves; rather, the pattern of water displacement around the moving fish abruptly undergoes deformation at the near approach of an obstacle as the result of compression; the fish encounters a sudden rise in water resistance in the immediate vicinity of the obstruction. Nor do the lateral-line organs function to regulate or coordinate the animal's movements on the basis of the water flow or pressure variations along its body produced by swimming; neither do they serve for the reception of water-transmitted propagated sound waves (hearing).

**Ampullary lateral-line organs (electroreceptors).** Perhaps the most interesting specialization of the lateral-line system is the formation in several groups of fish of deeply buried, single electrically sensitive organs. Such structures, for example, are found on the head of all the elasmobranchs (e.g., sharks and rays), and are called ampullae of Lorenzini. Similar organs include those on the head of *Plotosus*, a marine bony fish (teleost); structures called mormyromasts in freshwater African fish (mormyrids) and in electric eels (gymnotids); what are named small pit organs of catfishes (silurids); and possible related organs in several other fish groups. These are known as ampullary lateral-line organs, and they have features in common. The sensory cells are withdrawn from the body surface, lack kinocilia, and have no mechanical contact with the surrounding water through a cupula. The latter attribute, indeed, is typical for all the acousticolateral end organs, except ampullary sense organs, in which the sense cells lie within the wall of a vesicle (or ampulla) that opens to the surface through a tubelike duct. Ampulla and duct are filled with a gelatinous substance that has excellent electrical conductivity.

Fish with ampullary sense organs are found to be remarkably sensitive to electrical stimuli—i.e., minute, local potential differences in the surrounding water at their body surface. In behavioral experiments with sharks and rays, sensitivity to changes of 0.01 microvolt per centimetre (one microvolt = 1/1,000,000 of a volt) along the body surface has been found for the ampullae of Lorenzini. Similar, though somewhat higher, values have been recorded from the ampullary nerve fibres. A decrease in voltage at the opening of the ampulla causes an increase of the spontaneous nerve-impulse frequency; an increase in voltage at the opening produces the opposite response. Through their electrical sensitivity, such fish can detect and locate other organisms in darkness, in turbid water, or even when these organisms are hidden in the sand or in the mud of the bottom.

Sharks, rays, and most catfishes are able to detect electrical changes (biopotentials) emanating from other organisms. The freshwater mormyrids and eels, on the other hand, have special signal-emitting electric organs. They produce a series of weak electric shocks (up to a few volts), sometimes quite regularly and frequently; for example, about 300 shocks per second in the mormyrid fish *Gymnarchus*. In this way, a self-generated electric field is created in the immediate surroundings. Any appropriate object (for example, a prey animal with good conductivity in relation to freshwater) will cause a deformation of the electric field and can thus be detected in a radar-like manner through the sensitive ampullary electroreceptors.

Some theorists suggest that initially mechanoreceptive lateral-line organs evolved into electroreceptors. At any rate, evidence of a certain double sensitivity—to mechanical and to electrical stimuli—has been observed in electrophysiological experiments with Lorenzian ampullae. This double sensitivity has not been found, however, in behavioral experiments; alterations in behaviour indicate that ampullary lateral-line organs merely serve the animal as electroreceptors in adapting to the environment.

**Other varieties of mechanoreception. Surface waves.** Several species of animals living at or near the water surface use surface waves or ripples emanating from potential or struggling victims to locate their prey quickly: examples are the toad *Xenopus*, several fish species, and such insects as the back swimmer (*Notonecta*) and the water strider (*Gerris*). The whirligig beetle (*Gyrinus*) also uses surface ripples to avoid collisions with obstacles and companions. The sensory structures involved range from specialized tactile hair receptors (trichobothria) to internally located cells (proprioceptors) in movable body appendages and lateral-line organs.

**Water and air currents.** Special water-displacement receptors found in lobsters (*Homarus*) are most reminiscent of the lateral-line organs in vertebrates. Water-current receptors also enable several kinds of bottom-dwelling invertebrates to orient themselves (rheotaxis) in rivers and tidal currents. Many predators among these animals also respond chemically (see CHEMORECEPTION), moving against the current (positive rheotaxis) until the prey is reached. In this way, for example, certain marine snails easily find their particular prey (sea anemones). Similarly among insects, the chemical "smell" of prey or of potential sex partners elicits a tendency to move against the wind (anemotaxis) until the source of the chemical stimulus is found. Several types of air-current receptors (true mechanoreceptors) on the heads of insects enhance such chemoreceptive behaviour. In flying locusts, an air current directed appropriately toward the head elicits compensatory reflex flight movements. The receptors involved (groups of hair sensilla on the head) mediate small corrections in the maintenance of straight flight; major guidance, however, derives from the insect's visual contact with the ground below.

**Vibration reception.** Adaptation and recovery occur most rapidly among touch receptors, and they tend to respond well to repeated stimulation, even of relatively high frequency. Thus, a person can feel whether an object is vibrating; above a threshold frequency of about 15 cycles per second (cps), discretely perceived tactual stimuli seem to fuse into a quite new and distinct vibratory sensation. The upper frequency limit of this vibration sense is found at several thousand cps among normal individuals, with sensitivity being maximal in the range of 200 cps (above a threshold amplitude of about 100 millimicrons). Just as pitch is discriminated in hearing, differences of about 12 to 15 percent in vibration frequencies can be distinguished by most people.

Vibration sensitivity is not limited to man; fish, for instance, also may respond to low-frequency water vibrations with tactile receptors. In addition, several kinds of animals have special vibration receptors. In some insects, a group of specialized structures (chordotonal sensilla) in the upper part of each tibial segment of the leg signal vibrations from the ground below. In the cockroach, the threshold amplitude for vibrational stimuli of this kind has been found to be less than 0.1 millimicron. Birds have special receptors (corpuscles of Herbst in the tibiotarsal bone of the leg) with which they can detect slight vibrations of the twig or branch on which they sit. Perhaps birds are alerted at night in this way to approaching predators; maximal sensitivity is at about 800 cps, and the threshold amplitude is close to 20 millimicrons. Spiders also use their vibration sense to locate prey in the web.

**Generalized hydrostatic pressure.** Several types of aquatic animals are sensitive to small changes of hydrostatic, or water, pressure. Among fish, this applies particularly to the order Ostariophysi (Cypriniformes), which includes about 70 percent of all the freshwater species of bony fishes. The swimbladder in these animals is connected with the labyrinth (sacculus) of the inner ear through a chain of movable tiny bones, or ossicles (weberian apparatus). Alterations in hydrostatic pressure change the volume of the swimbladder and thus stimulate the sacculus. These fish can easily be trained to respond selectively to minute increases or decreases in pressure (for example, to a few millimetres of water pressure), indicating that they have a most refined sense of water depth. All of these fish are so-called physostomes, which means that

Specialized  
vibration  
receptors

Electrical  
"radar"

they have a swimbladder duct through which rapid gas exchange with the atmosphere can occur; many live in relatively shallow water. The hydrostatic-pressure sense can function to inform the animals about their distance from the surface or about the direction and velocity of their vertical displacement. It also appears that improvement and refinement of the sense of hearing arises through the swimbladder's connections via the weberian apparatus with the labyrinth.

The sensitivity of several kinds of crustaceans to relatively small hydrostatic-pressure changes (as low as five to ten centimetres of water pressure) is most remarkable because these animals have no gas-filled cavity whatsoever. The mechanism by which the stimuli are detected remains a puzzling question, although information about changing water depth during tidal ebb and flow clearly would seem to have adaptive value.

#### RECEPTION OF INTERNAL MECHANICAL STIMULI

Some proprioceptors (internal receptors) for mechanical stimuli provide information about posture and movements of parts of the body relative to each other; others contribute to an undisturbed course of coordinated muscular actions (*e.g.*, in locomotion). Best known from studies of vertebrates and arthropods, some are tonic proprioceptors (serving to maintain muscle tone in posture); others are of the phasic type (serving movement); still others have a mixed phasic-tonic character. In principle, proprioceptors can be stimulated adequately by pressure or stretching during active movements of the animal (reafferent stimulation) as well as through passive external pushing and pulling (exafferent stimulation). One passive factor, particularly in land-inhabiting animals, is gravity as it acts on bodily tissues or organs. Proprioceptors thus not only serve reflex adjustments in posture and relatively automatic movements of parts of the body with respect to each other (as in driving an automobile) but they also provide gravitational information about the position of limbs or of the whole body in space. To the extent that they are gravity detectors, these sensory structures are properly called external receptors (exteroceptors instead of proprioceptors). For receptors that are diffusely located within the body, a clean distinction between proprioceptive and possible exteroceptive function (gravity reception) is experimentally practicable only under conditions of weightlessness, as in space travel.

**Vertebrates. Muscle spindles.** Well-known proprioceptors of all the four-limbed vertebrates studied are the muscle spindles occurring in the skeletal (striate) muscles; fish muscles show structurally simpler but functionally comparable receptors. Each muscle spindle in mammals consists of a few slender, specialized (intrafusal) muscle fibres that are surrounded by a sheath of connective tissue filled with lymph fluid (Figure 2). The muscle spindle itself is surrounded by and arranged parallel to the ordinary (extrafusal) muscle fibres. Each intrafusal fibre consists of contractile (motor) parts at both ends and a noncontractile sensory midsection that serves as a receptor for stretch (changes of length and tension). There is double (primary and secondary) sensory innervation in mammals, but the secondary endings are lacking in lower vertebrates. Even when the animal is at rest, both types of endings are active (under the tension of normal muscle tonus). Additional stretch (lengthening) of the intrafusal midsection increases the nerve impulse frequency, and relaxation (shortening) causes a decrease. The primary (phasic-tonic) ending responds quickly; responses of the secondary (tonic) endings are slower.

The length of the muscle spindle as a whole varies with the contraction phase and the length of the muscle to which it belongs. The length of the sensory midsection, however, may change more or less independently because its motor nerve endings function apart from the innervation of the extrafusal muscle fibres. Thus the ratio of extrafusal-intrafusal contraction determines whether or not a change of length in the midsection will occur during muscle activity. There are reasons to suppose that midsection stretch remains more or less unchanged dur-

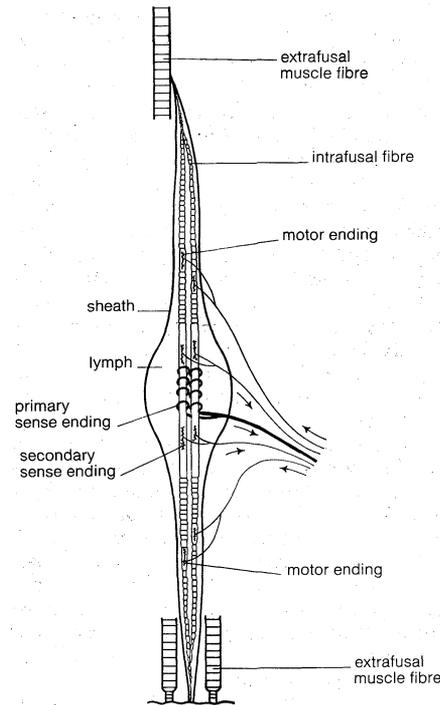

Figure 2: Mammalian muscle spindle.

ing self-initiated ("voluntary") movements; reafferent stimulation of muscle spindles would be avoided in this way. But as soon as an unexpected (exafferent) stretch of a muscle occurs—for example, when a leg pushes against an obstacle during locomotion—the midsections stretch to produce an increase of impulse frequency. This neural activity elicits a compensatory reflex contraction of the stretched muscle, as in the knee jerk during medical examinations: a blow beneath the kneecap causes stretch of a thigh muscle, stimulation of its muscle spindles, and a compensatory jerking contraction of the same muscle.

Knee jerk

**Tendon organs.** Branched nerve endings on vertebrate tendons (not far from their point of attachment to muscle) also respond to stretch; however, they are decidedly less sensitive than are muscle spindles. These tendon organs produce no impulses under the stretch of normal, resting muscle tonus. Neither is there a mechanism preventing reafferent stimulation of tendon organs, nor does it make any difference whether the stretch is brought about by active muscle contraction or passively following external influence. In both cases tendon receptors respond according to the intensity of the stretch; their response causes relaxation of the attached muscle and may serve (among other functions) to prevent anatomical damage.

Human awareness of posture and movement of parts of the body with respect to each other (kinesthetic sensations) is attributable neither to muscle spindles nor to tendon organs. The sensations are based on stimulation of sensory nerve endings of various types at the joint capsules and of stretch receptors in the skin. There are also mechanoreceptors in the walls of some blood vessels (*e.g.*, in the aorta and the carotid sinus); these are sensitive to blood-pressure changes and play a regulatory role in the circulatory system.

**Invertebrates.** Among invertebrates, the arthropods exhibit the most readily distinguished proprioceptors, called muscle-receptor organs and chordotonal proprioceptors. Both types of structure occur in crustaceans as well as in insects. Adequate stimuli are variations in length and tension (stretch).

**Muscle receptor organs.** Although they structurally and functionally resemble the muscle spindles of vertebrates, arthropod muscle receptor organs are always situated outside of the muscles proper. Numerous branches of multipolar primary nerve cells are connected with the noncontractile midsection of specialized muscle fibres, both ends of which are contractile and have an efferent (motor) innervation. In crustaceans, the muscle re-

ceptor organ contains two elements: a slowly contracting, nonadapting tonic fibre and a quickly contracting, rapidly adapting phasic element.

**Chordotonal proprioceptors.** Widely distributed among arthropods, chordotonal receptor organs are thin, elastic, innervated strands of connective tissue, stretched between adjacent segments of the body or of leg joints. The sensory endings of a few bipolar primary nerve cells, each provided with a spiny sensillum (scolopidium), are attached to the strand. Chordotonal proprioceptor organs generate neural impulses that show them to contain both phasic movement receptors and tonic pressure receptors; sometimes two varieties of each. Thus there are receptors that selectively respond only during flexion, only in the flexed position, only during stretch, or only in the stretched state of the given strand. Several kinds of insects, apart from their clearly proprioceptive-chordotonal functions, have other chordotonal elements that serve as typical exteroceptors. Sense organs of this type (tympanic and subgenual organs in legs, organs of Johnston in the antennae) may function in the reception of sound waves, of vibrations in the ground, or of other external mechanical stimuli. Many insects also have a special type of chordotonal-proprioceptor structure (campaniform sensilla) not found in crustaceans. Sensory endings of primary nerve cells are connected with thin, dome-shaped (campaniform) spots on the exoskeleton. These campaniform sensilla respond to local tensions and deformations of the body surface. They function in the regulation of such movements as the beating of wings in locusts. Similarly functioning proprioceptors (lyriform organs) are also observed among spiders.

In insects, posture and movements of body parts with respect to each other can be detected through groups of external tactile hairs implanted near the joints between adjacent skeletal elements. Some function as rotation receptors or exteroceptors to detect the direction of gravity.

Among other invertebrates, the cephalopod *Octopus* clearly exhibits proprioceptive abilities, though specific receptors have not yet been identified. These animals, however, seem unable to integrate proprioceptive data in the central nervous system with other sensory information in learning. Thus an octopus readily can be taught to discriminate between two small cylindrical objects (both provided with longitudinal ribs) if the ribs on one of them are somewhat coarser than those on the other. But the animal cannot learn to distinguish between cylinders of the same size if the ribs are equally coarse and if they are longitudinal on one and transverse in the other; nor can it learn to discriminate between small objects of different form or different weight. This indicates that an octopus cannot learn any discrimination that depends on sensory information about the position of the arms and suckers making contact.

Octopus learning

#### EQUILIBRIUM

Active maintenance of equilibrium during bodily movement (e.g., in locomotion) requires appropriate sensory functions. Although many animals usually maintain their bodies with the long axis horizontal (backside up), man being a notable exception, there are frequent departures from the usual position. A fish may dive steeply downward; a spiny lobster may crawl along a perpendicular cliff, and a man may alter his normal orientation by lying down at full length. In no case, however, need there be any loss of equilibrium. Every deviation from the actively pursued posture means an equilibrium disturbance and evokes compensatory reflex movements, not only a deviation from the usual position as in most laboratory experiments.

Maintenance of equilibrium is based upon contact of the animal with the external world; several sensory systems may play a role in this context. When an animal moves over a solid surface, tactile stimuli usually predominate as cues. It has been noted above how proprioceptors in vertebrates and arthropods can also contribute to spatial orientation; bodily tissues under gravity weigh vertically down and stimulate internal mechanoreceptors in a way

that depends on, and varies with, the animal's spatial position. When they are out of contact with the ground, many animals orient themselves in space by keeping their back (dorsal) side turned up toward the light. Visual cues also can serve equilibration; for example, through compensatory body movements (optomotor reflexes) brought about by the shifts of the image of the environment over the retina of the eye. For the receptors mentioned thus far, however, equilibration is not the unique function. There are other sensory structures that are genuine organs of equilibrium in that they primarily and exclusively serve orientation of posture and movement in space.

**Gravity receptors.** Because of the constancy of its magnitude and direction, gravity is most suitable in providing animals with cues to their position in space. The sense organs involved (statoreceptors) usually have the structure of a statocyst, a fluid-filled vesicle containing one or more sandy or stonelike elements (statoliths). Sensory cells in the wall of the vesicle have hairs that are in contact with the statolith, which always weighs vertically down. Hence, depending on the animal's position, different sense cells will be stimulated in statocysts with loose statoliths (Figure 3A); or the same sense cells will be stimulated in different ways in statocysts with a statolith loosely fixed to the sense hairs (Figure 3B).

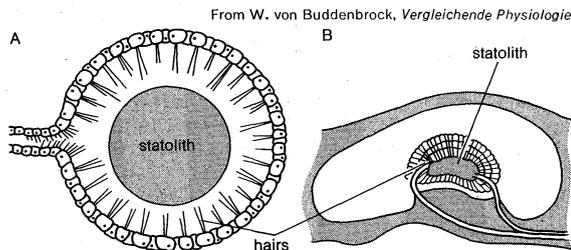

Figure 3: Statocyst gravity receptors. (A) With a free-moving statolith, as in a mollusk (scallop), and (B) with statolith loosely fixed to hair cells, as in a crustacean (opossum shrimp).

Statocysts are found in representatives of all of the major groups of invertebrates: jellyfish, sandworms, higher crustaceans, some sea cucumbers, free-swimming tunicate larvae, and all the mollusks studied thus far. Analogous receptors that occur generally in vertebrates are the ear's utricle and probably (to a degree) also two other otolith organs (sacculus and lagena) of the ear (labyrinth). Statocysts (including vertebrate labyrinthine statoreceptors) develop embryologically from local invaginations of the body surface. In primitive evolutionary forms, the interior of the statocyst is in open communication with the surrounding sea and thus is filled with water; statoliths usually are sand particles taken up from outside. In a few animal groups, this developmental stage is only found during the larval phase, the initial opening to the exterior being closed in the adult animal. In more advanced forms, the liquid content (statolymph) and the statoliths are produced by cells in the wall of the organ. This specialized type of closed statocyst is found in many snails, in all the cephalopods such as the squid (except *Nautilus*), and in the vast majority of vertebrates (from bony fishes up to and including mammals).

Statocyst function may be studied by observing compensatory reflexes under experimental conditions. When the position of a laboratory animal is appropriately changed, movements of such body parts as the eyes, head, and limbs can be observed. Such movements tend to counteract the imposed change and to restore or to maintain the original position. Evidence of statoreceptor function is provided if these reflexes are abolished after surgical elimination of both statocysts. Many animals exhibit locomotion that is gravitationally directed vertically down or up (positive or negative geotaxis, respectively). Geotactic behaviour may be experimentally altered by whirling the animal in a centrifuge to change the direction and to increase the intensity of the force exerted on the sensory hairs by the statoliths. Molting crustaceans shed the contents of their statocysts along with their exoskeleton.

Geotactic behaviour

If such an animal is placed in clean water containing iron filings, it takes up new iron statoliths instead of the usual sand grains. By moving a magnet to vary the direction of the force exerted by the metal statoliths, the animal can be made to adopt any resting position, even to stay upside down. Statoliths can be washed out of the open statocysts of a shrimp without damaging the sensory hairs. When the hairs are pushed in different directions with a fine water jet, the shrimp exhibits compensatory reflexes. In this way, it has been shown that each statocyst signals a change of position around the animal's long axis; the same reaction is found to occur after removal of the statocyst on one side only. Electrical impulses in the statocyst nerve can be recorded while the animal is in different spatial positions, or during experimental deflection of the sensory hairs. Such experiments reveal that both vertebrates and decapod crustaceans (e.g., shrimp) exhibit spontaneous and statolith-induced neural activity in the lining (epithelium) of the gravity receptor.

**Spontaneous activity.** The sensory epithelium of a statocyst is spontaneously active, initiating a continuing series of impulses directed toward the central nervous system (even when the statoliths are experimentally removed from the statocyst). This resting frequency of neural activity is fairly constant and completely independent of the animal's position in space. In vertebrates and in crustaceans, spontaneous activity of the left statocyst affects the central nervous system to produce a tendency of the animal to roll to the right about its long axis; spontaneous activity of the right statocyst prompts a tendency to roll to the left. Normally, these rolling tendencies neutralize each other in the central nervous system, not becoming manifest unless the statocyst on one side of the body is functionally eliminated by complete surgical removal, by destruction of its sensory epithelium, or by cutting its nerve. This intervention permits the influence of the spontaneous activity generated in the remaining statocyst to be felt, and the animal tends to roll toward the operated side. Unilateral (one-sided) removal of the statoliths alone, however, does not produce such an effect so long as the sensory cells in the epithelium remain intact. The rolling tendency of a unilaterally operated animal usually diminishes little by little in the course of hours or days, until it finally disappears completely. If the remaining statocyst is then removed, rolling occurs again, but this time to the other (last operated) side. This tendency also diminishes and disappears with time. Apparently the unbalancing effect of the spontaneous influx from a statocyst is gradually counteracted in some unknown way by the central nervous system.

**Statolith influences.** Vertebrates and crustaceans have statoliths that are loosely connected to the sensory hairs by a sticky substance. With such a mechanical arrangement, the statolith stimulates the sensory cells by parallel (shearing) motion rather than by pressure or pull at right angles to the epithelium. The effects are demonstrable in experiments with fish, based on the dorsal-light orientation noted above. In a laboratory darkroom, if light shines at a fish from one side, the animal assumes an oblique position. While the fish tends to turn on its side (with its back side to the light), gravity tends to keep it vertical; the oblique position is the resultant. In a whirling centrifuge, the pressure exerted by the statoliths may be increased. When this is done, the fish rights itself almost precisely to the degree that the shearing force exerted by the statoliths is held constant.

In vertebrates, statoreception is localized in the head within the labyrinth, particularly within the utriculus, one of the three statolith (or otolith) organs (Figure 4). The statolith is surrounded by a gelatinous substance akin to the cupula of the lateral-line organs. In most higher vertebrates, the head moves rather flexibly because it is not rigidly connected to the trunk. Thus information coming from the utriculi has to be neurally integrated centrally with impulses from proprioceptors that signal the position of the head with respect to the limbs and trunk (for example, neck receptors), if the animal is to orient its head and body appropriately in space.

The roles played by the remaining otolith organs of the

labyrinth (sacculus and lagena) in statoreception remain unclear. Their sensory epitheliums (maculae) are roughly at right angles to each other and to that of the utriculus. In view of their arrangement, it was once supposed that the three otolith organs of the labyrinth would serve to detect position in three spatial planes (indeed, the three semicircular canals do serve to detect rotation in different planes). It has been found, however, that the sacculus and the lagena (as far as it is present) can be put out of function bilaterally in representatives of all the classes of vertebrates without causing overt equilibration disturbances. On the other hand, some secondary statoreceptor function has been demonstrated for these otolith organs in all the animals from fish up to and including man.

In the special case of flatfishes (e.g., halibut, sole, flounder), the normal upright position in the juvenile stage changes to one of swimming and lying on one side as an adult. The eye from that side migrates to the upper surface; but the situation of both labyrinths remains unchanged. Hence, the originally horizontal maculae of the utriculi are now oriented vertically. In these fish, the sacculi (usually the major organs of hearing in bony fishes) indeed may be shown to serve as statoreceptors. At any rate, the same otolith organ may function in one fish species as an organ of hearing and in another as a gravity receptor; clearly, both functions depend on basically identical mechanical stimulation.

As receptors belonging to the acousticolateralis system, the otolith organs of vertebrates have hair cells of the same type that is found in lateral-line neuromasts. Under the electron microscope, the sensory hair cells show a pattern of polarization (arrows in Figure 4) throughout

From Cold Spring Harbor Symposia on Quantitative Biology (1965)

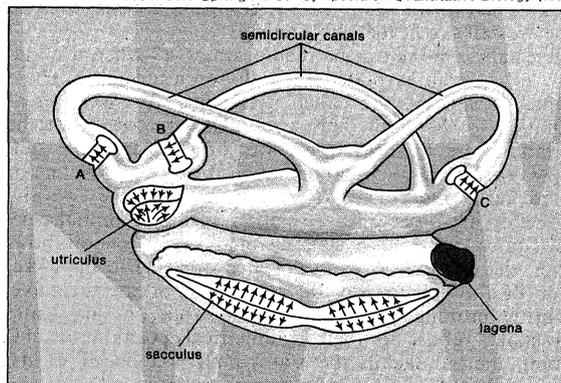

Figure 4: Right labyrinth of a codlike fish called the burbot, seen from above. Ampullae of anterior, horizontal, and posterior semicircular canals are lettered A, B, and C, respectively. Arrows show direction of hair-cell polarization.

the macula, indicating the directions in which the shearing otolith should have an activating or an inhibiting influence. Results of physiological investigations thus far performed agree well with these deductions.

Among the invertebrates, most statocyst research has been done with such decapod crustaceans as lobsters. The working mechanism of their statocysts conforms with the physiological principles of vertebrate statoreception discussed above. The results of electrophysiological investigations support the conclusions drawn from behavioral observations. In some crustacean statocysts (for example, in the lobster, *Homarus*), special statoreceptors are found that signal the same bodily position differently, depending on the direction of movement through which it was reached (hysteresis effect). The part played by the statocyst in equilibration has been investigated in several other invertebrate groups, among them jellyfish, sandworms, and such mollusks as scallops, common snails, sea hare, and octopus. Each sensory cell from the vertical macula in a statocyst of the octopus bears up to 200 kinocilia, and all the cilia of each cell are polarized in the same direction. On the macula as a whole, there is a radiating polarization pattern, the activating direction pointing everywhere from the centre to the margin. Compensatory eye reflexes resulting from tilting the animal

organs in  
verte-  
brates

head down or head up around a transverse axis reveal a hysteresis effect. After unilateral-statocyst removal, mollusks do not tend to roll toward the operated side (as do vertebrates and crustaceans) but toward the side of the remaining statocyst.

The almost complete absence of statocysts in insects is remarkable in view of evidence that many of them have a high degree of sensitivity to the direction of gravity. Receptors involved are specialized tufts of tactile hairs at the external body surface; in the honeybee, such groups of hairs are notably found between head and thorax and between thorax and abdomen. The adaptive function of these static (gravity) receptors becomes manifest in the honeybee "dance language" performed on a vertical comb in the hive. The angle between the dancing bee and the perpendicular seems to direct other bees to sources of nectar and pollen.

**Rotation receptors.** In addition to having tonic statoreceptors (signalling position with respect to gravity), several groups of animals have purely phasic rotation receptors that respond only to angular acceleration or deceleration, as produced on a turntable. Vertebrates, cephalopods (e.g., squid), and decapod crustaceans (e.g., lobsters) have special rotation receptors at the inner surface of the fluid-filled organ of equilibrium (labyrinth or statocyst). This fluid lags inertially with respect to the wall of the organ at the onset and arrest of every rotation. Among crustaceans, such as crabs or lobsters, the rotation receptors incorporate relatively long, delicate hairs that extend more or less at right angles to the wall freely into the statocyst fluid. The hairs respond quickly to fluid motion, swaying around their point of attachment and returning slowly through their elasticity to resting position. Their stimulation causes compensatory reflexes of the eyestalks or of the whole animal.

Eyestalk reflexes can be readily observed when a blinded, legless crab is rotated while flat on a turntable. These reflex movements are called nystagmus. At the onset of rotation to the right, both eyestalks move at about the rotation rate to the left by way of compensation until they reach their maximal deviation. In most cases, one or more jerky movements of the eyestalks in the opposite direction are observed per rotation during the initial period (quick, restoring nystagmus phases). In general, however, the eyestalks remain deviated opposite to the direction of rotation for several revolutions of the turntable. During prolonged constant-velocity rotation, the crab's eyestalks return to their symmetrical position; at this point, inertial lag in the statolymph is reduced to the degree that the fluid finally rotates together with the statocyst wall. Sudden arrest of the turntable under these circumstances causes afternystagmus: the eyestalks move promptly to the right (at about the same velocity as they moved to the left at the onset of rotation) until their maximal deviation toward this side is reached. After a quick jerk in the opposite direction, the eyes continue their slow movement to the right, and in this way as many as three or more after nystagmus jerks may occur with decreasing intensity. Such aftereffects may last many seconds, but finally the eyestalks return slowly to their symmetrical position. All of these nystagmic effects from such horizontal rotation are abolished in a blinded crab, however, after bilateral elimination of the long, delicate statocyst hairs by their denervation or by cauterization of the hair bases.

In vertebrates, rotation reception occurs within the labyrinth. Each labyrinth has three semicircular canals arranged in planes at right angles to each other (Figure 4); the canals communicate with the utriculus. One end of each canal is widened into an ampulla, and the sensory cells (hair cells) are arranged in a row on a ridge (crista) of the ampullar wall. The crista is oriented at right angles to the plane of the canal, and the extended hairs of its sensory cells are imbedded in a jellylike cupula that reaches to the opposite wall of the ampulla. Endolymph displacement through a canal makes the cupula move aside, as if it were a swinging door. In vertebrates, the inertial lag of the endolymph at the onset of rotation is very brief, the fluid catching up with the angular velocity

of the labyrinth within a fraction of a second. An ampulla with its crista and cupula is reminiscent of a lateral-line canal neuromast, except that all of the hair cells of a crista are polarized in the same direction. In the cristae belonging to the vertical semicircular canals the kinocilium is implanted at the side facing the canal; in the horizontal cristae all of the sensory cells are polarized toward the opposite side (facing the utriculus). This structural arrangement is in keeping with differences between the vertical and the horizontal canals observed in behavioral and electrophysiological experiments.

A turn of the animal's head around the vertical axis to the left increases the neural-impulse frequency (activation) in the left horizontal crista; a turn of the head to the right causes a frequency decrease (inhibition). Opposite effects occur at the same time in the right horizontal crista. Recordings from the different crista nerves, while the animal is being rotated successively around all three major body axes, show the horizontal crista to respond only to rotation of the animal around its vertical axis; the vertical cristae, however, respond to rotation about all three axes. Behavioral data (compensatory eye reflexes) provide similar results, except that the eyes fail to exhibit an observable response associated with the vertical semicircular canals during rotation around the vertical axis. Stimulation of the vertical cristae under these circumstances gives rise to the simultaneous contraction of antagonistic pairs of eye muscles; hence the absence of a compensatory eye rotation.

In decapod crustaceans, particularly crabs, the statocyst is anything but a simple spherical vesicle; it has a very complicated shape with several curved invaginations and projections. In a small corner in the lowest (most ventral) part of the crab statocyst, a cluster of minuscule sand particles (statoliths) is found in contact with specialized (hooked) hairs. Apart from these hook-hair gravity receptors, there is a single, slightly curved row of relatively straight "thread" hairs atop an oval invagination in the middle of the lower statocyst wall. These hairs are the rotation receptors described above in the blinded crab revolving on a turntable. Bilateral elimination of the thread hairs alters the reflexes of the eyestalks. Instead of reacting immediately, at the very onset of rotation, in the absence of thread hairs on both sides, the eyes initially maintain their symmetrical position. They start their compensatory movement only after rotation has begun or at the end of rotation after the animal has reached a new, steady position. Furthermore, the velocity of this compensatory eye movement seems to be independent of the rate of angular acceleration or deceleration. The delayed nature of the response suggests that loss of rotation sensitivity about horizontal axes results from thread-hair elimination.

That the thread hairs are indeed responsive to rotation about all three major body axes is supported by a number of observations. Bilateral elimination of the impulses from the statolith hairs (position receptors) by selective nerve cutting, for example, does not affect the animal's response to rotation around the vertical axis. Despite their loss of impulses from position receptors, crabs subjected to angular acceleration or deceleration about either horizontal axis exhibit the normal compensatory eyestalk reflexes at the very onset of rotation. When a new (inclined) position of the animal is maintained, the eyestalks again become symmetrical, although complete return to symmetry may require several minutes. On the other hand, when both thread hairs and statolith hairs are eliminated, all such rotation and position reflexes of the eyestalks and related aftereffects are abolished. After unilateral elimination of the thread hairs or removal of one entire statocyst in a blinded crab, both eyes still react to rotation around the vertical axis in both directions. When electrical recordings are made of the activity of the primary sensory neurons innervating the thread hairs, similar results are obtained, the receptors responding only to angular acceleration and deceleration. They are spontaneously active, and the neural response to rotation that is superimposed upon the spontaneous background consists of a coded sequence of impulse-frequency increases and

Rotation  
of a  
blinded  
crab

Eyestalk  
reflexes

decreases. The same reception unit responds to acceleration about all three major axes.

The statocysts of cephalopods (nautilus, squid, octopus) rival the complexity of crab statocysts. In addition to the perpendicular macula with its statolith (for gravity reception), the octopus has three cristae (containing many hair cells with two-directionally polarized kinocilia) arranged approximately at right angles to each other. Rotation (turntable) experiments and surgical removal of statocyst receptors have shown that the octopus cristae function as rotation receptors. Nystagmus and afternystagmus persist almost unchanged after unilateral statocyst removal, but they are completely abolished after the additional removal of the second statocyst in a blinded octopus. In the cuttlefish (*Sepia*), the statocyst is structurally even more complicated; besides three cristae, it has three maculae (statolith organs) also arranged in different planes.

Rotation receptors of quite a different type are found in some groups of insects. Dragonflies (for example, *Aeshna*) have external hair receptors between the head and thorax. If a gust of wind turns the animal around its long axis during flight, the relatively heavy head lags with respect to the thorax. The resulting stimulation of the hair receptors in the neck region elicits compensatory flight reflexes and restores the insect to a normal position. These receptors do not respond to static head displacements. In the Diptera (true flies), the posterior knobbed "wings" (halteres) serve as flight stabilizing rotation receptors. During flight, the halteres beat in a vertical plane, synchronously with the forewings. Rotational instability as the insect flies is gyroscopically counteracted by the beating action. Receptors are campaniform sensilla at the base of the haltere.

## Medical Education

Medical education is directed toward imparting to persons seeking to become physicians the knowledge and skills used in the prevention and treatment of disease and also toward developing the methods and objectives appropriate to the study of the still unknown factors that produce disease or favour well-being. Medical education may be classified as (1) the basic training, (2) the training of specialists, and (3) the continuing education of the practicing physician. Attention in this article is focussed primarily on the basic education.

### BACKGROUND

The Greeks' spirit of rational inquiry may be considered the starting point of medical education because it introduced the practice of observation and reasoning regarding disease. Rational interpretation and discussion lend

themselves to teaching and thus to the formation of schools such as that at Cos, where the Greek physician Hippocrates taught in the 5th century BC. Later, the Christian religion greatly contributed to both the learning and the teaching of medicine because it favoured as acts of Christian piety not only the protection and care of the sick but the establishment of institutions where collections of sick people encouraged observation, analysis, and discussion among physicians by furnishing excellent opportunities for comparison. With the rise of the universities in Italy and later in Cracow, Prague, Paris, Oxford, and elsewhere in western Europe, the teachers of medicine were in some measure drawn away from the life of the hospitals and were offered the attractions and prestige of university professorships and lectureships. As a result, the study of medicine led more often to a familiarity with theories about disease than with actual sick persons. The establishment in 1551 of the Royal College of Physicians of London, however, largely through the energies of Thomas Linacre, who in 1518 had obtained from Henry VIII the original letters patent for a body of regular physicians, produced a system of examination of medical practitioners. The discovery of the circulation of the blood by William Harvey provided the necessary stimulus to the scientific study of the processes of the body, so that gradually the emphasis upon theory and doctrine decreased, although it lasted well into the 18th century.

Little by little, in the 17th and 18th centuries, the value of hospital experience and the training of the students' sight, hearing, and touch in studying disease were reasserted. In Europe, medical education began slowly to assume its modern character in the application of a gradually increasing knowledge of natural science to the actual care of patients. This return to the bedside aided the hospitals in their long evolution from dwelling places of the poor, the diseased, and the infirm, maintained by charity and staffed usually by religious orders, to the well-equipped, efficient places of today, used by every part of the community, maintained by charity or at public expense, and staffed by trained nurses, physicians, surgeons, and lay assistants.

The 19th-century discoveries of Louis Pasteur, which showed the relation of micro-organisms to certain diseases, Joseph Lister's application of Pasteur's concepts to surgery, and the studies of Rudolf Virchow and Robert Koch in cellular pathology and bacteriology brought immense stimulus to the practice of medicine and surgery. The passage of the Medical Act of 1858 has been termed the most important event in British medicine. It established the General Medical Council, which thenceforth controlled admission to the medical register and thus had great powers over medical education and examinations.

In the United States, medical education was greatly influenced by the example set in 1893 by the Johns Hopkins Medical School in Baltimore. It admitted only college graduates with a year's training in the natural sciences. Its clinical work was superior because the school was supplemented by the Johns Hopkins Hospital, created expressly for teaching and research carried on by members of the medical faculty. The number of inadequate medical schools in the United States was reduced after the Carnegie Foundation for the Advancement of Teaching published in 1910 a report by Abraham Flexner. The report attracted attention to the need of medical schools for better laboratory facilities, better access to patients in hospitals, and larger, better trained teaching staffs. Aided by the General Education Board, the Rockefeller Foundation, and a large number of private donors, U.S. and Canadian medical education was characterized by substantial improvements from 1913 to 1929 in the matters of endowments, buildings, laboratories, clinical facilities, teaching staffs, and methods of instruction.

### PATTERN ESTABLISHED IN THE FIRST HALF OF THE 20TH CENTURY

**General characteristics.** As medical education developed after the Flexner report was published, the distinctive feature was the thoroughness with which theoret-

School

ical and scientific knowledge were fused with what experience teaches in the practical responsibility of taking care of human beings. The clinical teacher has an immediate and absolute responsibility.

The premedical courses required in most countries emphasized the subjects of physics, chemistry, and biology. Graduation from a recognized secondary school was required. The courses in physics, chemistry, and biology were required in order to make it possible to present subsequently the subjects of anatomy, physiology, biochemistry, and pharmacology with precision and economy of time to minds prepared in scientific method and content. Each of the required courses included laboratory periods ranging from two hours to six hours a week for a full academic year. The extent of the student's familiarity with the use of instruments and laboratory procedures varied widely from country to country, however.

The medical schools began their work with the study of the structure of the body and its formation: anatomy, histology, and embryology. Concurrently, or soon thereafter, came the studies related to function—*i.e.*, physiology, biochemistry, pharmacology, and, in most schools, biophysics. Usually after the microscopic study of normal tissues (histology) had begun, the student was introduced to pathological anatomy, bacteriology, immunology, parasitology—in short, to the agents of disease and the changes that they cause in the structure and function of the tissues. Courses in medical psychology, biostatistics, and public health sometimes were given in the first two or two and a half years of the medical course, but this was not common before 1935. Wide differences were observed from country to country and from decade to decade in the sequence and emphasis given the courses in the above-named medical sciences and in the balance between laboratory work, lectures, and seminars.

The two or more clinical years of an effective curriculum were characterized by active student participation in small group conferences and discussions, a decrease in the number of formal lectures, and an increase in the amount of contact with patients in teaching hospitals and clinics. Through work with patients, under the supervision and guidance of experienced teachers, students learned methods of obtaining comprehensive, accurate, and meaningful accounts of illness, how to conduct physical examinations, and how to develop judgment in the selection and utilization of laboratory diagnostic aids. During this period they learned to apply the knowledge gained in their pursuit of the basic medical sciences to the study of general medicine and the medical and surgical specialties.

On completion of medical school, the physician usually sought graduate training and experience in a hospital under the supervision of competent clinicians and other teachers. In Britain after 1953, a year of resident hospital work was required after qualification and before admission to the medical register. In North America, the first year of such training is known as an internship. Persons seeking further graduate education and training to qualify themselves as specialists or to fulfill requirements for a higher academic degree subsequently became hospital residents or fellows for periods of from one to four or five years.

The second type of advanced training is known as postgraduate education. It consisted of courses and training opportunities of from a few days to several months in duration, designed to enable physicians to learn of new developments within their special areas of concern. Such courses, fostering the continuing education of physicians, were offered by medical schools, hospitals, and medical societies in many parts of the world.

**Pedagogical aspects.** Abraham Flexner rightly insisted that medical education is a form of education and not a mysterious process of professional initiation or apprenticeship. In terms of educational methods the following points deserve mention:

In the United States, Great Britain, and the Commonwealth countries, medical schools were inclined to limit the number of students admitted so that each student might have a reasonably good opportunity. In western

Europe, South America, and most other countries, no exact limitation of numbers of students was effected, though there was a trend toward such limitation in some of the western European schools. Some medical schools in North America were able to show ratios of teaching staff to students as high as 1 to 1 or 1 to 2, in contrast with 1 teacher to 20 or even 100 students in certain European universities.

As applied to clinical teachers the term full time originally implied an educational ideal: that a clinician's salary from the university should be large enough to relieve him of any reason for seeing private patients for the sake of supplementing his salary by professional fees. Full time came to be applied, however, to a variety of modifications; it could mean that a clinical professor might supplement his salary as a teacher up to a defined maximum, might see private patients only at his hospital office, or might see such patients only a certain number of hours per week. The intent of full time has always been to place the professor's capacities and strength entirely at the service of his students and the patients entrusted to his care as a teacher and investigator.

Courses in the medical sciences commonly followed the formula of three hours of lectures and six to nine hours of laboratory work per week for a three-, six-, or nine-month course. Instruction in the clinical subjects, though retaining the formal lecture, tended to diminish the time and emphasis allowed to lectures in favor of experience with and attendance on patients. Nonetheless, the level of lecturing and formal presentation in continental Europe remained high. Formality and a considerable measure of emphasis on status also characterized the relationship between professor and student in European schools.

In the United States, the fifth, or intern, year was of special importance and value, though it was not usually directly controlled by the medical school and ordinarily followed the award of the M.D. degree. The intern usually lived in an approved hospital and in any case devoted his entire time to the work of the hospital. Often the intern year led to a second year called assistant residency or residency, a continuation of this extremely valuable practical experience. In the United States, approximately three-fourths of graduate physicians entered residency training for a period of two to five years after the internship.

The clinicopathological conference is a distinctive feature of medical education in North America. As a public exercise, a clinician comments upon the record of a case of fatal illness in a patient he has not seen and discusses from this record the probable cause and nature of the illness. The pathological anatomist who examined the organs of the deceased then reports upon the actual findings. The lessons are vivid, and the effect upon the fullness and accuracy of hospital records is excellent.

In Great Britain, Canada, Australia, New Zealand, South Africa, and Ireland, the academic degrees given at the end of five years of study were the M.B. and B.Ch. (bachelor of surgery). Only after considerable further study was the M.D. given, and only to a few persons; only these persons are entitled to be addressed as "doctor." It is customary in Great Britain and the British Commonwealth to address all physicians as "doctor," however, whether or not they hold the M.D. degree; but surgeons, including holders of the M.D. degree, prefer to be called "mister," although in northern England and in Scotland they are called doctor.

In some countries of western Europe, in South America, North America, China, and the Philippines, the M.D. was given at the end of four to six years of study and was not, therefore, an advanced degree.

The quality of medical education is supervised in the English-speaking countries by councils appointed by the profession as a whole—*e.g.*, the Council on Medical Education and Hospitals of the American Medical Association in the United States—or, in the case of Great Britain, by a statutory body, the General Medical Council, most of whose members are from the profession, although only a minority of the members are appointed by it. In other countries this is a function of the Ministry of Public

Licensure  
in  
United  
States  
and  
Canada

Instruction with, in some cases, the help of special councils to represent professional knowledge and experience.

**Social factors.** In the United States, licensure to practice medicine is controlled by boards of licensure in each of the states. These boards set and conduct examinations of applicants to practice within the state, and they examine the credentials of applicants who wish licences obtained in other states to be accepted in lieu of examination. In 1915 the National Board of Medical Examiners was created as a voluntary organization with two representatives each from the army, navy, and Public Health Service, three representatives from state licensure boards, and seven other physicians to hold examinations leading to a diploma that would be acceptable to all the state boards. National laws regulating professional practice cannot be enacted in the United States.

In Canada, the Medical Council of Canada conducts examinations and enrolls successful candidates on the Canadian medical register. The provincial governments accept the certificate of this registration as the main requirement for licensure. In Great Britain, the medical register is kept by the General Medical Council, which supervises the licensing bodies; unregistered practice, however, is not illegal. In most European countries graduation, on conditions set by law, from the state-controlled university or medical school in effect serves as a licence to practice; and the same is true for the Union of Soviet Socialist Republics and Japan.

After 1920 there was a steady growth and improvement of preventive medicine and public health in the United States, in terms of its importance in the medical curriculum as well as in the number and qualifications of professional personnel employed by cities, counties, states, and the U.S. Public Health Service. A similar development characterized many other countries, especially the Union of Soviet Socialist Republics.

It became apparent that it is of special advantage to a patient to obtain care in a teaching hospital because, if his case is to be used for discussion or teaching, there is every likelihood that the examination, diagnosis, and treatment will receive particular care and repeated attention; hence, a hospital's affiliation with a medical school for research and teaching purposes is highly desirable. This was realized by the U.S. Veterans Administration in 1945, when the deans' committee assured collaboration between the medical schools and the hospitals of the Veterans Administration. Collaboration between school and hospital has given rise to the so-called medical centres.

**Economic aspects.** The income of a medical school is derived from four principal sources: (1) tuition and fees; (2) endowment income or appropriation from the government (taxation); (3) gifts from private sources; and (4) donation of teachers' services. Tuition or student fees are large in the English-speaking countries (except in United States state universities) and small throughout the rest of the world. Only rarely does income from tuition exceed 50 percent of a school's total income. The total cost of maintaining a medical school, if prorated among the students, would give a figure from three to 50 times the tuition or other charges paid by the student.

The expenses of medical education fall into two groups: those of the instruction given in the medical sciences and those connected with hospital teaching. In the medical sciences, costs of building maintenance, laboratory equipment and supplies, research expenses, salaries of teachers, and wages of employees are heavy but comparable to those in other departments of the university. In the clinical subjects all expenses in connection with the care of patients usually are considered as hospital expenses and are not carried from the medical school budget, which is normally reserved for expenses of teaching and research. Here the heavy expenses are salaries of clinical teachers and the cost of studying cases of illness with a thoroughness appropriate to their use as teaching material.

To a considerable degree in all capitalist countries, the cost of securing an adequate medical education has tended to exclude the student whose family cannot contribute a large share of his living expenses and tuition for a period of four to ten years. This difficulty is offset in some

medical schools by loan funds and scholarships, but these aids are commonly offered only in the second or subsequent years. In Britain, scholarships and maintenance grants are available, through both state and local educational authority funds, so that a clever boy or girl can have the opportunity of a medical education even though the parents may not be able to afford its cost.

**Scientific aspects.** Medical education has the double task of passing on to students what is known and of attacking what is still unknown. The cost of research is borne by a few; the benefits are shared by many. There are countries whose inhabitants are too poor to support physicians or use them; countries that can support a few physicians but are too poor to maintain a good medical school; countries that can maintain medical schools where what is known can be taught but no research can be carried out; and a few countries in which teaching and research in medicine can be carried on to the great advantage of the world at large.

A medical school having close geographical as well as administrative relationships with the rest of the university of which it forms a part usually profits by this intimate and easy contact. Medicine cannot wisely be separated from the biological sciences, and it continues to gain immensely from chemistry, physics, mathematics, and psychology. The social sciences have a contribution to make in helping physicians provide a better distribution of medical care. Contact with teachers and the advancing knowledge in other faculties of the university would extend and improve the chances of progress in medicine.

**International aspects.** With the development of the World Health Organization and the World Medical Association after World War II, there has been increasing international interest in medical education. World War II showed the advantages and economy derived from satisfactory systems of medical education. Defects and diseases were more widely and accurately detected among recruits than ever before, health and morale were effectively maintained among combatants, and disease and battle injuries were effectively treated only in the armed forces of those nations whose medical schools had been of high quality. As a result of the war, however, the medical schools of Norway, Finland, the Union of Soviet Socialist Republics, Poland, Czechoslovakia, Germany, Austria, the Balkan states, Italy, France, Belgium, The Netherlands, and Britain, as well as those of China, Japan, the Philippines, Java, and Thailand, suffered either physical destruction of laboratories, hospitals, and libraries or serious losses of teaching personnel and students. (A1.Gr./E.L.T.)

#### THE SITUATION SINCE 1960

The essential features of the medical education that was established in the early 20th century survived in much of the world during the 1960s and early 1970s, especially in the developed countries of the West; but need for more physicians, desire for improvement in the quality of medical care, and efforts to relate medical care more closely to the needs of the populace to be served brought some changes and many plans for change. The most dramatic changes occurred in China.

**People's Republic of China.** In 1966 the medical schools of the People's Republic of China were closed. The students, then accepted as graduates, and the faculty were sent out to give medical care where it was needed, particularly in the rural areas.

The medical schools remained closed until December 1970. Meanwhile, the administrative structure of the schools (like the administrative structures of other organizations) was placed under the control of revolutionary committees consisting of representatives of the People's Liberation Army, of workers or students, and of the administration or faculty. The chairman of the committee in each school was an army officer.

The curriculum was still undergoing discussion, but when the schools reopened in December 1970, the contemplated three-year program was as follows:

The first nine months are academic and include instruction in anatomy, physiology, biochemistry, Chinese tradi-

in China

tional medicine, political education, pharmacology, and microbiology. Then, after two months devoted to military and physical training and manual labour, the student has one month of vacation before six months of training, consisting of lectures and clinical demonstrations in internal medicine, surgery, obstetrics, and gynecology. After a second sequence of two months of military and physical training and manual labour followed by a month's vacation, nine months are devoted to on-the-job training. Faculty and students form medical teams that serve the rural populace during the day. They also do manual labour. During the evenings students and faculty repair to local classrooms, where lectures are given in clinical practice and basic science. During this same period the students learn the science of acupuncture—the elaborate system of pricking precise points on the body in diagnosis and treatment of disease—and the recognition, collection, and use of herbs.

Three months of intensive training at a teaching hospital and three months of military and physical training, labour, and vacation complete the course.

**Africa.** In the developing countries of Africa, a number of medical schools were established after 1960, but there were still too few institutions to train an adequate number of qualified personnel. A majority of the practicing physicians in the area were still non-nationals who had received their training elsewhere.

A survey of the region carried out by the World Health Organization in 1967 indicated that about 1,300 African medical students were studying abroad and that about 1,800 were attending African medical schools. The report of the survey stated that there was at that time one physician for 20,000 people in the countries surveyed, one registered nurse for 12,000 people, and one sanitary engineer for 2,000,000 people. Furthermore, 70 percent of the faculty members in the medical schools were non-nationals; this may account in part for the fact that the medical education given in Africa was deemed unsuitable for the situations in which the physicians were to practice.

**India.** The number of physicians graduating annually from the medical schools of India increased ninefold in the period from 1947–48 to 1968–69, but the physician-population ratio still remained far behind that of Europe and North America. The medical schools remained conservative in their methods and were criticized on the ground that their curricula were overloaded with details; that preclinical and clinical training were inadequately related; and that in the clinical course too much time was spent in lectures and too little in demonstrations. In certain institutions, however, efforts were begun to acquaint students with the problems of the rural areas, where eight-tenths of the Indian population resided.

**United States.** In the United States, in response to the need for more physicians, many medical schools changed their program leading to a medical degree from four years to three. Responses to a questionnaire sent in 1968 to the deans of all the medical schools in the United States indicated that 19 schools had started three-year programs or would soon do so and that 14 other institutions were studying the possibility of making this change.

Various methods were used to achieve the reduction in time spent in education. In some institutions, the fourth year, which had been devoted to elective work in research laboratories, for example, or to gaining clinical experience in a hospital, was simply dropped, and the student received his degree after completion of three years at the medical school and one year of internship. In other schools, the conventional curriculum was preserved and the four-year course was compressed into three by elimination of summer vacations. Still another program eliminated from the curriculum courses in subjects in which students had been adequately prepared before entering medical school. One program, based on careful coordination between premedical and medical training, achieved a five-year program from high school graduation to receiving an M.D. degree.

In the 1960s the first steps were taken toward computer-assisted medical education. In one such program, funds

for which were supplied by the Division of Physician Manpower of the National Institutes of Health, the computer served as a "patient" and the medical student as a physician in a simulated situation. In interviewing the patient, for example, the student typed out his questions and the computer answered on a television-like screen.

The questions and answers might relate to the symptoms, to the results of laboratory tests, or to the physical examination. After making his diagnosis, the student typed out his course of treatment, and the patient recovered or died, depending upon the suitability of the treatment chosen.

In 1968 the Lister Hill Center for Biomedical Communications was established as one of the five major divisions of the National Library of Medicine. A committee of the Council of Academic Societies of the Association of Medical Colleges recommended that the Lister Hill Center

should have as its eventual goal the development of educational methods which will render obsolete the current systems of libraries, textbooks, medical school curricula, and total dependence on memory and pattern recognition in clinical decision-making and problem-solving. These major changes will come only with the development of new sources and new types of manpower ready to devise new approaches to the problems of medical education and the delivery of health care. Their long-term objective will not be limited to improving existing systems but will include devising newer systems using a different mix of men and machines than now familiar. This revolution will require a faculty who have mastered communications technology and who are eager to sail in yet uncharted educational waters. (From *Journal of Medical Education*, July 1971, part 2.) (T.F.R.)

**BIBLIOGRAPHY.** For new developments in medical education and for recent accounts of the situation prevailing in particular countries and regions, the periodicals *Journal of Medical Education*, *British Journal of Medical Education*, and *WHO Chronicle* are recommended. Also of interest are JULIUS B. RICHMOND, *Currents in American Medicine: A Developmental View of Medical Care and Education* (1969); FREMONT J. LYDEN, H. JACK GEIGER, and OSLER L. PETERSON, *The Training of Good Physicians: Critical Factors in Career Choices* (1968); and JOHN H. KNOWLES (ed.), *Views of Medical Education and Medical Care* (1968). ## Medical Jurisprudence

Medical jurisprudence, or forensic medicine, is, in the strict sense, the application of the science of medicine in courts of law. In practice the subject includes many other matters that are not necessarily concerned with court proceedings. These include the medical aspects of proceedings before administrative or quasi-judicial bodies (such as pensions tribunals, industrial injuries boards, and medical appeal tribunals) and medicolegal aspects of administrative law (such as the control of dangerous drugs and poisons, the disposal of dead bodies and stillbirths, and the exercise of compulsory powers of admission to a hospital over persons of unsound mind). Legal and ethical aspects of medical practice itself are included, such as the functions of professional disciplinary bodies, medical registration and licensing of doctors, professional negligence, medical certification, and the code of medical ethics. The European practice of referring to the subject as "legal medicine" (*médecine légale* in French, *gerichtliche Medizin* in German) is, therefore, a more correct description of its scope, and the

Hill  
Center

term legal medicine is increasingly used in the United States.

The broad canvas that the subject now covers is a reflection of the increasing part played by medicine in the social life of the community. Inevitably there is overlap into subjects such as public health, industrial medicine, criminology, drug dependence, and into the wider field of forensic science. In some European countries, university chairs of legal medicine are combined with criminology or with social or insurance medicine.

**Growth of medical jurisprudence.** Although instances of medical evidence being given in courts of law can be cited back to classical antiquity, the basis of modern medical jurisprudence cannot be traced beyond the 13th century, when the laws of the north Italian states first provided for the appointment of medical experts to advise the courts and laid down the requirements necessary to qualify as an expert medical witness. About the same time the first appointments as police surgeons were made. Post-mortem examinations (autopsies) were carried out for medicolegal purposes, particularly in cases of suspected poisoning. It was this practice that revived the interest in anatomical dissection, itself to have a profound effect on the development of modern European medicine.

By the 16th century, the procedure for assembling medical evidence and presenting it in courts of law in criminal cases was well developed. It found expression in the penal codes promulgated by the bishop of Bamberg (1507), the elector of Brandenburg (1516), and Charles V of the Holy Roman Empire (1533). At the same time the procedure for investigating cases of violent or sudden deaths was also laid down. Centuries were to pass before these principles were accepted in Britain, where the development of medical jurisprudence was apparently unaffected by the important events taking place on the European continent. Until 1836 the coroner in England had no power to pay for medical evidence in inquests, and it was even doubted whether he could order a postmortem examination.

*Acceptance as part of medical education.* Similarly, the teaching of medical jurisprudence at British universities lagged behind the Continent. More than 150 years elapsed between the presentation of lectures on legal medicine at Leipzig (1642) and at Edinburgh University (the elder Andrew Duncan was the lecturer in 1801). Meanwhile, chairs of legal medicine, often combined with public health and hygiene, had been set up in many universities on the Continent. The first chair in the United Kingdom was established by crown commission in 1807 and was held by the younger Andrew Duncan. At about the same time, James S. Stringham delivered a course of lectures in New York at Columbia College (1804); he was appointed, in 1813, to the first chair of medical jurisprudence in the United States, instituted by the College of Physicians and Surgeons in New York city. Other courses were given by Charles Caldwell at Philadelphia Medical College in 1812-13 and by T.R. Beck at the College of Physicians and Surgeons for the Western District at Fairfield, New York. Since that period the majority of medical schools in the United States have included the subject in their courses of instruction.

Post-graduate instruction

Postgraduate instruction in legal medicine has been available on the continent of Europe for a considerable time. From the beginning of the 19th century attendance at courses at the medicolegal institute in Vienna was a condition of appointment as police surgeon in many European countries. Recognition as an expert in the subject on the Continent is dependent upon a long course of postgraduate instruction at a medicolegal institute or a university department of forensic medicine. This contrasts favourably with the position in British and American courts, where any medically qualified person may give evidence in court as an expert witness. In parts of England and of the United States, coroners' postmortem examinations may be carried out by any qualified doctor, irrespective of his experience in medicolegal work; in other parts only experienced pathologists are employed for the purpose; *e.g.*, in London, and in particular in Los Angeles, where coroners' autopsies may be carried out

only by official autopsy surgeons. Concern has been expressed that there was no mention at all of legal medicine in a report of the British Royal Commission on Medical Education (1968).

**Medical evidence in courts of law.** Both criminal and civil courts receive medical evidence. In criminal courts such evidence is concerned chiefly with the identification and interpretation of injuries in support of charges of crimes such as murder, manslaughter, infanticide, woundings, poisonings, assaults (both sexual and nonsexual), rape, and criminal abortion. The identification of human remains, the distinction between injuries received before death and after death, the time elapsed since death, the distinction between live birth and stillbirth, the signs of drowning, traumatic asphyxia, hanging, strangulation, suffocation, throttling, electrocution, burning, and wounds received from instruments or firearms are but a few of the wide range of matters upon which medical evidence may be required in criminal courts.

The sensational nature of this kind of evidence usually overshadows the importance of medical evidence in the civil courts, where it may be needed in common-law actions based on negligence that results in personal injuries; *e.g.*, traffic accidents and nervous shock cases. In such cases medical evidence may be relevant, both as to the cause and extent of the injuries and to their possible consequences in terms of assessing damages. Medical evidence may also be needed by the courts in connection with such considerations as the mental capacity to make a will disposing of property (testamentary capacity), presumption of survivorship, inability to consummate a marriage, the state of mind of one or other spouse, duration of pregnancy, and illegitimacy. In England the president (senior judge) of the probate, divorce, and admiralty division of the high court appoints special medical inspectors to examine the parties in nullity (annulment) cases. Courts may also require medical evidence in the exercise of their jurisdiction over the property of persons of unsound mind (in England, court of protection orders). Other civil cases in which medical evidence may be required include paternity orders, maintenance orders, and noncohabitation orders, which are often dealt with by lower courts of summary jurisdiction. Jurisdiction in civil cases in the United States varies considerably from state to state.

*Investigation of sudden death.* Coroners have jurisdiction over violent, unnatural, or sudden deaths of unexplained cause, and it is in these cases that medical evidence is essential. In some areas coroners themselves are medically qualified, and in those parts of the United States where coroners have been replaced by medical examiners, a medical qualification is a condition of appointment. The coroners in London are qualified both in medicine and in law. The main evidence received by the coroner is the report of the autopsy carried out on the body of the deceased person, and in many areas such examinations are carried out in nearly every case. Corresponding, though less comprehensive, investigations are carried out by the procurator fiscal in Scotland. There is no corresponding procedure for investigating sudden death on the continent of Europe. Deaths attract investigation in such cases only where there is manifest suspicion of crime or wrongdoing. They are often notified to the police or local public prosecutor (*e.g.*, *procureur de la république*). Unlike the coroner, neither the police nor public prosecutors have power to order medicolegal autopsies, and the authorization of an investigating judge (*judge d'instruction*) may have to be obtained. Exceptions include Denmark, Finland, and Portugal, where the police are so authorized, and The Netherlands and the Union of Soviet Socialist Republics, where the local public prosecutor may authorize an autopsy. In some countries (*e.g.*, the Federal Republic of Germany), the judge must be present at the autopsy. Finally, the right, and in some cases duty, of the coroner to hold a public inquest, at which persons can be examined under oath and a verdict of a jury can be obtained on the cause of death, is peculiar to the Anglo-American coroner system and does not exist under the medical

examiner or continental systems of medicolegal investigation. The coroner system, therefore, secures a far more comprehensive check on sudden deaths. In England investigation was undertaken in 1964 of the entire system of death certification and of coroners, under a governmental committee.

*Two types of medical evidence.* Two kinds of medical evidence may be given in courts of law. Evidence can be given as to facts that have come within the doctor's knowledge in the course of his practice, and in respect of which he is in the same position, in principle, as other witnesses to fact; he can also be called to give expert evidence on facts that have been presented to him for his opinion and have not come within his knowledge in the course of his practice, or on facts that he has secured from making special examinations or investigations for the specific purpose of providing the evidence.

Confidential information

The question whether information obtained in a professional capacity should be disclosed without prior consent of the patient may bring the physician into conflict with the law. The international code of medical ethics that has been adopted in principle by all countries whose medical associations are affiliated to the World Medical Association embodies the Declaration of Geneva (1949), which states: "I will respect the secrets which are confided in me." In circumstances in which the court requires disclosure of information, the physician may risk imprisonment for contempt of court if he declines to give the information. This is the position in Great Britain and in about 15 states of the United States. In about 35 states, however, varying degrees of privilege, precluding disclosure of confidential information obtained in the course of treating a patient, are allowed, but the privilege can be waived in certain circumstances; *e.g.*, if the patient offers himself or his physician as a witness, although this is not the invariable rule. The tendency is to allow privilege to physicians.

As a general rule, evidence as to opinion is excluded from the courts on the grounds that it is for the court to form its own opinion on the facts that are before it, and the admission of expert evidence based on opinion would, therefore, trespass on the function of the judge and jury. In cases in which the matter before the court is complicated or technical in nature, however, it has become customary for the courts to admit evidence of expert opinion in order to assist it to reach its conclusions on the facts before it. Accordingly, specialists in various branches of medicine may be called to assist the courts. It is in the field of pathology that expert medical evidence is most frequently required. Expert psychiatric opinion is also sought increasingly in connection with the state of mind of persons who have been accused of committing criminal offenses or in other circumstances that have been mentioned above. The frequent need for courts to obtain evidence in these two fields has led to the development of specialties in forensic pathology and forensic psychiatry.

Other specialties on which the courts frequently require expert opinion include forensic odontology, which is concerned with the identification of persons or their remains through examination of their teeth; forensic immunology and serology, concerned with the identification of persons from examination of blood stains or of other secretions of the body such as spermatozoa, and with related problems such as disputed paternity; and forensic toxicology, concerned with the unlawful or accidental use of poisons or drugs and their identification by analysis of specimens. Specialists in these fields are not necessarily medically qualified. The interpretation of a bullet wound may depend on a knowledge of ballistics, for example, and the question whether a person is fit to have control of a motor vehicle may depend on the concentration of alcohol in the body tissues. Expert medical evidence in courts of law has become associated increasingly with supporting evidence of investigations carried out in the field of forensic chemistry, such as spectrophotometry, chromatography, activation analysis for minute amounts of various elements, and the identification of fibres, soils, or other substances.

The handling of expert medical evidence by continental

courts (based on civil-law "inquisitorial" procedure) is very different from the procedure in English and United States courts (based on common-law "accusatorial" procedure), and the difference is most marked in criminal or quasi-criminal (delictual) cases. In England, documentary evidence is admitted only subject to strict limitations, whereas on the Continent the expert medical evidence is almost entirely documentary and is included in the dossier. Either side in an English trial may call expert medical witnesses, who may frequently disagree in their opinions, and who may be examined, cross-examined by the other side, and re-examined. Under the classical continental system, expert medical evidence is given only by the court's officially recognized expert, who will appear in person only when it is necessary to explain any doubtful points in his written evidence. Even then, he may be examined only by the presiding judge and cannot be questioned by counsel for the parties to the action. The limitation of medical evidence to experts recognized by the courts means that the spectacle of medical witnesses giving directly contrary evidence on behalf of either side—the so-called battle of the experts—is not a feature of continental courts. In most continental countries medicolegal institutes have been set up by the state to provide the courts with the best evidence; the more famous ones being in Vienna (founded 1803), Berlin, and Leipzig. In Denmark the courts are advised by the State Medico-Legal Council, which examines about 4,000 cases each year. Each case referred by the courts is examined by three members of the council. These institutes are equipped to carry out investigations covering the whole field of forensic sciences and may deal with matters such as the examination of individuals injured in industrial accidents, in addition to court work. They may also arrange for operations such as castration or sterilization of certain offenders when the laws of the country permit it. Their nearest equivalent in English-speaking countries is the forensic science laboratories that have been set up by the Home Office in England on a regional basis, but their scope is limited and restricted mainly to the field of chemical analysis.

**Medical certification.** A physician in any country will be asked to give certificates required by law for various purposes. Medical certification, in terms of legal duty, forms an important part of a doctor's practice, and the consequences of inaccurate certification are serious. In many cases, international forms of medical certificates have been introduced; *e.g.*, death certificates and certificates of vaccination. Stillbirth certification by doctors or midwives is obligatory in most countries, and the detention of a person of unsound mind in a hospital or under guardianship must always be supported by a medical certificate. Methods of disposal of dead bodies other than earth burial (*e.g.*, cremation), which destroy all evidence of the cause of death, must generally be authorized by special medical certificates. An increasing number of countries now require a medical examination and report on the child as well as the prospective adoptive parents before legal adoption of a child is permitted. Certain infectious diseases, depending on the country concerned, must be reported by physicians to public-health authorities. Certificates of incapacity for work on account of illness or injury are universally required from physicians, while many medical certificates are required in the insurance field in support of prospective policy holders or of claims for sickness or injury benefits.

**Medical discipline and conduct.** Most countries have introduced regulations to enable the public to distinguish between duly qualified physicians and unqualified practitioners, and this is achieved by licensing or registration procedure. In the United States, licensing is administered by the various states and may be either general or limited. General licenses are issued to duly qualified physicians after scrutiny of their qualifications, character, and experience. No license to practice medicine is required in Great Britain, but it is an offense for a person to pretend to the public that he is a registered medical practitioner, as by willfully and falsely using certain titles calculated to deceive (*e.g.*, in Britain, M.D.). Licenses to practice

U.S. and English practices contrasted with continental

Types of medical certificates

are required in the United States. Persons who are not licensed or registered are prohibited from various functions for which licensed or registered doctors are empowered; e.g., prescribing dangerous drugs (narcotics), treating venereal disease, giving medical certificates, or attending maternity cases (except for certified midwives). Reciprocal recognition of degrees or diplomas is not extensive, but it forms an important part of the so-called Brussels Directives, which will regulate the practice of medicine in countries belonging to the European Economic Community (Common Market).

Disciplinary  
measures

The various registration and licensing bodies have power to suspend registration or a license upon proof of professional misconduct in certain circumstances. For example, in Great Britain conviction of certain offenses or the judgment of the disciplinary committee of the General Medical Council is grounds for removal from the register. Professional misconduct can include adultery or other improper conduct with patients, procuring illegal abortions, drunkenness or drug dependence, advertising, and canvassing. The standards of professional conduct, however, vary greatly in different countries. Adultery with patients, for example, is not generally regarded as grounds for prohibiting a doctor from practicing in most European countries, with the exception of Britain. An increasing number of countries have introduced state health services, and disciplinary bodies have been set up to pronounce upon alleged breaches by doctors of their terms of service with the state health service. Finally, national medical associations may expel from membership physicians who are found guilty of infringing their association's own code of medical ethics, and many associations (e.g., the British Medical Association [B.M.A.]) have set up means to deal with such cases.

**Law relating to medical practice.** Finally, medical jurisprudence is concerned with the relationship of medical practice itself to the laws of the country. The legality of certain practices such as termination of pregnancy, sterilization, castration, artificial insemination, transplantation, contraception, animal experiments, anatomical dissection, and euthanasia is a matter of very considerable importance to doctors, and their position in law in relation to many of these practices is often obscure; e.g., it is an offense in parts of the United States to run a birth control clinic, yet the supply of contraceptives for prophylaxis against venereal disease may be allowed. Sterilization is permitted in some states and not in others. The grounds on which pregnancy can be terminated in different countries vary from absolute prohibition to almost any medical, eugenic or social consideration.

The physician is in exactly the same position as any other professional man, in that failure to exercise reasonable care may result in an action being brought against him in negligence if the patient suffers damage as a consequence. The same rules as to presumptive and contributory negligence apply. Both in England and in the United States a mistaken diagnosis or treatment is not per se actionable in negligence; it must be shown that the physician omitted or committed some procedure that a reasonable physician in his position would have done or not done; e.g., failure to X-ray head injuries or omission to give antitetanic serum in the appropriate cases. Physicians will also be liable in trespass (assault) for carrying out procedures without the express or implied consent of the patient. The age at which consent can be given became a subject of much controversy with the increased demand by adolescent girls for induced abortion. Finally, patients may sue their physicians in contract for inadequate or faulty provision of services.

## Medici Family

Medici is the name of the Italian family that ruled Florence, and later Tuscany, for more than three centuries, from 1434 to 1737, except for two brief intervals (from 1494 to 1512 and from 1527 to 1530). Unique in the history of dynasties, their founder was not a "soldier of fortune," and consequently their entourage and their court continually showed an astonishing lack of men of the sword. The basis of their power was gold, accumulated by a long succession of shrewd merchants and bankers, whose genius consisted in taking the greatest possible advantage of the economic renaissance of Europe after the 12th century. Yet in time these financiers desired to exercise real power, instead of operating behind the scenes as did so many of their kind. Although they tried to avoid becoming involved in politics, they eventually recognized that, in a city as jealous of rank and position as was republican Florence they were at the mercy of spoliatory laws voted by the popular assemblies under pressure from either various demagogues or their competitors. The most illustrious of the Medici, Lorenzo the Magnificent, wrote in capital letters in his diary: "One cannot live in wealth in Florence without the state."

Basis  
of the  
family's  
power

#### ORIGINS OF THE MEDICI

**The three lines.** Three lines of Medici successively approached or acquired positions of power (see the Table). In the 14th century, the attempt ended in failure. In the 15th century, the Medici set up a hereditary principate in Florence but without legal right or title, hence subject to sudden overthrow; crowns burgeoned, however, on the last branches of their genealogical tree, for two of them were dukes outside Florence, their last heir in a direct line became queen of France, and their final offspring, a bastard, was duke of Florence. In the 16th century, a third line renounced republican notions, imposed its tyranny, and its members made themselves grand dukes.

The differences between these three collateral lines are

due essentially to circumstances, for there was, in all the Medici, an extraordinary persistence of hereditary traits. In the first place, not being soldiers, they were constantly confronting their adversaries with gold-bearing mules rather than with battalions of armed men. In addition, the early Medici resolutely courted favour with the middle and poorer classes in the city, and this determination to be *popolani* ("plebeian") endured a long time after them. Finally, all were consumed by a passion for arts and letters and for building. They were more than beneficent and ostentatious patrons of the arts; they were also enlightened and were probably the most magnificent such patrons that the West has ever seen.

**The line of Chiarissimo II.** The Medici were originally of Tuscan peasant origin, from the village of Cafaggiolo in the Mugello, the valley of the Sieve, north of Florence. Their descendants never forgot that they were of rustic stock, and this possibly accounts for their love of gardens that may correctly be included among their hereditary characteristics. Some of these villagers, in the 12th century perhaps, became aware of the new opportunities afforded by commerce and emigrated to Florence. There they settled near the Church of San Lorenzo, at that time still outside the walls of the city. The Medici would always remain faithful to their parish and even to the name of its patron saint. They were neither doctors nor apothecaries, in spite of the false stories later circulated at the French court when Catherine de Médicis married Henry II. The balls on their coat of arms, the famous *palle*, represent not pills but a Byzantine coin—the bezant—heraldic symbol of their true trade, money changing.

In 1201 the name of a Medici was mentioned for the first time in a notarial document, that of Chiarissimo, son of a certain Giambuono. By the following century, the Medici were counted among the wealthy notables, although in the second rank after leading families of the city. After 1340, an economic depression throughout Europe forced these more powerful houses into bankruptcy. The Medici, however, were able to escape this fate and even took advantage of it to establish themselves among the city's elite. But their policy of consolidating their position by controlling the government—the work of the grandsons of Chiarissimo II (himself the grandson of the first known Medici)—resulted in 50 years of serious misfortunes for the family (1343–93). Giovanni, one of the grandsons, persuaded the Florentines to seize Lucca, but the plan failed, and he paid for the debacle with his life. His cousin Salvestro took up his policy of alliance with the *popolo minuto* ("common people") and was elected gonfalonier, head of the *signoria*, the council of government, in 1378. Salvestro more or less willingly stirred up an insurrection of the *ciompi*, the artisans of the lowest class, and, after their victory, was not above reaping substantial monetary and titular advantages. But in 1381, when the popular government fell, he had to go into exile. His memory, however, was still alive in 1393, when the *popolo magro* ("lean people") once more thought it possible to take over the *signoria*. The mob hastened to seek out his first cousin, Vieri, who was, however, able to fade away without losing face. With Vieri this branch of the Medici was to disappear definitively from history.

#### THE LINE OF COSIMO THE ELDER, THE PRINCIPATE

The restoration of the Medici fortune was the work of Giovanni di Bicci, who was descended from Averardo, a brother of Chiarissimo II. Giovanni's father, Averardo III, had acquired the surname Bicci. Nothing is known about the first 40 years of Giovanni's life. His name first appears in 1401 on the list of those judging the open competition for the door of the Baptistery of San Giovanni, of which he was also a donor. He must certainly have lived dangerously, for the Medici name did not ring favourably in the ears of the Albizzi-Capponi-Uzzano oligarchy that had ruled Florence since 1381; and he had done nothing to re-establish himself in their good graces, for he had remained a *popolano*. To them he was at once dangerous and elusive, for experience had taught him to act with the utmost prudence. The oligarchs thought they

must overthrow him before he was elected gonfalonier in 1421, but Niccolò da Uzzano made them realize that it was already too late: his popularity and his wealth, reinforcing each other, elicited respect. His bank had realized enormous profits from its management of the Council of Constance's finances. And although so much wealth risked arousing the envy of a fiercely egalitarian proletariat, Giovanni was protected from it by his simple life-style, his inexhaustible largesse, his support of an income tax plan (the *catasto*, based on landed property), and finally, his patronage. He had recognized the genius of Filippo Brunelleschi and provided him with the means to employ it by building the Ospedale degli Innocenti and reconstructing the church of San Lorenzo. Giovanni's portrait, the first of a Medici still extant, shows a small and somewhat stoutish man whose restrained smile masks an ill-concealed anxiety. He died on February 28, 1429, warning his two sons to "take no more from the state than man and law allow, if you wish to live in safety." One of these sons, Cosimo the Elder, was destined to establish an uncrowned monarchy in Florence, while the younger son, Lorenzo, would much later become the ancestor of the grand-ducal dynasty. Thus, Giovanni must be considered the real founder of the family.

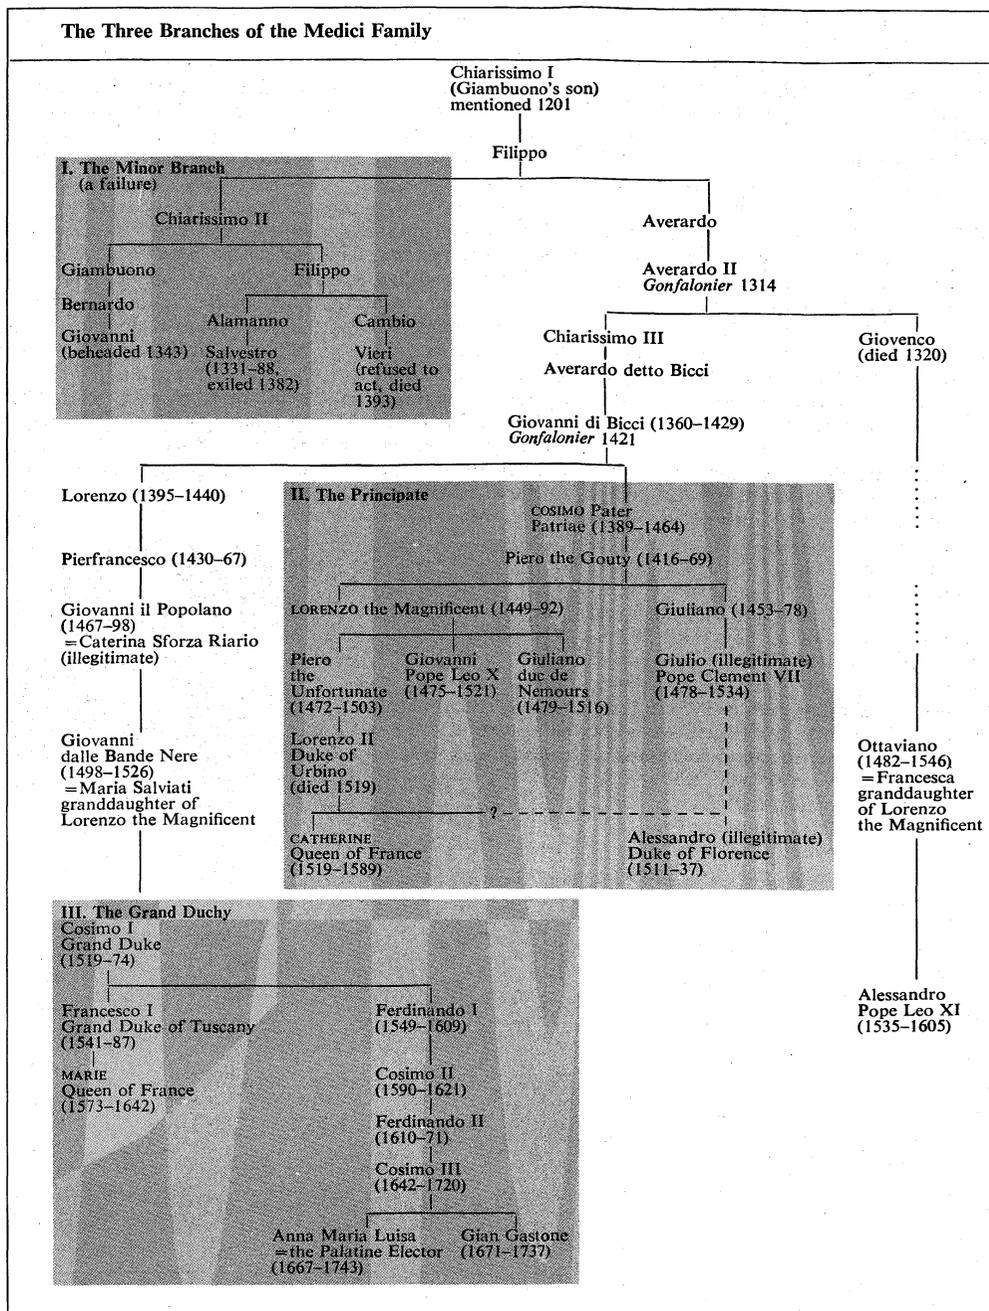

**Cosimo the Elder.** Cosimo, born in 1389, resembled his father very little in physical appearance. He was tall and lean, with a hooked nose and a wide mouth in an emaciated face. But here the differences between them ended. The son possessed his father's prudence, patience, and talent for sharp speculation and was to achieve even greater success than he. Cosimo had been initiated into affairs of high finance in the corridors of the Council of Constance, where he represented the Medici bank. He went on from there to manage the papacy's finances and in 1462 filled his coffers to overflowing by obtaining from Pius II the Tolfa alum mines monopoly, alum being indispensable to Florence's famed textile industry. He was certainly the wealthiest man of his time, not only in terms of bullion but also in the amount of bank and promissory notes payable to his bank in Florence and to its branches operating in all the important financial markets of Europe. Such great power alone would have been sufficient to set the oligarchy against him; his "popular" policies rendered him completely intolerable. The death of Niccolò da Uzzano in 1431 left the Albizzi, one of the other leading families, free to attempt a coup. Cosimo was vacationing in Cafaggiolo when he received a summons to reply to his indictment for the capital crime "of having sought to elevate himself higher than others." He could have taken refuge in Bologna, but instead he chose to let himself be incarcerated in a small dungeon in the Palazzo Vecchio. Although the Medici may have been somewhat lacking in valour, they often evinced a calm audacity. The Albizzi soon discovered that so wealthy a man could not be assassinated so easily. The jailer was bribed to taste Cosimo's food beforehand, and the gonfalonier, assuaged by the famous gold-bearing mules, arranged to have the usual death sentence reduced to banishment. Cosimo retired to Padua (Padova) and Venice, where he was received like a sovereign. Exactly one year later, a sudden and unexpected move by the Medici, in which they doctored elections, gave them back the *signoria*. Cosimo triumphantly re-entered the city; and his enemies went into exile, never to return. The Medici principate had begun (1434).

Cosimo traditionally has been accused of destroying Florentine liberties; but these ancient liberties, more of an illusion than a reality, had already ceased to exist in the Florence of the Albizzi. Cosimo only had to perpetuate the formula of those he was evicting, in other words, to maintain the appearance of a constitutional régime. But, in order not to be taken by surprise like the Albizzi, he perfected the system. He made no changes in the law's actual administration, but in the spirit of the law he changed everything. Previously, it was the rule to fill high official positions by drawing lots. The process was now manipulated so that only the names of men who could be depended upon were drawn. The independent mood of

Cosimo's  
wealth

Political  
manipulation

Giovanni  
di Bicci

the two municipal assemblies was neutralized by making the exceptional procedure of the Balia—the committee of magistrates—the rule: it now granted dictatorial powers for a fixed term that was always renewed. The people, Cosimo believed, would not soon forget the flood of assistance, free distributions, and benefices dispensed by a man “who reckoned only in order to give away.” Cosimo had unquestionably won the hearts of his countrymen, but he realized that his machinations were barely tolerated. He understood that a return to power of the *fuorusciti* (“exiles”) continued to constitute a threat. In his own words, a state could not be kept under control with pater-nosters: a sword was necessary. The sword he managed to obtain was that of Francesco Sforza, duke of Milan, whom he won over in 1450 by tirelessly refurbishing the chronically depleted ducal finances. This alliance permitted him to crush the rising opposition by a coup d’etat in August 1458 and to create a Senate composed of 100 loyal supporters (the Cento, or Hundred); thus he was able to live out the last six years of his life in security. “Although Cosimo is practically the lord of the city,” wrote Pope Pius II, “he conducts himself so that he appears to be a private citizen, preferring actions to appear-

ances.” Such was this strange principate that had no equivalent in Europe at that time and can only vaguely be compared with the “dictatorship of influence” enjoyed by Pericles.

Cosimo required undivided power in order to carry out his plans as well as to satisfy his passions, above all, his passion for building. “Fifty years will scarcely pass,” he would say, “before we are chased out, but the buildings will remain.” He continued to rely on Brunelleschi and discerned the genius of Michelozzo. Brunelleschi completed the “marble hat” of his famous cupola by a happy coincidence, at the time of Cosimo’s return in 1434; in addition, he almost completed the work on San Lorenzo and on the Sagrestia Vecchia and began work on the strange rotunda of Santa Maria degli Agnoli. He drew up plans for a princely palace for Cosimo; but the latter preferred the less lofty plans of Michelozzo, although Michelozzo’s Medici Palace (the modern Palazzo Medici-Riccardi) was only slightly less grandiose and provided the first break with the family’s traditional stance of humility. Under the patronage of Cosimo, Michelozzo also built the convent of San Marco, the Medici Chapel at Santa Croce, and a chapel at San Min-

Patron of the arts

iato. In addition to architects, Cosimo gathered around him all the masters of an age abounding in geniuses: the sculptors Lorenzo Ghiberti and Donatello and the painters Andrea del Castagno, Fra Angelico, and Benozzo Gozzoli. He not only assured these artists of commissions but also treated them as friends at a time when people still looked upon them as manual workers.

In his youth Cosimo had been a good student, but his active life had prevented him from continuing his studies. In order to assuage his unsatisfied passion for books he organized a methodical search for ancient manuscripts, both within Christendom and even, with Sultan Mehmed II's permission, in the East. The manuscripts picked up by his agents form the core of the incomparable library that is rather unjustly called the Laurentian (Laurenziana), after his grandson. He opened it to the public and employed copyists in order to disseminate scholarly editions compiled by, among others, the Humanists Poggio and Marsilio Ficino.

In short, he was well prepared for the singular opportunity that came his way in 1439 when he succeeded in enticing the ecumenical council from Ferrara to Florence. The Council of Florence, Cosimo's most important success in foreign relations, deluded itself into believing it had finally ended the schism with the Eastern Church. As for Cosimo, he assiduously attended the lectures delivered by the Greek scholars, and at the age of 50 he became an ardent admirer of Plato. He then re-created Plato's ancient academy in his villa of Careggi, where Marsilio Ficino became the Platonic cult's high priest. At the same time the University of Florence, with conspicuous success, resumed the teaching of Greek, which had been unknown in the West for 700 years. Thus Cosimo was one of the mainsprings of Humanism and of a form of rationalistic thinking that has distinguished Western thought down to the present age. Cosimo and his followers nevertheless did not renounce Christianity, Platonism being for them a confirmation and a renewal of faith. His closest friend, the man with whom he sought refuge in times of depression, was a Dominican called Antonino, who became bishop of Florence and, in 1523, Saint Antoninus.

In 1440 Cosimo prematurely lost his brother, who had been his staunchest supporter. In 1463 he had to face the loss of his most gifted son, Giovanni, thus leaving the succession to Piero, born in 1416, who was sickly and almost constantly bedridden. The future seemed dark to the old man as he roamed through his palace, sighing, "Too big a house for such a small family." He died in Careggi on August 1, 1464, and a huge crowd accompanied his body to the tomb in San Lorenzo. The following year, the *signoria* conferred upon him the deserved title of Pater Patriae ("Father of His Country").

The succession was not without its hazards in a principate lacking any lawful basis, yet for a time Piero's rule remained uncontested. Once again, the sympathy of the little people for a *popolano* played its role. Most of the notables, the *ottimati*, were favourable, and the support of Milanese arms caused the malcontents to hesitate before launching a coup. Piero did not lack opponents, for, badly advised, he provoked a panic by calling in credits granted in profusion by his father, which the beneficiaries had regarded as gifts. On the other hand, his gout forced him to live the life of a recluse and gave his enemies a free hand. Luca Pitti, formerly a bulwark of the regime, organized the opposition that had been encouraged by the death of Duke Francesco Sforza of Milan in 1466. But Piero, supported by the new duke of Milan, Galeazzo Maria, took the offensive by convoking a Balia that re-established and strengthened his authority. In the five years of his rule, he mainly assured the transmission of power from one great Medici, his father, to one even greater, his son. He was not unworthy of either of them. He acted as patron of the Platonic Academy and provided work for such great artists as Donatello, Antonio and Piero Pollaiuolo, Andrea del Verrocchio, and Sandro Botticelli.

**Lorenzo the Magnificent.** Piero died on December 2, 1469, leaving two young sons, Lorenzo, born on January

1, 1449, and then almost 21, and Giuliano, 16. The very next day, the thorny question of the transfer of power was resolved. "The *principati* (leading citizens) came to me," wrote Lorenzo in his *Ricordi* (Memoirs), "and urged me to look after the city and the government as my father and my grandfather had done." Two days previously, however, he had taken the precaution of writing to the Duke of Milan: "You have been the bulwark of our government and our greatness. May you now assure my protection and preservation." Lorenzo was the only one old enough to govern, but, in the years that followed, the friendly and lighthearted Giuliano continued to let his brother do the governing. Their mother, Lucrezia Tornabuoni, a capable woman with a certain talent as a poet, had given her sons a well-balanced education. They had studied music, under the organist Squarcialupi, as well as the humanities, under the best masters, including Marsilio Ficino, and in addition they had become accomplished athletes. And they had grown up in a palace crammed with masterpieces and frequented by the greatest artists as well as the best minds of the time.

Brogi—Alinari

Lorenzo the Magnificent, detail from the fresco "The Procession of the Magi" by B. Gozzoli (1420-97). In the chapel of the Palazzo Medici-Riccardi, Florence.

Lorenzo immediately let it be known that he intended to follow his father's and grandfather's example and "use constitutional methods as much as possible." In saying this, he was, however, keeping up appearances. In 1471 the popular assemblies lost their financial powers, and the Cento, which had demonstrated independence, was severely purged. The Milanese ambassador was able to reassure his master, who had taken Lorenzo's constitutional intentions literally: "Lorenzo will always have the *signoria* he wants." According to the historian Francesco Guicciardini's apt definition, Lorenzo's regime was "that of a benevolent tyrant in a constitutional republic." It was, moreover, a tyranny tempered by the festivals that Florentines always loved passionately: carnivals, balls, tournaments, weddings, and princely receptions. During these golden days in the early years of the "reign," it seemed that "youth was permanently in the prow and pleasure at the helm." The Pazzi Conspiracy in 1478 came as a rude shock to a carefree city.

The Pazzi bank, in the course of a treacherous war in which the adversaries did not scruple to use the most disgraceful methods, had taken the business affairs of the papacy away from the Medici. Sixtus IV, his nephew Riario, and Francesco Salviati, the archbishop of Pisa,

Piero  
the Gouty

The Pazzi  
Conspiracy

supported the Pazzi and in the end formed one of the most lamentable conspiracies in modern history with them. They decided to assassinate Lorenzo and Giuliano in the cathedral during Easter mass on April 26, while the Archbishop was to take over the *signoria*. They were counting on Florence to rise up at the old cry of *popolo e libertà* ("people and liberty"). Giuliano was indeed killed in front of the altar, but Lorenzo succeeded in taking refuge in a sacristy. The Archbishop clumsily accosted the Medici gonfalonier, a harsh and suspicious man who immediately had him hanged from a window of the Palazzo Vecchio wearing his episcopal robes. The crowd stood by the Medici, seized the conspirators, and tore them limb from limb. Sixtus IV, forgetting the murder in the cathedral—in which two priests had taken part—refused to consider anything else than the hanging of a prelate and threatened Florence with interdiction unless it handed over Lorenzo to him. The city and its clergy rejected the proposal. The situation was all the more critical because Ferdinand I, king of Naples, was supporting the papacy. Florence's ruler could count on nothing more than very limited aid from Milan and the encouragement of the King of France. Lorenzo thereupon went, alone, to Naples. In his situation it required unusual audacity to present himself before one of the cruelest rulers of the century. But Lorenzo's boldness was crowned with success. Ferdinand, disconcerted, perhaps intimidated, yielded and concluded a peace; and Sixtus IV, now isolated, could only comply with it.

Lorenzo  
the Wise

Lorenzo emerged from the conflict with greatly increased prestige. From then on he was considered the Wise, "the needle on the Italian scales." He did not take advantage of his position by imitating the Sforza and making himself a duke. He contented himself with creating a Council of Seventy that he hoped would be even more manageable than the Cento. This amazed Europe, for he had all the attributes of a true sovereign. Louis XI of France called him "his noble cousin" and sought his advice, and the timorous humility of his forebears had given way to an assurance and ostentation worthy of a king. His new villa, at Poggio a Caiano, had all the majesty of a royal residence, as the emperor Charles V noted half a century later.

Thus, step by step, the Medici were approaching the status they continued to refuse. Earlier, Louis XI had authorized Piero the Gouty to unite their coats of arms by decorating one of his *palle* with three fleurs-de-lis; and Lorenzo had married an Orsini, of the high Roman nobility. His daughter Maddalena was married to a son of Pope Innocent VIII (born before his father's entry into religious orders), and his eldest son Piero married another Orsini. When his son Giovanni was 13, Lorenzo obtained a cardinal's hat for him from Innocent VIII, that, in the words of Machiavelli, "was the ladder upon which the Medici climbed to heaven." To be sure, Lorenzo remained a simple citizen, and yet he was called "the Magnificent." In Italy during this period, this was a title of commonplace obsequiousness used in addressing the great; but it was Lorenzo who raised it to its current high stature.

There was, however, one difference between Lorenzo and titled kings, who are able to live in pomp and ceremony even when their treasury is empty. Lorenzo could not do so, and the stream of florins that fed his munificence was becoming less abundant. This was partially his own fault for, with the Medici, the aptitude for business diminished as the thirst for power increased. In addition, economic conditions were deteriorating. New competitors were appearing in Europe and the branches in London, Bruges, and Lyons became insolvent. But the recurrent accusation that the Medici bank was kept solvent at the expense of the public treasury is not borne out by the facts. The movement of funds between the Medici bank and the treasury of the *signoria* was the equivalent of that occurring between private and public banks in modern states. The family's patronage of artists, architects, and writers also imposed a considerable burden upon its resources. When Lorenzo the Magnificent made an accounting of these expenses going back as far as 1434, the

date of Cosimo's re-entry into the city, he found the total expenditure "unbelievable" and added,

Many deem that it would have been preferable to keep part of the funds in the treasury; I think that our patronage was the great splendor of our regime and, in my opinion, the money was well spent.

Posterity has agreed with him. He himself contributed more than anyone to the flowering of Florentine genius during the second half of the 15th century. As a Venetian writer felicitously put it, "Literature owes much to the Florentines, but among these, most of all to the Medici, and among these, most of all to Lorenzo."

He continued collecting ancient texts, and in his villas in Careggi, Fiesole, and Poggio a Caiano he assembled what is called the Platonic Academy but was more like a circle of good friends: his teacher Marsilio Ficino, the Humanist Pico della Mirandola, and the man who was always closest to his heart, Politian (Angelo Poliziano), the poet, who had saved his life on the day of the Pazzi Conspiracy. Lorenzo's reputation did not rest on lavish hospitality alone. He was also respected as a poet of great talent. His preference for the Tuscan dialect over Latin was remarkable for this time. Equally rare was his custom of treating artists with "the affectionate and warm-hearted familiarity that allows a protégé to stand erect at the side of his protector, as man to man." The artists under his protection included Giuliano da Sangallo, Botticelli, Verrocchio, and Verrocchio's pupil Leonardo da Vinci. Toward the end of his life, Lorenzo opened a school of sculpture in his garden of San Marco. There a 15-year-old pupil attracted his attention and was brought up in the palace like a son of the family; it was Michelangelo.

On the recommendation of Pico della Mirandola, Lorenzo permitted the Dominican monk Girolamo Savonarola to preach at San Marco in 1490. He mounted the pulpit on August 1 and henceforth launched an unceasing deluge of denunciations of the Medici, the papacy, and the whole of Christianity. The Florentines, who had grown weary of festivities, listened feverishly to his appeals for asceticism and to his terrifying prophecies, among which was the imminent death of the "tyrant." But it was easy for him to be thus prophetic, for Lorenzo's health had been declining for three years, and the secret had not been well kept. His condition grew rapidly worse. Suffering from "intolerable stomach pains," he awaited death at Careggi, spending his last days chatting with his friends, or reading Virgil, Homer, or Plato with them. On his deathbed, he sent for Savonarola who, according to a doubtful tradition, called upon him to "give Florence back her freedom," and in the face of the dying man's silence, refused to grant him absolution. Lorenzo's obsequies were simple, as he had requested; but the presence of the entire population of Florence, sincerely moved by his premature death (April 9, 1492)—he was 43—took on the character of a plebiscite. He was buried in San Lorenzo, where the grandiose tomb that his son Giovanni, who later became Pope Leo X, had planned was never executed. His tombstone passes almost unnoticed at the side of the monuments erected by Michelangelo to Giuliano, one of his sons, and to his grandson Lorenzo, both very insignificant persons.

Lorenzo the Magnificent died at the very moment when a new historical era was beginning. Six months later Christopher Columbus was to reach the New World. And two years later the foolish Italian expedition of the French king Charles VIII was to plunge the peninsula into a half century of suffering from which it could only have been saved, according to Machiavelli, by Lorenzo. The opinion of such an astute observer, more than a handsome eulogy, merits the historian's most serious attention.

## TWO EXILES—TWO RETURNS (1494-1530)

**Piero the Unfortunate.** Like his father, Piero, born in February 1471, came to power too young—at the age of 21. Nevertheless, the succession took place without difficulty, and the régime appeared to have a firm foundation. The King of Naples thought that the time had come to

Savonarola  
and  
Lorenzo

make the offer of a baron's crown, but Piero refused it, preferring, like his forebears, no title other than that of "simple private citizen." He had been endowed with beautiful features, notoriously denied to Lorenzo the Magnificent; and he could turn a pretty verse. And when forced by circumstance, he showed himself a good soldier, a new trait in the family. But unfortunately, he was painfully lacking in political sense; and if he has gone down in history with the surname of "the Unfortunate," it is above all because of his errors of judgment. Threatened domestically by Savonarola's denunciations and by the intrigues of the younger branch of the Medici family and abroad by the imminence of a French invasion of Italy, he made the foolish and dangerous decision of abandoning the old French alliance in favour of one with Naples. Suddenly realizing the danger when the "barbarians" from beyond the Alps poured into Tuscany under Charles VIII, Piero thought he could save the day by imitating his father and hastened to meet the invader. The disastrous agreement—the only one possible under the circumstances—that he obtained from Charles aroused a wave of indignation in Florence. A revolt broke out, and Piero was forced to flee while the populace sacked the Medici Palace; only at the risk of his life did the cardinal Giovanni succeed in saving the most precious manuscripts. Piero henceforth led the restless life of a *fuoruscito*. He never again saw Florence and was drowned in the shipwreck of an armed galley in 1503.

**Giovanni (Leo X) and the problem of the succession.** After having plunged with splanetic joy into the mortifications of the flesh decreed by Savonarola's theocracy, mercurial Florence burned its prophet in 1498. But it did not recall the Medici. Furthermore, Donatello's "Judith and Holofernes" had been removed from the Medici Palace and placed in front of the *signoria* "as a salutary example to tyrants"; and in 1504, for the same purpose, Michelangelo's "David" was placed at its side. Yet in 1512, when the Spanish troops, allied with the papacy, entered Florence, bringing Giovanni Cardinal de' Medici with them, he was received enthusiastically. When Giovanni was elected pope—as Leo X—the following year, he had to content himself with keeping a watchful eye from Rome on his nephew Lorenzo, the son of Piero the Unfortunate, to whom he had left the government of the city (it was to him that Machiavelli dedicated *The Prince*). Faithful to the Medici tradition, Leo X did not grant Lorenzo a princely title in Florence but preferred to seize the duchy of Urbino and give it to his nephew, who, however, was unable to maintain himself there. Lorenzo climbed one more rung of the nobility ladder when, in 1518, he married Madeleine de La Tour d'Auvergne, a relative of the Bourbons. Two years earlier, at the French court, his uncle Giuliano had charmed Francis I with his elegant manners and had married the sovereign's young aunt, receiving the duchy of Nemours as a dowry.

These few years are often considered to be the apogee of the Medici age. The period has even been called "the century of Leo X." From 1513 to 1521, surrounded by five nephews and cousins whom he had named cardinals, Leo X reigned less over Christianity than over arts and letters in the style of his father, the Magnificent, too occupied with patronage to pay sufficient attention to an unimportant monk by the name of Martin Luther.

Just when the future of the dynasty seemed assured, death struck two irreparable blows. Giuliano, duc de Nemours, died in 1516, one year after his marriage, and Lorenzo, duke of Urbino, died a year after his marriage as well (and only a few days after the birth of his daughter Catherine), the last scion of Cosimo the Elder's line. The succession was now in question, for it seemed more than improbable that a woman would ever be admitted to the principate. But apart from Catherine, only bastards remained: Giulio, posthumous son of Giuliano, the brother of Lorenzo the Magnificent, who had been assassinated in the cathedral; Ippolito, son of the Duc de Nemours; and Alessandro, a mulatto whom the Medici tried to pass off as the son of the Duke of Urbino but who was very probably Giulio's son by a Nubian slave

girl. It is said that illegitimacy did not constitute a major obstacle at this time. In fact, the French statesman and historian Philippe de Commines noted that "in Italy they do not make a great distinction between bastards and legitimate children." There were, however, certain reservations. First of all, the church refused ecclesiastical honours to bastards. This is why Leo X had hastened to declare his cousin Giulio born of a secret marriage before appointing him cardinal. And then, for purposes of nobiliary succession, in Italy as elsewhere, the illegitimate branch did not count. When the cardinal Giulio installed Ippolito and Alessandro in the Medici Palace, their aunt Strozzi protested loudly that the family home was not a "stable for he-mules" (bastards). Even so, the two adolescents were the nominal rulers of Florence, at first under the guardianship of the cardinal Giulio, who showed a marked preference for Alessandro, and later under that of Silvio, Cardinal Passerini, when the cardinal Giulio donned the tiara under the name of Clement VII in 1523.

Florence, usually turbulent and ungovernable, seemed to be mired in resignation when the news arrived in 1527 of Rome's sacking by imperial bands and of Clement's undignified flight. A republican uprising immediately expelled the unpopular Cardinal Passerini and his two wards. For the second time in 33 years the Medici lost control of Florence. But not for long. The emperor Charles V came to terms with Clement VII and sent an army to besiege Florence, which capitulated in August 1530. The Emperor and Clement VII then decided to destroy the Florentine hornet's nest of republican insurgents. Alessandro was given the ducal crown that his ancestors had so long refused. On May 1, 1532, the 1,572nd and last gonfalonier surrendered his powers to him.

Clement thus kept Ippolito from the succession but in compensation made the unwilling Ippolito a cardinal. He then turned his attention to the legitimate heir, Catherine. In order to balance the imperial influence, he married Catherine to the Duc d'Orléans, second son of the King of France, who in 1547 after the unexpected death of the Dauphin, became king of France as Henry II.

As for Alessandro, unlettered, perverse, and debauched, he reigned by terror over a city that resigned itself to its fate. Upon the death of Clement VII in 1534, a shade of opposition emerged around Ippolito, who died by poisoning shortly thereafter. All indications were that the new duke would perpetuate his dynasty when he married Margaret of Austria, the illegitimate daughter of Charles V. Then the younger branch of the Medici intervened.

#### THE GRAND DUKES

Descending from Lorenzo the Elder, the son of Giovanni di Bicci and brother of Cosimo Pater Patriae (see Table), this branch had taken an active part in Medici affairs but had played no political role. In the third generation, however, the brothers Lorenzo and Giovanni appealed for popular support, took the name of Popolano, and contributed to the downfall of Piero the Unfortunate. Their grandsons were to complete the ruin of the family's older branch. Lorenzo's grandson, a puny fellow called Lorenzino, should by all rights have received the succession when the older branch was reduced to a girl and a few bastards. But ousted by Clement VII, he kept his silence and even misled people regarding his intentions by joining Alessandro in his dissolute life. But in January 1537 he suddenly ambushed Alessandro and killed him in hand-to-hand combat. He then fled without asserting his rights. This enigmatic Medici, the author of the *Ardosio*, a play displaying much talent, was later to attract the attention of the Romantics and in fact become the model for the tragedy *Lorenzaccio* by the French poet Alfred de Musset. Cosimo, a grandson of Giovanni, then took up matters where his cousin had left them. Cosimo's father had been Giovanni dalle Bande Nere (John of the Black Bands), the single great military leader among all the Medici; and his mother was a granddaughter of Lorenzo the Magnificent. Thus the blood of the two lines was united in him. As soon as

Duke  
Alessandro

The  
Popolano

Apogee  
of the  
Medici  
age

Annexation of Tuscany

he heard of Alessandro's assassination, he rushed off to Florence. This young man, born on June 12, 1519, was regarded as relatively inoffensive and was warmly welcomed. The notables handed the government over to him after having proclaimed the deposition of Lorenzo; and Charles V even named him duke and his son-in-law's successor. Some *fuorusciti* were dispersed or captured as soon as they set foot in Tuscany in July 1537.

**Cosimo I.** It did not take long to determine what sort of master Florence had acquired. Prisoners were mercilessly executed, and the opponents of the régime were secretly liquidated throughout his reign. The historian Francesco Guicciardini, who let his disillusionment show too clearly, died of poisoning, according to general opinion; and Lorenzo, pursued from Paris to Constantinople and overtaken in Venice was assassinated there in 1548. On the other hand, Cosimo created the Order of Santo Stefano for the loyal nobility and took care to assure his subjects of equitable justice. The European wars were now bypassing Tuscany, except for Siena, which had to surrender to the imperial forces in 1555 after a memorable siege. Cosimo, allied with the emperor Charles V, annexed Florence's ancient rival. He himself had not been present at the siege, for this son of a courageous captain was singularly lacking in bravery. Immediately after the surrender, however, he hastened to the city and saved the survivors from the customary atrocities.

In 1539 Cosimo had married Eleonora de Toledo, the daughter of the Spanish viceroy of Naples, by whom he had eight children. In 1562 Eleonora and two of their young sons died within a few days of each other. Subsequently, it was claimed that one of the boys had assassinated his brother, that Cosimo had killed the assassin on the spot, and that their mother had died of grief. The true cause of these deaths was malaria; and these rumours merely belong to the tradition of "Medicean tragedies" that holds that "never was there a race more iniquitous." An examination of the archives and of the tombs, in which the bodies repose in an excellent state of preservation, refutes these tales. Cosimo did not poison his daughter Maria, and it is doubtful that he had incestuous relations with another daughter, Isabella. Neither was his daughter Lucrezia poisoned by her husband, Alfonso of Ferrara.

Sovereign ruler of a unified Tuscany, Cosimo believed that he should be crowned king; but neither the emperor Charles V nor Ferdinand I after him encouraged him in these ambitions. So he turned toward the papacy. In 1559 a Medici from Milan, elected pope as Pius IV, appropriated the Medici coat of arms, even though he was not related to the family. Cosimo did not protest, and Pius IV, pleased with what he considered his adoption into the family, offered to make him a grand duke. But the offer seemed untimely and was reluctantly refused. A new occasion presented itself under Pius V. Cosimo handed over to him Pietro Carnesecchi, a suspected Lutheran who had taken refuge at his court. In return, Pius V proclaimed Cosimo "grand duke of the province of Tuscany" in August 1569 and crowned him at Saint Peter's the following February. But this constituted a usurpation of the rights of the Emperor who, followed by Spain, refused to recognize the pontifical action.

Cosimo amazed Europe by displaying the old Medici traits, particularly those of the shrewd and mercenary banker, insatiable for big profits. In his administration of Tuscany he showed that he was energetic and concerned with exactitude and economy in his accounts; and his passion for efficiency inspired him with the idea, extremely advanced for the times, of uniting all public services into a single building, the Uffizi (or offices), which was built for him according to Giorgio Vasari's grandiose yet practical design. In order to satisfy his taste or, better said, his Medici passion for buildings, he made Vasari his superintendent of buildings and had him redecorate the interior of the Palazzo Vecchio. He then adopted as his residence the Pitti Palace, which Eleonora had purchased unfinished in 1549. Here he entrusted the extensive work of enlargement to the architect and sculptor Bartolomeo Ammannati. In 1564 Cosimo and Vasari boldly

Cosimo's support of the arts

built the gallery that permits convenient passage from one palace to the other by utilizing the Ponte Vecchio. Behind the Pitti Palace, the vast expanses of the hill of Boboli enabled Cosimo to indulge still another of his hereditary passions in designing, with Tribolo's help, the plan of the famous gardens.

Yet in his patronage of the arts, Cosimo was increasingly frustrated, for the great period of the *officina*, the workshop of Florentine masterpieces, was drawing to its close. Michelangelo could no longer be induced to stay on. In 1534 he departed for Rome, leaving the Sagrestia Nuova tombs and the Laurentian Library unfinished. But Cosimo had the artist's body brought back in 1564 and buried it himself with great pomp at Santa Croce. On the other hand, he kept Jacopo Pontormo and Bronzino, the official court portraitists, and Ammannati, who was also an engineer and who had rebuilt the bridge of Santa Trinità after the disastrous flood of 1557 according to a design that must be considered a stroke of genius. Cosimo, an archaeologist by temperament, was a true forerunner in this field. He opened up excavations on Etruscan sites from which such world-renowned pieces as the "Orator" and the "Chimera" were taken. Finally, he established the Florentine Academy, which engaged in serious linguistic studies.

According to his portraits, Cosimo was of athletic build, with harsh features lit by the dark velvety eyes of the Medici. He had aged prematurely and in 1571 handed over effective power to his eldest son, Francesco, born on March 25, 1541. He retired to the villa of Castello, where his childhood had been spent and where he died on April 21, 1574. Though a ruthless despot, he must be considered one of the great Medici.

**Francesco I.** Francesco's regency ended with his father's death. Like Cosimo, Francesco was a crafty and brutal tyrant to those opposing him. But Tuscany was well governed; it remained out of the wars that were dividing Europe and suffered mainly from the burden of taxes. Francesco married Joanna, archduchess of Austria, sister of Emperor Maximilian II, who consented in 1576 to officially proclaim his brother-in-law grand duke, at the same time raising Tuscany to the status of a grand duchy. Francesco I's work was along the lines of Medici tradition. He had Bernardo Buontalenti build the Tribuna of the Uffizi; he assembled the first collections of the celebrated gallery; and, at his new villa of Pratolino, he freely indulged his love of artistically designed gardens. In addition, his interest in philology prompted him to found the Accademia della Crusca and to entrust it with compiling a dictionary of the Tuscan language in its purest form. But—and this was a sign of the times—his real passion was of a scientific nature. He spent the greater part of his time in his chemical laboratory, where he was the first to make a porcelain somewhat similar to the Chinese model.

In spite of all his accomplishments, Francesco largely lives on in the romantic popular memory because of his love affair with Bianca Cappello. While he was still heir presumptive, he had taken this young patrician as his mistress—after she had been abandoned by the lover with whom she had fled from Venice. Nothing could ever deflect Francesco from this passion—neither the marriage with Joanna of Austria, nor the reproaches of his family and of the Emperor, nor public censure. When Joanna died, after giving him three children, he married Bianca and had her solemnly crowned in the Palazzo Vecchio. Their end was such as famous lovers wish for; they died within a few hours of each other in 1587. Perhaps consumption, but certainly malaria, caused their deaths. Popular imagination refused to believe this. It was said that Bianca had prepared a poisoned tart intended for her brother-in-law Ferdinand, that Francesco had eaten some of it by mistake, and that Bianca in desperation then ate some of it in order not to survive her lover and husband.

Francesco's affair with Bianca Cappello

**Ferdinando I.** Ferdinando, born on July 30, 1549, succeeded his brother. A cardinal at 14, he had been living in Rome in the midst of his collections of antiques, among which was the "Venus de' Medici." In order to succeed

his brother Francesco, who had no children by Bianca and was survived only by a daughter, Maria, the child of Joanna of Austria, Ferdinando renounced the purple and perhaps even the tiara, for he had been spoken of as eligible for the papacy. He tried to rule as a just prince and came close to his ideal, for the conspiracies of the exiled Strozzi family became more rare. Certain of his acts, however, astonished his contemporaries: he had Alfonso Piccolomini, an old-fashioned *condottiero* who was ravaging Tuscany, hanged as a criminal but had his daughter brought up in an aristocratic convent; he also promulgated a constitution that welcomed to Leghorn (Livorno), a city founded by Cosimo I, all immigrants, with no distinction as to religion. His foreign policy leaned toward France. He married Christine of Lorraine, the granddaughter of Catherine de Médicis, and loans from his bank, as well as his influence in Rome, played no small part in Henry IV's accession to the French throne. Naturally enough, he married his niece Maria to the new king and made her the second Medici to become queen of France. Five years later, in 1605, Alessandro, a great-grandson of Lorenzo the Magnificent and a grandnephew of Leo X, became the third Medici to ascend the throne of Saint Peter. He took the title of Leo XI; he died, however, 27 days after his election. The Medici dynasty was thus keeping pace with the great royal houses of Europe. To place the tombs of past and future grand dukes under one roof, Ferdinando undertook to build the Cappella dei Principi from the designs of Don Giovanni, a natural son of Cosimo I. And on Belvedere Hill near the Pitti Palace, Buontalenti, the greatest architect of the day, built a fortress that was intended as a place of refuge but was never used. But Ferdinando's great desire to be a patron of the arts was thwarted by the impoverishment of the Florentine genius, which became increasingly evident. Giambologna, who executed the equestrian statues of Cosimo I and of Ferdinando, was Flemish.

Ferdinando died on February 7, 1609, after a prosperous reign of 22 years.

**Cosimo II.** Cosimo II, born on May 12, 1590, was 19 years old when he succeeded his father. Less than a year later, on January 7 and 13, 1610, Galileo discovered four satellites of Jupiter that he named the Medicea Sidera. Cosimo had been Galileo's pupil at Padova and had called him to his court as "first mathematician." He had just closed the family bank, feeling that after 400 years of such business the Medici had no further need to demean themselves. Tuscany still cut a rather mediocre figure in comparison to the great western monarchies, even though Cosimo's father had married into the French court. To keep on good terms with the imperial court at Vienna, Cosimo on his part married Emperor Ferdinand II's sister Maria Magdalena. The court at the Pitti Palace continued to be a brilliant one: the favourite portrait painter was the Fleming Sustermans. Although in his youth Cosimo had shown great promise, illness prevented him from fulfilling it. He died before he was 31, on February 28, 1621.

**Later Medici rulers.** Many of the Medici had come to power very young, but regencies had always been avoided. This time one was inevitable, for Cosimo's son Ferdinando, born on July 14, 1610, was only 10 years old when his father died. His grandmother Christine and his mother, Maria Magdalena, together squandered the treasures so wisely amassed by Cosimo. But they inculcated in their ward such complete submission to the Holy See that he let Urban VIII take over the duchy of Urbino to the detriment of his future wife, Vittoria della Rovere; and he also showed a distressing lack of initiative in the trial by the church of his father's friend Galileo. When Ferdinando married Vittoria della Rovere she brought him as a dowry, in place of the duchy of Urbino, her rich collections of paintings. His 49-year reign (1621-70) at least saw Leopoldo, Ferdinando's brother, act like a true Medici. It was he who founded the Accademia del Cimento, one of the first European scientific academies, who collected the *autoritratti* (self-portraits) of the great painters and assembled in the Pitti Palace and in the Uffizi many of the masterpieces that had been scattered

among the various Medici residences. He died on May 24, 1670.

Cosimo, Ferdinando's eldest son, was born on August 14, 1642. He reigned for 53 years (1670-1723), longer than any other Medici. Dull-witted and solitary, he limited his patronage to musicians. During Louis XIV's wars, he maintained a benevolent neutrality toward the empire and was rewarded with the title of Royal Highness in 1695. He had appeased the Bourbons by marrying Marguerite-Louise d'Orléans, a niece of Louis XIV. Unfortunately, she had been forced into this marriage and, being a gay, cultured, and worldly woman, felt repugnance toward her husband. Although long rebuked by the court at Versailles and even temporarily confined in the villa of Poggio a Caiano, she finally returned to France. As she had given the crown two sons and a daughter, there was no reason to foresee the extinction of the dynasty: but these children were all to be without posterity.

Ferdinando, the eldest, married Violante of Bavaria. Charitable and a patron of the arts (he assembled a famous collection of musical instruments), he died before his father in 1713. Gian Gastone, the youngest, lived apart from the court, occupying himself with archaeology and natural history. Cosimo forced him to marry the widow of a count palatine, Anne of Saxe-Lauenburg, an eccentric woman who refused to leave her Reichstadt castle in Bohemia. Gian Gastone, losing his patience, returned alone to Florence. Cosimo then procured a ruling from the Florentine Senate that the succession would pass to his daughter Anna Maria Luisa. But the European powers rejected this stratagem and, over Cosimo's protests, in 1718 chose Don Carlos, the son of Isabella of Parma, queen of Spain, as heir presumptive of Tuscany. Then, in 1735, the choice fell on Francis, duke of Lorraine, who was to marry Maria Theresa of Austria, who became empress in 1740.

Born in May 1671, Gian Gastone was 52 at the time of his accession in 1723. A liberal intellectual, he loosened the hold of the clergy on Tuscany, but, disheartened by the impatience of those who were waiting for him to die, he quickly slipped into debauchery. Even so, he had the energy to insist that the Medici property be exempted from the escheat of the Grand Duchy. Following his death on July 9, 1737, Francis of Lorraine was installed in the Pitti Palace. In October, Gian Gastone's sister bequeathed the enormous mass of masterpieces accumulated by the Medici to the House of Lorraine, on condition that nothing be removed from it or transported outside of Tuscany. She died on February 18, 1743, and on her tomb in the Cappella dei Principi (Chapel of the Princes) was engraved *Ultima della stirpe reale dei Medici* ("Last of the royal Medici line").

**BIBLIOGRAPHY.** Among many historians and memorialists contemporary with the Medici, Niccolò Machiavelli, Francesco Guicciardini, and, to a lesser degree, Scipione Ammirato cannot be dispensed with. Modern works, for a general view, include G.F. YOUNG, *The Medici*, 2 vol. (1909, reprinted 1933; Italian trans., 1935; French trans., 1969), dated but still useful; ALBERT JOURCIN, *Les Médicis* (1968; German trans., 1969); GAETANO PIERACCINI, *La stirpe de' Medici di Cafaggiolo*, 2nd ed., 3 vol. (1947), extensive researches on the hereditary features and diseases that run in the Medici family; and MARCEL BRION, *Le Siècle des Médicis* (1969; Eng. trans., *The Medici: A Great Florentine Family*, 1969). More specialized monographs are CURT S. GUTKIND, *Cosimo de' Medici, Pater Patriae, 1389-1464* (1938); ALISON M. BROWN, "The Humanist Portrait of Cosimo de' Medici. . .," *Journal of the Warburg and Courtauld Institutes*, 24:186-221 (1961); and ANDRE ROCHON, *La Jeunesse de Laurent de Médicis* (1963). On institutions and banking, NICOLAI RUBINSTEIN, *The Government of Florence Under the Medici, 1434 to 1494* (1966), based on a masterly examination of the Florentine archives, is fundamental; while RAYMOND DE ROOVER, *The Rise and Decline of the Medici Bank, 1397-1494* (1963), excellently clears up a difficult matter. The story of the dynasty of the grand dukes has been less thoroughly investigated. Nevertheless, three good titles cannot be omitted: LUIGI CARCERERI, *Cosimo I Granduca*, 3 vol. (1926-29); HAROLD ACTON, *The Last Medici*, rev. ed. (1958); G.E. SALTINI, *Tragedie medicæ domestiche, 1577-87* (1898), a cool restatement of the traditional story of Medicean crimes and turpitude.

## Medicine, History of

The history of medicine and surgery is the account of man's efforts to deal with human illness and disease, from the primitive attempts of preliterate man to the present complex array of specialties and treatments.

An article on so vast a subject can trace only an outline of the rise and development of medical thought and practice from the earliest times. No rigid classification can be applied to the history of medicine, and the story cannot be unfolded as a steadily progressive series of events. It has had many developments and setbacks and is best understood as a simple narrative, rather than as a chapter of epochs. It is often stated that medicine, like so many other arts and sciences, had its origin in ancient Greece, but that is only a partial truth. There were many great men before the ancient Greeks, and, even before the tale could be written down, the healing art was taught and practiced.

This article is divided into the following sections:

- I. Medicine and surgery before 1800
  - Primitive and prehistoric medicine
  - Babylonian and Egyptian medicine
  - Traditional medicine and surgery in the Orient
  - Early Greek and Roman medicine
  - Arabian teaching and the school of Salerno
  - Reform and revival in medicine
  - Medicine in the 17th century
  - Medicine in the 18th century
- II. The rise of scientific medicine in the 19th century
  - Verification of the germ theory
  - Medicine and anesthesia
  - Advances at the end of the century
- III. Medicine in the 20th century
  - Chemotherapy
  - Immunology
  - Endocrinology
  - Advances in other fields
- IV. Surgery in the 20th century
  - The opening phase
  - World War I
  - Between wars
  - World War II and after

Extensive supplementary material on the history of medicine and surgery appears in other articles, including those on the major subdivisions of medicine and surgery, the major concepts of illness and treatment, the chief therapeutic agents, and most of the persons mentioned in this article.

### I. Medicine and surgery before 1800

#### PRIMITIVE AND PREHISTORIC MEDICINE

Unwritten history is not easy to interpret, and, although much may be learned from a study of the drawings, bony remains, and surgical tools of early man, it is difficult to reconstruct his mental attitude toward the problems of disease and death. It seems probable that man, as soon as he had reached the stage of reasoning, discovered, by the process of trial and error, which plants might be used as foods, which of them were poisonous, and which of them had some medicinal value. Folk medicine or domestic medicine, consisting largely in the use of vegetable products, or herbs, originated in this fashion and still persists.

But that is not the whole story. Man did not at first regard death and disease as natural phenomena. Common maladies, such as colds or constipation, he accepted as part of existence and dealt with by means of such herbal remedies as were available. Serious and disabling diseases, however, he placed in a very different category. These were of supernatural origin, the work of a malevolent demon or of an offended god who had either projected some object—a dart, a stone, a worm—into the body of the victim or had abstracted something, usually the soul of the patient. The treatment then applied was to lure the errant soul back to its proper habitat within the body or to extract the evil intruder, be it dart or demon, by suction, incantations, or other means. One curious method of providing the disease with means of escape from the body was by making a hole in the skull of the victim—i.e., the practice of trepanning, or trephining. Trepanned skulls of prehistoric date have been found in Brit-

Belief in supernatural causes of illness

ain, France, and other parts of Europe and in Peru. The practice still exists among primitive people in parts of Algeria, in Melanesia, and perhaps elsewhere, though it is fast becoming extinct.

Magic and religion played a large part in the medicine of prehistoric or primitive man. Administration of the vegetable drug or remedy by mouth was accompanied by incantations, dancing, grimaces, and all the tricks of the magician. Thus, the first doctors, or "medicine men," were witch doctors or sorcerers. The use of charms and talismans, still prevalent in modern times, is of ancient origin. Apart from the treatment of wounds and broken bones, the folklore of medicine is probably the most ancient aspect of the art of healing, for primitive physicians showed their wisdom by treating the whole man, soul as well as body.

#### BABYLONIAN AND EGYPTIAN MEDICINE

The establishment of the calendar and the invention of writing marked the dawn of recorded history. The clues to early knowledge are scanty, consisting of clay tablets bearing cuneiform signs and seals that were used by Babylonian physicians about 3000 BC. In the Louvre, in Paris, there is preserved a stone pillar on which is inscribed the Code of Hammurabi, an early king of Babylon. This code includes laws relating to medical practice; the penalties for defaulters were severe. For example, "If the doctor, in opening an abscess, shall kill the patient, his hands shall be cut off"; if, however, the patient was a slave, the doctor was simply obliged to supply another slave. The Greek historian Herodotus in his *History* states that every Babylonian was an amateur physician, since it was the custom to lay the sick in the street so that anyone passing by might offer advice. Divination, from the inspection of the liver of a sacrificed animal, was widely practiced and applied to foretell the course of a disease. Little else is known regarding Babylonian medicine, and the name of not a single physician has survived.

It is only with the study of the medicine of ancient Egypt that the picture becomes clearer. The first physician to emerge was Imhotep, grand vizier to King Djoser (Zoser) of Egypt (2980–2900 BC), who designed one of the earliest pyramids, the Step Pyramid at Saqqārah, and who, as the Egyptian god of medicine, rivals the Greek god Asclepius, or Aesculapius, with whom he is sometimes confused. Knowledge becomes surer with the study of Egyptian papyri, especially the so-called Ebers and Edwin Smith papyri discovered in the 19th century. The former is a list of remedies, with appropriate spells or incantations, while the latter is a surgical treatise on the treatment of wounds and other injuries. One might imagine that the widespread practice of embalming the dead body would have stimulated the study of human anatomy, but that was not so.

The search for information regarding ancient medicine leads naturally from the papyri of Egypt to Hebrew literature. Strangely enough, the Bible contains little on the subject of the medical practices of Old Testament times. It is, however, a mine of information on social and personal hygiene. The Jews were indeed pioneers in matters of public health. (D.J.G.)

#### TRADITIONAL MEDICINE AND SURGERY IN THE ORIENT

**India.** Indian medicine is ancient. Its earliest concepts are set out in the sacred writings called the Vedas, especially in the metrical passages of the Atharvaveda, which may possibly date as far back as the 2nd millennium BC. According to a later writer, the system of medicine called Ayurveda was received by a certain Dhanvantari from Brahma, and Dhanvantari was deified as the god of medicine. In later times his status was gradually reduced, until he was credited with having been an earthly king who died of snakebite. Legend tells of Dhanvantari's relations with snakes and illustrates the skill with which early Indian practitioners treated snakebite.

The period of Vedic medicine lasted until about 800 BC. The Vedas are rich in magical practices for the treatment of diseases and in charms for the expulsion of the demons traditionally supposed to cause diseases. The chief con-

Medicine of ancient Egypt

ditions mentioned are fever (*takman*), cough, consumption, diarrhea, dropsy, abscesses, seizures, tumours, and skin diseases (including leprosy). The herbs recommended for treatment are numerous.

Brahmanistic period of Indian medicine

The golden age of Indian medicine, from 800 BC until about AD 1000, may be termed the Brahmanistic period. It is marked especially by production of the medical treatises known respectively as the *Caraka-saṃhitā* and *Suśruta-saṃhitā*, attributed, respectively, to the physician Caraka and Suśruta, traditionally a surgeon. Both these works were formerly regarded as being of great antiquity, and hence claims arose for the priority of Indian scientific medicine over its Greek counterpart. Another school asserted that these works were written many centuries after the beginning of the Christian Era. The most recent estimates place the *Caraka-saṃhitā* in its present form as dating from the 1st century AD, and there were earlier versions. The *Suśruta-saṃhitā* probably originated in the last centuries of the pre-Christian Era and became fixed in its present form in the 7th century AD at the latest. Other medical treatises of lesser importance are those attributed to Vagbhata (c. 8th century). All later treatises were based on these works.

Because the Hindus were prohibited by their religion from cutting the dead body, their knowledge of anatomy was limited. The *Suśruta-saṃhitā* recommends that a body be placed in a basket and sunk in a river for seven days. On its removal the parts could be easily separated without cutting. As a result of these crude methods, the emphasis in Hindu anatomy was given to the bones, and then to the muscles, ligaments, and joints. The nerves, blood vessels, and internal organs were very imperfectly known.

The Hindus believed that the body contains three elementary substances, microcosmic representatives of the three divine universal forces, which they called spirit (air), phlegm, and bile. These were comparable with the humours of the Greeks. Health depends on the normal balance of these three elementary substances. The spirit has its seat below the navel, the phlegm above the heart, and the bile between the heart and the navel. The seven primary constituents of the body—blood, flesh, fat, bone, marrow, chyle, and semen—are produced by the action of the elementary substances. Semen was supposed to be produced from all parts of the body and not from any individual part or organ.

Both Caraka and Suśruta state the existence of a large number of diseases (Suśruta says 1,120). Rough classifications of diseases are given. In all texts "fever," of which numerous types are described, is regarded as important. Phthisis (wasting disease, especially pulmonary tuberculosis) was apparently common, and the Hindu physicians knew the symptoms of cases likely to terminate fatally. Smallpox was common, and it is probable that smallpox inoculation was practiced.

Hindu writings on diagnosis and prognosis

In diagnosis the Hindu physicians used all five senses. Hearing was used to distinguish the nature of the breathing, alteration in voice, and the grinding sound produced by the rubbing together of broken ends of bones. They appear to have had a good clinical sense, and their sections on prognosis contain acute references to symptoms that are of grave import. Magical beliefs still persisted, however, until late in the classical period; the prognosis could be affected by such fortuitous factors as the cleanliness of the messenger sent to fetch the physician, the nature of his conveyance, or the types of persons whom the physician met on his journey to the patient.

Indian therapeutics was largely dietetic and medicinal. Dietetic treatment was important and preceded any medicinal treatment. Fats were much used, internally and externally. The most important methods of active treatment were referred to as the "five procedures": the administration of emetics, purgatives, water enemas, oil enemas, and sneezing powders. Inhalations were frequently employed, as were leeching, cupping, and bleeding.

The Indian materia medica was extensive and consisted mainly of vegetable drugs, all of which were from indigenous plants. Caraka knew 500 medicinal plants, and Suśruta knew 760. But animal remedies (such as the milk

of various animals, bones, gallstones) and minerals (sulfur, arsenic, lead, copper sulfate, gold) were also employed. The physicians collected and prepared their own vegetable drugs. Among those that eventually appeared in Western pharmacopoeias are cardamom and cinnamon.

As a result of the strict religious beliefs of the Hindus, hygienic measures were important in treatment. Two meals a day were prescribed, with indications of the nature of the diet, the amount of water to be drunk before and after the meal, and the use of condiments. Bathing and care of the skin were carefully prescribed, as were cleansing of the teeth with twigs from named trees, anointing of the body with oil, and use of eyewashes.

Hindu surgery

In surgery, ancient Hindu medicine reached its zenith. Detailed instructions about the choice of instruments and the different operations are given in the classical texts. It has been said that the Hindus knew all ancient operations except the arrest of hemorrhage by the ligature. Their operations were grouped broadly as follows: excision of tumours; incision of abscesses; punctures of collections of fluid in the abdomen; extraction of foreign bodies; pressing out of the contents of abscesses; probing of fistulas; and stitching of wounds.

The surgical instruments used by the Hindus have received special attention in modern times. According to Suśruta the surgeon should be equipped with 20 sharp and 101 blunt instruments. The sharp instruments included knives of various patterns, scissors, trocars (instruments for piercing tissues and draining fluid from them), saws, and needles. The blunt instruments included forceps, specula (instruments for inspecting body cavities or passages), tubes, levers, hooks, and probes. The *Suśruta-saṃhitā* does not mention the catheter, but it is referred to in later writings. The instruments were largely of steel. Alcohol seems to have been used as a narcotic during operations.

In two types of operations especially, the ancient Hindus were outstanding. Stone in the bladder (vesical calculus) was common in ancient India, and the surgeons frequently carried out the operation of lateral lithotomy for removal of the stones. They also introduced plastic surgery. Amputation of the nose was one of the prescribed punishments for adultery, and repair was carried out by cutting from the patient's cheek a piece of tissue of the required size and shape and applying it to the stump of the nose. The results appear to have been tolerably satisfactory, and the modern operation is certainly derived indirectly from this ancient source. The Hindu surgeons, also performed an operation for the cure of anal fistula, and in this they were definitely in advance of the Greeks.

In the past there has been much speculation as to whether the Greeks derived any of their medical knowledge from the Hindus. Mid-20th-century opinion held that there was certainly intercommunication between Greece and India before the time of Alexander the Great.

**China.** The Chinese system of medicine is of great antiquity and is independent of any recorded external influences. According to legend it commenced with Fu Hsi (c. 2953 BC) and was continued by the emperors Shen Nung (died 2698 BC) and Huang Ti (died 2598 BC). The latter, the Yellow Emperor, was always regarded as the author of the canon of internal medicine called the *Nei Ching*, but there is some evidence that in its present form it does not date from earlier than the 3rd century BC. Most of the Chinese medical literature is founded on the *Nei Ching*, and it is still regarded as a great authority. Other famous works are the *Mo Ching* (known in the West as the "Pulse Classic"), composed c. AD 300; and the *Golden Mirror*, a compilation, made about AD 1700, of medical writings of the Han dynasty (202 BC–AD 221). Chinese medicine continued to make substantial progress until about AD 170, and, until about AD 960, some progress was made; then, after a static period, it degenerated because progress was considered simply as the detailed elaboration of the ancient themes. European medicine began to obtain a footing in China early in the 19th century, but the native system is still widely practiced.

Basic to traditional Chinese medicine is the dualistic cosmic theory of the Yin and the Yang. The Yang, the male

The  
Yin/Yang  
theory in  
Chinese  
medicine

principle, is active and light and is represented by the heavens; the Yin, the female principle, is passive and dark and is represented by the earth. The human body, like matter in general, is made up of five elements: wood, fire, earth, metal, and water. With these are associated other groups of five, such as the five planets, the five conditions of the atmosphere, the five colours, and the five tones. Health, character, and the success of all political and private ventures are determined by the preponderance, at the time, of the Yin or the Yang. In the body their proportions can be controlled, and this is the great aim of ancient Chinese medicine.

The teachings of the religious sects forbade the mutilation of the dead human body; hence traditional anatomy rests on no sure scientific foundation. One of the most important writers on anatomy, Wang Ch'ing-jen, gained his knowledge from the inspection of dog-torn children who had died in a plague epidemic in AD 1798. Traditional Chinese anatomy is based on the cosmic system, which postulates the presence of such hypothetical structures as the 12 channels. Anatomical knowledge is therefore simply a corroboration of the system; when there is a contradiction, the system is assumed to be right. The body contains five organs (heart, lungs, liver, spleen, and kidneys), which store up but do not eliminate; and five viscera (such as the stomach, intestines, gallbladder, and bladder), which eliminate but do not store up. Each organ is associated with one of the planets, colours, tones, smells, and tastes. There are 365 bones and 365 joints in the body. There are also three so-called burning spaces, but there is little agreement concerning the form and position of these hypothetical structures.

According to the physiology of traditional Chinese medicine, the blood vessels are supposed to contain blood and air, in proportions varying with those of the Yin and the Yang. These two cosmic principles circulate in the 12 channels and control the blood vessels and hence the pulse. The *Nei Ching* says that "the blood current flows continuously in a circle and never stops. It may be compared to a circle without beginning or end." On this insubstantial evidence it has been claimed that the Chinese anticipated Harvey's discovery of the circulation of the blood. Tears are supposed to be secreted by the liver, and there are two kinds of salivary secretion, one arising from the heart and the other from the kidneys.

Traditional Chinese pathology is also dependent on the theory of the Yin and the Yang; this led to an elaborate classification of diseases in which most of the types listed are without any scientific foundation.

In diagnosis, detailed questions are asked about the history of the illness and the patient's taste, smell, dreams, etc. Attention is paid to the quality of the voice, and far-reaching conclusions are drawn from it. Note is made of the colour of the face and of the tongue. The most important part of the investigation, however, is the examination of the pulse.

Doctrine  
of the  
pulse

The doctrine of the pulse is ancient. Some say that it was introduced about 255 BC; Wang Shu-ho, who wrote the "Pulse Classic," lived about AD 280. This work (with innumerable commentaries) asserts that health depends on the harmonious balance of the Yin and the Yang. If the flow of one of these principles is obstructed, disharmony and disease result. The state of the pulse indicates the point at which obstruction in the hypothetical channels has occurred. Feeling the pulse is the most important aspect of diagnosis. Three fingers are used to feel the radial artery (serving the forearm, wrist, and hand); and, as there are six pulses, each of which must be felt three times with strong, medium, and weak pressure successively, the number of possible variations is large. Several other qualities of the pulse at any point are also noted, and the pulses on the two sides differ. The pulse also varies according to the time of day and season of the year. These comments refer only to the radial pulse at the wrist; but there are ten other places at which the pulse can be, and often is, felt. The minimum time necessary to feel the pulse is ten minutes, and the operation may take three hours. It is often the only examination made, and it is used not only for diagnosis but also for prognosis. Some

say that from it the organs that are diseased can be ascertained and the time of death or recovery foretold.

For the Western observer, traditional Chinese medical treatment has three points of interest: the materia medica, moxibustion, and acupuncture.

The materia medica has always been extensive and consists of vegetable, animal (including human), and mineral remedies. There were famous herbals from ancient times; but all these, to the number of about 1,000, were collated, correlated, corrected, and used by Li Shih-chen in the compilation of *Pen-ts'ao kang-mu* (AD 1552-78; "Great Pharmacopoeia"). This work, in 52 volumes, has been frequently revised and reprinted and is still authoritative. The use of drugs is mainly to restore the harmony of the Yin and the Yang. The drugs are also related to such matters as the five organs, the five planets, and the five colours. The art of prescribing is therefore complex. Almost every conceivable natural substance has at one time or another been used therapeutically. In addition, in prescribing there are often the elements of sympathetic magic, and the doctrine of signatures, long since abandoned by Western medicine. (The doctrine of signatures held that the shapes of plants or natural marks on them indicated their proper use by man.) Various plasters are often applied, sometimes far from the seat of the pain.

Among the drugs taken over by Western medicine from the Chinese are rhubarb, iron (for anemia), castor oil, kaolin, aconite, camphor, and *Cannabis sativa* (Indian hemp). Chaulmoogra oil was used by the Chinese for leprosy from at least the 14th century, and about a century ago it began to be used for this purpose by Western physicians. The herb mahuang has been used in China for at least 4,000 years. Botanically it is *Ephedra vulgaris* (or *E. sinica*), and the isolation of the alkaloid ephedrine from it has greatly improved the Western treatment of asthma and similar conditions. The most famous and expensive of Chinese remedies is ginseng. Western methods have shown that it has diuretic and other properties but is of doubtful value.

In recent years reserpine, the active principle of the Chinese plant *Rauwolfia*, has been isolated; it is now effectively used in the treatment of high blood pressure and some emotional and mental conditions.

Hydrotherapy is probably of Chinese origin, since cold baths were used for fevers as early as 180 BC. The inoculation of smallpox matter, in order to produce a mild but immunizing attack of the disease, was practiced in China from ancient times and came to Europe about 1720.

Moxibustion consists in making a small, moistened cone (moxa) of powdered leaves of mugwort, or wormwood (*Artemisia* species), applying it to the skin, igniting it, and then crushing it into the blister so formed. Other substances are also used for the moxa. Dozens of these are sometimes applied at one sitting. The practice is often associated with acupuncture.

Acupuncture consists of the insertion into the skin and underlying tissues of a metal needle, either hot or cold. The theory is that the needle will affect the distribution of the Yin and the Yang in the so-called burning spaces and in the hypothetical channels of the body. The site of the insertion is chosen to affect a particular organ or organs. The practice of acupuncture dates from before 2500 BC and is peculiarly Chinese. Little of practical importance has been added since that date, although there have been many well-known treatises on the subject.

A bronze model, c. AD 860, shows the hundreds of specified points for the insertion of the needle; this was the forerunner of the innumerable models and diagrams that were later produced. The needles used are three to 24 centimetres (about one to nine inches) in length. They are often inserted with considerable force and after insertion may be screwed to the left or right. One Western observer saw unsterilized needles driven up to 15 centimetres (six inches) into solid organs such as the liver. Acupuncture, often combined with moxibustion, is still widely used for many diseases, including fractures.

**Japan.** The most interesting features of Japanese medicine are the extent to which it was derivative and the rapidity with which, after a slow start, it became Western-

medicine

Moxi-  
bustion  
and  
acupunc-  
ture

ized and scientific. In the early pre-Christian Era disease was regarded as sent by the gods or produced by the influence of evil spirits. Treatment and prevention were based largely on religious practices, such as prayers, incantations, and exorcism. At a later date drugs and blood-letting were also employed.

Chinese  
influence

The first known intrusion of a foreign influence occurred in AD 458, when a Korean physician settled in Japan. His stay there did not have much influence, but, a century and a half later (AD 608), young Japanese physicians were sent for a long period of study in China, and that episode marks the real beginning of Chinese influence on Japanese medicine. In 984, Tamba Yasuyori completed the 30-volume *Ishinhō*, the oldest Japanese medical work still extant. This work discusses diseases and their treatment, classified mainly according to the affected organs or parts. It is based entirely on older Chinese medical works. During the next 600 years, the influence of China was paramount, and the Yin and the Yang played a marked role in the theory of disease causation. In 1528 the first medical book to be printed in Japan was published; it was a Chinese work.

In 1570 a 15-volume medical work was published by Menase Dōsan, who, in the next ten years, published at least five other works. In the most significant of these, the *Keiteki-shū* (a manual of the practice of medicine, 1574), diseases—or sometimes merely symptoms—are classified and described in 51 groups. For the period in which the work was written, the descriptions of symptoms, signs, and treatment are reasonably good; the work is also unusual in that it includes a section on the diseases of old age. Another distinguished physician and teacher of the period, Nagata Tokuhon, whose important books were the *I-no-ben* (1585) and the *Baika mujinzo* (1611), held that the chief aim of the medical art was to support the natural force, and consequently that it was useless to persist with stereotyped methods of treatment unless the physician had the cooperation of the patient.

European  
influences

During the 16th century, important cultural and social changes occurred. The Portuguese first landed briefly in Japan about 1530, and in 1549 the Jesuit missionary Francis Xavier brought Christianity to the country. In 1556 a hospital was established in Funai for the treatment of lepers and the poor; the care of the patients was entrusted to Louis Almeida, a member of the Jesuit mission, who was the first European to practice medicine in Japan. At about the same time a Japanese named Pohl, who had been taught the art of medicine by the Portuguese, began medical practice. This date marks the introduction of European medicine to Japan.

In 1568 a church, named Namban-ji (Church of the South Barbarians—i.e., the Portuguese), was built in Kyōto by order of the government. Two native physicians who had learned medicine from the Portuguese were attached to the church; they treated the poor, performed operations, and founded hospitals. Then a reaction set in, and, within 20 years, the Portuguese had been exiled and Christianity had been stamped out. These events were succeeded by the foundation of several Japanese schools of medicine, all based on Chinese works.

The Dutch, who had first visited Japan in 1597, formed in 1641 a trading colony at Deshima, an island near Nagasaki. A few years later their physician, Caspar Schamberg, arrived at Nagasaki, and, during the next 50 years, other Dutch physicians resided at the Dutch embassy there and taught Japanese students. One of these students published, in 1706, an abstract in Japanese of the works of the French surgeon Ambroise Paré. Within 40 years the court librarian and the court physician were ordered by the shogun to learn Dutch.

Maeno Ryotaku was a well-known physician who knew Dutch thoroughly. In 1771 he and three colleagues dissected the body of a female subject and compared their findings with the plates in a Dutch anatomical work. They decided that the plates were correct and that the Chinese and Japanese works were wrong. In consequence they made a translation of the Dutch book, which was published in 1773. This work had great influence. It was later followed by translations of other European books

on anatomy and internal medicine. It was not until 1836 that a work on physiology, written in Japanese, appeared. It was based on the German work by Blumenbach, and it opened new horizons.

In 1791 a medical academy—the Igakukan—had been founded in Edo (in 1868 renamed Tokyo). The Dutch also had a medical school, described as the European Medical School. In 1849 there came a sudden change of official policy, the study of European medicine—except surgery—was forbidden, and medical books could only be published with the permission of the Igakukan. This state of affairs was soon changed, for in 1857 a group of Japanese physicians, trained in the European School, founded a medical school in Edo. Three years later it was taken over by the government, and it is regarded as the beginning of the medical faculty of the Imperial University of Tokyo. In 1868 the European Medical School was reorganized and a large hospital was built. But in 1871 the government suddenly decided that thenceforth all medical instruction was to be after the German model, and two German military surgeons, Müller and Hoffman, arrived in Tokyo to organize the new education. As a result of the government's eagerness to westernize Japanese medicine, very great progress was made in the foundation of medical schools and the encouragement of research. The first important medical discovery by the Japanese was that of the plague bacillus, in 1894. This was followed by the discovery of a dysentery bacillus in 1897; the isolation of adrenaline in crystalline form in 1901; the first experimental production of a tar-induced cancer in 1918; and other discoveries in the field of tropical medicine. (E.A.U.)

#### EARLY GREEK AND ROMAN MEDICINE

**Before Hippocrates.** The transition from magic to science was a gradual process that lasted for centuries, and there is little doubt that ancient Greece inherited much from Babylonia and Egypt, and even India and China. Twentieth-century readers of the Homeric tales the *Iliad* and the *Odyssey* may well be bewildered by the narrow distinction between gods and men among the characters and between historical fact and poetic fancy in the story. Two characters, the military surgeons Podaleirius and Machaon, are said to have been sons of Asclepius. Asclepius, the god of medicine, may have originated in a human Asclepius who lived about 1200 BC and is said to have performed many miracles of healing. The divine Asclepius was worshiped in hundreds of temples throughout Greece, the remains of which may still be seen at Epidaurus, Cos, Athens, and elsewhere. To these resorts or hospitals many sick persons went for the healing ritual known as incubation, or temple sleep; they lay down to sleep in the dormitory, or *abaton*, and were visited in their dreams by Asclepius or by one of his priests, who gave advice. In the morning the patient often departed cured. There are at Epidaurus many inscriptions recording the cures, but there seem to have been no failures and no deaths. Diet, baths, and exercises played their part in the treatment, and it would appear that these temples were the prototype of modern health resorts. Each had its theatre for amusements and its stadium for athletic contests. The cult of incubation continued far into the Christian Era. In Greece some of the Aegean islands, Sardinia and Sicily, sick persons are still taken to spend a night in certain churches in the hope of a cure.

Cure by  
incubation

It was, however, the work of the early Greek philosophers, rather than that of the priests of Asclepius, that provided the impetus that led men to refuse to be guided solely by supernatural influence and to seek out for themselves the causes and reasons for the strange ways of nature. The 6th-century philosopher Pythagoras, whose chief discovery was the importance of numbers, also investigated the physics of sound. In the 5th century BC Empedocles set forth the view that the universe is composed of four elements—fire, air, earth, and water; this conception led to the doctrine of the four bodily humours: blood; phlegm; cholera, or yellow bile; and melancholy, or black bile. The maintenance of health was held to depend upon the harmony of the four humours.

**Hippocrates.** Medical thought had reached this stage and had partially discarded the conceptions based upon magic and religion by 460 BC, the year that Hippocrates is said to have been born. Little is known of his life, and there may, in fact, have been several men of this name, or Hippocrates may have been the author of only some, or none, of the books that make up the *Hippocratic Collection*, or the *Corpus Hippocraticum*. Ancient writers held that Hippocrates taught and practiced medicine in Cos, the island of his birth, and in other parts of Greece, including Athens, and died at an advanced age.

Whether Hippocrates was one man or several seems immaterial. The works attributed to him were written by someone, and they do indicate a stage in the progress of medicine. For convenience, Hippocrates is referred to in the following material as if he were known to be one man who wrote all the works of the *Hippocratic Collection*. Some of the works, notably the *Aphorismi (Aphorisms)*, were used as textbooks until the 19th century. Admittedly they contain much that is obsolete, but they embody a code of teaching and principles that are surprisingly modern. The first aphorism is, "Life is short, and the art long; opportunity fleeting; experiment dangerous, and judgment difficult." This is followed by a large number of brief comments on diseases and symptoms, many of which remain true. The thermometer and the stethoscope were not then known. Employing only his own powers of observation and of logical reasoning, Hippocrates had an almost uncanny ability to foretell the course of the malady, laying more stress upon the expected outcome, or diagnosis.

On the mainland, close to Cos, was a rival school of Cnidus, the members of which were apt to confuse symptoms and diagnosis; they insisted upon naming the disease and treating it and were not concerned with prognosis or with causes. Hippocrates had no patience with the idea that disease was a punishment sent by the gods. Writing of epilepsy, then called "the sacred disease," he said, "It is not any more sacred than other diseases, but has a natural cause, and its supposed divine origin is due to man's inexperience. Every disease," he continued, "has its own nature, and arises from external causes." He noted the effect of food, of occupation, and especially of climate in causing disease, and one of his most interesting books, entitled *De aëre, aquis et locis (Air, Waters and Places)*, would today be classed as a treatise on human ecology. Pursuing this line of thought, Hippocrates stated that "Our natures are the physicians of our diseases" and that this tendency to natural cure should be fostered; he laid much stress on diet and the use of few drugs. He knew well how to describe illness clearly and concisely and recorded failures as well as successes; he viewed disease with the eye of the naturalist and studied the entire patient in his environment.

Perhaps the greatest legacy of Hippocrates was the charter of medical conduct known as the oath of Hippocrates, which has been adopted as a pattern by medical men throughout the ages and is still used during the ceremony of graduation at many universities and schools of medicine:

I will look upon him who shall have taught me this Art even as one of my parents. I will share my substance with him, and I will supply his necessities, if he be in need. I will regard his offspring even as my own brethren, and I will teach them this Art, if they would learn it, without fee or covenant. I will impart this Art by precept, by lecture and by every mode of teaching, not only to my own sons but to the sons of him who has taught me, and to disciples bound by covenant and oath, according to the Law of Medicine.

The regimen I adopt shall be for the benefit of my patients according to my ability and judgment, and not for their hurt or for any wrong. I will give no deadly drug to any, though it be asked of me, nor will I counsel such, and especially I will not aid a woman to procure abortion. Whatsoever house I enter, there will I go for the benefit of the sick, refraining from all wrongdoing or corruption, and especially from any act of seduction, of male or female, of bond or free. Whatsoever things I see or hear concerning the life of men, in my attendance on the sick or even apart therefrom, which ought not to be noised abroad, I will keep silence thereon, counting such things to be as sacred secrets.

The term oath should not be interpreted too narrowly. It was, rather, an ethical code or ideal and in no sense a law. It is an appeal for correct conduct but contains no threat of punishment. In one or other of its many versions, it has guided the practice of medicine for more than 2,000 years.

**Between Hippocrates and Galen.** In the following century, Aristotle flourished, the first great biologist, whose work was of inestimable value to medicine. A pupil of Plato at Athens and tutor to Alexander the Great, Aristotle studied the entire world of living things, laying the foundations of comparative anatomy and of embryology.

After the time of Aristotle, Greek culture began to fade in the land of its birth. The scene shifted to Alexandria, where a famous medical school was established c. 300 BC. There, the two best medical teachers were Herophilus, whose treatise on anatomy may have been the first of its kind, and Erasistratus, regarded by some as the founder of physiology, who noted the difference between sensory and motor nerves but thought that the nerves are hollow tubes containing fluid and that air enters the lungs and heart and is carried through the body in the arteries. Alexandria continued as a centre of medical teaching even after the Roman Empire had attained supremacy over that of Greece, and medical knowledge remained predominantly Greek.

Aulus Cornelius Celsus, the Roman nobleman who wrote *De medicina* about AD 30, based his knowledge on Greek medicine. His book, overlooked in his day, became well known after it was printed at Florence, in 1478. Celsus followed the teaching of Asclepiades of Bithynia (born 124 BC), who differed from Hippocrates in that he denied the healing power of nature and insisted that disease could be treated safely, speedily, and agreeably.

An opponent of the humoral theory, Asclepiades drew upon the atomic theory of the 5th-century Greek philosopher Democritus in advocating a doctrine of *strictum et laxum*—the attribution of disease to the constricted or relaxed condition of the solid particles that he believed make up the body. To restore harmony among the particles and thus effect cures, Asclepiades used typically Greek remedies: massage, poultices, occasional tonics, fresh air, and corrective diet. He gave particular attention to mental disease, clearly distinguishing hallucinatory conditions from those marked by delusions. He released the insane from confinement in dark cellars and prescribed a regimen of occupational therapy, soothing music, soporifics (especially wine), and exercises to improve the attention and memory. Asclepiades did much to win acceptance for Greek medicine in Rome. After his death came a period of much disputation as to the nature of disease. This period was brought to a close by the career of Galen, who began practising in Rome in AD 164.

**Galen.** During the early centuries of the Christian Era, Greek doctors thronged to Rome. The most illustrious of them was Galen, who acknowledged his debt to Hippocrates and followed the Hippocratic method, accepting the doctrine of the humours. He laid stress on the value of anatomy, and he virtually founded experimental physiology. Galen recognized that the arteries contain blood and not merely air and showed how the heart sets the blood in motion in an ebb and flow fashion, but he had no idea that the blood circulates. Dissection of the human body was at that time illegal, so that he was forced to base his knowledge upon the examination of apes and pigs. A voluminous writer who stated his views forcibly and with confidence, he remained for centuries the undisputed authority from whom no one dared to differ.

Although the contribution of Rome to the practice of medicine was negligible compared with that of Greece, it must be admitted that in matters of public health Rome set the world a great example. The city of Rome had an unrivaled water supply. Gymnasiums and public baths were provided, and there was even domestic sanitation and adequate disposal of sewage. The Roman army had its medical officers; public physicians were appointed to attend the poor; and hospitals were built; in fact, a Roman hospital excavated near Dusseldorf, Germany, was found to be strangely modern in design.

## ARABIAN TEACHING AND THE SCHOOL OF SALERNO

After the fall of Rome, learning was no longer held in high esteem, experiment was discouraged, and originality became even a dangerous asset. During the early Middle Ages medicine passed into the widely contrasting hands of the Christian Church and the Arab scholars.

**The Christian reservoir of learning.** It is sometimes stated that the early Christian Church had an adverse effect upon medical progress: disease was regarded as a punishment for sin, and such chastening demanded only prayer and repentance. Furthermore, the human body was held sacred and dissection was forbidden. It seems probable, however, that the infinite care and nursing bestowed upon the sick by the Christian Church far outweighs any intolerance shown toward medicine in the early days. Perhaps the greatest service rendered to medicine by the church was the preservation and transcription of the classical Greek medical manuscripts. This work was carried on in many medieval monasteries and was also pursued by the Nestorian Christians (an Eastern church not affiliated with the Patriarchy of Constantinople), who established a school of translators to render the Greek medical texts into Arabic. This famous school, and also a great hospital, were located at Jundi Shāhpūr in southwest Persia, where the chief physician was Jurjīs ibn Bukhtīshū, the first of a dynasty of translators and physicians that lasted for six generations. A later translator of great renown was Hunayn ibn Ishāq, or Johannitus (born AD 809), whose translations were said to be worth their weight in gold.

About this time there appeared a number of saints whose names were associated with miraculous cures. Among the earliest of these were twin brothers, Cosmas and Damian, who suffered martyrdom (c. AD 303) and who became the patron saints of medicine. The Christian Church sought to replace the signs of the zodiac, to which parts of the human body were referred, by various patron saints: St. Blaisius dominated the throat and lung; St. Apollonia, the teeth; St. Erasmus, the abdomen; SS. Lucia and Triduana, the eyes. Other saints were powerful healers of certain diseases: St. Vitus, for example, was invoked for chorea, or St. Vitus' dance, and St. Anthony for erysipelas, or St. Anthony's fire. The cult of these saints was widespread in medieval times, and a later cult, that of St. Roch for plague, was widespread in the 15th century when that disease was prevalent.

**The Arabian medical reservoir.** The second reservoir of medical learning during those early times was the great Muslim Empire, which extended from Persia to Spain. Although it is customary to speak of Arabian medicine in describing this period, it must be remembered that the physicians were not all Arabs or natives of Arabia. Nor, indeed, were they all Muslims: some were Jews, some Christians, and they were drawn from all parts of the great empire, extending along the entire northern coast of Africa and invading Spain. Only a few of the leading figures need be mentioned. One of the earliest was Rhazes, a Persian born in the last half of the 9th century near the modern Teheran, who wrote a voluminous treatise on medicine, *Kitāb al-hāwī* ("Comprehensive Book"), but whose most famous work, *De variolis et morbillis* (*A Treatise on the Smallpox and Measles*), deals with the distinction between these two diseases and gives a clear description of both.

Of later date was Avicenna (980–1037), who has been called the prince of physicians. Like Rhazes, Avicenna was a Persian. Born near Bukhara, he could repeat the Koran before he was ten years old and at the age of 18 became court physician. His principal medical work, *Al-Qānūn fī'l-Tibb* (*The Canon of Medicine*), became a classic and was used at many medical schools—at Montpellier, France, as late as 1650—and is still said to be used in the East. Avicenna died at Hamadan, where his tomb is a place of pilgrimage.

The greatest contribution of Arabian medicine was in chemistry and in the knowledge and preparation of medicines; many drugs now in use are of Arab origin, as also are such processes as distillation and sublimation. Often the chemistry of that time was mainly a search for the

philosopher's stone, which supposedly would turn all common metals to gold. Astronomers were astrologers and chemists were alchemists. It is, therefore, surprising that, despite all this, the physicians of the Muslim empire did make a noteworthy contribution to medical progress.

At that period and, indeed, throughout most historical times, surgery was regarded as inferior to medicine. One Arab surgeon, however, Abū al-Qāsim (Albucasis) of Córdoba, wrote the first illustrated book on surgery, which was widely used. He was a careful and conservative surgeon who did much to raise the status of surgery in Córdoba, an important centre of commerce and culture with a hospital and medical school equal to those of Cairo and Baghdad.

Another great doctor of Córdoba, born in the 12th century, just as the sun of Arabian culture was setting, was a Jew, the philosopher Maimonides. Banished from the city because he would not become a Muslim, he eventually went to Cairo, where the law was more lenient and where he acquired a reputation so high that he became physician to Saladin, the Saracen leader. He was the original of El Hakim in Sir Walter Scott's *Talisman*. A few of his works, written in Arabic, were eventually translated into Latin and printed; perhaps the best known is *Yad-Hachazakah* (*The Code of Maimonides*), an ethical code still esteemed in Jewish medical circles.

**Salerno.** At about the same time that Arabian medicine flourished, there was established at the city of Salerno, in southern Italy, the first organized medical school in Europe. Although the school of Salerno produced no brilliant genius and no startling discovery, it was the parent of the great medieval schools soon to be founded at Montpellier and Paris, in France, and at Bologna and Padua, in Italy. The Salerno school owed much to the enlightened Holy Roman emperor Frederick II, who decreed in 1221 that no one should practise medicine until he had been publicly approved by the masters of Salerno.

Salerno drew scholars from near and far. One of the earliest was the 11th-century physician Constantine the African, who, after years of wandering in the East, sought refuge in Salerno. (He later retired to Monte Cassino, the monastery founded by St. Benedict in the 6th century, there to translate from Arabic into Latin many of the Greek classic writings.) The Salernitan school also produced a literature of its own; the best known work, of uncertain date and of composite authorship, was the *Regimen Sanitatis Salernitanum* ("Salernitan Guide to Health"). Written in verse, it has appeared in numerous editions and has been translated into many languages. The *Regimen* is said to have been written as a handbook of domestic medicine for Robert, duke of Normandy, a crusader who visited Salerno for the treatment of a wound, but the most authentic contemporary manuscript is that of Arnald of Villanova. Among its oft-quoted couplets is the following:

Use three physicians still, first Doctor Quiet,  
Next Doctor Merryman, and Doctor Diet.

## REFORM AND REVIVAL IN MEDICINE

**The spread of new learning.** Salerno yielded its place as the premier medical school of Europe to Montpellier in about 1200. John of Gaddesden, the model for the "doctour of physick" in Chaucer's *Canterbury Tales*, was one of the English students there. That he relied upon astrology and upon the doctrine of the humours is evident from Chaucer's description:

Well could he guess the ascending of the star  
Wherein his patient's fortunes settled were.  
He knew the course of every malady,  
Were it of cold or heat or moist or dry . . .

Among the teachers of medicine in the medieval universities there were many who clung to the past, but there were not a few who determined to explore new lines of thought. The new learning, or Renaissance, born in Italy, grew and expanded slowly. Two great 13th-century scholars who influenced medicine were Roger Bacon, an active observer and tireless experimenter, and Albertus Magnus. About this time, also, Mondino de'Luzzi taught at Bologna, Italy, performing his own dissections rather than

Preservation of Greek medical manuscripts

Abū al-Qāsim and Maimonides

The "Salernitan Guide to Health"

following the then usual procedure of entrusting the task to a menial. Although he perpetuated the errors of Galen, his anatomy, published in 1316, was the first practical manual of anatomy.

Foremost among the surgeons of the day was Guy de Chauliac, a good physician as well as a surgeon and one who based his writing on observation and experience. His *Chirurgia magna* ("Great Surgery") had a profound influence upon the progress of surgery.

The Renaissance, a movement of the 14th, 15th, and 16th centuries, was much more than merely a reviving of interest in Greek and Roman culture; it was rather a change of outlook, an eagerness for discovery, a desire to escape from the limitations of tradition and to explore new fields of thought and action. In medicine, it was perhaps natural that anatomy and physiology, the knowledge of the human body and its workings, should be the first aspects of medical learning to receive attention from those who realized the need for reform.

The work  
of Vesalius

It was in 1543 that Andreas Vesalius, a young professor of anatomy at the University of Padua, published *De humani corporis fabrica* ("On the Fabric of the Human Body"). The work, the fruit of his own observations, showed that Galen could no longer be regarded as the final authority from whom none dared to differ; Vesalius corrected many of Galen's errors. His good work at Padua was continued by Gabriel Fallopius and, later, by Hieronymus Fabricius ab Aquapendente, whose work on the valves in the veins, *De venarum ostiis*, published in 1603, suggested to his pupil William Harvey the idea of the circulation of the blood.

Surgery profited from the new outlook in anatomy, and a great surgical reformer, Ambroise Paré, now appeared on the scene. Paré was surgeon to four kings of France in succession, and he well earned for himself the title of "the father of modern surgery." In his autobiography, written after he had retired from 30 years of service as an army surgeon, Paré described how he had abolished the painful cautery for gunshot wounds and used soothing dressings instead; his favourite expression, "I dressed him; God healed him," is characteristic of this humane and careful surgeon.

**Medical colleges in Britain.** At about the time of these developments in Italy and France, surgery, which was ahead of medicine in the establishment of organizational controls, underwent reorganization in Britain. As early as 1505 a decree, or "seal of cause," was granted to the Incorporation of Barber-Surgeons of Edinburgh; it was confirmed by King James IV of Scotland a year later. In 1540, King Henry VIII of England granted a royal charter to Thomas Vicary, the first master of the Barber-Surgeons Company, which became the Company of Surgeons of London in 1745, the Royal College of Surgeons in 1800, and still later the Royal College of Surgeons of England. Thus were founded the bodies that became the Royal Colleges of Surgeons in Scotland and in England. At the end of the century, in 1599, Peter Lowe obtained from King James VI of Scotland a charter for the Faculty (now Royal College) of Physicians and Surgeons of Glasgow to control practice in and around the city. Lowe had the foresight to include all who practised medicine or surgery and thus sought to unite the two aspects of the healing art that had long been separated.

Another event of great importance during the 16th century was the foundation of the College of Physicians in London, which received its charter from Henry VIII in 1518. The College had the sole privilege of permitting persons to practise as physicians in London and the surrounding district. The first president was Thomas Linacre, the leading Oxford scholar of his day. He was succeeded by John Caius, honoured by inclusion of his name in that of the modern Gonville and Caius College, Cambridge, and author of an excellent account of the curious disease called sweating sickness, which ravaged the country in a series of epidemics attended by a high mortality. The Royal College of Physicians of Edinburgh was founded in 1681. Edinburgh University was the first British university to found (1726) a medical faculty and to provide a complete training in medicine.

**Paracelsus.** No account of Renaissance medicine can afford to omit some mention of the strange man, the alchemist known as Paracelsus. Theophrastus Bombastus von Hohenheim, who called himself Phillipus Aureolus Paracelsus, was the son of the country doctor of Einsiedeln, near Zürich. He travelled extensively in Europe, practising and teaching as he went. Eager for reform, he allowed his intolerance to outweigh his discretion, as when he prefaced his lectures at Basel by publicly burning the works of Avicenna and Galen. The authorities were understandably annoyed. To this day, Paracelsus is highly regarded by some and as strongly decried by others. He remains an enigma. There is no doubt, however, that he simplified prescribing and introduced chemical drugs in place of vegetable remedies.

**Fracastoro.** A contemporary of Paracelsus, Girolamo Fracastoro, of Verona, Italy, was a scholar of very different mold. His account of the disease syphilis, entitled *Syphilis sive morbus Gallicus* (1530; "Syphilis or the Gallic Disease"), was written in verse. Fracastoro called syphilis the French disease; others called it the Neapolitan disease, for it was said to have been brought to Naples from America by the sailors of Columbus; its origin is still questioned. Fracastoro was also interested in epidemic infection, about which his ideas were surprisingly modern. In 1546 he published his great work, *De Contagione*, in which he theorized that the seeds of certain diseases are imperceptible particles carried by air or by contact.

Fracastoro  
on syphilis

#### MEDICINE IN THE 17TH CENTURY

**William Harvey and the experimental method.** The medical progress of the 17th century can now be considered, together with the leading part played by William Harvey, whose classic little book *Exercitatio anatomica de motu cordis et sanguinis in animalibus* ("An Anatomical Experiment Concerning the Movement of the Heart and Blood in Animals"), often called for short *De motu cordis*, was printed at Frankfurt am Main in 1628.

Born at Folkestone, Kent, the eldest of the seven sons of the mayor, Harvey studied at Caius College, Cambridge, and then spent several years at Padua, where he came under the influence of Fabricius. By the time that Harvey began to lecture in London, in 1616, he had already reached his conclusion regarding the circulation of the blood, although he waited for 12 years before printing his views. That the book aroused much controversy is not surprising. There were still many who adhered to the ancient teaching of Galen and affirmed that the blood follows an ebb and flow movement in the blood vessels. Harvey's work was the result of many careful experiments, but few of his critics took the trouble to repeat the experiments; instead, they simply argued in favour of the older view, in their bookish and scholastic fashion. His second great book, *Exercitationes de generatione animalium* ("Experiments Concerning Animal Generation"), published in 1651, laid the foundation of modern embryology. Harvey's discovery of the circulation of the blood was a most important landmark of medical progress; the new experimental method by which the results were secured was as noteworthy as the work itself. He drew the truth from experience and not from authority, following the method described by the philosopher Francis Bacon.

There was one gap in Harvey's argument—he was obliged to assume the existence of the capillary vessels that conveyed the blood from the arteries to the veins at the periphery. This link in the chain of evidence was supplied by Marcello Malpighi of Bologna, who was born in 1628, the year of publication of *De motu cordis*. With a primitive microscope Malpighi saw a network of tiny blood vessels in the lung of a frog. Harvey also failed to show why the blood circulated. After Robert Boyle had shown that air is essential to animal life, it was Richard Lower who traced the interaction between air and the blood. Eventually the importance of oxygen, which masqueraded for a time as phlogiston, was revealed, but it was not until 1775 that Antoine Laurent Lavoisier discovered the nature of oxygen and solved a problem that had puzzled many.

**Invention and development of microscope**

The invention of the compound microscope is usually attributed to a spectacle maker named Zacharias Janssen, in Holland, but its development, like that of the telescope, was the work of Galileo, who was the first to lay stress upon the value of measurement in science and in medicine, thus replacing theory and guesswork with accuracy. One of the greatest of the early microscopists was Anton van Leeuwenhoek of Delft, who devoted his long life to microscopical studies and who was probably the first to see and describe bacteria, reporting his results to the Royal Society of London. In England, Robert Hooke, who was Boyle's assistant and curator to the Royal Society, published his classic book *Micrographia* in 1665.

**The futile search for an easy system.** It was during the 17th century that several attempts were made to discover an easy system as a clue to the problems of medical practice. A substratum of superstition still remained at this time; e.g., Richard Wiseman, surgeon to Charles II, affirmed his belief in the "royal touch" as a cure for king's evil, or scrofula, while even the learned English physician Sir Thomas Browne stated that witches really existed. There was, however, a general desire to discard the past and to adopt new ideas.

The view of the 17th-century French philosopher René Descartes that the human body is a machine had its repercussions in medical thought. One group adopting this explanation called themselves the iatrophysicists; another school, preferring to view life as a series of chemical processes, were called iatrochemists. Sanctorius, at Padua, an early exponent of the iatrophysical view, did much pioneer work in what is now called metabolism, being especially concerned with the measurement of what he called "insensible perspiration," described in his book *De statica medicina*, published in 1614. Another Italian who developed the idea still further was Giovanni Alfonso Borelli, a professor of mathematics at Pisa University, who busied himself with the mechanics and statics of the body and with the physical laws that govern its movements. The iatrochemical school was founded at Brussels by Jan Baptista van Helmont, whose writings are tinged with the mysticism of the alchemist. A more logical and intelligible view of iatrochemistry was advanced by Franciscus Sylvius, at Leiden, while in England a leading exponent of the same school was Thomas Willis, who is better known for his description of the brain in his *Cerebri anatome nervorumque descriptio et usus* ("Anatomy of the Brain and Descriptions and Functions of the Nerves"), published in 1664 and illustrated by Sir Christopher Wren.

It soon became apparent that no easy road to medical knowledge was to be found along these channels and that the best method is the age-old system of straightforward clinical observation originally initiated by Hippocrates. The need for a return to Hippocratic views was strongly urged by Thomas Sydenham, well named "the English Hippocrates." Sydenham was not a voluminous writer and, indeed, had little patience with book learning in medicine, but nevertheless he gave excellent descriptions of the phenomena of disease. His greatest service, much needed at the time, was to divert men's minds from speculation and to lead them back to the bedside, for there only could the art of medicine be studied.

#### MEDICINE IN THE 18TH CENTURY

**Brown and Hahnemann.** Sydenham's praiseworthy appeal for a return to Hippocratic methods was not accepted by everyone. Even in the 18th century the search for a simple way of healing the sick continued. In Edinburgh a writer and lecturer named John Brown expounded, at the Royal Medical Society (of which he was president three times), his Brunonian system. In his view, there were only two diseases, sthenic (strong) and asthenic (weak) and two treatments, stimulant and sedative. Lively and heated debates took place between Brunonians and the more orthodox Cullenians (followers of William Cullen), and the disturbance spread to Europe. Meantime, the unfortunate Brown, at war with all his colleagues, became a victim of his own system and died in debt and poverty, his end hastened by his two chief reme-

dies, opium and alcohol. At the opposite end of the scale, at least in regard to dosage, was Samuel Hahnemann, of Leipzig, the originator of homeopathy, a system of treatment involving the administration of minute doses of drugs whose effects resemble the effects of the disease being treated. His ideas had a salutary effect upon medical thought at a time when prescriptions were lengthy and doses were large; his system has had many followers.

**Medical teaching in Britain.** Before the 18th century, there was little organized medical teaching in Britain. Those who wished to become doctors first became apprentices; they could then also attend classes in anatomy, botany, and chemistry, the tripod of learning upon which medicine was then founded. Those who could afford it studied and even graduated at one of the European universities, as William Harvey did at Padua in 1602. When the centre of medical learning shifted from Padua to Leiden, many students were attracted there from abroad. Among them was John Monro, an army surgeon, who resolved that his native city of Edinburgh should have a similar medical school. He specially educated his son Alexander with a view to having him appointed professor of anatomy, and the bold plan was successful. Alexander Monro studied at Leiden under Hermann Boerhaave, the central figure of European medicine and the greatest clinical teacher of his time, and on returning to Edinburgh was appointed professor of anatomy. Monro was followed in the chair by his son Alexander Monro II, and he, in turn, by the grandson Alexander Monro III; although in the third generation the high standard was not maintained, the three Alexander Monros taught anatomy in Edinburgh University over a continuous period of 126 years. Robert Sibbald and Archibald Pitcairne, who had helped to found the Royal College of Physicians of Edinburgh in 1681, were now gone; but medicine was brilliantly taught by Robert Whytt, then by the Gregorys, John and James, and still later by William Cullen, who in 1747 founded the faculty of medicine in Glasgow.

**Surgery and obstetrics.** In the early years of the 18th century the leading surgeons of London were William Cheselden and Percivall Pott, although their work tends to be overshadowed by their more famous pupil, John Hunter. John left his home in Lanarkshire in 1748 to assist his elder brother, William, who was already well established in London as an obstetrician and anatomist. Although he made no great single discovery, John, by his vast researches in comparative anatomy and physiology, raised surgery to the level of a definite branch of science and was actually the founder of surgical pathology. After his death, the museum that he had laboriously collected eventually became the property of the Royal College of Surgeons, which honours his memory with the Hunterian oration, although the museum was mostly destroyed by German air raids in World War II. Just as John Hunter raised the status and prestige of surgery, so his contemporary William Smellie performed a similar service for midwifery. Like the Hunters, Smellie was a native of Lanarkshire. After practising medicine in the town of Lanark for 16 years, he settled in London, in 1739. He soon became the leading obstetrician, or man midwife, as specialists of this kind were then called. He placed midwifery on a sound scientific footing. His well-known *Treatise on the Theory and Practice of Midwifery* was published in three volumes in 1752-64.

**Pathology and diagnosis.** In the 18th century, too, the science of modern pathology was created. Giovanni Morgagni, of Padua, in 1761 published the great work *De sedibus et causis morborum* ("On the Sites and Causes of Diseases"), a description of the appearances found by postmortem examination of almost 700 cases, revealing many new facts.

On the basis of work begun in the 18th century, René Laënnec, a native of Quimper, Brittany, who became a physician in Paris, invented the stethoscope, or *cylindre*, as it was originally called. In 1819 he wrote a treatise, *De l'auscultation médiate* ("On Indirect Auscultation"), describing many of the curious sounds in the heart and lungs that are revealed by the stethoscope.

Meanwhile a Viennese physician, Leopold Auenbrug-

**The iatrochemical school**

**The work of John Hunter and William Smellie**

**The Brunonian system**

ger, discovered another method of investigating diseases of the chest, that of percussion. The son of an innkeeper, he is said to have conceived the idea of tapping with the fingers when he recalled that he had used this method to gauge the level of the fluid contents of his father's casks.

**Public health.** Public health and hygiene began to attract attention in the 18th century, although a more lively awakening was later to accompany the Industrial Revolution. Toward the end of his life, early in the 18th century, Bernardino Ramazzini wrote the first work on occupational diseases, *De morbis artificum diatriba (On the Diseases of Artificers)*, a most interesting book of the period. At this time, too, Johann Peter Frank evolved his scheme of health legislation and attempted to awaken a health consciousness in the people and in their rulers. In his *System einer vollständigen medicinischen Polizey* ("System of a Complete Medical Policy"), published in 1779, he was one of the first to suggest that a government should be responsible for the health of its people.

**Smallpox and digitalis.** One important discovery of the 18th century was vaccination. Smallpox, disfiguring and often fatal, was then prevalent. Inoculation, which had been practiced in the East, was popularized in England in 1721–22 by Lady Mary Wortley Montagu, who is best known for her letters. She observed the practice in Turkey; it produced a mild form of the disease, thus securing immunity, although not without danger. The next step was taken by Edward Jenner, a country practitioner of Berkeley, Gloucestershire, who had been a pupil of John Hunter. He observed that those who became infected with cowpox (the bovine form of the disease) did not become infected with smallpox. In 1796 he performed the first vaccination on a certain James Phipps; he found, on inoculating Phipps with smallpox eight weeks later, that the disease did not appear. The advantage of the method became apparent everywhere.

William Withering's discovery of the value of foxglove, or digitalis, as a remedy for dropsy and for heart disease is another example of the good work of a general practitioner. Withering, who practised in Shropshire, noted that the country folk often used a decoction of foxglove leaves. After many experiments, he wrote his classic *An Account of the Foxglove*, in 1785.

**Phrenology and mesmerism.** Phrenology and mesmerism first emerged in the 18th century. Phrenology was a belief that one could judge the development of any faculty by the configuration of the skull over the point on the brain where the faculty was thought to be centred, while mesmerism, a belief in animal magnetism, probably owed any success that it had to suggestions given while the patient was under hypnosis. The first owed its birth to Franz Joseph Gall and his pupil Johann Kaspar Spurzheim. Mesmerism, another product of Vienna, was sponsored by Franz Anton Mesmer.

**Scurvy and military hospitals.** No account of 18th-century medicine would be complete without a reference to two important advances affecting the health of the navy and of the army. Observing the prevalence of scurvy among English sailors, James Lind, a graduate of Edinburgh who had entered the navy, recommended the use of lemon juice, which caused scurvy to disappear. He probably adopted the practice from the Dutch, who, in the 16th century, had discovered the value of citrus fruits in the diet of sailors. Several years passed before Lind's advice was put to use in England. Lind's account of his researches, *A Treatise on the Scurvy*, was published in 1754.

In 1752 there was published another medical classic entitled *Observations on the Diseases of the Army*. The author was Sir John Pringle, who had been professor of moral philosophy at Edinburgh before embarking upon his military career and who rendered valuable service by his recommendations for the health and comfort of the troops. During the War of the Austrian Succession, he had suggested, at the battle of Dettingen, in 1743, that military hospitals on both sides should be regarded as sanctuaries. This plan eventually led to the establishment of the Red Cross organization, although the first Geneva convention was not assembled until 1863, at the instigation of the Swiss banker Jean Henri Dunant.

## II. The rise of scientific medicine in the 19th century

The portrayal of medical history becomes more difficult as modern times are approached. Discoveries multiply and the number of eminent doctors is so great that the story is apt to become a mere string of biographies. This synopsis selects some of the leading trends in medical thought in order to provide a scaffolding upon which the reader may build.

By the beginning of the 19th century, the structure of the human body was almost fully known, thanks to new methods of microscopy and of injections. Even the minute structure of the body was understood. Much more important than anatomical knowledge was the knowledge of physiological processes that was becoming rapidly elucidated, especially in Germany. There, physiology became established as a distinct science under the guidance of Johannes Müller, who was professor at Bonn and then at the University of Berlin. An energetic worker and an inspiring teacher, he described his discoveries in a famous textbook, *Handbuch der Physiologie des Menschen* ("Manual of Human Physiology"), published 1833–40. Among his pupils were Hermann von Helmholtz, who made great discoveries relating to sight and hearing and who invented the ophthalmoscope, and Rudolf Virchow, also of Berlin, whose greatest achievement was his conception of the cell as the centre of all pathological changes. Virchow's work, *Die Cellular-pathologie*, published in 1858, gave the deathblow to the outmoded "humoral" pathology.

In France, the leading physiologist of the time was Claude Bernard, all of whose work was the outcome of carefully planned experiments. His first researches were directed to digestion. Next, he explained the presence of the carbohydrate glycogen in the liver, while his third discovery was that of the vasomotor mechanism, the system of controls of the contraction and expansion of blood vessels. Toward the end of his life, in 1865, he expounded his methods and principles in his *Introduction à l'étude de la médecine expérimentale* ("Introduction to the Study of Experimental Medicine"), a classic still worthy of study by all who undertake research. Meantime, physiology had made progress in Britain under the leadership of Marshall Hall, whose greatest discovery was that of reflex action; William Sharpey, the first in Great Britain to devote his exclusive attention to physiology, separating it from anatomy and physics and placing it among the sciences; and Sir Charles Bell, whose researches on the nervous system yielded notable advances in that field. His *Idea of a New Anatomy of the Brain*, first expounded in 1811, has been called the Magna Carta of neurology, although it is true that François Magendie of France gave a more complete demonstration of the functions of motor and sensory nerves.

### VERIFICATION OF THE GERM THEORY

Perhaps the greatest medical advance of the 19th century, certainly the most spectacular, was the conclusive demonstration that certain diseases, as well as the infection of surgical wounds, were directly caused by minute living organisms. This discovery changed the whole face of pathology and effected a complete revolution in the practice of surgery.

The idea that disease was caused by the entry into the body of tiny imperceptible particles was of ancient date. It had been expressed by the Roman encyclopedist Varro as early as 100 bc, by Fracastoro in 1546, by Athanasius Kircher and Pierre Borel about a century later, and by Francesco Redi, who in 1684 wrote his *Osservazioni intorno agli animali viventi che si trovano negli animali viventi* ("Observations on Living Animals Which Are to Be Found Within Other Living Animals"), in which he sought to disprove the idea of spontaneous generation. Everything must have a parent, he wrote; only life produces life. Another worker in this field, regarded by some as founder of the parasitic theory of infection, was Agostino Bassi, who showed that a disease of silkworms was caused by a fungus that could be destroyed by chemical agents.

Nevertheless, the main credit for the establishment of

the science of bacteriology must be accorded to Louis Pasteur. It was Pasteur who, by a brilliant series of experiments, proved that fermentation, or putrefaction, was not a chemical process but was caused by the living organisms known as bacteria. He solved one problem after another during his strenuous life—problems concerning the fermentation of wine, the prevention of anthrax in sheep and cattle, of chicken cholera, and, finally, of rabies in man and dogs. The later was a bold experiment that resulted in the widespread establishment of Pasteur institutes.

Lister's  
introduc-  
tion of  
antiseptics

From Pasteur, Joseph Lister borrowed, with full acknowledgment, the idea that led to his introduction of the antiseptic system in surgery. Lister, who was born close to London, at Upton, Essex, made known in 1865, while professor of surgery at Glasgow University, his great discovery, the placing of an antiseptic barrier between the wound and the germ-containing atmosphere. Though Lister did not at first realize that infection not only is airborne but also can be carried by the hands, skin, or instruments, he left a noble example and a priceless heritage. Besides creating a complete revolution in the surgical outlook, he is to be remembered as one of the founders of bacteriology.

Obstetrics had already been robbed of some of its terrors by Alexander Gordon at Aberdeen, Scotland, Oliver Wendell Holmes at Boston, and Ignaz Semmelweis (1818–65) at Vienna and Pest (Budapest), who advised disinfection of the hands and clothing of midwives and students who attended confinements.

Another pioneer of bacteriology was Robert Koch, who showed how bacteria could be cultivated and stained and how their specificity could be proved. Koch discovered the tubercle bacillus in 1882 and the vibrio of cholera in 1883. Before the turn of the century many other disease-producing organisms had been identified.

#### MEDICINE AND ANESTHESIA

There was a danger at this time that in the feverish search for bacteria, other causes of disease would escape detection. Physicians of slightly earlier date, who worked along other lines, deserve to be remembered. Among them were physicians attached to Guy's Hospital, London: Richard Bright, Thomas Addison, and William Gull. Bright made important advances in the knowledge of diseases of the kidneys, including so-called Bright's disease, while Addison gave his name to a disease. Gull, a great clinical teacher, left a legacy of pithy and helpful aphorisms that might well rank alongside those of Hippocrates.

In Dublin, two eminent physicians were Robert Graves and William Stokes (1804–78), while, in Paris, Pierre-Charles-Alexander Louis was attracting many students from the United States by the excellence of his teaching. By this time, the United States—having drawn from Leiden, Edinburgh, and London the learning that went to found in the 18th century the first medical schools at Philadelphia and elsewhere, under the guidance of such pioneers as John Morgan, William Shippen, and Benjamin Rush—was now ready to send back the results of its own researches. Daniel Drake founded medical schools at Cincinnati and described the diseases of the Ohio River Valley; Ephraim McDowell performed a bold ovariectomy (removal of an ovary) in a small Kentucky village in 1809; and William Beaumont, in treating a gunshot wound of the stomach, was led to make many original observations that were published in 1833 as *Experiments and Observations on the Gastric Juice and the Physiology of Digestion*.

The most famous contribution by the United States to medical progress at this period was undoubtedly the introduction of general anesthesia, a discovery that was marred by controversy. Crawford Long, Gardner Colton, Horace Wells, and Charles Jackson are all claimants for priority: some used nitrous oxide gas, and others employed ether, which was less capricious. There is little doubt, however, that it was William Thomas Morton who, on October 16, 1846, at Massachusetts General Hospital, first demonstrated before a gathering of physi-

cians the use of ether as a general anesthetic. News of the discovery soon reached Europe. In Edinburgh, the professor of midwifery, James Young Simpson, had been experimenting upon himself and his assistants, inhaling various vapours with the object of discovering a general anesthetic. In November 1847 chloroform was tried with complete success. Within a few days it was tested in an operation, and soon it was preferred to ether and became the anesthetic of choice. Although Simpson is remembered mainly as the discoverer of chloroform, he did a great deal more to enhance the reputation of Edinburgh, and was created a baronet in 1866.

#### ADVANCES AT THE END OF THE CENTURY

While antiseptics and anesthesia placed surgery on an entirely new footing, similarly important work was carried out in other branches of medicine. Sir Patrick Manson showed in Amoy, China, in 1877, how insects may carry disease and how the embryos of the little worm *Filaria*, which causes elephantiasis, are transmitted by the mosquito. Manson explained his views to the young doctor who became Sir Ronald Ross, then working on the problem of malaria, and Ross discovered the malarial parasite in the stomach of the *Anopheles* mosquito in 1897. Carlos Finlay in Cuba expressed the view, in 1881, that yellow fever is carried by the *Stegomyia* mosquito; following him, Walter Reed, William Gorgas, and others conquered the scourge of yellow fever and made possible the completion of the Panama Canal by reducing the death rate there from 176 per 1,000 to 6 per 1,000.

An event of equally startling significance was the control of typhoid by the method of inoculation devised by Almroth Wright. There were other victories in preventive medicine because the maintenance of health had now become as important a duty as the cure of disease; and the 20th century was to witness the evolution and progress of national health services in a number of countries. In addition, spectacular advances in diagnosis and treatment followed the discovery of X-rays by Wilhelm Conrad Röntgen, in 1895, and of radium by Pierre and Marie Curie in 1898. The new field of psychiatry was opened up by Sigmund Freud. The development of chemotherapy, immunology, endocrinology, and the science of nutrition, which were later advances, are described below.

(D.J.G.)

### III. Medicine in the 20th century

The first six decades of the 20th century witnessed such a plethora of discoveries and advances that in some ways the face of medicine was changed out of all recognition. In 1901, for instance, the standardized mortality ratio (*i.e.*, the ratio of observed deaths to expected deaths for the whole population, expressed as a percentage) in England and Wales was 266; in 1962 it was 92. For tuberculosis the standardized mortality ratio in the decade 1901–10 was 649; in 1962 it was 22. Even more striking was the position with regard to diphtheria in children. In the decade 1901–10 the death rate per 1,000,000 population at ages under 15 years was 571; in 1969 it was zero. Indeed, the outlook was so altered that, with the notable exception of cancer, attention became focussed on morbidity rather than mortality, and the emphasis has changed from keeping people alive to keeping them fit.

In the medical kaleidoscope of this era, four main trends may be distinguished: the first and the most important was the development of chemotherapy; the second, and closely associated, was the development of immunology; the third was progress in endocrinology; and the fourth was progress in nutrition.

#### CHEMOTHERAPY

**Development of arsphenamine.** At the turn of the century, Germany was well to the forefront in medical progress. The scientific approach to medicine had been developed there long before it spread to other countries, and postgraduates flocked to German medical schools from all over the world. The opening decade of the 20th century has been well described as the "golden age" of Ger-

Cures for

Paul  
Ehrlich

man medicine. Outstanding among its leaders was Paul Ehrlich. While still a student at Strasbourg, Ehrlich carried out some work on lead poisoning from which he evolved the theory that was to guide all his subsequent work—that certain tissues have a selective affinity for certain chemicals. A quarter of a century was to pass before he gained success. By his discovery of arsphenamine, once sold under the commercial names of Salvarsan and 606, he inaugurated the chemotherapeutic era, which revolutionized the treatment and control of infectious diseases. Salvarsan is a synthetic arsenical preparation that is lethal to the micro-organism responsible for syphilis. Until the introduction of penicillin, Salvarsan or one of its modifications remained the standard treatment of syphilis and went far toward bringing this social and medical scourge under control.

**Sulfonamide drugs.** In 1932, a quarter of a century later, the German scientist Gerhard Domagk announced that the dye Prontosil rubrum is active against streptococcal infections in mice and in man. Soon afterward French workers showed that the active antibacterial agent is sulfanilamide. In 1936, the English physician Leonard Colebrook and his colleagues provided overwhelming evidence of the efficacy of both Prontosil and sulfanilamide in streptococcal septicemia (bloodstream infection), thereby ushering in the sulfonamide era. New sulfonamides appeared with almost embarrassing rapidity—with greater potency, a wider antibacterial spectrum, or lower toxicity. Some stood the test of time; others, like the original sulfanilamide and its immediate successor, sulfapyridine, were replaced by safer and more potent successors.

**Antibiotics.** *Penicillin.* Finally came the era of the antibiotics—in some ways the most dramatic episode in modern medicine. It was in 1928 that Alexander Fleming noticed the inhibitory action of a stray mold on a plate culture of staphylococci in his laboratory at St. Mary's Hospital, Paddington, London. Many another bacteriologist must have made the observation, but none had realized the possible implications. The mold was a strain of *Penicillium*—*P. notatum*; from this name was derived the term penicillin, which became known throughout the whole world. In spite of his conviction that penicillin is a potent antibacterial agent, Fleming was unable to carry his work to fruition, mainly because biochemists at the time were unable to isolate it in sufficient quantities or in a sufficiently pure form to allow its use on patients. Ten years later Howard Florey, Ernst Chain, and their colleagues at Oxford took up the problem again and solved it. By the time that Florey and his team had isolated penicillin in a form that was relatively pure by standards then current, though hopelessly crude by modern ones, and had demonstrated its potency and relative lack of toxicity, World War II had begun. In some ways this was an advantage because, if it had not been for the top priority given to commercial production, penicillin would not have become available in adequate amounts in such an amazingly short time.

**Antituberculous drugs.** While penicillin is the most useful and the safest antibiotic, it suffers from certain disadvantages. The most important of these is that it is not active against *Mycobacterium tuberculosis*, the bacillus of tuberculosis. In view of the importance of tuberculosis as a public health hazard, this is a serious defect, but the position was rapidly rectified when, in 1944, Selman A. Waksman and his colleagues announced the discovery of streptomycin from cultures of a soil organism, *Streptomyces griseus*, and stated that it is active against *Mycobacterium tuberculosis*. Subsequent clinical trials amply confirmed this claim. Unfortunately, streptomycin suffers from the great disadvantage that the *Mycobacterium tuberculosis* tends to become resistant to it. Fortunately, other drugs became available that compensated for this, the two most important being para-aminosalicylic acid (or PAS, as it is usually referred to) and isoniazid. With a combination of two or more of these preparations, the outlook in tuberculosis was revolutionized. Tuberculosis was not conquered but—provided reasonable precautions were taken—it was well under control.

Strepto-  
mycin,  
PAS, and  
isoniazid

Apart from its inadequacy as an antituberculosis drug, the other main disadvantage of penicillin is that its antibacterial spectrum does not cover the entire field of micro-organisms pathogenic to man. The pharmaceutical companies of the world—and particularly those of the United States—devoted a large part of their energies during the 1950s to a search for antibiotics to fill this gap. The search was amazingly successful and resulted in a steady stream of antibiotics, some with a much wider antibacterial spectrum than penicillin (the so-called broad-spectrum antibiotics) and some capable of coping with those micro-organisms that are inherently resistant to penicillin or have developed resistance through exposure to penicillin.

**Derivatives of penicillin.** This tendency of micro-organisms to develop resistance to penicillin at one time threatened to become almost as serious a problem as the development of resistance to streptomycin by the bacillus of tuberculosis. Fortunately, early appreciation of the problem by clinicians, resulting in more discriminate use of penicillin, combined with the availability of new antibiotics for general use, brought the problem largely under control.

Further developments related to penicillin occurred. The chemical synthesis of penicillin is possible but not practical on a commercial scale. The alternative method—by fermentation—is practical but cumbersome. Hence a search was made for a more effective means not only of production but also of producing a variety of penicillins, some of which might overcome the problem of the development of resistance in micro-organisms and at the same time might also be active when given by mouth. The fact that benzylpenicillin (the major penicillin) must be given by injection is one of its minor handicaps.

In 1959, British research workers achieved a major breakthrough by the isolation of 6-aminopenicillanic acid, the penicillin "nucleus." As a result, it became possible to introduce a new series of what became known as semisynthetics, some of which are active when given by mouth, while others are active against micro-organisms resistant to benzylpenicillin. Within a decade, over 2,000 new penicillins were produced in this way, six of which proved of clinical value.

#### IMMUNOLOGY

Dramatic though they undoubtedly were, the advances in chemotherapy still left one point vulnerable, that of the viruses, and it was in bringing them under control that advances in immunology—*i.e.*, the study of immunity—played such a striking part. It is one of the paradoxes of medicine that the first large-scale immunization against a virus disease was instituted and established long before viruses were discovered. When Edward Jenner introduced smallpox vaccination, as it is now known, against the virus that causes smallpox, the identification of viruses was still 100 years ahead, and almost another half century had to pass before an effective method was discovered of producing antiviral vaccines that were both safe and effective. In the meantime immunization against bacterial diseases made rapid progress.

**Developments through World War II.** *Typhoid and paratyphoid.* In 1897 the English bacteriologist Almroth Wright introduced a vaccine prepared from killed typhoid bacilli as a preventive of typhoid. Preliminary trials in the Indian army produced excellent results, and typhoid vaccination was adopted for the use of the troops serving in the South African War. Unfortunately, the method of administration was inadequately controlled, and all the War Office would sanction was that only such men would be inoculated as "voluntarily presented themselves for this purpose prior to their embarkation for the seat of war." The result was that, according to the official records, only 14,626 men volunteered out of a total strength of 328,244 who served during the three years of war. Although later analysis showed that inoculation had had a beneficial effect, there were 57,684 cases of typhoid—approximately one in six of the British troops engaged—with 9,022 deaths. In the subsequent embittered discussions, Karl Pearson, a statistician, challenged the valid-

Smallpox  
vaccination

ity of the claims put forward by Wright. To settle the matter an anti-typhoid commission was set up. On the strength of its report, published in 1913, the British Army officially adopted immunization against typhoid, Lord Kitchener decreeing that no man would be sent abroad who had not been inoculated. The result was that almost 100 percent of the British Expeditionary Force was immunized by the end of 1915. If figures mean anything, those for the South African War and World War I provide striking confirmation of the value of anti-typhoid inoculation, even when all due allowance is made for better sanitary arrangements in World War I. In the South African War the annual incidence of enteric infections (typhoid and paratyphoid) was 105 per 1,000 strength, and the annual death rate was 14.6 per 1,000 strength. The comparable figures for World War I were 2.35 and 0.139 respectively.

It is perhaps a sign of the increasingly critical outlook that developed in medicine in the post-1945 era of therapeutic advance that in the 1970s the experts still differed on some of the aspects of typhoid immunization. There was no question as to its fundamental efficacy, but there was considerable variation of opinion as to the best vaccine to use and the most effective way of administering it. A theoretical point that also worried the purist was that in many instances it was difficult to decide to what extent the decline in typhoid is due to improved sanitary conditions and what to the greater use of the vaccine.

Tetanus  
antitoxin

*Tetanus.* The other great hazard of war that was brought under control in World War I was tetanus. This was achieved by the prophylactic injection of tetanus antitoxin into all wounded men. The World War I use of this serum, which was originally prepared by the bacteriologists Emil von Behring and Shibasaburo Kitasato in 1890-92, was the first large-scale trial of tetanus antitoxin, and the results amply confirmed its efficacy. (Tetanus antitoxin is a sterile solution of antibody globulins—a type of blood protein—from immunized horses or cattle.) But it was not until the 1930s that an efficient vaccine, or toxoid, as it is known in the cases of tetanus and diphtheria, was produced against tetanus. (Tetanus toxoid is a preparation of the toxin—or poisons—produced by the micro-organism. Injected into humans, the toxoid stimulates the body's own defenses against the disease, thus bringing about immunization). Again, a war was to provide the opportunity for testing on a large scale, and experience with tetanus toxoid in World War II indicated that it gave a high degree of protection.

*Diphtheria.* The story of diphtheria is comparable to that of tetanus, though even more dramatic. First came the preparation of diphtheria antitoxin, as in the case of tetanus antitoxin, by Behring and Kitasato in 1890. As diphtheria antitoxin came into general use for the treatment of cases, the death rate began to decline. There was no significant fall in the number of cases, however, until a toxin-antitoxin mixture, introduced by Behring in 1913, was used to immunize children. A more effective toxoid was introduced by the French bacteriologist G. Ramon in 1923, and with subsequent improvements this became one of the most effective vaccines available in medicine. Where mass immunization of children with the toxoid has been practiced, as in the United States and Canada beginning in the late 1930s and in England and Wales in the early 1940s, cases of diphtheria and deaths from the disease became almost nonexistent. In England and Wales, for instance, the number of deaths fell from an annual average of 1,830 in 1940-44 to zero in 1969.

Immuni-  
zation  
against  
tuber-  
culosis

*BCG vaccine.* If, as is universally accepted, prevention is better than cure, immunization is the ideal way of dealing with diseases caused by micro-organisms. An effective, safe vaccine protects the individual from disease, whereas chemotherapy merely copes with the infection once the individual has been affected. In spite of its undoubted value, however, immunization was a recurring cause of controversy. Reference has already been made to the controversy surrounding the introduction of typhoid immunization; the later controversy over poliomyelitis (infantile paralysis) immunization was another

example. Yet another form of immunization, or vaccination, that evoked widespread controversy was that for tuberculosis. In 1908 Albert Calmette, a pupil of Pasteur, and Camille Guérin produced an avirulent (attenuated) strain of the bovine *Mycobacterium tuberculosis*. About 13 years later, vaccination of children against tuberculosis was introduced, with a vaccine made from this avirulent strain and known as BCG (bacillus Calmette-Guérin) vaccine. Although it was adopted in France, Scandinavia, and elsewhere, British and United States authorities frowned upon its use on the grounds that it was not safe and that the statistical evidence in its favour was not convincing. One of the stumbling blocks in the way of its widespread adoption was what came to be known as the Lübeck disaster. In the spring of 1930, 249 infants were vaccinated with BCG vaccine in Lübeck, Germany; by autumn, 73 of the 249 were dead. Criminal proceedings were instituted against those responsible for giving the vaccine; the final verdict was that contamination of the vaccine had occurred, and BCG vaccine was exonerated from any responsibility for the deaths. A bitter controversy followed, but in the end the protagonists of the vaccine won when a trial sponsored by the Medical Research Council showed that the vaccine was safe and that it protected four out of five of those vaccinated.

**Recent virus advances.** So far as viruses were concerned, with the exception of smallpox, it was not until well into the 20th century that efficient vaccines became available. This is scarcely surprising when it is realized that it was not until the 1930s that much began to be known about viruses. The two advances that contributed most to the rapid advance in knowledge since then were the introduction of tissue culture as a means of growing viruses in the laboratory and the development of the electron microscope. Once the virus could be cultivated with comparative ease in the laboratory, the research worker could study it with care and evolve methods for producing one of the two desiderata for a safe and effective vaccine: either a virus that was so attenuated that it could not produce the disease for which it was responsible in its normally virulent form or a dead virus that retained the faculty of inducing a protective antibody response in the vaccinated individual.

The first of the viral vaccines to result from these advances was for yellow fever, developed by the microbiologist Max Theiler in the late 1930s. About 1945, the first relatively effective vaccine was produced for influenza; in 1954, the American physician Jonas E. Salk introduced a vaccine for poliomyelitis; and in 1960, an oral poliomyelitis vaccine, developed by the virologist Albert B. Sabin, came into wide use. These vaccines went far toward bringing under control three of the major diseases of the time although, in the case of influenza, a major complication was the disturbing proclivity of the virus to change its character from one epidemic to another. Even so, sufficient progress was made to ensure that a pandemic of the order of the one that swept the world in 1918-19, killing more than 15,000,000 people, is unlikely to occur again. In guarding against such a tragic eventuality, one of the most potent safeguards was the World Influenza Centre, which was established in London by the World Health Organization. Thither information about outbreaks of influenza anywhere in the world is immediately sent, together with samples of the causative virus. This means that the identity of the virus can quickly be established and that, if necessary, steps can be taken to produce an effective vaccine. If the virus is a new one, a vaccine may not be ready for the early stages of the epidemic, should one occur, but it will be available for the later stages.

During the 1960s effective vaccines came into use for measles and rubella (German measles). Both evoked a certain amount of controversy. In the case of measles in Western civilization, it was contended that, if acquired in childhood, it is not a particularly hazardous disease, and the naturally acquired disease evokes permanent immunity in the vast majority of cases. Conversely, the vaccine induces a certain number of reactions, and the duration of the immunity it produces is problematical. In the end the official view was that universal measles vaccination is

Polio-  
myelitis  
vaccine

to be commended. The problem in the case of rubella vaccine was different. This is a fundamentally mild disease, and the only cause for anxiety is its proclivity to induce congenital deformities should a pregnant woman acquire the disease. Once an effective vaccine was available, the problem was the extent to which it should be used. Ultimately the commonsense compromise was achieved that all girls who had not already had the disease should be vaccinated around the age of 12 years.

The isolation of the virus of trachoma by Chinese and British workers raised hopes for the possibility of evolving a vaccine that would be effective in curbing the ravages of the greatest blinding disease in the world. In the early 1970s these hopes had not yet been realized.

Up until the turn of the century, for all practical purposes immunology was used in the narrow sense of the study of the means of resistance of an animal to invasion by a parasite or micro-organism. Around the midcentury, however, there came a growing and clearer realization of the fact that immunity, and the study thereof, cover a much wider field and are concerned with mechanisms for preserving the integrity of the individual (or animal). The introduction of organ transplantation, with its dreaded complication of organ rejection, brought this wider field of immunology to the fore. At the same time, research workers and clinicians began to appreciate the far-reaching implications in endocrinology, genetics, cell biology, tumour biology, and a range of so-called autoimmune diseases. In thus stretching out into the unknown, the searching mind in medicine began to probe mysteries of great magnitude.

#### ENDOCRINOLOGY

At the beginning of the 20th century, endocrinology was in its infancy. Indeed, it was not until 1905 that Ernest H. Starling, one of the many brilliant pupils of Sir Edward Sharpey-Schafer, the dean of British physiology during the early decades of the century, introduced the term hormone for the internal secretions of the endocrine glands. In 1891 the English physician George Redmayne Murray was the first to treat myxedema (the common form of hypothyroidism) successfully with an extract of the thyroid gland. Three years later, Sharpey-Schafer and George Oliver demonstrated in extracts of the adrenal (suprarenal) glands a substance that raised the blood pressure, and in 1901 Jokichi Takamine (1854–1922), a Japanese chemist working in the U.S., isolated this active principle: epinephrine (as it is known in the *United States Pharmacopeia*) or adrenaline (as it is known in the *British Pharmacopoeia*).

**Discovery of insulin and cortisone.** During the first two decades of the century, steady progress was made in the isolation, identification, and study of the active principles of the various endocrine glands, but the outstanding event was the discovery of insulin by Sir Frederick Banting, Charles H. Best, and John James Rickard Macleod in 1921. Almost overnight the lot of the diabetic patient was changed from a sentence of almost certain death to a prospect not only of survival but of being able to lead a long and healthy life. As so often happens with the great discoveries in medicine, this one came from a most unexpected source. For more than 30 years, some of the greatest minds in physiology had been seeking the cause of diabetes mellitus. In 1889, the German physicians Joseph von Mering (1849–1908) and Oskar Minkowski (1858–1931) had shown that removal of the pancreas in dogs produced diabetes. In 1901, the American pathologist Eugene L. Opie described degenerative changes in the clumps of cells in the pancreas known as the islets of Langerhans, thus confirming the association between failure in the function of these cells and diabetes. Sharpey-Schafer concluded that the islets of Langerhans secrete a substance that controls the metabolism of carbohydrate. In 1921 Banting, then a young Canadian orthopedic surgeon interested in physiology, working with Best, a medical student, in the laboratory of Macleod at the University of Toronto, succeeded in isolating the elusive hormone and gave it the name of insulin. Insulin was available in a variety of forms, but synthesis on a commercial scale was

not achieved, and the only source of the hormone was the pancreas of animals. One of its practical disadvantages is that it has to be given by injection, and, during the subsequent years, an intense search was conducted for some alternative preparation that would be active when taken by mouth. Various preparations—oral hypoglycemic agents, as they are known—appeared that were effective to a certain extent in controlling diabetes, but all the available evidence indicated that these were only of value in relatively mild cases of diabetes. For the person with advanced diabetes, a normal healthy life remained dependent upon the continuing use of insulin injections.

Another major advance in endocrinology came with an announcement from the Mayo Clinic, in Rochester, Minnesota. In 1949 Philip S. Hench and his colleagues announced that a substance isolated from the cortex of the adrenal gland has a dramatic effect upon rheumatoid arthritis. This was compound E, or cortisone, as it came to be known, which had been isolated by Edward Calvin Kendall and his colleagues at the Mayo Clinic in 1935. The subsequent course of events showed that cortisone is not the answer to the problem of rheumatoid arthritis, but ample evidence was forthcoming to show the potent influence of cortisone and its many derivatives as anti-inflammatory agents. It is not a cure for rheumatoid arthritis, but as a temporary measure it can often control the acute exacerbation caused by the disease, just as it can aid in such other diseases as acute rheumatic fever, certain kidney diseases, certain serious diseases of the skin, and some allergic diseases, including acute exacerbations of asthma. Of even more long-term importance is the valuable role it has as a research tool.

**Use of sex hormones.** Not the least of the advances in endocrinology was the increasing knowledge and understanding of the sex hormones. This ultimately culminated in the application of this knowledge to helping solve the world population problem. After an initial stage of hesitancy, the contraceptive pill, with its basic rationale of preventing ovulation, was accepted by the vast majority of family-planning organizations and a not inconsiderable number of gynecologists as the most satisfactory method of contraception. Its risks, practical and theoretical, introduced a note of caution, but this was not sufficient to detract from the wide appeal induced by its effectiveness and ease of use.

#### ADVANCES IN OTHER FIELDS

**Nutrition. Discovery of vitamins.** In the field of nutrition, the outstanding advance of the 20th century was the discovery and the appreciation of the importance of the "accessory food factors," or vitamins. Although various workers had shown that animals did not thrive on a synthetic diet containing all the correct amounts of protein, fat, and carbohydrate and even suggested that there must be some then-unknown ingredients in natural food that were essential for growth and the maintenance of health, little progress was made in this field until the classical experiments of the English biologist F. Gowland Hopkins were published in 1912. So conclusive were these that there could be no doubt that what he termed "accessory substances" were essential for health and growth. The name vitamin was suggested for these substances by the biochemist Casimir Funk in the belief that they were amines, certain compounds derived from ammonia. In due course, when it was realized that they were not amines, the term was altered to vitamin.

**Identification of vitamins.** Once this concept of vitamins was established on a firm scientific basis it was not long before their identity began to be revealed; soon there was a long series of them, best known by the letters of the alphabet after which they were originally named when their chemical identity was still unknown. Deficiency diseases such as rickets (due to deficiency of vitamin D) and scurvy (due to lack of vitamin C, or ascorbic acid) practically disappeared from Western communities, while deficiency diseases such as beriberi (caused by lack of vitamin B<sub>1</sub>, also called thiamine or aneurin), which were endemic in Eastern countries, either disappeared or could be remedied with the greatest of ease.

Isolation  
of  
epineph-  
rine

Isolation  
of

Vitamin  
B<sub>12</sub> and  
pernicious  
anemia

The last of this group of essential factors to be isolated—vitamin B<sub>12</sub>, or cyanocobalamin—was of particular interest because it rounded off—or almost rounded off—the fascinating story of how pernicious anemia was brought under control. Throughout the first two decades of the century, the diagnosis of pernicious anemia, like that of diabetes mellitus, was almost equivalent to a death sentence. Unlike the more common form of so-called secondary anemia, it did not respond to the administration of suitable iron salts, and no other form of treatment touched it; hence, the grimly appropriate title of pernicious anemia. In the early 1920s, George R. Minot, one of the many brilliant investigators whom Harvard University contributed to medical research, became interested in work being carried out by the American pathologist George H. Whipple into the beneficial effects of the administration of raw beef liver in severe experimental anemia. With a colleague at Harvard, William P. Murphy, he decided to investigate the effect of raw liver in patients with pernicious anemia, and in 1926 they were able to announce that this form of therapy was successful. The validity of their findings was amply confirmed, and all fears of pernicious anemia were ended. As so often happens in medicine, many years were to pass before the rationale of liver therapy in pernicious anemia was fully understood. In 1948, however, almost simultaneously in the United States and in Britain, the active principle was isolated from liver. It was originally known as vitamin B<sub>12</sub> but came to be known as cyanocobalamin. It became the standard treatment for pernicious anemia.

**Malignant disease.** While progress was the hallmark of medicine after the beginning of the 20th century, there was one field in which a gloomier picture must be painted, that of malignant disease, or cancer. It was the second most common cause of death in most Western countries early in the second half of the 20th century, being exceeded only by deaths from heart disease. Some progress, however, was achieved. The cause of cancer was not known, but many more methods were available for attacking the problem; surgery remained the great therapeutic standby, but radiotherapy and chemotherapy played increasingly important parts.

Radiation  
treatment  
of cancer

Soon after the discovery of radium was announced, in 1898, its potentialities in treating cancer were realized; in due course it assumed an important role in therapy. Simultaneously, deep X-ray therapy was developed. Finally, with the atomic age came the use of radioactive isotopes. (A radioactive isotope is an unstable variant of a substance that has a stable form; during the process of breaking down, the unstable form emits radiation.) High-voltage X-ray therapy and radioactive isotopes largely replaced radium. Whereas irradiation had long depended upon X-rays generated at 250 kilovolts, machines that were capable of producing X-rays generated at 8,000 kilovolts and betatrons of up to 22 million electron volts (MeV) were in clinical use. In the application of radioactive isotopes to the treatment of malignant disease, the most important development was the use of radioactive cobalt. Telecobalt machines (*i.e.*, those that hold the cobalt at a distance from the body) were available containing 2,000 curies or more of the isotope, an amount equivalent to 3,000 grams (100 ounces) of radium (an unheard-of amount of radium), and sending out a beam equivalent to that from a 3,000-kilovolt X-ray machine.

Of even more significance were the developments in the chemotherapy of malignant disease. Nothing remotely resembling a chemotherapeutic cure was achieved, but in certain forms of malignant disease, such as leukemia, which cannot be treated by surgery, palliative effects were achieved that prolonged life and allowed the patient in many instances to lead a comparatively normal existence.

Fundamentally, however, perhaps the most important advance of all in this field was the increasing appreciation of the importance of prevention. The discovery of the relationship between cigarette smoking and cancer of the lung was the classic example. Less publicized, but of equal import, was the continuing supervision of new techniques in industry and food manufacture to ensure that they did not involve the use of cancer-causing substances.

**Tropical medicine.** In the field of tropical medicine, the first six decades of the 20th century witnessed the virtual conquest of three of the major diseases of the tropics: malaria, yellow fever, and leprosy. At the turn of the century, as for the preceding two centuries, quinine was the only known drug to have any appreciable effect on malaria. With the increasing development of tropical countries and rising standards of public health, it became obvious that quinine was not completely satisfactory. Intensive research between World Wars I and II indicated that several synthetic derivatives in the acridine and quinoline groups of organic compounds, as well as other synthetic aromatic compounds, were more effective than quinine. The first of these to become available, in 1934, was quinacrine (mepacrine, Atabrine, or Atebrin), an acridine derivative. In World War II it amply fulfilled the highest expectations and helped to reduce disease among Allied troops in Africa, Southeast Asia, and the Far East. Other effective antimalarial drugs that subsequently became available included chloroquine (Aralen), a 4-aminoquinoline, 1939; chloguanide (Paludrine or Proguanil), 1946; primaquine, an 8-aminoquinoline, 1946; amodiaquin (Camoquin), 1948; hydroxychloroquine (Plaquenil), 1950; and pyrimethamine (Daraprim), 1951.

An even brighter prospect—the virtual eradication of malaria—was opened up by the introduction, during World War II, of the insecticide DDT (chlorophenothane in the *U. S. Pharmacopeia*, dicophane in the *British Pharmacopoeia*). It had long been realized that the only effective way of controlling malaria was to eradicate the anopheline mosquitoes, which transmit the disease. The older methods of mosquito control, however, were cumbersome and expensive. The lethal effect of DDT on the mosquito, its relative cheapness, and its ease of use on a widespread scale provided the answer. An intensive worldwide campaign, sponsored by the World Health Organization, was planned and went far toward bringing malaria under control. The major problem encountered with respect to effectiveness was that of the developing resistance of the mosquito to DDT, but the introduction of other insecticides, such as dieldrin and lindane (BHC), helped to overcome this difficulty. In recent years the use of these and other insecticides has been criticized by ecologists.

DDT and  
malaria

Reference has already been made to the important part that the introduction of an effective vaccine played in bringing yellow fever under control. Since this is another mosquito-transmitted disease, the prophylactic value of the introduction of modern insecticides was almost as great as in the case of malaria. The forest reservoirs of the virus present a more difficult problem than in the case of malaria, but the combined use of immunization and insecticides did much to bring this disease under control.

Until the 1940s, the only drugs available for treating leprosy were the chaulmoogra oils and their derivatives. These, though helpful, were far from satisfactory. In the 1940s the group of drugs known as the sulfones appeared; it soon became apparent that they were infinitely better than any other group of drugs in the treatment of leprosy. Several other drugs that later became available proved of promise. Although it was clear that there was as yet no known cure—in the strict sense of the term—for leprosy, the outlook so changed that there were good grounds for believing that this age-old scourge could be brought under control and the victims of the disease saved from those dread mutilations that gave leprosy such a fearsome reputation throughout the ages. (Wm.A.R.T.)

#### IV. Surgery in the 20th century

##### THE OPENING PHASE

Three seemingly insuperable obstacles beset the surgeon in the years before the mid-19th century: pain, infection, and shock. Once these were overcome, he believed he could burst the bonds of centuries and become the master of his craft. Unfortunately life is not that simple. There is more to anesthesia than putting the patient to sleep. Infection, despite first antiseptics (destruction of microorganisms present) and later asepsis (avoidance of con-

tamination), is still an ever-present menace; and shock continues to perplex. But, in the 20th century, surgery has progressed further, faster, and more dramatically than in all preceding ages.

**The situation encountered.** The shape of surgery that entered the new century was clearly recognizable as the forerunner of today's, blurred and hazy though the outlines may now seem. The operating theatre still retained an aura of the past, when the surgeon played to his audience and the patient was little more than a stage prop. In most hospitals it was a high room lit by a skylight, with tiers of benches rising above the narrow, wooden operating table. The instruments, kept in glazed or wooden cupboards around the walls, were of forged steel, unplated, and with handles of wood or ivory.

The means to combat infection hovered between antiseptics and asepsis. Instruments and dressings were mostly sterilized by soaking in dilute carbolic acid (or other antiseptic), and the surgeon often endured a gown freshly wrung out in the same solution. Asepsis was gaining ground fast, however. It had been born in the Berlin clinic of Ernst von Bergmann where, in 1886, steam sterilization had been introduced. Gradually, this led to the complete aseptic ritual, which has as its basis the bacterial cleanliness (as opposed to social cleanliness) of everything that comes in contact with the wound. Hermann Kümmell, of Hamburg, devised the routine of "scrubbing up." William Stewart Halsted, of Johns Hopkins, in 1890 had rubber gloves specially made for operating, and, in 1896, Johannes von Mikulicz-Radecki, a Pole working at Breslau, invented the gauze mask. Many surgeons, brought up in a confused misunderstanding of the antiseptic principle—believing that carbolic would cover a multitude of sins, many of which they were ignorant of committing—failed to grasp what asepsis was all about. Thomas Annandale blew through his catheters to make sure that they were clear, and another Scottish surgeon periodically removed his pince-nez for a closer inspection of his work. Many an instrument, dropped accidentally, was simply given a quick wipe and returned to use. Tradition died hard, and asepsis had an uphill struggle before it was fully accepted—"I believe firmly that more patients have died from the use of gloves than have ever been saved from infection by their use," wrote W.P. Carr, an American, in 1911—but over the years a sound technique was evolved as the foundation for the growth of modern surgery.

Anesthesia, at the turn of the century, was progressing slowly. Few physicians made a career of the subject, and frequently the patient was rendered unconscious by a student, a nurse, or a porter wielding a rag and bottle. Chloroform was overwhelmingly more popular than ether, on account of its ease of administration, despite the fact that it was liable to kill by stopping the heart. Although by the end of the first decade, nitrous oxide (laughing gas) combined with ether had displaced—but by no means entirely—the use of chloroform, the surgical problems were far from ended. For years to come the abdominal surgeon besought the anesthetist to deepen the level of anesthesia and thus relax the abdominal muscles; the anesthetist responded to the best of his ability, acutely aware that the deeper he went, the closer the patient was to death. When other anesthetic agents were discovered, the anesthetist came into his own, and many advances in spheres such as brain and heart surgery would have been impossible without his skill.

The third obstacle, shock, is perhaps the most complex and the most difficult to define satisfactorily. The only major cause properly appreciated at the start of the 20th century was loss of blood, and once that had occurred nothing could, in those days, be done. And so, as the years passed, the study of shock, its causes, its effects on human physiology, and its prevention and treatment, became all important to the progress of surgery.

Thus, in the latter part of the 19th century, surgeons had been liberated from the age-old bogies of pain, pus, and hospital gangrene. Hitherto, operations had been restricted to amputations, cutting for stone in the bladder, tying off arterial aneurysms (bulging and thinning of ar-

tery walls), repairing hernias, and a variety of procedures that could be done without going too deeply beneath the skin. But the anatomical knowledge, a crude skill derived from practice on dead bodies, and, above all, the enthusiasm were there, waiting. Largely ignoring the mass of problems they uncovered, surgeons launched forth into a mighty exploration of the human body.

They acquired a reputation for showmanship; much of their surgery, though speedy and spectacular, was rough and ready. A few there were who developed a supreme skill and dexterity and could have undertaken a modern operation with but little practice—indeed, some devised the very operations still in use today. One such was Theodor Billroth, head of the surgical clinic at Vienna, who collected a formidable list of successful "first" operations. He represented the best of his generation—a surgical genius, an accomplished musician, and a kind, gentle man who brought the breath of humanity to his work. Moreover, the men he trained, including von Mikulicz, Vincenz Czerny, and Anton von Eiselsberg, consolidated the brilliant start that he had given to abdominal surgery in Europe.

**Changes before World War I.** The opening decade of the 20th century was a period of transition. Flamboyant exhibitionism was falling from favour as surgeons, through experience, learned the merits of painstaking, conscientious operation—treating the tissues gently and carefully controlling every bleeding point. The individualist was not submerged, however, and for many years the development of the various branches of surgery rested on the shoulders of a few clearly identifiable men. Teamwork on the grand scale arrived only after World War II. The surgeon, at first, was undisputed master in his own wards and theatre, but as time went on and he found he could not solve his problems alone, he called for help from specialists in other fields of medicine and, even more significantly, from his colleagues in other scientific disciplines.

The increasing scope of surgery led to specialization. Admittedly, most general surgeons had a special interest, and for a long time there had been an element of specialization in such subjects as ophthalmology, orthopedics, obstetrics, and gynecology, but before long it became apparent that, to achieve progress in certain areas, surgeons had to concentrate their attention on that particular subject.

By the start of the 20th century, abdominal surgery, which provided the general surgeon with the bulk of his work, had grown beyond infancy thanks largely to Billroth. In 1881 he had performed the first successful removal of part of the stomach for cancer. His next two cases were failures, and he was stoned in the streets of Vienna; yet, he persisted and by 1891 had carried out 41 more of these operations with 16 deaths—a remarkable achievement for that era. Peptic (gastric and duodenal) ulcers appeared on the surgical scene (perhaps as a new disease, but more probably because they had not been diagnosed previously), and in 1881 Ludwig Rydygier cured a young woman of her gastric ulcer by removing it. Bypass operations—gastro-enterostomies—soon became more popular, however. Gastro-enterostomies enjoyed a considerable vogue that lasted into the 1930s, even though fresh ulcers at the site of the juncture were not uncommon. The other end of the alimentary tract was also subjected to surgical treatment; cancers were removed from the large bowel and rectum with mortality rates that gradually fell from 80 to 60 to 20 to 12 percent as the surgeons learned their lessons. In 1908 the British surgeon Ernest Miles carried out the first abdomino-perineal resection for cancer of the rectum; that is, the cancer was attacked both from the abdomen and from below through the perineum (the area at the base of the trunk between the anus and the genital organs), either by one surgeon, who really did two operations, or by two working together. This technique formed the basis for all future developments.

Much of the new surgery in the abdomen was for cancer, but not all. Appendectomy became accepted treatment for appendicitis (in appropriate cases) in the United

Antisepsis

Billroth's  
influence

Abdominal  
surgery

States before the close of the 19th century, but in Great Britain surgeons were reluctant to remove the organ until King Edward VII's coronation (1902) was dramatically postponed on account of appendicitis. The publicity attached to his operation caused the disease and its surgical treatment to become fashionable—despite the fact that the royal appendix remained in the King's abdomen; the surgeon Frederic Treves merely drained the abscess.

Neurosurgery, probably the most demanding of all the surgical specialties, was nevertheless one of the first to emerge. The techniques and principles of general surgery were inadequate for work in such a delicate field. William Macewen, a Scottish general surgeon of outstanding versatility, and Victor Alexander Haden Horsley, the first British neurosurgeon, showed that the surgeon had much to offer in the treatment of disease of the brain and spinal cord. Macewen, in 1893, recorded 19 patients operated on for brain abscess, 18 of whom were cured; at that time most other surgeons had 100 percent mortality rates for the condition. His achievement remained unequalled until the discovery of penicillin. An American, Harvey Williams Cushing, almost by himself consolidated neurosurgery as a specialty. From 1905 on, he advanced neurosurgery and neurology every time he picked up his scalpel to operate or his pen to write. Tumours, epilepsy, trigeminal neuralgia, and pituitary disorders were among the conditions he treated. (Trigeminal neuralgia, *tic douloureux*, is sharp pain along branches of the trigeminal nerve, particularly those serving the jaws and the eyes.)

Importance of the discovery of X-rays

In 1895 a discovery in Würzburg had far-reaching effects in medicine and surgery, opening up an entirely fresh field of diagnosis and study of disease and leading to a new form of treatment (radiation therapy). Wilhelm Conrad Röntgen, professor of physics, discovered X-rays. Within a matter of months of the discovery there was an extensive literature on the subject—Robert Jones, a British surgeon, had localized a bullet in a boy's wrist before operating; stones in the urinary bladder and gallbladder had been demonstrated; fractures had been displayed; and experiments had started on introducing radio-opaque substances into the body to outline the normal and the abnormal. Walter Bradford Cannon, a Boston physiologist, used X-rays in 1898 in his studies of the alimentary tract. Friedrich Voelcker, of Heidelberg, devised retrograde pyelography (introduction of the radio-opaque medium into the kidney pelvis by way of the ureter) for the study of the urinary tract in 1905; in 1921, in Paris, Jean Athanese Sicard X-rayed the spinal canal with the help of an oily iodine substance, and the next year he did the same for the bronchial tree; and in 1924 Everts Ambrose Graham, of St. Louis, used a radio-opaque medium in viewing the gallbladder. Air was also used to provide contrast; in 1918, at Johns Hopkins, Walter Edward Dandy injected air into the ventricles (liquid-filled cavities) of the brain. The problems of injecting contrast media into the blood vessels took longer to solve, and it was not until 1927 that António Egas Moniz, of Lisbon, succeeded in obtaining pictures of the arteries of the brain. Eleven years later, George Porter Robb and Israel Steinberg of New York overcame some of the difficulties of cardiac catheterization (introduction of a small tube into the heart by way of veins or arteries) and were able to visualize the chambers of the heart on X-ray film. After much further research, the final refinement came in 1962, when Frank Mason Sones and Earl K. Shirey of Cleveland, Ohio, showed how to introduce the contrast medium into the coronary arteries (the arteries that supply oxygen-rich blood to the heart muscle).

#### WORLD WAR I

The battlefields of the 20th century stimulated the progress of surgery and taught the surgeon innumerable lessons, which he subsequently applied in civilian practice. Regrettably, though, the principles of military surgery and casualty evacuation, which can all be traced back to Dominique-Jean Larrey in the Napoleonic Wars, had to be learned over and over again.

World War I broke, quite dramatically, the existing surgical hierarchy and rule of tradition. No longer had

the European surgeon to waste his best years in apprenticeship before seating himself in his master's chair. Suddenly, young surgeons began conquering problems that would have daunted their elders. Furthermore, their training had been in "clean" surgery performed under aseptic conditions. Now they found themselves confronted by the need to treat large numbers of grossly contaminated wounds in improvised theatres. They rediscovered débridement (the surgical excision of all dead and dying tissue and the removal of all foreign bodies whatever their nature). The cry of the older surgeons was "back to Lister," but antiseptics, no matter how strong, were no match for putrefaction and gangrene. One method of antiseptic irrigation—devised by Alexis Carrel and Henry Drysdale Dakin and called the Carrel-Dakin treatment—was, however, beneficial, but only after the wound had been adequately débrided. The scourges of tetanus and gas gangrene were controlled to a large extent by antitoxin and antiserum injections, yet surgical treatment of the wound remained an essential requirement.

Abdominal casualties fared badly for the first year of the war, because experience in the utterly different circumstances of the Boer War had led to a belief that these men were better left alone surgically. Fortunately, the error of continuing with such a policy 15 years later was soon appreciated, and every effort was made to deliver the wounded men to a suitable surgical unit with all speed. Little progress was made with chest wounds beyond more extensive operations to drain pus from the pleural cavity (*i.e.*, from between the membrane lining the chest and that covering the lungs).

Perhaps the most worthwhile and enduring benefit to flow from the war of 1914–18 was rehabilitation. For almost the first time, surgeons realized that their work did not end with a healed wound. In 1915 Robert Jones set up special facilities for orthopedic patients, and at about the same time Harold Delf Gillies founded British plastic surgery in a hut at Sidcup, Kent. In 1917 Gillies popularized the pedicle type of skin graft (the type of graft that consists of skin and subcutaneous tissue that is attached for nourishment as long as necessary to the site from which the graft was taken). Since then the specialty has given freely of its techniques and principles to other branches of surgery.

#### BETWEEN WARS

The years between the wars may conveniently be regarded as the time when surgery consolidated its position. A surprising number of surgical firsts and an amazing amount of fundamental research had been achieved even in the late 19th century, but the knowledge and experience could not be converted to practical use because the human body could not survive the onslaught. In the years between World War I and World War II, it was realized that physiology (in its widest sense, including biochemistry and fluid and electrolyte balance) was of major importance along with anatomy, pathology, and surgical technique.

**The problem of shock.** The first problem to be tackled was shock, which was, in brief, found to be due to a decrease in the effective volume of the circulation. To combat shock, the volume had to be restored, and the obvious substance was blood itself. In 1901 Karl Landsteiner, there in Austria, discovered the ABO blood groups, and in 1914 sodium citrate was added to freshly drawn blood to prevent clotting. Blood was occasionally transfused during World War I, but three-quarters of a pint was considered a large amount. These transfusions were given by directly linking the vein of a donor with that of the recipient. The continuous drip method, in which blood flows from a flask, was introduced by Hugh Leslie Marriott and Alan Kekwick at the Middlesex Hospital, London, in 1935.

As blood transfusions increased in frequency and volume, blood banks were required. Although it took another world war before these were organized on a large scale, the first tentative steps were taken by Sergey Sergeyevich Yudin, of Moscow, who, in 1933, used cadaver blood, and by Bernard Fantus, of Chicago, who, four

Treatment of contaminated wounds

Restoration of blood volume after shock

years later, used living donors as his source of supply. Saline solution, plasma, artificial plasma expanders, and other solutions are now also used in the appropriate circumstances.

Sometimes after operations (especially abdominal operations) the gut becomes paralyzed. It is distended, and quantities of fluid pour into it, dehydrating the body. In 1932 Owen Hardy Wangenstein, at the University of Minnesota, advised decompressing the bowel, and in 1934 two other Americans, Thomas Grier Miller and William Osler Abbott, of Philadelphia, invented apparatus for this purpose, a tube with an inflatable balloon on the end that could be passed into the small intestine. The fluid lost from the tissues was replaced by a continuous intravenous drip of saline solution on the principle described by Rudolph Matas, of New Orleans, in 1924. These techniques dramatically improved abdominal surgery, especially in cases of obstruction, peritonitis (inflammation of the membrane lining the abdomen and pelvis and covering the viscera) and acute emergencies generally, as they made it possible to keep the bowel empty and at rest.

**Anesthesia and thoracic surgery.** The strides taken in anesthesia from the 1920s onward allowed surgeons much more freedom. Rectal anesthesia had never proved satisfactory, and the first improvement on the combination of nitrous oxide, oxygen, and ether was the introduction of the general anesthetic cyclopropane by Ralph Milton Waters of Madison, Wisconsin, in 1933. Soon afterward, intravenous anesthesia was introduced; John Silas Lundy of the Mayo Clinic brought to a climax a long series of trials by many workers when he used Pentothal (thiopental sodium, a barbiturate) to put a patient peacefully to sleep. Then, in 1942, Harold Randall Griffith and G. Enid Johnson, of Montreal, produced muscular paralysis by the injection of a purified preparation of curare. This was harmless since, by then, the anesthetist was able to control the patient's respiration.

Methods  
for  
prevention  
of lung  
collapse

If there was one person who was aided more than any other by the progress in anesthesia, it was the thoracic (chest) surgeon. What had bothered him previously was the collapse of the lung, which occurred whenever the pleural cavity was opened. Since the end of the 19th century, many and ingenious methods had been devised to prevent this from happening. The best known was the negative pressure cabinet of Ernst Ferdinand Sauerbruch, then at Mikulicz' clinic at Breslau; the cabinet was first used clinically in 1904 but destined soon to become obsolete. The solution lay in inhalational anesthesia administered under pressure. Indeed, when Théodore Tuffier, in 1891, successfully removed the apex of a lung for tuberculosis, this was the technique that he used; he even added an inflatable cuff around the tube inserted in the windpipe to ensure a gas-tight fit. Tuffier was ahead of his time, however, and other surgeons and research workers went wandering into confused and complex byways before Ivan Whiteside Magill and Edgar Stanley Rowbotham, working at Gillies' plastic-surgery unit, found their way back to the simplicity of the endotracheal tube and positive pressure. In 1931 Waters showed that respiration could be controlled either by squeezing the anesthetic bag by hand or by using a small motor.

These advances allowed thoracic surgery to move into modern times. In the 1920s, operations had been performed mostly for infective conditions and as a last resort, but the operations necessarily were unambitious and confined to collapse therapy—thoracoplasty (removal of ribs), apicolysis (collapse of a lung apex and artificially filling the space), or phrenic crush (this paralyzed the diaphragm on the chosen side)—to isolation of the area of lung to be removed by first creating pleural adhesions; and to drainage. The technical problems of surgery within the chest were daunting, and despair was never far away until Harold Brunn of San Francisco reported six lobectomies (removals of lung lobes) for bronchiectasis with only one death. (In bronchiectasis one or more bronchi or bronchioles—small bronchi—are chronically dilated and inflamed, with copious discharge of mucus mixed with pus.) The secret of Brunn's success had been intermittent suction after operation to keep the

cavity free of secretions until the remaining lung could expand to fill the space. In 1931 Rudolf Nissen, in Berlin, removed an entire lung from a girl with bronchiectasis. She recovered to prove that the risks were not as bad as had been feared.

Throughout the 20th century the pattern of disease has continually been changing, whether in the natural course of events or because man has disturbed the balance. Tuberculosis and bronchiectasis still exist but are nowhere near the problems that they were. In their place has come cancer of the lung—maybe a genuine increase, maybe modern techniques of diagnosis reveal it more often. As far back as 1913 a Welshman, Hugh Morrison Davies, had removed a lower lobe for cancer, but the start of the present era was Everts Graham's removal of a whole lung for cancer, in 1933. The patient, a doctor, was still alive at the time of Graham's death in 1957.

The thoracic part of the esophagus, or gullet, was particularly difficult to reach, but in 1909 the British surgeon Arthur Henry Evans operated successfully for cancer. The results were generally poor until, in 1944, John Harry Garlock, of New York, showed that it is possible to excise the esophagus and to bring the stomach up through the chest and join it to the pharynx. Lengths of colon are also used as grafts to bridge the gap.

Cancer of  
esophagus

#### WORLD WAR II AND AFTER

Once the principles of military surgery were relearned and applied to modern warfare, instances of death, deformity, and loss of limb were reduced to levels previously unattainable. This was due largely to a thorough reorganization of the surgical services, adapting them to prevailing conditions, so that the casualty received the appropriate treatment at the earliest possible moment. Evacuation by air (first used in World War I) helped greatly in this respect. Diagnostic facilities were improved, and progress in anesthesia kept pace with the surgeon's demands. Blood was transfused in adequate—and hitherto unthinkable—quantities, and the blood transfusion service as it is known today came into being. Surgical specialization and teamwork reached new heights with the creation of units to deal with the special problems of injuries to different parts of the body. But the most revolutionary change was in the approach to wound infections brought about by the use of sulfonamides and (after 1941) of penicillin. The fact that these drugs could never replace meticulous wound surgery was, however, another lesson learned only in the bitter school of experience.

When the war ended, surgeons returned to civilian life feeling that they were at the start of a completely new, exciting era, and indeed they were, for the intense stimulation of the past few years had led to developments in many branches of science that could now be applied to surgery. Nevertheless, to keep matters in correct perspective, it must be remembered that these developments merely allowed surgeons to realize the dreams of their fathers and grandfathers; they opened up remarkably few original avenues. The two outstanding phenomena of the 1950s and 1960s—heart surgery and organ transplantation—both originated in a real and practical manner at the turn of the century.

At first, perhaps, the surgeon tried to do too much himself, but before long his failures taught him to share his problems with experts in other fields. This was especially so with respect to difficulties of biomedical engineering and the exploitation of new materials. The relative protection from infection given by antibiotics and chemotherapy allowed the surgeon to become far more adventurous than hitherto in repairing and replacing damaged or worn-out tissues with foreign materials. Much research was still needed to find the best material for a particular purpose and to make sure that it would be acceptable to the body. Plastics, in their seemingly infinite variety, were used for almost everything from suture material to heart valves; for strengthening the repair of hernias; for replacement of the head of the femur (first done by the French surgeon Jean Judet and his brother Robert Louis Judet, in 1950); for replacement of the lens of the eye after extraction of the natural lens for cataract; for

Use of  
plastics  
in  
surgery

valves for use in draining fluid from the brain in patients with hydrocephalus; and for many other applications. A far cry, indeed, from the unsatisfactory use of celluloid to restore bony defects of the face by the German surgeon Fritz Berndt in the 1890s. Inert metals, such as vitallium, have also found a place, largely in orthopedics for the repair of fractures and the replacement of joints.

The scope of surgery was further expanded by the introduction of the operating microscope. This brought the benefit of magnification in particular to neurosurgery and to aural (ear) surgery. In the latter it opened up a whole field of operations on the drum and within the middle ear. The principles of these operations were stated in 1951 and 1952 by two German surgeons, Fritz Zöllner and Horst Wullstein; and in 1952 Samuel Rosen of New York mobilized the footplate of the stapes to restore hearing in otosclerosis—a procedure attempted by the German Jean Kessel in 1876. (The stapes, or stirrup bone, is the innermost of the three minute bones in the middle ear which, linked together, convey sound vibrations from the eardrum membrane to the liquid in the inner ear; in otosclerosis the stapes becomes rigidly fixed to the sides of the opening into the inner ear and can no longer transmit the vibrations.)

Although surgeons aim to preserve as much as disease permits, they are sometimes forced to radical measures to save life; for instance, when cancer affects the pelvic organs. Pelvic exenteration (surgical removal of the pelvic organs and nearby structures) in two stages was devised by Allen Oldfather Whipple of New York, in 1935, and in one stage by Alexander Brunshwig, of Chicago, in 1937. Then, in 1960, Charles S. Kennedy, of Detroit, after a long discussion with Brunshwig, put into practice an operation that he had been considering for 12 years: hemicorporectomy—surgical removal of the lower part of the body. The patient died on the 11th day. The first successful hemicorporectomy (at the level between the lowest lumbar vertebra and the sacrum, the fused vertebrae that form the back portion of the bony pelvis) was performed 18 months later by J. Bradley Aust and Karel B. Absolon, of Minnesota; this operation would not have been possible without all the technical, supportive and rehabilitative resources of modern medicine.

The attitude of the medical profession toward heart surgery was for long overshadowed by doubt and disbelief. Wounds of the heart could be sutured (first done successfully by Ludwig Rehn, of Frankfurt am Main, in 1896); the pericardial cavity—the cavity formed by the sac enclosing the heart—could be drained in purulent infections (as had been done by Larrey in 1824); and the pericardium could be partially excised for constrictive pericarditis when it was inflamed and constricted the movement of the heart (this operation was performed by Rehn and Sauerbruch in 1913); but little beyond these could find acceptance. Yet, in the first two decades of the 20th century, much experimental work had been carried out, notably by the French surgeons Théodore Tuffier and Alexis Carrel. Tuffier, in 1912, had operated successfully on the aortic valve. In 1923, Elliott Carr Cutler of Boston had used a tenotome, a tendon-cutting instrument, to relieve a girl's mitral stenosis (a narrowing, that is, of the mitral valve, which is between the upper and lower chambers of the left side of the heart), and in 1925, at The London Hospital Henry Sessions Souttar used a finger to dilate a mitral valve in a manner that was 25 years ahead of its time.

Despite these achievements, there was too much experimental failure, and heart disease remained a medical matter. Resistance, however, began to crumble in 1938, when Robert Edward Gross successfully tied off a persistent ductus arteriosus (a fetal blood vessel between the pulmonary artery and the aorta), and was finally swept aside by Dwight Emary Harken's wonderful record in World War II (134 missiles—13 in the heart chambers—removed from the mediastinum [the area between the two lungs] without the loss of one patient). After the war, advances came rapidly, with the initial emphasis on the correction or amelioration of congenital defects. Gordon Murray, of Toronto, made full use of his amazing tech-

nical ingenuity to devise and perform many pioneering operations. And Charles Philamore Bailey of Philadelphia, adopting a more orthodox approach, was responsible for establishing numerous basic principles in the growing specialty. Until 1953, however, the techniques all had one great disadvantage—they were done "blind." The surgeon's dream was to stop the heart so that he could see what he was doing and be allowed more time in which to do it. In 1952 his dream began to come true when Floyd John Lewis, of Minnesota, used hypothermia (artificial reduction of the temperature of the body) so as to lessen its need for oxygen while he closed a hole between the two upper chambers, the atria. The next year John Haysham Gibbon of Philadelphia brought to fulfillment the research he had begun in 1937, by using his heart-lung machine to supply oxygen while he closed an interatrial septal defect—a hole in the partition between the atria. Unfortunately, neither method alone was ideal, but intensive research and development led, in the early 1960s, to their being combined as extracorporeal cooling. That is, the blood circulated through a machine outside the body which cooled it (and, after the operation, warmed it); the cooled blood lowered the temperature of the whole body. With the heart dry and motionless, the surgeon operated on the coronary arteries, he inserted plastic patches over holes, he sometimes almost remodelled the inside of the heart, but when it came to replacing valves destroyed by disease he was, and still is, faced with a choice between human tissue and man-made valves (and even valves from animal sources).

In 1967 surgery arrived at a climax that made the whole world aware of its medicosurgical responsibilities when the South African surgeon Christiaan Neethling Barnard transplanted the human heart. Reaction, both medical and lay, contained more than an element of hysteria. Yet, in 1964, two prominent research workers, Richard Rowland Lower and Norman E. Shumway, had written: "Perhaps the cardiac surgeon should pause while society becomes accustomed to resurrection of the mythological chimera." And, again in 1964, James Daniel Hardy, of the University of Mississippi, had transplanted a chimpanzee's heart into a man. And, finally, research has been remorselessly leading up to just such an operation since Charles Claude Guthrie and Carrel, at the University of Chicago, had perfected the suturing of blood vessels in 1905 and had then carried out experiments in the transplantation of many organs, including the heart.

Other organs had already been transplanted clinically with varying degrees of failure. For instance, the lung (first by James Daniel Hardy, in 1963); liver (Thomas Earl Starzl, in 1963); the pancreas (Richard Carlton Lillehei, in 1966); and the kidney (since 1902, although the operation that advanced the procedure beyond the experimental stage was performed in Boston in 1954 between identical twins). The transplanting of a kidney has been the most successful of these, but it is exceptional in that there is an artificial kidney machine (invented by Willem Johan Kolff in wartime Holland) to prepare the patient for operation and to support him in times of crisis. Such a machine does not exist for the liver or the heart (despite research since 1960 to invent an artificial heart that will support life for a reasonable length of time). Moreover, the kidney is a paired organ. Nevertheless, the major problem of transplantation of organs between different individuals is rejection by the body of the patient of the transplanted organ. And until this highly complex problem is overcome, there is small prospect of worthwhile progress in this area. (R.G.R.)

GUTHRIE, *Blood-Vessel Surgery and Its Applications* (1912); and V.P. DEMIKHOV, *Experimental Transplantation of Vital Organs* (Eng. trans. 1962), intriguing accounts of their authors' experiments—in the United States and Russia—on organ transplantation, remarkable more for their similarities than their differences.

## Medicine and Surgery, Practice of

Until the great scientific discoveries of the 19th and 20th centuries, physicians were almost helpless before nearly all maladies. Though the best they could do was to comfort the patient until nature cured him, they often gave remedies recommended by authority and dependent on false theory that worsened the chances of recovery. The most important development in the 19th century was in the field of public health; water supplies were made safe, and waterborne diseases such as cholera were largely eliminated. Surgery also made great strides in the same century with the discovery of anesthetics and measures to prevent wound infection. But, leaving aside malaria (for which quinine or its precursor cinchona bark has been a known cure for centuries), only in the last 50 years have physicians possessed effective remedies for more than a minute proportion of the ills of mankind. Even now little can be done for many important maladies, including most of the degenerative conditions related to arterial disease, many kinds of cancer, most rheumatic conditions, the virus infections, and many kinds of psychological disorders.

Until modern times medicine was little unified. In the medieval period, separate bodies of physicians, barber-surgeons, and apothecaries developed in Britain and other countries of western Europe. The physicians were educated men, mostly graduates of universities; in England, of Oxford and Cambridge. The barber-surgeons were unlettered craftsmen whose skills were often handed on from father to son. The apothecaries, who made their physics from herbs, were usually members of the Grocers' Company.

By the beginning of the 19th century, the distinction between physicians, surgeons, and apothecaries was breaking down, and most medical men were becoming general practitioners. Indeed, any physician was competent to deal with almost every medical problem, because nothing useful could be done for the vast majority of patients. Some general practitioners had partners, but most worked in isolation, though perhaps with an arrangement with a colleague. They went into practice where they believed they could make a living, either by buying a practice from a retiring physician or "putting up a plate" in an expanding area. They worked from surgeries in their own houses with a minimum of equipment and dispensed their own usually valueless physics. Their greatest contribution to the community was, no doubt, to be wise men who could give help and advice to people in distress.

From about 1920 the proportion of medical practitioners in general practice has steadily declined in all the developed countries. In the Union of Soviet Socialist Republics general practice as it is known in Britain hardly exists, and in the United States and many western European countries, a high proportion of medical practitioners to whom the public has direct access are specialists of some kind.

(In this article the terms medical practitioner and physician are used interchangeably of a person who is qualified to practice medicine, without implications as to specialization.)

This article is divided into the following sections:

- I. The kinds of medical practice
  - General practice and first-contact care
  - Hospital and specialist practice
  - Industrial medicine
  - Governmental practice
  - Clinical research
- II. Maintenance of professional standards
  - Ethical basis of medical practice
  - Licensure requirements for practice
  - Legal restrictions on practice
  - Professional organizations
  - and the maintenance of standards

### I. The kinds of medical practice

#### GENERAL PRACTICE AND FIRST-CONTACT CARE

In countries in which the general practitioner does still exist, it is sometimes said that he is an obsolescent figure, that medicine covers an immense, rapidly changing, and complex field, and no physician can possibly master more than a small fraction of it. The very concept of the general practitioner who tries to know a little about everything, it is thus argued, may, therefore, seem absurd.

The obvious alternative to general practice is the direct access of patient to specialist. If a patient cannot see, he goes to an eye specialist, and, if he has a pain in his chest (which he fears is due to his heart), he goes to a heart specialist. One objection to this plan is that the patient often cannot know which organ is responsible for his symptoms, and the most careful physician, after doing many investigations, may remain uncertain as to the cause of the pain in the chest. And the severity of all pain is influenced by the patient's state of mind as well as by the nature of the bodily disease that is causing it. Breathlessness—a common symptom—may be due to heart disease, to lung disease, to anemia, or to emotional upset. The inability of the patient to know why he is unwell provides one overriding reason for the doctor of first contact to be a generalist.

A large proportion of maladies provide a general, not a specialist, problem. Among the commonest symptoms

The need for generalists

are a general malaise—feeling run-down or always tired; others are headache, chronic low backache, rheumatism—the meaning of which often is aches and pains in various places—and abdominal discomfort, poor appetite, constipation, and wind, or gas. Many persons are also overtly anxious or depressed. Among the most subtle medical skills is the ability to assess people with such symptoms and to distinguish between symptoms that are caused predominantly by emotional upset and those that are predominantly of bodily origin and, if there is a physical basis for the symptoms, to decide whether there is some benign process or some more serious disease that require investigation. A specialist may be capable of such a general assessment; but, if he is, he succeeds by virtue of his general qualities and not his specialized knowledge. Too often the specialist, with his inevitable emphasis on his own subject, fails at this point. The man best fitted to make this kind of assessment is the generalist.

It is usually felt that there are also great practical advantages for the patient in having “my doctor,” who knows about his background, who has seen him through various illnesses, and who has often looked after his family as well. This personal physician is in the best position to decide when he himself can take full charge and when the patient should be referred to a consultant—and, if so, which consultant.

The advantages of general practice and specialization are combined when the physician of first contact is a pediatrician. Although he sees only children and so can acquire a special knowledge of childhood maladies, he remains a generalist who looks at the whole patient, and the patient (or his mother) does not have to decide which organ is responsible for the symptoms. On the other hand, this kind of specialization implies that parents and children have a different physician, a situation that many people believe has disadvantages.

Another method of attempting to combine the advantages of general practice and specialization is by what has come to be called a group practice, the members of which partially specialize. All are general practitioners, but one may be also a surgeon, a second an obstetrician, a third a pediatrician, and a fourth an internist with a particular interest in obscure medical disorders. In isolated communities group practice may be a satisfactory compromise, but in advanced countries, where nearly everyone can be sent quickly to hospital by motor vehicle or airplane, the specialist surgeon working in a fully equipped hospital is in a far better position to treat persons needing operation than is a part-time general practitioner surgeon in a small clinic hospital. Moreover, partial specialization in general practice implies that there is no individual who is, to the patient, “my doctor.”

**Britain.** Before 1948, general practitioners in Britain settled where they could make a living. Patients fell into two main groups: weekly wage earners, who were compulsorily insured, were on a doctor’s “panel” and were given free medical attention (for which the doctor was paid quarterly by the government); and the remainder, who mostly paid the doctor a fee for service at the time of the illness. In 1948 the National Health Service started. Under its provisions, everyone was entitled to free medical attention with a general practitioner with whom he registered. Though general practitioners in the National Health Service were not debarred from also having private patients, these must be people who are not registered with them under the National Health Service. Any physician was free to work as a general practitioner entirely independent of the National Health Service, though outside the West End of London there were few who did so. Ninety-seven percent of the population were registered with a National Health Service general practitioner, and the vast majority automatically saw this physician, or one of his partners, when they required medical attention. A few people, mostly rich, while registered with a National Health Service general practitioner, regularly saw another physician privately; and a very few, although they usually saw their National Health Service general practitioner, might occasionally seek a private consultation with another physician because they were dissatisfied.

A general practitioner under the National Health Service remained an independent contractor, paid by capitation fee; that is, according to the number of people registered with him. He might work entirely from his own house in premises modified by himself, and he provided and paid his own receptionist, secretary, and other ancillary staff. Most general practitioners had one or more partners and worked more and more in premises built for the purpose. Some of these structures were erected by the physicians themselves, but many were provided by the local authority, the physicians paying rent for using them. Health centres, in which up to 20 or more general practitioners worked, were steadily increasing in number in the 1970s.

In Britain only a small minority of general practitioners can admit patients to a hospital and look after them personally. Most of this minority are in country districts, where, before the days of the National Health Service, there were cottage hospitals run by general practitioners; many of these hospitals continued to function in a similar manner. All general practitioners use such hospital facilities as X-ray departments and laboratories, and many general practitioners work in hospitals in casualty departments or as clinical assistants to consultants.

Although general practitioners are spread more evenly over the country than formerly, when there were many in the richer areas and few in the industrial towns, physicians (or their wives) may still be unwilling to settle in the larger and less pleasant industrial towns, even though they can be assured of a larger income there than in other places. The maximum allowed list of National Health Service patients per doctor in the early 1970s was 3,500; the average was about 2,500. Patients had free choice of physician with whom they registered, with the proviso that they could not be accepted by one who already had a full list and that a physician could refuse to accept them (though such refusals were rare). In remote country places there would be only one physician within a reasonable distance.

In the past, upper class patients expected physicians to visit them when they were unwell, but recent trends have been for more work to be done in the doctor’s office, usually by appointment. Many home visits were still needed to care for patients who were acutely ill, frail, or crippled and whose going to the surgery would be unpleasant or dangerous. In some large towns during evenings and weekends, it could at times be difficult to obtain a physician for a home visit. The problem was met in some places by the development of off-duty deputizing services that chiefly employed young physicians, usually for short periods between hospital appointments. By paying to this service, a general practitioner could be assured that his patients would be seen in emergency in his absence and that a report about the situation would be given to him. The system was much less satisfactory for the patient than the usual one in which partners take turns in doing evening and weekend work.

**United States.** Whereas in Britain the doctor of first contact is regularly a general practitioner, there is no such uniformity in the United States. In country districts far from the big cities, there are still many family general practitioners, and there have been many voices deploring the demise of this kind of physician in the cities. The American Academy of General Practice and the Section on General Practice of the American Medical Association in 1969 created the American Board of General Practice, but to date few young graduate physicians have been attracted back to this field, and the decline of general practice has not been halted, though it may have been delayed.

In the larger cities the needs of the poor for first-contact medical attention were largely met in the early 1970s by hospital emergency rooms mainly staffed by newly qualified physicians seeking experience. The care provided under such methods, although it might be the best possible in the circumstances and satisfactory for trivial injuries and brief self-limiting infections, cannot deal properly with maladies for which prolonged treatment is indicated.

The middle and upper classes in the cities had many

National  
Health  
Service

Medical  
care  
of the  
poor

varieties of primary medical care. Children were mostly taken to pediatricians. Many adults went to internists, whose field is mainly that of medical (as opposed to surgical) illnesses; many others went directly to the narrower specialists such as dermatologists, allergists, gynecologists, ophthalmologists, and abdominal surgeons. Critics believed that some inevitably went to the wrong specialist. The specialist who has seen someone through an illness may, especially if he is young, continue to give the patient care of a more general kind in the future. Indeed, whereas in the usual sense there was much less general practice in the United States than in Britain in the 1970s, in another sense there was more, for in Britain the specialist or consultant did not give primary medical care; in the United States he often did.

Most physicians in the United States giving primary medical care worked entirely independently; partnerships were uncommon. Doctors provided their own equipment, often very lavish, and paid their own ancillary staff. Some had their own X-ray equipment. In smaller cities they mostly had full hospital privileges, but in larger cities these privileges were more likely to be restricted to certain types of case and certain types of procedures, and some primary physicians had no access to hospital beds.

In the early 1970s the complaint was often heard that it was impossible to persuade some physicians in the large cities to make home visits to the sick. Reluctance to make such visits could to some extent be justified on the grounds that the physician worked more effectively in his office and that the patient too ill to come to the office was better off in hospital.

Medicare and Medicaid, government-supported programs, enabled the elderly and the poor to have medical attention that they previously lacked; in the early 1970s these services did not appear to have changed the general pattern of medical care.

**Soviet Union.** In the Union of Soviet Socialist Republics, there are no general practitioners covering every aspect of medicine except in the most thinly populated rural areas. Pediatricians deal with children up to the age of 15. Internists look after the medical ills of adults, and occupational physicians deal with the workers, sharing care with the internists. Patients have no free choice of physician, but, if there is friction between patient and physician, it may be possible for a change to be made at the instigation of either. Attention is free, though some drugs have to be paid for.

Soviet  
poly-  
clinics

Physicians work from polyclinics, clinics at which many types of diseases are treated. In small towns there was usually one polyclinic for all purposes in the early 1970s, but in large cities there were separate polyclinics for children and adults, as well as clinics for special purposes such as women's diseases, mental illnesses, and venereal diseases. Polyclinics usually had X-ray apparatus and facilities for examination of tissue specimens, facilities associated with the departments of the district hospital.

Home visits were common, and much of the physician's time was spent in doing routine checkups for preventive purposes. This was of value because tuberculosis—a malady for which early diagnosis and immediate treatment are important—was still comparatively common in the Soviet Union.

Some patients in sparsely populated rural areas were first seen by feldshers, nurses, or midwives who worked under the supervision of a polyclinic or hospital physician. The feldsher was once a lower grade physician in the army or peasant communities, but, by the 1970s, he had become a paramedical worker acting in cooperation with a physician. There were also some feldshers in the towns.

**Japan.** In Japan, with less rigid legal restriction of the sale of pharmaceuticals than in the West, there was formerly a strong tradition of self-medication and self-treatment. This was modified by the institution, in 1961, of health insurance programs that covered a large proportion of the population; there was then a great increase in visits to the outpatient clinics of hospitals and to private clinics and individual physicians.

When Japan abandoned traditional Chinese medicine

and adopted Western medical practices in the 1870s, Germany became the chief model. As a result of German influence and of their own traditions, Japanese physicians tended to prefer professorial status and scholarly research opportunities at the universities or positions in the national or prefectural (*i.e.*, district) hospitals to private practice. There were some pioneering physicians, however, who brought medical care to the ordinary people and who cared for seriously ill patients in their homes.

In December 1969, the number of private general clinics registered had reached 68,305. Most of these clinics had several physicians on their staffs, and 40 percent of the clinics had beds (in accordance with the Medical Service Law medical clinics are classified as hospitals if the number of beds is 20 or more).

In 1970 in Japan there were approximately 128 physicians per 100,000 people, but the physicians tended to cluster in the urban areas. The Medical Service Law of 1963 had been amended to empower the Ministry of Health and Welfare to control the planning and distribution of future public and nonprofit medical facilities, partly to redress the urban-rural imbalance. Meanwhile, mobile services were being expanded. More fundamental medical reforms were under way.

The influx of patients into hospital and private clinics after the passage of the national health insurance acts of 1961 had, as one effect, a severe reduction in the amount of time available for any one patient. Perhaps in reaction to this situation, there has been a modest resurgence in the popularity of traditional Chinese medicine, with its leisurely interview, its dependence on herbal and other "natural" medicines, and its other traditional diagnostic and therapeutic practices. One practice that has shared in this growth of popularity is acupuncture, a form of surgery consisting in the insertion of needles into one or more of 365 precise points on the trunk, the extremities, and the head. In the People's Republic of China, since 1957, acupuncture has also been employed in anesthesia.

**Other developed countries.** On the continent of Europe there are great differences both within single countries and between countries in the kinds of first-contact medical care. General practice, while declining in Europe as elsewhere, is still rather common even in some large cities, as well as in remote country areas, where it always tends to be the norm.

In The Netherlands, departments of general practice are run by general practitioners in all the medical schools—an exceptional state of affairs—and general practice flourishes. In the larger cities of Denmark, general practice on an individual basis is usual and popular, because the physician works only during office hours, there being a duty doctor service for nights and weekends. In the cities of Sweden, primary care is given by specialists. In the remote regions of the north of Sweden, district doctors act as general practitioners to patients spread over huge areas and delegate much of their home visiting to nurses.

In France there are still general practitioners, but their number is declining. Many medical practitioners advertise themselves directly to the public as specialists in internal medicine, ophthalmologists, gynecologists, and other kinds of specialist. As elsewhere, there is said to be tension at times between specialists and general practitioners, who feel that their status has declined. Even when patients have a general practitioner, they may still go directly to a specialist. Attempts to stem the decline in general practice are being made by the development of group practice (in place of the single-handed practice that used to be the norm in France) and of small rural hospitals equipped to deal with less serious illnesses, where general practitioners can look after their own patients.

Although Israel has a high ratio of physicians to population (about one to 450), there is a shortage of general practitioners, and only in rural areas is general practice common. In the towns many people go directly to pediatricians, gynecologists, and other specialists. In the early 1970s there was a reaction against this direct access to the specialist. Since then more general practitioners have been trained than in the recent past, and the Israel Medi-

cal Association has recommended that no patient should be referred to a specialist except by the family physician or on instructions given by the family nurse. At Tel Aviv University there is a department of family medicine. In some newly developing areas, where the doctor shortage is greatest, there are medical centres at which all patients are initially interviewed by a nurse. She herself deals with many minor ailments, thus allowing the physician to occupy his time on the more seriously ill. This system is popular with the nurses because it gives them more responsibility and is said to work well.

Nearly half the medical doctors in Australia are general practitioners—a far higher proportion than in most other advanced countries—though, as elsewhere, the proportion is declining. They tend to do far more for their patients than in Britain, many performing such operations as removal of appendix, gallbladder, or uterus, operations that elsewhere would be carried out by a specialist surgeon. Group practices with some degree of specialization are common. Most general practitioners have access to hospital beds.

**The developing world.** In the rich countries most people can obtain some kind of medical care; in the poor countries most cannot do so. Few developing countries spend more than one dollar per year for each inhabitant on medical care. In Northern Nigeria and Nepal, there was, according to the latest available figures, about one physician per 100,000 people, in India one per 6,000, and in Brazil one per 3,000, whereas in Britain there was one per 1,000, in the United States one per 800, and in the Soviet Union and Israel one per 450. In those developing countries in which the proportion of medical practitioners is comparatively high, nearly all are concentrated in the towns. In Kenya, for example, the overall ratio of physicians to patients was one per 10,000, but in the rural areas it was one per 50,000.

Medical needs in developing countries

Along with the shortage of physicians, there is a shortage of everything else needed to provide medical care—of equipment, of drugs, of suitable buildings, and of nurses, technicians, X-ray technicians, and all other grades of staff, whose presence is taken for granted in the affluent societies. Yet medicine has far more to offer to the sick in the poor countries than in the rich countries. In the poor countries a high proportion of people are young, and all are liable to many infections, including tuberculosis, syphilis, typhoid, and cholera (which, with the possible exception of syphilis, are now rare in the rich countries), and also malaria, yaws, worm infestations, and many other conditions occurring primarily in the warmer climates. Nearly all these infections respond to the antibiotics and other drugs that have been discovered since the 1920s. There is also much malnutrition and anemia, which can be cured if money is available. Many people have goitres, cataracts, and other disorders remediable by surgery. Preventive medicine can achieve much by ensuring clean water supplies, destroying insects that carry infections, teaching hygiene, and showing how to make the best use of meagre resources.

Urban and rural differences

In most poor countries there is a small number of rich people, usually living in the cities. They can afford to pay for medical care, and in a free market system the physicians go where they can make a living; this situation explains why the doctor-patient ratio is so much higher in the towns than in country districts. A physician in Bombay or in Rio de Janeiro may have equipment as lavish as that of a physician in the United States and can earn an excellent income. The poor, both in town and country, can get satisfactory medical attention only if it is paid for by the state, by some supranational body, or by a mission or other charitable organization. In practice, hospitals run by a mission may cooperate closely with state-run health centres.

The gross national product of the developing countries is only about one-twentieth that of the rich countries. In Britain, where most of the cost of medical care is provided by public funds, around 4 percent of the gross national product is spent on health. Few developing countries expend this proportion of their small gross national product on health. With such an enormous amount to be done

with so small an expenditure, the overriding consideration is to concentrate on what can be provided most cheaply.

It is now generally believed that, because physicians are scarce, their skills must be used to best advantage; that most of the work normally done by physicians in the rich countries has to be delegated to various kinds of auxiliaries or nurses, who have to diagnose the common conditions, give treatment, take blood samples, help with operations, supply simple posters containing health advice, and carry out many other tasks. In such places the doctor has time only to perform major operations and deal with the more difficult medical problems.

Because hospital care is expensive, people are treated as far as possible on an outpatient basis from health centres housed in simple buildings. Few people can travel except on foot, and, if they are more than five miles or so from a health centre, they tend not to go there. Health centres are also used as centres for propaganda to the local inhabitants, who can perhaps be persuaded to improve their hygiene—by the better disposal of excrement, by improving the water supply, and by the destruction of some insects—and can be taught to improve their dietary habits, mainly by being shown how their protein intake can be increased.

The developing countries vary widely in the medical care that they have made generally available. In some, such as Kenya, there has been extensive development of simple health centres providing medical care to most of the population; in others, vast numbers have no medical care at all. There is also a tendency to spend too much of the little money available on expensive hospitals, where elaborate investigations and complicated operations are performed.

#### HOSPITAL AND SPECIALIST PRACTICE

In the Middle Ages, hospitals were places of refuge for the aged poor, the crippled, and the destitute and were attached to monasteries. In the 18th and 19th centuries, hospitals under religious auspices persisted, but many other voluntary hospitals were founded all over the Western world as independent secular organizations financed by subscriptions and endowments. In the 19th century these voluntary hospitals increasingly restricted their clientele to the noninfectious acutely sick. The needs of the mentally and chronically sick and of the tuberculous and those with other infections were met by the erection of public hospitals financed by government or local authorities.

Whereas there are great differences between and within the Western countries in the kinds of primary medical care, there is more uniformity in hospital care. The new hospitals in the poorer countries are largely modelled on those in the West. Most patients in or attending hospital are looked after by a specialist.

The main specialties are, in surgery: general surgery; gynecology and obstetrics; orthopedic and traumatic surgery; neurosurgery; thoracic and cardiac surgery; ear, nose, and throat surgery; and ophthalmic surgery. In medicine they are: general or internal medicine; dermatology; physical medicine or rheumatology; neurology; pediatrics; geriatrics; and psychiatry. The important non-clinical specialties are anesthetics, radiology, and pathology, which is usually subdivided into morbid histology (study of diseased tissue), biochemistry, bacteriology, and hematology (which is concerned with blood disorders).

Principal surgical and medical specialties

The trend is to more and more specialization, largely as a result of the vast increase in knowledge in recent years. But specialization in clinical medicine can lead to problems: patients cannot be separated into categories, each to be looked after by a particular specialist; they are sick people who should be looked at as a whole. A patient with heart disease is not necessarily given better advice by a cardiologist than by a general physician. The general physician is widely held to be an obsolescent figure who should be replaced by specialists in the various systems of the body, but there are good reasons for the existence of general physicians. A large proportion of the patients for

whom the general practitioner wishes a second opinion are not clearly affected by a disease of some organ; they are obscurely unwell.

Specialization in surgery can be much better justified than can specialization in medicine, because the practice of surgery implies technical skills. Wisdom and understanding are important qualities in the cardiac surgeon, but they are not enough; he must also have a knowledge of the heart and of the craft of heart operations that only regular practice can give.

Radiation therapy, also known as radiotherapy, is unique in that it is a specialty of treatment, patients being given X-rays or radium. It can be justified because the apparatus and the methods of treatment are so complicated that only a specialist can master them.

There are few objections to increasing specialization in nonclinical spheres. The bacteriologist is likely to give a better bacteriology service than the general pathologist can, and the radiologist who has made a special study of X-ray views of the alimentary tract will probably give a better opinion of this tract than will the radiologist who covers the whole body.

*Organization of the specialist's work.* Clinical specialists divide their time between dealing with inpatients in a hospital or nursing home and dealing with patients who attend at the outpatient department of a hospital or in private consulting rooms. They may also visit patients in their own homes occasionally.

In remote districts and developing countries, specialists may work with little help. In the rich countries, many specialists have junior medical staff who handle much of the emergency work, carry out various procedures such as blood transfusions, help at operations, and accompany their chief on his ward rounds and carry out his instructions. This kind of work is an important part of the young doctor's education.

The work of nonclinical specialists is largely determined by their equipment. The radiologist must have his massive and expensive X-ray machines, with technicians to help him and with equipment to process his films. The anesthetist inevitably works largely in operating rooms, though he may occasionally give anesthetics to outpatients with trivial conditions. In the past his equipment was simple; now it is elaborate. The pathologist needs his laboratory, with its equipment and technical staff.

*Medical schools.* The most sought after posts in the hospital world are in the hospitals with medical schools. Newly qualified physicians wish to work there because doing so will aid their future careers, though the actual experience may be wider and better in a hospital without a medical school. Senior physicians hope to make their careers in hospitals with medical schools, because consultant, specialist, or professorial posts there usually carry the highest prestige of any that the medical profession can offer. When the posts are salaried, the salaries are sometimes, but not always, higher; and, when the consultant makes all or part of his living by private practice, he is likely to earn far more when on the staff of a medical school.

In many medical schools, especially on the European continent, there are clinical professors in each of the major specialties, such as surgery, internal medicine, obstetrics and gynecology, psychiatry, and often of the smaller specialties as well. There are also professors of pathology, radiology, and radiotherapy. Whether professors or not, all senior doctors in teaching hospitals have the two functions of caring for the sick and educating students. They give lectures and seminars and, when doing ward rounds, are accompanied by students with whom they discuss the patients' problems.

**Britain.** Before the National Health Service the most famous hospitals were the voluntary teaching hospitals. The senior medical staff gave their services free, deriving their income from seeing well-to-do patients privately. Most patients were in local-authority hospitals, many of which developed in the 19th century from workhouses controlled by boards of guardians of the poor. The local authorities also built large mental hospitals, infectious-diseases hospitals, and tuberculosis sanatoriums. In 1928

the boards of guardians were abolished, and their hospitals were taken over by the local authorities. During World War II, nearly all hospitals were incorporated in the Emergency Medical Service.

When the National Health Service began in 1948, virtually all hospitals became part of it. They are administered centrally by the Ministry (later the Department) of Health and locally by regional boards (responsible for a population of several million people) through management committees responsible for individual hospitals or groups of hospitals. The pattern of hospitals varies widely, but the plan in the early 1970s was that district hospitals of some 600 beds would in time largely replace smaller hospitals and provide the basic hospital services, including some care for the mentally sick and those with infectious diseases. In addition, some hospitals, especially the teaching hospitals, had departments for highly specialized treatment, such as cardiac surgery and radiotherapy, and there would continue to be hospitals especially for long-term mentally disturbed, mentally subnormal, and geriatric patients.

As a rule, the only part of a hospital to which the public has direct access is the casualty department, which is usually staffed by doctors of intermediate status. Consultative outpatient departments are under the charge of consultants, who sometimes run them single-handedly but more often are assisted by a registrar, to whom some patients are delegated. Patients have to be referred by a general practitioner, another consultant, or a casualty officer. After examination and investigation, many are referred back to their general practitioners with a letter giving the consultant's suggestions. Other patients, especially those requiring surgery, are admitted or placed on a waiting list for admission when a bed is available. The acutely sick are admitted directly to the hospital by arrangements between the general practitioner and the admissions officer.

Although the vast majority of all the patients in hospital are treated free, in most hospitals there are a small number of private beds. Patients who occupy them make payments to the National Health Service and also pay the consultant's fee.

**United States.** There are federal, state, local government, church, nonprofit voluntary, and proprietary hospitals in the United States. The federal hospitals, which have 10 percent of all beds and are staffed by full-time federal employees, include military, Veterans Administration, and Public Health Service hospitals. The state hospitals, mostly of more than 1,000 beds each and containing 42 percent of all beds, care for the mentally and chronically sick and the tuberculous. Many are widely believed to be understaffed in both nurses and physicians, who are full-time state employees. Local government hospitals, with 13 percent of all beds, are run by the local municipalities and councils. They are the district general hospitals for those who cannot afford the fees of the private institutions and mostly provide care for the usual acute and chronic illnesses. Some of their staff are full-time employees, and others are part-time. The voluntary nonprofit community hospitals, which contain 19 percent of all the beds, range from the world-renowned teaching hospitals to small community hospitals with fewer than 20 beds. Most of the community hospitals have a few beds for highly specialized work and are staffed by the local physicians. Among the staff of the teaching hospitals are most of the most eminent specialists. They also have a large number of junior physicians. Proprietary hospitals, with 3 percent of all beds, are mostly small, are privately owned, and are organized to make profit for their shareholders.

Most of the voluntary nonteaching hospitals and all the proprietary hospitals offer open access to beds and other facilities for all local physicians who satisfy certain—and not always very exacting—criteria. There may thus be an extremely large medical staff, each member of which may have only one or two patients in the hospital at any time. Whereas in poor rural areas there may be a shortage of facilities, in prosperous districts there is sometimes an excess, with resultant competition for patients.

Hospitals under National Health Service

Hospital admission in the U.S. and Britain

About 75 percent of the United States population contribute to insurance schemes that provide some cover for hospital costs. These schemes tend to encourage admission to hospital for brief periods while investigations, which would be feasible on an ambulatory basis, are done. In 1964, 14.8 percent of all American citizens were admitted to hospital, by comparison with 10.5 percent in Britain. Investigations that in Britain would be done in the outpatient department are in the United States more often done in the physician's office. There are outpatient facilities in some American hospitals, mainly for the indigent. The emergency rooms of larger hospitals also provide first-contact care for the U.S. poor.

**Japan.** In the era after World War II, the technology and language employed in the Japanese laboratories have been predominantly American, but the educational philosophy, with teaching through the lecture and with emphasis on research, still shows the influence of the German professors who helped to found the modern Japanese medical system. Efforts have begun to give greater emphasis to clinical laboratory instruction and bedside teaching.

In 1971, research institutions included 118 associated with universities, of which 57 were national, 17 prefectural or municipal, and 44 private, and 111 medical institutes not affiliated with universities; of the 111 about one-half were privately financed.

Japan is especially advanced in the study of radiation-induced cancer through the work of the Atomic Bomb Casualty Commission, organized in 1947 by the National Academy of Sciences of the United States to study the long-term effects of the atomic bombing of Hiroshima and Nagasaki. Japanese researchers also work closely with the World Health Organization committees that study prevention or treatment programs for such diseases as cancer, leprosy, and tuberculosis.

The National Cancer Centre in Tokyo (founded in 1956) includes Asia's largest cancer hospital and sophisticated research facilities. There are also nine regional cancer institutes and some 160 prefectural and municipal cancer clinics supplemented by more than 300 mobile units equipped for examinations.

A number of contagious diseases have yielded in some measure to research and prevention programs. Tuberculosis, for example, the leading cause of death in Japan in 1950, had been reduced, by 1968, to eighth place in the order of causes. Pneumonia and bronchitis, which caused 8.6 percent of deaths in 1950, caused 4.6 percent in 1968.

In 1969 there were approximately 8,000 hospitals in Japan, with somewhat more than 1,000,000 beds. The governmental hospitals (national, prefectural, and municipal) were about one-third the total number and had somewhat less than two-thirds of the beds. Of the remaining hospitals, 85, with about 43,000 beds, were associated with universities.

**Other countries.** Most hospitals in the Soviet Union are of standard types, ranging from small general hospitals of 15 to 100 beds—located in remote rural areas and staffed by pediatricians, internists, surgeons, and sometimes pathologists and radiologists—through district hospitals, of 250–500 beds; to regional and republic hospitals. Medical schools are associated with the last, and specialists tend to be concentrated in the regional and republic hospitals. Mental and tuberculosis hospitals are separate from the other hospitals.

#### INDUSTRIAL MEDICINE

The Industrial Revolution greatly changed, and as a rule worsened, the health hazards caused by industry, while the numbers at risk vastly increased. In Britain, where the Industrial Revolution began, the first small beginnings of efforts to ameliorate the lot of the workpeople in factories and mines began in 1802, with the passing of the first factory act, the Health and Morals of Apprentices Act. The second factory act, in 1819, stipulated nine years as the minimum age for employing children. The factory act of 1838 was the first really effective measure in the industrial field. It forbade night work for children and

restricted their hours to 12 per day. Children under 13 were required to attend school. A factory inspectorate was established, the inspectors being given powers of entry into factories and power of prosecution of recalcitrant owners. Thereafter, there was a succession of acts with detailed regulations about safety and health in all industries. Industrial diseases were made notifiable, and those who develop any one of the 40 prescribed industrial diseases are entitled to industrial injuries benefit.

In Britain the industrial physician is, then, bound by all sorts of legal restrictions and must report those who develop the specified industrial diseases. The situation is similar in other developed countries. The industrial physician's most important function, however, is to prevent industrial diseases. Many of the measures to this end have evolved over the years and become standard practice, but, especially in new industries working with new substances, the physician may be able to detect evidence that the workers are being damaged and suggest measures to prevent this. He will be able to advise management about industrial hygiene and the design of buildings so as to minimize health hazards. He should ensure that individual workers are aware of the risks they are running and that they have the means to minimize these risks.

In many factories there are arrangements for giving first aid in case of accidents. In practice, the facilities range from one simple first-aid box to a large suite of rooms lavishly equipped with all kinds of first-aid equipment and also X-ray and physical-therapy equipment, with a staff of qualified nurses and physiotherapists. In the larger places one or more full-time physicians may be on duty.

**Periodic medical examination.** Physicians in industry carry out many medical examinations, especially on recruits and on employees returning to work after sickness or injury. In addition, those liable to health hazards may be examined regularly in the hope of detecting evidence of incipient damage. In some organizations every employee may be offered a regular medical examination.

When a potential employee is medically examined, the physician may advise whether he should be accepted and, if he is, the kind of work for which he is fit.

**The industrial and the personal physician.** There may be doubt as to which physician bears the main responsibility for someone's health, especially in such countries as Britain, where most people consult a general practitioner. In the United States the problem is less likely to arise because few have a single personal physician. In the Soviet Union the occupational physician acts to some extent also as a general practitioner.

Dealing with the health hazards of industry is clearly within the province of the industrial physician. When someone has an accident or becomes acutely ill at work, the first aid is given or directed by him. Subsequent treatment may either be given at the clinic at work or be arranged by the personal physician. Difficulties may arise when an employee returns to work after an illness. He may feel that, whereas his own personal physician is a friend, the industrial physician represents the organization and is not to be trusted.

**Industrial health services.** Only in the Soviet Union and other Communist countries is there a fully developed state industrial health service. At the larger industrial establishments in the Soviet Union employing 5,000 or more workers, there are polyclinics that provide both occupational and general care to the workers and their families. Each occupational physician is responsible for about 1,000 workers. His work includes the prevention of occupational diseases and injuries, health screening, immunization, and health education. He may be assisted by feldshers who have been specially trained in this work.

In the Western countries there is no fixed pattern of industrial health service. Legislation impinges upon health in various ways, including the provision of safety measures, the restriction of pollution, and the enforcement of minimum standards of lighting, ventilation, and space per person. This legislation started in Britain in 1802 and has continued in all developed countries ever since.

Even in Britain, which has the most comprehensive health service in the non-Communist world, there is no

Industrial physician's function

Industrial health service in the Soviet Union

occupational health service as a general bureau of service of the government. There is, instead, an infinite variety of schemes financed and run by individual firms or, equally, by huge nationalized industries, such as the Coal Board and the Gas Council. The smaller firms usually have no scheme of any kind, some intermediate firms may employ a general practitioner for a few hours a week, and, in a few industrial estates, firms have joined forces in promoting a local industrial health service. There is a similar variety in the United States and throughout the Western world.

#### GOVERNMENTAL PRACTICE

**Public health practice.** The physician working in the field of public health is mainly concerned with the environmental causes of ill health and in their prevention. Bad drainage, polluted water and atmosphere, noise and smells, infected food, bad housing, and poverty in general are all his especial concern. Perhaps the most satisfying title he can be given is that of community physician. In Britain he has been customarily known as the medical officer of health and, in the United States, as the health officer.

Public health measures of the 19th century

The spectacular improvement in the expectation of life in the affluent countries has been due far more to public health measures than to curative medicine. These public health measures were largely put into operation in the 19th century. At the beginning of that century, drainage and water supply systems were all more or less primitive; nearly all the cities of that time had poorer water and drainage systems than Rome had possessed 1,800 years previously. The drains regularly infected the water supply, and vast outbreaks of typhoid, cholera, and other waterborne infections were common. By the end of the century, at least in the larger cities, water supplies were usually safe, and wastes were carried away in underground drains, though often to pollute the rivers lower down. Food-borne infections were also drastically reduced by the enforcement of laws concerned with the preparation, storage, and distribution of food. Insect-borne infections, such as malaria and yellow fever, which were common in the southern United States and in other hot countries, were eliminated by the destruction of the responsible insects, chiefly by getting rid of the pools where they bred. Fundamental to this improvement in health has been the diminution of poverty, for most public health measures are expensive. The peoples of the developing countries fall sick and die from infections that the affluent countries have almost abolished.

**Britain.** Whereas the general practitioner and hospital services are part of the National Health Service, public health services are organized locally, under the county and county-borough councils and the smaller local councils. This separation between the largely preventive local health services and the national curative health service has been widely criticized. In the near future there may be a fusion of all these services, accompanied by a widespread change in the local government areas.

Medical officer of health

The medical officer of health is employed by the local council and is their expert adviser in health matters. The larger councils employ a number of medical officers with a hierarchical structure under a chief. Most are full-time employees, but, in some small rural areas, a general practitioner may be employed part-time as medical officer of health.

The medical officer of health has various statutory powers conferred by acts of Parliament, regulations and orders, such as food and drugs acts, milk and dairies regulations, and factories acts. He supervises the work of sanitary inspectors in the control of health nuisances. The compulsorily notifiable infectious diseases are reported to him, and he takes appropriate action, such as X-raying persons who have come in contact with tuberculosis and tracing the source of infection of typhoid.

The medical officer of health is involved with the work of the district nurse, who carries out nursing duties in the home, and the health visitor, who gives advice on health matters, especially to the mothers of small babies. He has other duties in connection with infant welfare clinics,

crèches, day and residential nurseries, the examination of schoolchildren, child guidance clinics, foster homes, factories, problem families, and the care of the aged and the handicapped.

**United States.** Federal, state, county, and city governments all have public health functions. Under the United States Department of Health, Education and Welfare is the Public Health Service, headed by the surgeon general. The commissioner of health, usually a physician, is the head of the state health department and is often in the governor's cabinet. He usually has a board of health that adopts health regulations and holds hearings on their alleged violations. A state's public health code is the foundation on which all county and city health regulations must be based. A city health department may be independent of its surrounding county health department, or there may be a combined city-county health department. The physicians of the local health departments are usually called health officers, though occasionally people with this title are not physicians. The larger departments may have a public health director, a district health director, or a regional health director.

The minimal complement of a local health department is a health officer, a public health nurse, a sanitation expert, and a clerk who is also a registrar of vital statistics. There may also be sanitation personnel, nutritionists, social workers, laboratory technicians, health educators, and others.

**Japan.** Japan's Ministry of Health and Welfare directs public health programs at the national level, maintaining close coordination among the fields of preventive medicine, medical care, and welfare and health insurance. The departments of health of the prefectures and of the 29 largest municipalities operate health centres that totalled 832 in 1970. The integrated community health programs of the centres encompass maternal and child health, communicable disease control, health education, family planning, health statistics, food inspection, and environmental sanitation. The national government meets one-half of the cost of a new health centre and provides for one-third of the operating expenses. Private physicians, through their local medical associations, help to formulate and execute particular public health programs needed by their localities.

About 80 relevant laws are administered through the Ministry's ten bureaus and agencies, which range from Public Health, Environmental Sanitation, and Medical Affairs to the Children and Families Bureau. The approximately 20 categories of institutions run by the Ministry, in addition to the national hospitals, include research centres for cancer and leprosy, homes for the blind, rehabilitation centres for the physically handicapped, and the port quarantine services.

**Military practice.** The medical services of armies, navies, and air forces are geared to war. During campaigns the first requirement is the prevention of sickness. In all wars before the 20th century, many more combatants died of disease than of wounds. And even in World War II, although few died of disease, vast numbers became casualties from disease, especially in the tropical theatres.

The main means of preventing sickness that have been highly successful in temperate theatres are: the provision of food and pure water, thus eliminating starvation, avitaminosis, and dysentery and other bowel infections, which used to be particular scourges of armies; the provision of proper clothing and other means of protection from the weather; the elimination from the service of those likely to fall sick; the vaccination of all against various infections, notably typhoid and smallpox; in malarious areas, provisions for the regular taking of suppressive drugs to prevent the symptoms of the disease; and the education of all in hygiene. In addition, the maintenance of high morale has a striking effect on the casualty rates, for, when morale is poor, men are likely to suffer psychiatric breakdowns, and malingering is more prevalent.

Most of these preventive methods are the concern of the service as a whole. The medical branch may provide advice about disease prevention through the proper preparation of food, the provision of water, the disposal of

Military prevention of sickness

excrement, the elimination of insects, and the taking of suppressive drugs, but the actual execution of this duty is through the ordinary chains of command. It is the duty of the colonel, not of the medical officer, to ensure that the troops do not drink infected water and that they take tablets to suppress malaria.

When army casualties occur during war, the supreme requirement is rapid evacuation of the wounded from the front. A sick or wounded man at the front interferes with his comrades' activities. The general principle is to give first aid on the spot and then to evacuate quickly to the rear. Air transport has revolutionized the means of achieving this. The situation in air forces and navies considerably differs from that of armies. When a man is wounded in a plane, little can be done except by the self-application of dressings, but, if he gets to base alive, he can immediately go to a well-equipped hospital. In a naval action there may be massive casualties that overwhelm the available medical services, especially in isolated small ships. On the other hand, the action is usually brief, and, when it is over, casualties are evacuated to hospital ships or land-based hospitals.

*Army medical organization.* The medical doctor of first contact to the soldier is an officer in the medical corps, usually fairly junior. He may be designated battalion or regimental medical officer. In peace conditions, he sees the sick and has functions similar to those of the general practitioner. He prescribes drugs and dressings and may have a sick bay where lightly sick men can remain for a few days. He is usually assisted by orderlies. If a further medical opinion on a soldier is required, the patient can be referred to a specialist at a military hospital or, when occasion demands, to a civilian hospital.

Dealing  
with the  
wounded

In war conditions, the regimental medical officer has a regimental aid post where, with the help of one or more orderlies, he applies first aid to the walking wounded and to the more seriously wounded who are brought in by the stretcher-bearers. The casualties are evacuated as quickly as possible by field ambulances, of which there are usually three to each division. Each field ambulance has two companies and a headquarters. The companies have medical officers, stretcher-bearer officers (nonmedical), and men of the medical corps who man an advanced dressing station. There, further treatment may be given before evacuation to the main dressing station at the headquarters of the field ambulance, where a surgeon may perform emergency operations. Thereafter, evacuation may be to casualty clearing stations, to advanced hospitals, or to base hospitals, but no general description can be given, because circumstances vary. Air evacuation, which can immediately take men thousands of miles, is widely used.

In peace conditions most of the intermediate medical units exist only in skeleton form; the active units are at battalion and hospital level. A military hospital is much the same as a civilian hospital, with various specialists, laboratory, X-ray department, physical therapy department, and so on.

When a physician joins the medical corps, he may join with specialist qualifications, or he may obtain such qualifications while in the army, sometimes by secondment to a civilian hospital. A feature of army medicine is promotion to administrative positions. The commanding officer of a hospital and the medical officer at headquarters may have no contacts with actual patients. This practice is often held to be an unsatisfactory feature of a military doctor's life.

Although the medical officer in peacetime has some choice of the kind of work he will do, he also expects to be moved at intervals. He is in a hierarchical organization with a chain of command.

The medical officer is a soldier and under military discipline in ordinary matters, but, when dealing with patients, he is in a special position. He cannot be ordered by a superior officer to give some treatment or take other action that he believes is wrong. The medical officer also does not bear or use arms, except when patients under his care are being attacked.

*Naval medicine.* Naval medical services are run on similar lines to those of the army. Junior Medical officers

are attached to ships or to shore stations and deal with most cases of sickness in their units. When at sea, the medical officer has an exceptional degree of responsibility in that he is working alone, unless he is on a very large ship. In peacetime, only the larger ships carry a medical officer; in wartime, destroyers and other small craft may also carry medical officers.

Medical  
organiza-  
tion  
in the  
navy

In a navy there is no need, even in war, for intermediate medical units corresponding to the field ambulances and casualty clearing stations of the army. The main requirements are a doctor of first contact, who has a sick bay, and either a shore-based hospital or a hospital ship. When war comes, an increase in medical facilities, though with no great change in organization, is needed.

*Air force medicine.* Flying has many medical repercussions. Cold, oxygen lack, and the changing of direction at high speed all have important effects on bodily and mental functions. These problems are studied in special institutes devoted to aviation medicine.

Most armies and air forces share the same medical service; others have air force medical services entirely separate from those of their armies. The organization is similar to that of the navy, in that there is no need for intermediate medical units. Air bases have medical units where minor cases are dealt with. Major cases are sent to hospitals.

A recent development is aerospace medicine. This involves medical problems such as have never been known before, for the main reason that men in space are not under the influence of gravity, a situation that has profound physiological effects. Aerospace medicine is dealt with in a separate article.

#### CLINICAL RESEARCH

When any new treatment is introduced, someone must be the first on whom it is tried; this trial is an important kind of clinical research. The practical problem is to advance medicine without appreciable risk for the patients.

Although the most spectacular changes in the medical scene during the 20th century, and the most widely heralded, have been the development of potent drugs and elaborate operations, another striking change has been the abandonment of most of the remedies of the past. In the mid-19th century, persons ill with numerous maladies were starved (partially or completely), bled, purged, cupped (by applying a tight-fitting vessel filled with steam to some part and then cooling the vessel), and rested, perhaps for months or even years. Much more recently they were prescribed various restricted diets and were routinely kept in bed for weeks after abdominal operations, for many weeks or months when their hearts were thought to be affected, and for many months or years with tuberculosis. The abandonment of these measures may not be thought of as involving research, but the physician who first encouraged persons who had peptic ulcers to eat what they wanted (rather than to live on the customary mince and slops) and the physician who first got his patients out of bed a week or two after they had had minor coronary thrombosis (rather than insisting on a minimum of six weeks of strict bed rest) were as much doing research as is the physician who first tries out a new drug on a patient. This research by observing what happens when remedies are abandoned has been, indeed, of inestimable value, and the need for it has not yet gone, for practice is still to some extent shackled to the past.

Abandon-  
ment  
of  
remedies  
of the  
past

Many controlled clinical trials of traditional remedies have been performed, alternate patients being given them and the others denied them, and these trials have often shown which remedies should be abandoned.

**Drugs.** The commonest kind of clinical research is the trial of new drugs. The usual course of events in developing a new drug is about as follows: a compound is synthesized in the laboratory or isolated from some natural source; endless laboratory observations are made, including vast numbers of animal experiments. Only a minute proportion of compounds pass these preliminary tests. The few survivors that seem likely to be superior to existing drugs must then be tried on patients.

The justification for using a new drug depends on the nature of the malady from which the patient is suffering. If he has far advanced cancer, remedies with serious side effects can properly be used. If he has a common cold, a drug likely to have any but the most trivial side effects must not be used.

When one deals with progressive or little-changing maladies, useful conclusions can be drawn from observing the effect of treatment in single cases. But, when maladies have a short and usually favourable course (as do colds, influenza, and lumbago) or a recurrent and unpredictable course (as do duodenal ulcer, multiple sclerosis, and colitis), observations on single cases, or even on large numbers when all are treated alike, are of little value. In such situations controlled series are needed, certain patients being given the drug to be tested and alternate patients being denied it. Best of all is the double blind trial in which neither patients nor observers know who is having the drug to be tested and who are having dummy tablets. The effect of suggestion, which can be important, is thus eliminated. If the patients given the drug regularly do better than those who have the dummy tablets, there is evidence of the drug's value.

In dealing with minor maladies such as colds or boils, there are few ethical problems in doing controlled trials, but, when there is a risk of death or permanent disability, it is justifiable to give dummy tablets only when evidence is lacking that any remedy will improve the outcome. Frequently, a number of drugs are all known to be effective for a certain malady, but there is doubt as to which is the best. It is then justifiable to perform a controlled trial in which certain patients are given one of the drugs and alternate patients are given another.

Before patients take part in a trial, they are told of the implications, and their permission is obtained. In practice, nearly all patients agree. Difficulties arise when patients are unconscious or mentally confused—and so cannot validly give consent—or when they are children. The legal position in most countries appears to be obscure in these situations. According to British law, parents probably cannot give consent to experimental procedures on their children that involve risk, though there seems some doubt about this.

However much care is taken in research with new drugs, disasters can occur. This is especially so when the drugs appear harmless to all experimental animals, when only very few patients are harmed, and when there is delay before the harm becomes manifest. There can indeed be extreme difficulty in deciding whether a drug has been responsible for some disorder. An example of the difficulty is provided by the thalidomide disaster. Only after a long time and after numerous deformed babies had been born all over the world did it become clear that thalidomide taken by the mother as a sedative had been responsible.

In hospitals in which clinical research is carried on, ethical committees often consider each research project. Then, if the committee believes that the risks are not justified, the project is rejected. Official bodies give general advice on this matter.

**Surgical operations.** In drug research the essential steps are taken by the chemists who synthesize or isolate new drugs in the laboratory; clinicians play only a subsidiary part. In developing new operations clinicians play a more important role, though laboratory scientists and others in the background may also contribute largely. Many new operations have been made possible by advances in anaesthesia, and these in turn depend upon engineers who have devised machines and chemists who have produced new drugs. Other operations are made possible by new materials, such as the alloys and plastics that are used to make artificial hip and knee joints.

Whenever practicable, new operations are tried on animals before they are tried on patients. This practice is particularly relevant to organ transplants. Surgeons themselves—not experimental physiologists—transplanted kidneys, livers, and hearts in animals before attempting these procedures on patients. But experiments on animals are of little or no value in developing some opera-

tions. This may be because no animal suffers from a malady similar to that of the patient. An important advance after World War II was valvulotomy, dilation of the mitral valve of the heart that had become narrowed from rheumatic disease. The need for the operation had long been obvious; it had not been devised because anaesthesia had not advanced enough. When machines and drugs enabled the heart to be approached without the lungs' collapsing, valvulotomy became possible. The essential research could be done only by a surgeon operating on a patient.

**Observing the natural history of maladies.** The one kind of clinical research that any physician can carry out single-handedly with little or no equipment and with no ethical repercussions, is the long-term observation of patients with certain maladies. This type of research is not popular. Those who conduct research mostly aim to achieve results quickly; a lapse of 20 or 30 years before a paper can be published is unattractive. Yet, this kind of research can yield valuable information. What happens to persons with many common maladies, including such relapsing conditions as peptic ulcer, colitis, and multiple sclerosis, is still not known. Any hospital physician knows of the variety of relapses that the victims of these conditions may have, but he does not know how many patients never have relapses, because they do not consult him. Little is known as to how many of those who develop these maladies in their 20s are alive and free of symptoms in their 60s. Careful observations by a number of general practitioners lasting throughout their careers and published when they retire would be most valuable.

Even longer term research of this kind can usefully be done for hereditary maladies. Few families have been properly observed for two generations, and virtually none for three, and yet only by such studies can satisfactory knowledge be obtained of an important range of human maladies, and only with such knowledge can sound genetic counselling be given to people with hereditary conditions.

## II. Maintenance of professional standards

### ETHICAL BASIS OF MEDICAL PRACTICE

The first great exposition of the ethical basis of medicine was the Hippocratic oath. No one knows how and when the oath was formulated. It is part of the large Hippocratic collection, of which the earliest complete manuscript is of the 9th century AD. Some of the ideas behind the oath date back long before Hippocrates (who lived in the 5th century BC). The most important part of the oath is usually rendered:

The regimen I adopt shall be for the benefit of my patients according to my ability and judgment, and not for their hurt or for any wrong. I will give no deadly drug to any, though it be asked of me, nor will I counsel such, and especially I will not aid a woman to procure abortion. . . . Whatsoever house I enter, there will I go for the benefit of the sick, refraining from all wrongdoing or corruption, and especially from any act of seduction, of male or female, of bond or free. Whatsoever things I see or hear concerning the life of men, in my attendance on the sick or even apart therefrom, which ought not to be noised abroad, I will keep silence thereon, counting such things to be as sacred secrets.

Many of the precepts in the oath express noble ideals, and yet such is the difficulty of laying down criteria to cover any eventuality that in practice exceptions have to be allowed. Few would insist that in no circumstances should a woman procure an abortion, and occasionally it may be justifiable to disclose a patient's secrets to others.

In the everyday practice of medicine, physicians spend little time in considering the ethical basis of their work. They simply take for granted a few moral principles—whether they believe these are derived from Hippocrates, from the natural law, from the divine law, or just from plain common sense. They do their best to benefit their patients, by curative methods, if possible, and otherwise by relieving symptoms and by kindness and reassurance; they tell the truth (except when the truth is too wounding); and they do not reveal their patients' confidences. Ethical problems are likely to arise in only a few special circumstances.

Hospital  
ethical  
commit-  
tees

Hippo-  
cratic  
oath

Problem  
of  
loyalties

One such circumstance is when the doctor is employed by a corporation to examine potential and actual employees. He then must decide to whom his allegiance lies—whether to the corporation or to the individual. When the individual is applying for a job in which his ill health may endanger others (as in the case of an airplane pilot) and if the physician finds evidence of some disorder likely to cause sudden incapacity, he is, without doubt, morally entitled to advise the corporation not to employ the person. When the question of danger to others does not arise and the physician finds some abnormality, he will, if he abides strictly by the Hippocratic oath, advise hiring the applicant.

A widely discussed moral dilemma is presented by the patient who is artificially kept alive by a machine. The question then may be whether the machine should be switched off. The frequency of this situation has been greatly exaggerated by some popular writers. In practice, most of the persons who are so maintained are young people with severe brain injuries. When they are first admitted to hospital, the extent of brain damage may be impossible to assess. Because many profoundly unconscious people recover, the patient is rightly attached to a machine. If, as time passes, it becomes clear that his brain is damaged beyond hope of recovery, the machine may properly be switched off, though the decision to do so is repugnant to make.

The commonest ethical problems involving doctors in the Western world relate to abortion and religious scruples against it.

#### LICENSURE REQUIREMENTS FOR PRACTICE

There are wide variations between countries in the requirements for practice, and a license to practice in one country only occasionally implies the right to practice in another. Even within some countries that have a federal system of government, there may be no equivalence of medical qualifications. The physician who qualifies in one state of the United States or in a province of Canada is not automatically entitled to practice in another state or province.

Throughout the world the most important requirements for practice are the taking of a prescribed course of study in a medical school and the passing of examinations. Most medical schools are faculties of universities, and the qualifying examinations are usually run by the universities. After passing the final examination, the successful candidate becomes a doctor of medicine (M.D.) in most countries; he becomes a bachelor of medicine and bachelor of surgery or chirurgery (M.B., B.S., or M.B., Ch.B.) in Britain and many Commonwealth countries, where M.D. is a higher qualification. In some countries, bodies other than universities may hold qualifying examinations. In Britain many medical students take the examination of the conjoint board of the Royal Colleges of Physicians and Surgeons, becoming members of the Royal College of Surgeons and licentiates of the Royal College of Physicians (M.R.C.S., L.R.C.P.).

**Britain.** The General Medical Council was established by the Medical Act of 1858. The preamble to the act began: "It is expedient that persons requiring medical aid should be enabled to distinguish qualified from unqualified practitioners." The chief duties of the council are to keep a register of duly qualified doctors and to ensure that the educational standard of entry to the register is maintained. All except three of the 49 council members are physicians; eight are nominated by the crown, and the remainder either by the Royal Colleges of Physicians, of Surgeons, and of Obstetricians and Gynaecologists, in the universities, or directly by the medical profession.

The council influences medical education mainly by issuing recommendations to universities and medical schools on such matters as the range of subjects in the curriculum and the scope of the examinations. Since 1953, students who have passed their final examinations have been placed on a provisional register; only after they have spent a year as a resident house officer are they placed on the full register.

The council also places overseas graduates on the full or

provisional register. By law it can do so only for graduates of countries that have reciprocal arrangements for registration with Britain. Such arrangements have been made with most Commonwealth countries and with the Republic of South Africa. Graduates from other countries may be placed on a temporary register, entitling them to work only in certain approved hospitals.

The function of the council that brings it most to public notice is in medical discipline. The council's primary duty here is to protect the public. The chief varieties of "serious professional misconduct" that may cause a physician to be summoned before the council are addiction to drugs or alcohol, the abuse of his professional position (as by having sexual relations with a patient or by revealing confidential information), advertising, and canvassing for patients. The disciplinary committee of the council derives its information from lawcourt proceedings or by direct written complaints from individuals. If the committee finds that a physician has been guilty of "serious professional misconduct," it may warn him as to his future behaviour, put him on probation, advise him to have treatment (especially for addiction), suspend him from duty immediately (this is chiefly used when a physician appears mentally deranged), or, as the supreme penalty, direct the registrar to erase his name from the register.

**United States.** Each state has the constitutional right to grant licenses to practice medicine within its boundaries. In consequence, the policies and legislature provisions concerning the practice of medicine vary from state to state. A citizen of the United States who has qualified in medicine in one state is not automatically entitled to practice in any other state.

In the state of Illinois, for example, the Medical Practice Act lays down that no person may receive a license to practice medicine unless he has passed an examination of the Department of Registration and Education. The candidate must be a citizen of the United States or be in process of becoming one, and he must prove that he has had the preliminary general and professional education required by the act, detailed provisions as to the medical training required being laid down.

The Illinois Department of Registration and Education may, without examination, issue a license to a person who has been licensed in another state or country, provided he is a United States citizen or in process of becoming one and is a graduate of a medical college of good standing. The state or country in which the candidate was licensed must accord the same privileges to physicians licensed in Illinois. The department may also issue a limited license entitling the holder to practice only under supervision in certain hospitals.

In addition to the examinations of the individual states, there is a National Board of Medical Examiners, which holds regular examinations. Success in these entitles a physician to practice without further examination in all except five of the states. Only graduates of approved medical schools in the United States or Canada are allowed to take the national board examinations.

The State Department has ordered that visas not be issued to foreign physicians unless they have passed the examination held by the Educational Council for Foreign Medical Graduates. This examination includes a test in English. When the foreign physician has passed this examination, he must also satisfy the authorities in the state where he wishes to practice by either passing the examination held by the state examination board or by other means (such as the method just described for Illinois).

**Other countries.** In France, the medical practitioner must hold the French state diploma of doctor of medicine (unless he is covered by special provisions relating to Alsace and Lorraine and the Saar) and must, in general, be a French citizen. A citizen of a state that has granted the right of French citizens to practice on its territory may be authorized to practice medicine in France provided that an agreement to this effect with the state concerned has been reached and that the standing of the diploma is recognized by the minister of national education.

In the Federal Republic of Germany (West Germany),

Medical  
degrees

National  
Board of  
Medical  
Examiners

the medical practitioner must be a German citizen, must have passed the qualifying examination, and must have completed a two-year period of internship. In principle no foreigner may practice medicine in West Germany, though exceptionally a permit to do so may be granted to a person who has fulfilled the training requirements of the Federal Republic.

In other countries of western Europe, the situation is similar to that in France and Germany, though it is usually easier for foreign physicians to practice in the small countries than in the large ones. Italy has limited reciprocity arrangements with Germany, Portugal, and Spain, and physicians may obtain licenses to practice throughout the Scandinavian countries.

In India, a Medical Council maintains the Indian Medical Register, and any person on this register may practice anywhere in India. There are also state medical registers for the individual states, and people in these registers are also in the Indian Medical Register. Those who have obtained a degree from a university, usually M.B., B.S., or the qualification of licensed medical practitioner (L.M.P.) are entered in these registers. Qualifications from many foreign countries, including Britain, Australia, Burma, Canada, Pakistan, Ceylon, and Italy, are also recognized for entry to the registers.

#### LEGAL RESTRICTIONS ON PRACTICE

In most countries most physicians are only rarely conscious of legal restrictions on their activities. These restrictions are mainly concerned with procedures performed on minors and mentally disordered patients, operations for abortion and sterilization, the notification of certain maladies, death from unnatural causes, and the use of certain drugs.

Procedures are not usually done on minors without the agreement of the parents. The legal position when a parent is unavailable is, in Britain and the United States, not clear, but, if the physician does what he thinks best, there seems no risk of his being later taken to court. Legal difficulties with children largely arise when parents refuse to allow some action that the physician considers necessary.

When a patient dies, a death certificate must be issued by a physician who has been in attendance. If the physician suspects that death has been due to other than natural causes, he must by law report the matter to some official person. In England and most of the United States, this person is the coroner; and in Scotland, the procurator fiscal. The coroner is appointed in England, always has a legal qualification, and frequently also is a qualified physician. In most of the United States the coroner is elected, often on the party political ticket. Some states, starting with Massachusetts in 1888, have a medical examiner instead of a coroner. The coroner or medical examiner usually orders a postmortem examination. If this shows that death was due to natural causes, the coroner signs the death certificate. If death is found to be due to violence or other unnatural cause, an inquest is held, and, if appropriate, criminal proceedings follow. On the continent of Europe, no single executive officer is responsible for dealing with cases of sudden death. When there is a suspicion of crime, the death is reported to the police, who may inform the public prosecutor.

In civilized countries the only people other than criminals who can be legally incarcerated are those affected by so grave a degree of mental disorder that they are a danger to themselves or others. Physicians are concerned in this incarceration, for they have to sign appropriate certificates, though various legal officials may also be involved.

In most countries the physician has a legal obligation to report certain maladies. These requirements vary from place to place and time to time, but the main maladies involved are certain infections (which may result in epidemics) and certain industrial diseases.

There are legal restrictions on the use of certain drugs nearly everywhere. The sale of a few drugs is totally prohibited in some countries. Thus, heroin is prohibited in the United States and most other countries apart from

Britain and West Germany, because addiction to it is particularly likely. The sale of other dangerous or addictive drugs may be severely restricted. In Britain there is a Dangerous Drugs Act, under which there are stringent regulations as to the prescription, storage, and issuing of morphine and other drugs of addiction. Radioactive substances are also subject to severe restrictions.

In some countries there are laws compelling citizens to accept certain measures to prevent disease. Smallpox vaccination used to be compulsory for all children in Britain, though there was a clause excepting the children of conscientious objectors to vaccination. In a law of 1966, compulsory immunization against poliomyelitis was introduced for all infants in Italy.

There are laws restricting the termination of pregnancy in all countries. In most of the Communist countries and in Japan, a woman is entitled to have an abortion early in pregnancy if she wishes it, but abortion is illegal later than about the fourth month. In all other countries, there must be some specified ground for abortion, and the wish of the patient is not of itself a ground. In most of the predominantly Roman Catholic countries, such as Ireland and Italy, abortion is illegal except when the woman has a diseased womb that needs to be removed but that incidentally contains a fetus. The penalty for breaking the law may be a long term of imprisonment. In many predominantly Protestant countries, the abortion laws have been made more liberal in the second half of the 20th century, notably in Britain by an act of 1967. In these countries the decision for or against abortion is in practice more an ethical than a legal matter. If a physician's ethical views allow him to advise abortion, the law is such that he can usually recommend it legally on the practical ground that he believes it is in the woman's best interest to have it.

Suicide used to be a crime in all countries of Christendom, but this is no longer so in many countries, including Britain and many states of the United States. The doctor who deals with patients who have taken overdoses of drugs need not, therefore, consider the legal aspects of the matter.

Perhaps the way in which the physician is most likely to become involved with the law in most countries today is in suits for malpractice. Such actions are especially common in the United States. Those most likely to be sued are surgeons, since malpractice is much more easy to prove when a surgical operation is done. When, for example, a surgeon has left an instrument or a swab behind in the wound, he is clearly liable at law. The surgeon is also liable to be sued because a patient is dissatisfied with the result of the operation. Plastic surgeons are most of all at risk; many of their operations are done solely to improve the patient's appearance, and, if he does not like the result, he may sue. Consequently, plastic surgeons in the United States may find it prohibitively expensive, or even impossible in some states, to obtain insurance coverage against malpractice suits.

Internists and general practitioners are, by contrast, comparatively rarely sued for malpractice. They may make serious errors, especially by prescribing the wrong drug and occasionally by failing to prescribe the right drug, but such errors rarely come to light. Even if a patient or his relatives suspect that such errors have been made, it can hardly be proved in a court of law that the physician was criminally negligent. An error of judgment by a physician is not a crime.

In the United States, because of fear of suits for malpractice, many persons, both physicians and others, have been slow to go to the aid of victims of traffic accidents. In response to this problem, a number of states enacted legislation, so-called good samaritan laws, to protect physicians and others from such suits.

#### PROFESSIONAL ORGANIZATIONS AND THE MAINTENANCE OF STANDARDS

From medieval times there have been professional medical organizations concerned with maintaining standards. In England the physicians established their college in 1518, and candidates for admission were required to read certain books and were set examinations. The United

tions

Company of Barber-Surgeons was established in 1540, and apprentices had to serve for seven years as other apprentices did, attend lectures and dissections, and pass an examination before being allowed to practice on their own account.

The American and British medical associations, to which most physicians belong, publish weekly journals in which appear original articles and review articles. Both associations also publish numerous specialist journals. There are many other medical journals. The prime means by which most physicians keep up to date is by regularly reading their journals.

The medical associations hold meetings and conferences and run courses. There, papers are read, demonstrations made, and discussions held. All these practices help in the continuing education of the physician throughout his career. Participation in continuing medical education has been made a requirement for membership in some organizations.

In Britain the Royal Colleges also maintain standards by holding examinations. Medical doctors must pass the fellowship examination of the Royal College of Surgeons of England or the membership examination of the Royal College of Physicians of London (or of the sister colleges in Scotland and Ireland) before they can hope to become consultant surgeons or physicians. Gynecologists must pass the membership examination of the Royal College of Obstetricians and Gynaecologists. The British system is sometimes criticized because it involves too many examinations.

Most hospitals in the United States are assessed by the Joint Commission of Accreditation of Hospitals, set up by the American Medical Association, the American Colleges of Surgeons and Physicians, and the American Hospital Association. This assessment involves a triennial inspection of buildings, equipment, patients' records, and internal hospital organization. This accreditation process has a great effect in improving hospital standards.

Within the voluntary community hospitals, there are committees for the maintenance of standards. The credentials committee investigates the credentials of all applicants for membership of the medical staff. The tissue committee maintains an individual audit on all surgeons and investigates all cases of removal of normal tissue, discrepancies between preoperative and postoperative diagnosis, and cases of possibly unjustified surgery. General practitioners on the staffs of the hospitals are appointed to the department of medicine or surgery, depending on their experience and interest, and their staff privileges are exactly delineated. Thus, it may be specified that a doctor may perform appendectomy, but no other abdominal operation. In certain situations, such as a first cesarean section or sterilization operation, it is laid down that consultation with another doctor, preferably a specialist in the condition concerned, must be held. These detailed specifications have no counterpart in most other countries.

The situation in other developed countries is similar in other respects to that in Britain and the United States.

**BIBLIOGRAPHY.** JOHN FRY, *Medicine in Three Societies* (1969), compares hospital care and other medical facilities in the United States, Britain, and the Soviet Union. DONALD HUNTER, *Health in Industry* (1959), gives a succinct account, intended for the general reader, of the health problems of industry throughout the world, and includes a historical section. MAURICE H. KING (ed.), *Medical Care in Developing Countries* (1966), describes the grave health problems in the developing countries and discusses means of solving them.

### Mediterranean Folk Cultures, Western

The western Mediterranean folk cultures include the peoples of southern Portugal, southern Spain, and southern Italy—the dry zone in the south of Europe bordering on the Mediterranean. It forms in its entirety a region linking Europe with North Africa. In the past the societies on the southern shore of the Mediterranean have made incursions into the area to the north and left behind important elements of their culture. The Arabic expressions,

words, and place names abounding throughout the area bear witness to more than 200 years of domination by Arabic culture. So also does the architecture, notably the Moorish palaces and forts of southern Spain and Sicily. The seclusion of women, so customary in this area, probably also derives from Arabic influence.

In other respects the area shows a remarkable unity of European culture elements deriving from the Hellenic, Roman, and Christian traditions. The Mediterranean has always provided the communication necessary for the diffusion and maintenance of distinct cultural elements, and it has acted as a barrier to easy penetration from the south.

Though the area today is economically marginal to the rest of Europe because of its impoverished agricultural system, it has not always been poor. Once it was rich in agricultural and mineral resources. The mountains and hills, today eroded, were at one time densely forested. The countryside was sunny and reasonably well watered. It provided a fertile agricultural milieu that invited incursions from the Greeks, Romans, and Arabs, all of whom sought additional resources to sustain their expanding populations. This led to large-scale exploitation of the forest for wood and to the establishment of grain and livestock farming. The transformation had important consequences for the local climate and drainage: as the vegetation disappeared, the summers became relatively drier and the winter rains washed the soil from the eroding slopes, creating unhealthy marshes along the coast. The progressive deterioration of the terrain is one of the characteristic long-term processes in the area, continuing from ancient times to the present. National governments have recently sought to restrain it, but without success. One characteristic of the area is that central government has always been weak.

#### CULTURAL PATTERNS

The folk societies in the western Mediterranean all show a strong urban orientation and a pronounced polarization between landowners and peasants. The urban orientation is evident in the settlement pattern. Hill-top villages and huge farm towns predominate in much of the region, and in between them lies the empty countryside. Profit from the chief crops—cereals, wines, olive oil, and livestock products—does not flow back to the countryside in the form of investment in roads, farm buildings, irrigation, and general improvements on the land. Instead, it is spent by the absentee landlords living in towns and cities, often outside the area. This pattern of capital accumulation widens the gap between the elite and the peasantry, between town and country. There is a general disdain for manual work, and those who labour on the land are looked down upon. The countryside is regarded as devoid of civilized life. This social and geographical distance has made room for a rural middle class between the landowners and the peasants.

The gulf between city and country corresponds to the distribution of political power. Until recently there were few ties linking the various regions into a comprehensive whole. Because landowning elites held local and regional power, central government has had to find some form of accommodation with them in order to maintain peace and collect its revenues.

In the absence of effective state control, the people have been largely dependent upon themselves. They could not rely on organized corporate kinship groups, such as clans and tribes, for the dominant residential and productive unit throughout the area has been the small nuclear family. Instead, they have traditionally turned to particular kinsmen, friends, and powerful local strong men to settle conflicts and to right wrongs. This has meant a high level of open violence: banditry and feuding have been endemic, and until recently peasant rebellions were frequent. These conditions buttressed the local enclaves of power and set strong limits on the development of central control.

Mass emigration to the Americas in the period around 1900 reinforced this distribution of power, for it reduced the number of potential malcontents. In the period since

The gulf  
between  
town and  
country

World War II, the migration of workers to industrial areas in the north has altered the balance of power at local and regional levels. Wages earned in northern industries have given the peasants alternative resources, making them less dependent upon the local power holders.

**Social organization.** All western Mediterranean folk societies belong to larger political units or states. In each country there is considerable cultural, economic, and political variation from region to region. Such differences are often expressed in rivalry and competition between region and state. These decentralizing forces have recently been granted formal recognition in Italy. In Spain, on the other hand, such regional autonomy has been resisted by the authoritarian regime.

Throughout the whole area, states rather than nation-states have been predominant. People see themselves as subjects of rulers rather than as citizens of a nation.

To protect themselves from bandits and outlaws, not to mention Arab and Turkish pirates in search of booty and slaves, the population long ago crowded together in tightly knit villages and towns for mutual protection. Feudal lords, most notably in Sicily, founded a number of such farm towns to facilitate their control over the peasants as well as to extend the area of cultivated land. Cereal production and livestock breeding did not necessitate permanent settlement on scattered farms. With the growth of population in the 19th century, increasing numbers of peasants became landless and had to live near the labour market, which was located in the town's central square. Scarcity of water, the prevalence of malaria, and the absence of usable roads also encouraged concentration in towns. The political status of these communities for a long time was feudal, and even after feudalism ended in the early 19th century they remained dependent upon groups of local landowners.

The last century has seen a movement from inland areas to the coast, where a number of new settlements have been established. Following World War II the increasingly efficient state apparatus, aided by the World Health Organization, eliminated malaria in the western Mediterranean. The states also have succeeded in eliminating banditry in a number of areas. These factors have enabled many peasants to settle on the land. Scattered farms have been increasing, except in western Sicily and inland Sardinia where banditry is still rife.

**Economy.** The principal crops in the western Mediterranean are the same today as they were in Roman times: wheat, wines, and olive oil produced in conjunction with extensive cattle, sheep, and goat breeding. The agricultural structure is still highly polarized: on the one hand, small family farms produce a variety of products, both for consumption and for the market, but cover little of the total area; on the other hand, large holdings (*latifundia*) produce cereals and livestock for the market. Until the 19th century the *latifundia* covered most of the arable land.

The fields are rotated among wheat, pasturage, and fodder crops. On the large holdings there are various forms of sharecropping, in which both the cultivator and the owner-manager share the output. Sharecropping contracts are renewed annually. This form of tenure does not encourage capital investment by either of the parties involved. Harvest hands are recruited chiefly from the growing category of landless peasants.

The impact of recent land reforms has been slight; they have contributed more to the fragmentation of land holdings than to increased production. Cultivation methods are still traditional, despite the introduction of labour-saving machinery. The increasing scarcity of agricultural labour, which since 1955 has been migrating to north European industrial regions, and the abolition of protective tariffs had by 1970 seriously inhibited grain production. Marginal lands were increasingly being used to pasture livestock.

Under the traditional inheritance laws, property is divided equally among all heirs. With the growth of population, this has brought about a progressive division of the smaller holdings into very small plots. The heirs of

small holders do not inherit economically viable units. Wealthy landowners, on the other hand, often have fewer children, and their superior education enables them to take up alternative pursuits such as the church and the professions. Many also stay unmarried to maintain the family patrimony.

**Family and kinship patterns.** Western Mediterranean countrymen live primarily in small nuclear families—that is, in households consisting of married couples with their unmarried children. The family is also the primary production unit. The kinship structure is bilateral, the children having equal access to both the father's and the mother's relatives. Godparenthood and friendship are important in cementing relationships outside the household, for people cannot rely upon public institutions to protect their interests.

Authority over the economic activities of the family is vested in the father, who serves as business manager of the family and represents it in the public sphere. Unmarried children work under his supervision. The dominant position of the father is reinforced by the teachings of the Roman Catholic Church. A man's social status as a person with honour is closely linked to his ability to maintain or improve the economic position of his family and to safeguard his wife and daughters. His women constitute a permanent danger to his honour, being regarded as morally weak. The preoccupation of men with honour is a strong element in the culture of the area.

Women, although subordinate to the men and more or less confined to the household, are by no means without influence. The woman administers the household finances. Among the western Mediterranean peasants, the relatives of the mother are visited more often and tend to play a more important role in family affairs than those of the father. In fact, a landless labourer who is not tied by property considerations to his own place of birth frequently moves upon marriage to the village of his wife so that the latter can be near her own relatives. This clustering of female relatives is consistent with a marked segregation between the sexes.

**The distribution of power.** Beginning in the early 19th century, a rural middle class gradually emerged from the leaseholders and supervisors of large estates and from the millers and waggons, who formed an intermediary category between landowners and peasants. This new class derived its power from its control of the links between the main social strata, between the regions, and between town and country. Its strategic position enabled it to attract a following of peasants who depended upon the members of this middle class for access to land and for protection. Their local power basis also enabled them to perform important services for the urban elite, who needed them to run the estates and to mobilize the voters at election time. The urban elite depended upon these rural entrepreneurs not only for success in the national political arena but also for prestige and standing in the city.

Where government was especially weak, respect and prestige tended to belong to individuals who were successful in the use of violence. In mountainous areas in Greece, inland Sardinia, and Sicily, this pattern of respect for violence still holds.

During the past century the power of the landowning classes has been threatened by mass parties of the left in parliamentary elections. To defend their interests, the landed elite have often entered into coalition with other conservative forces and supported right-wing dictatorships such as that of Benito Mussolini in Italy. In fact, the only conservative dictatorships in Europe in 1970 were in Portugal, Spain, and Greece. In postwar Italy, however, pressure from mass parties led to certain land-reform measures and to more favourable contracts for peasant labourers. These to some extent reduced the power of the rural elite.

**Religion and art.** The established religion is Roman Catholicism. Not surprisingly, the church has been closely associated with the interests of the landowners, who have supported it by their financial contributions and their participation in church-run lay associations. The peasants, on the other hand, have been generally

Role  
of the  
father

The rural  
middle  
class

Farm  
towns

*Latifundia*  
and small  
holdings

unsympathetic to the church, when not openly hostile. This latent anti-clericalism has sometimes assumed extreme forms, as in the desecration of churches and the assassination of priests during the Spanish Civil War of the 1930s. The cult of the saints is particularly strong. There is a striking similarity between the role of saints as intermediaries between God and man and the role of the patron who intercedes with a powerful person on behalf of his client.

Belief in magic

Although nominally practicing the established religion, many peasants also adhere to other beliefs and practices. Many of these involve the use of love potions and the recitation of incantations and spells to cure ills, most often administered by wise old women who function as informal priestesses. The established religion generally condemns such practices, but in most rural areas they are firmly entrenched. Everywhere one finds belief in the evil eye and in the power of envy to do evil. This is related to the peasant notion that one person's gain must necessarily be at the expense of someone else.

The music of the peasants is often extemporaneous, played on simple stringed instruments and sung as a lament or a satirical attack on a rival. Much folk music still bears traces of Arabic influence. Everywhere, however, this traditional music is rapidly being replaced by the popular music of western Europe, which penetrates via television, transistor radio, and record player to even the most remote hamlet.

#### LONG-TERM TENDENCIES

The general social and cultural patterns sketched above are being modified by long-term developments in the wider societies in which the peasant communities are embedded. These long-term processes include the rising level of education, the growing division of labour, increasing centralization, and the growing economic dependence of southern Europe on the north. At the same time, modernization is eroding the traditional basis of peasant society and reducing the relative importance of the resources on which the traditional elite based its power.

The increasing dependence of Mediterranean Europe on its industrialized northern neighbours does not offer a fundamental solution to the economic problems of the area. Migrating peasants have become industrial labourers abroad. The vast sums of money that they send back to their families cannot be productively invested in the transformation of the economy because that would require a coordination of groups and regions that is still far from being realized. The funds are mainly spent on consumption goods and on the purchase of fragments of land.

The growing integration of Europe has made the south increasingly dependent upon the north. A sharp economic recession in the north not only would affect the industries in the Mediterranean countries, forcing them to lay off local workers, but also would send hundreds of thousands of migrant labourers back to the south. Such a recession would also severely curtail the flow of northern tourists. The south European, in short, is still the odd-job man of Europe: he cleans up after the Dutchman, the German, the Swiss, and the Belgian in their home countries, performing the tasks they no longer want to do, and waits upon them when they come to the Mediterranean on holiday. He is likely to be the first to suffer in time of economic difficulty. Peasants and post-peasants in the western Mediterranean are still among the most marginal men of Europe.

The odd-job man of Europe

## Mediterranean Sea

The Mediterranean Sea, the great expanse of waters that, stretching from the Atlantic Ocean on the west to Asia on the east, separates Europe from Africa, often has been called the incubator of Western civilization.

This ancient "sea between the lands" occupies a deep, elongated, and almost landlocked irregular depression lying between 30° and 46° N and between 5°50' W and 36° E. Its east-west extent is approximately 2,500 miles (4,000 kilometres), while its average north-south extent is about 500 miles. The Mediterranean Sea, including the Sea of Marmara and the Black Sea, occupies an area of 1,145,000 square miles (2,966,000 square kilometres); its area excluding the Black Sea is close to 970,000 square miles.

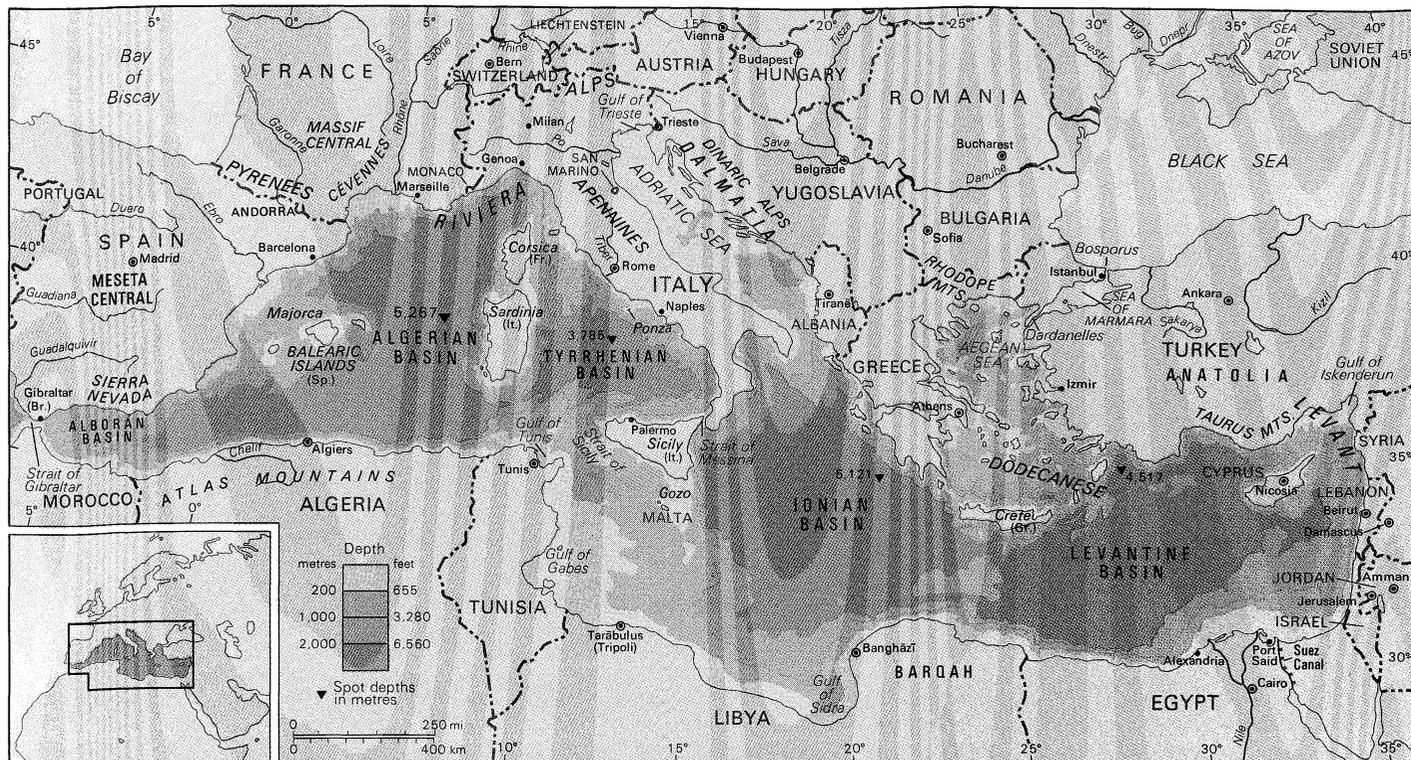

The western extremity of the Mediterranean connects with the Atlantic Ocean by the narrow and shallow channel of the Strait of Gibraltar, which is only eight miles wide at its narrowest point and the depth of the sill, or submarine ridge separating the basins, is 1,050 feet (320 metres). To the northeast the Mediterranean Sea is connected with the Black Sea through the Dardanelles (with a sill depth of 230 feet) the Sea of Marmara, and the strait of the Bosphorus. To the southeast it is connected with the Red Sea by the Suez Canal. (For further details, see EUROPE; ADRIATIC SEA; AEGEAN SEA; BLACK SEA.)

#### THE PHYSICAL ENVIRONMENT

**Natural divisions.** A submarine ridge between the island of Sicily and the African coast, with a sill depth of about 1,200 feet, divides the Mediterranean Sea into western and eastern parts. The western part, in turn, is subdivided into three principal submarine basins. The Alborán Basin is east of Gibraltar, between the coasts of Spain and Morocco. The Algerian (sometimes known as the Algero-Provençal, or Balearic) Basin, east of the Alborán Basin, is west of Sardinia and Corsica, extending from off the coast of Algeria to off the coast of France. The Tyrrhenian Basin, that part of the Mediterranean known as the Tyrrhenian Sea, lies between Italy and the islands of Sardinia and Corsica. The eastern Mediterranean is subdivided into two major basins. The Ionian Basin, in the area known as the Ionian Sea, lies to the south of Italy and Greece, where the deepest sounding in the Mediterranean, about 16,000 feet (4,900 metres), has been recorded. A submarine ridge between the western end of Crete and Barqah (Cyrenaica) separates the Ionian Basin from the Levantine Basin to the south of Asia Minor, and the island of Crete separates it from the Aegean Sea, which comprises that part of the Mediterranean Sea north of Crete and bounded on the west and north by the coast of Greece and on the east by the coast of Turkey. The Aegean Sea contains numerous islands known as the Grecian archipelago. The Adriatic Sea (*q.v.*), northwest of the main body of the Mediterranean Sea, is bounded by Italy to the west and north and by Yugoslavia and Albania to the east.

**Geology and physical geography.** The Mediterranean is the main existing fragment of the Tethys Sea, which formerly girdled the Eastern Hemisphere. The structure and present form of the basin and its bordering mountain system have been determined by the convergence and recession of the relatively stable continental blocks of Eurasia and Africa. The interpretation of geological data suggests that there are, at present, areas of constriction between Africa and Eurasia the amplitude of which appears to be several centimetres a year. The use of laser tellurometry has demonstrated the intermittent nature of this phenomenon.

**The western Mediterranean.** The Tyrrhenian Basin of the western Mediterranean has two exits into the eastern

The Mediterranean Sea and its basin.

Mediterranean, the Strait of Sicily and the Strait of Messina, both of which were of great strategic importance throughout Mediterranean history. The submarine relief of the Sicilian channel is rather complicated; the group of islands composed of Sicily, Malta, Gozo, and Comino, all of which are of Tertiary limestone, stands on a submarine shelf that extends southward from Sicily.

The widest of the continental shelves is off Spain's Ebro Delta, where it extends to 60 miles. Similarly, west of Marseille the shelf widens off the Rhône Delta area to 40 miles. Off the Italian peninsula the shelf is narrow, and the slopes are mostly quite low. The narrow shelves continue along the French Riviera, but the slopes show a marked increase where they are cut by many canyons and troughs.

Along the Atlas Mountain coast of North Africa, a narrow shelf bordered by slopes is found from the Strait of Gibraltar to the Gulf of Tunis. The slopes are cut by many canyons or troughlike indentations.

The coasts of the western Mediterranean, just as those of the eastern basin, have been subjected in recent geological times to the uneven action of deposition and erosion. This action, together with the movements of the sea and the emergence and submergence of the land, resulted in a rich variety of types of coasts. The Italian peninsula underwent considerable uplift in post-Pliocene times (the last 2,000,000 or so years), as a result of which a strip of Late Tertiary rocks has been exposed on the Adriatic flank of the Apennines. The Italian Adriatic coast exemplifies a coast owing much to emergence. Examples of coasts the outline of which is due to submergence are the granite coast in northeast Sardinia and the Dalmatian coast where the eroded land surface has been sunk, producing elongated islands parallel to the coast. The deltas of the Rhône, Po, Ebro, and Nile rivers are good examples of coasts resulting from the deposition of silt.

*The eastern Mediterranean.* The Sicilian straits scarcely exceed 1,500 feet in depth, so that there is essentially a shelf from Tunisia to Sicily separating the Mediterranean into two parts. South of the straits the shelf widens to as much as 170 miles off the Gulf of Gabes on the eastern coast of Tunisia. The first mud appears on the approach to the Nile Delta, and the shelf widens again to 70 miles off Port Said at the entrance to the Suez Canal. The shelves continue to be narrow along most of

the northern shore of the Mediterranean. An exception is the broad shelf extending for 300 miles along the inner portion of the Adriatic Sea. Relatively deep water is found along much of the coast of Yugoslavia and along the Italian coast, in contrast to the gentle slopes of the Po Valley.

The northern shores of the eastern Mediterranean are very complex and, unlike the southern shores, have variable fold mountains that offered favourable sites for the development of the Mediterranean civilizations.

The north coast of Africa bordering the eastern Mediterranean is low-lying and of monotonous uniformity except for the Barqah highlands in Libya, which lie to the east of the Gulf of Sidra.

The largest islands of the eastern Mediterranean are Crete and Cyprus, both of which are mountainous.

**Hydrology.** The hydrological conditions in the Mediterranean are dominated by the presence of three layers of water masses: the surface layer, the intermediate layer, and the deep layer that continues down to the bottom, a separate bottom layer being absent.

The surface layer has a thickness varying between 250 and 1,000 feet. This variable thickness is determined in the western basin by the presence of a minimum temperature at its lower limit. In the eastern basin the temperature minimum is generally absent, and a layer of low temperature decrease is found instead.

The intermediate layer is accompanied by warm and saline water coming from the eastern Mediterranean and characterized by temperature and salinity maxima at 1,300 feet. This layer is situated at depths between 1,000 and 2,000 feet.

The deep layer occupies the remaining zone between the intermediate layer and the bottom. The approximate temperatures in this zone are: 55.2° F (12.9° C) at 3,000 feet and 55.6° F (13.1° C) at 8,200 feet; its salinity is 38.40 parts per thousand or slightly less. In general, the water of this layer is very homogeneous.

**Currents.** The Mediterranean Sea receives from the rivers that flow into it only about one-third of the amount of water that it loses by evaporation. In consequence there is a continuous inflow of surface water from the Atlantic Ocean. After passing through the Strait of Gibraltar, the main body of the incoming surface water flows eastward along the north coast of Africa. This cur-

Continental shelves and coasts

rent is the most constant component of the circulation of the Mediterranean. It is most powerful in summer, when evaporation in the Mediterranean is at a maximum. This inflow of Atlantic water loses its strength as it proceeds eastward, but it is still recognizable as a surface movement in the Sicilian channel and even off the Levant coast.

A small amount of water also enters the Mediterranean from the Black Sea as a surface current through the Bosphorus, the Sea of Marmara, and the Dardanelles.

By evaporation, the Mediterranean water becomes more saline, with a corresponding increase in density. It therefore sinks, and the excess of this denser bottom water emerges into the Atlantic Ocean over the sill forming the shallow Strait of Gibraltar, as a west-going subsurface current below the inward current. The latter extends from the surface down to 230 or 260 feet. The Mediterranean has been metaphorically described as breathing, inhaling surface water from the Atlantic and exhaling deep water in a countercurrent below.

The fundamental surface circulation of the Mediterranean consists of separate counterclockwise movement of the water in each of the two basins.

Because of the complexity of the northern coastline and of the numerous islands, many small eddies and other local currents form essential parts of the general circulation. Tides, although only significant in range in the Gulf of Gabes and in the northern Adriatic, add to the complications of the currents in narrow channels such as the Strait of Messina.

Historically, large seasonal variations in the Nile discharge influenced the hydrology, productivity, and fisheries of the southeastern part of the Mediterranean. It reduced the salinity of the coastal waters and increased both the stratification and productivity of these waters. The Aswān High Dam (1970) stopped the seasonal fluctuation of the discharge of the Nile water into the Mediterranean.

The Suez Canal between the Mediterranean and Red seas passes negligible amounts of Red Sea water into the Mediterranean.

The general water budget of the Mediterranean is given in Table 1.

gains		cu ft/sec		cu m/sec		losses		cu ft/sec		cu m/sec	
Inflow from the Atlantic	61,800,000	1,750,000				Outflow to the Atlantic	59,330,000	1,680,000			
Inflow from the Black Sea	445,000	12,600				Outflow to the Black Sea	215,000	6,100			
Precipitation	1,115,000	31,600				Evaporation	4,075,000	115,400			
Runoff	260,000	7,300				Total	63,620,000*	1,801,500			
Total	63,620,000	1,801,500									

\*Totals do not correspond because of rounding.

**Seawater temperature.** The 40° N parallel runs through the middle of the western basin, whereas the corresponding latitude of the eastern basin is 6° farther south, a fact that explains the higher surface temperature of the latter.

The highest temperature of the Mediterranean is met within the Gulf of Sidra, off the coast of Libya, where the mean temperature in August is around 88° F (31° C). This is followed by the Gulf of Iskenderun, Turkey (mean temperature about 86° F [30° C]). The lowest sea temperatures are found in the extreme north of the Adriatic, where the mean temperature in February falls down to 41.4° F (5.2° C) in the Gulf of Trieste. In this region ice occasionally forms in the depth of winter.

**Salinity.** Just as in all other seas and oceans, chlorides constitute more than half of the total ions present in the Mediterranean water, and the proportions of all the principal salts in the water are constant.

Assuming that in Mediterranean waters the average salinity (weight of dissolved ions per 1,000 parts; *i.e.*, grams per kilogram) is 38, usually expressed as 38 per mille (thousand) or 38 ‰ (3.8 percent), as compared with 35 ‰ for the oceans, then the composition of the major ions in the Mediterranean would be as given in Table 2.

Table 2: Major Ions Dissolved in One Kilogram of Mediterranean Seawater

(salinity = 38 parts per thousand)

	gm/kg		gm/kg	
Chlorides	20.815		Magnesium	1.402
Sulfates	2.918		Calcium	0.437
Bicarbonates	0.156		Potassium	0.418
Sodium	11.636		Others*	0.218
Total				38.000

\*Present in minute quantities.

**Dissolved oxygen.** The distribution of oxygen is in agreement with the origin of the different water masses. The surface layer down to 700 feet shows a high oxygen content all over the Mediterranean. The intermediate layer that is formed by the sinking of the surface layer in the eastern basin has a high oxygen content where it is freshly formed in this basin; but, as it moves westward, it loses some of its oxygen content, the lowest values occurring in the Algerian Basin. The transition layer between the intermediate and the deep water is characterized by an oxygen minimum.

**Plant nutrients.** In the Mediterranean Sea, plant nutrients such as phosphates, nitrates, and nitrites are scarce. Just as in all other seas, these nutrients show seasonal fluctuations, generally with a rise in the spring, the blooming season. The scarcity of nutrients in Mediterranean waters is attributed to several factors, the most important being that the Mediterranean receives its main bulk of water from the surface water of the Atlantic Ocean, which is itself not rich in these nutrients.

In the western basin below 3,000 feet the contents of phosphates and nitrates are less than one-half of the amounts in the open ocean at the same depths.

The shortage of phosphates and nitrates in Mediterranean Sea water, so vital for the creation and the maintenance of the marine life cycle, results in the limited productivity of the region in terms of the life-forms it supports.

**Climate.** The flow of the air into the Mediterranean Sea takes place through gaps in the mountain ranges, except over the southern shores east of Tunisia. Strong winds funnelled through the gaps are the most important. The mistral, a cold, dry, northwesterly wind, passes through the Alps-Pyrenees gap, the strong northeasterly bora passes through the Trieste gap, and the cold easterly levanter and the westerly vendaval pass through the Strait of Gibraltar. The warm, dusty southeasterly that blows from Saharan Africa is known as the gibleh or khamsin. In the eastern Mediterranean the estian winds are steady, dry northwesterlies and northerlies; the sirocco, from Africa, is dry and hot.

The Mediterranean weather is characterized by windy, mild, wet winters and relatively calm, hot, dry summers. Spring, however, is a transitional season and is changeable. Autumn is relatively short.

The amount and distribution of rainfall in the Mediterranean cannot be generalized. Along the North African coast from Qābis (Gabes) in Tunisia to the Arab Republic of Egypt, more than ten inches (250 millimetres) of rainfall per year is rare, whereas, on the Dalmatian coast of Yugoslavia, there are places with 100 inches.

#### ANIMAL LIFE AND VEGETATION

Because the primary productivity of life-forms depends to a large extent on the concentration of the plant nutrient salts, it is, as would be expected, generally low in the Mediterranean Sea. The effective potential productivity in various regions of the Mediterranean as measured by radioactive methods using carbon-14 to determine the amount of carbon produced in milligrams of carbon per cubic metre of water (expressed as mg C/m<sup>3</sup>) per 24 hours, varies from five to 150 mg C/m<sup>3</sup> per 24 hours. The lowest values are observed in the Levant, ranging from five to 30 mg C/m<sup>3</sup> per 24 hours, and also in the Ionian Basin, where values ranging between seven and 21 mg C/m<sup>3</sup> per 24 hours are observed.

The highest primary-production values in the Mediter-

Scarcity of nutrients

anean Sea are observed in springtime (March–May) off the Egyptian coast in areas under the influence of the Nile. There primary-production values as high as 700 mg C/m<sup>3</sup> per 24 hours are found.

**Fish stocks and fisheries.** The environmental conditions of the Mediterranean already described, namely, the low concentration of phosphates and nitrates so necessary for the maintenance of marine pastures, together with the poor standing crop of bottom-dwelling organisms, provide no opportunity for the evolution of a big fisheries industry.

Although the general lack of large concentrations of fish has prevented the development of large-scale operations, the high prices of fresh fish in most Mediterranean countries have favoured the development of a large number of small-scale fisheries. Though the boats used are rather small, rarely exceeding 70 feet long, their numbers are sufficient to deplete the local stocks through overfishing. The tendency to overexploitation is strengthened by the use of trawl nets with very small mesh size that retain the smallest individuals.

The fish fauna of the Mediterranean is basically related to the fauna of the subtropical Atlantic with a large variety of species. Of the demersal (bottom-living) fishes, flounders, sole, turbot, whiting, congers, croakers, red mullet, gobies, gurnards, lizard fish, redfishes, sea bass, groupers, combers, sea breams, pandora, and jacks and cartilagenous fishes such as sharks, rays, and skates are all caught by the trawlers. Among the demersal fish, hake is one of the more important in all countries bordering the Mediterranean Sea. It is caught in deeper waters.

Rocky coasts provide a valuable harvest of lobsters, crabs, shrimp, and prawns. Oysters are more common on shallower alluvial coasts. The brackish lagoons and deltas provide eels, anchovies, and gray mullets.

Pelagic species

About half of the Mediterranean and Black Sea catches are of pelagic species (those caught in the upper layers of the sea). Sardines constitute the main catch in the western and northeastern parts of the Mediterranean. Occasionally sardines also appear in relatively small quantities in the southeastern part of the Mediterranean. The total yearly catch from the Mediterranean amounts to 366,000 tons. Closely related fishes (*Sardinella aurita* and *S. maderensis*), however, occur in considerable quantities in the southern and southeastern region of the Mediterranean. The sprat is taken in some quantities in the most northern parts of the Mediterranean such as the northern Adriatic. It also occurs in commercial quantities in the Black Sea. Anchovy is important in most of the regions of the Mediterranean and the Black Sea.

Of the really large fish there is one of great commercial value, the bluefin tuna that moves into the Mediterranean from the Atlantic and disperses in several directions, toward the southern and eastern coasts of Spain, the coasts of the Balearic Islands, the northern coast of Morocco, and the coasts of Sardinia, Sicily, Algeria, Tunisia, and Libya. Related species of economic value are the bonitos and the mackerels. They are caught in various quantities in practically all the countries of the region.

Of the nonedible products of the Mediterranean, the most important are the corals of Naples and the sponges of the Dodecanese, the Gulf of Gabes, and the western coasts of Egypt.

Annual catch

According to statistics of the Food and Agricultural Organization (UN), the total annual catch for the Mediterranean and Black seas' fisheries amounted in the early 1970s to about 1,200,000 tons. In terms of tonnage the leading catches are herrings, sardines, sprat, and anchovies over 300,000 tons; redfishes, basses, and congers, 100,000 tons; shads and milkfishes, 90,000 tons; and jacks and mullets, 70,000 tons. Catches of tunas, bonitos, and skipjack, of mackerels and bluefishes, and of cods, hakes, and haddocks are in the 25,000- to 30,000-ton range. Lesser amounts of sharks and rays, flounders, halibuts, and soles, river eels, porpoises, and sturgeons and paddlefishes are caught. Unsorted, or unclassified, fish account for almost 200,000 tons. Mollusks account for over 90,000 tons, and other crustaceans account for more than 25,000 tons.

**Vegetation.** The natural vegetations of the lands bordering the Mediterranean can be classified into six general types, one of which is the typical Mediterranean forest. The olive tree provides a satisfactory criterion for the distribution of Mediterranean climate. The holm (or holly) oak and the cork oak provide a better criterion. They tolerate low rainfall and a few months of drought. The conifers, especially the domestic pine, the maritime pine, and the Aleppo pine, are the remnants of the typical Mediterranean forests that suffered from extensive destruction by man. A characteristic feature of the landscape is provided by the macchia (or maquis, evergreen shrubs with hard, leathery leaves), which has widely replaced the conifers. Garigue in its different forms, including sage, prostrate prickly plants, and tuberous perennials, is commonly found in Greece, Spain, and Italy, especially where the soil is limey.

Another type of natural vegetation is the mixed green and deciduous forest, which occupies large areas in Greece, Albania, the north Aegean region, Spain, Portugal, the Alps, and the Apennines. It is made up of species adapted to short periods of drought and to cool winters, hence the presence of evergreens and also the deciduous oak.

A third type is the deciduous forest found in central Italy, where chestnuts occur between 2,000 and 3,000 feet. It extends to the Alps, Cévennes, and Pyrenees. The beech follows the chestnut in altitude.

Other vegetation types are the high coniferous zone, characterized by the white fir, widespread throughout the mountains of central Europe, the high pastures, and the arid zone.

Many plants have been introduced and cultivated in the Mediterranean lands by the Arabs and Spaniards. The more successful introductions include rice, cotton, oranges, sugarcane, maize, tobacco, potatoes, and sisal.

#### EARLY MEDITERRANEAN CULTURES

Some of the world's earliest civilizations originated in the Mediterranean and spread throughout the greater part of the world. The first of these was the ancient Egyptian civilization in the Nile Valley. Egypt and Babylonia long before the dawn of history struggled with their irrigation problems. They grew grain on a large scale and used the rivers for navigation. In the calm waters of the Aegean Sea, the Minoans (2800–1500 BC) learned the great lessons of navigation and were able to compete with the Phoenicians on equal terms so that they were ultimately driven from the east and established themselves more firmly in the west, and Carthage grew great along the north coast of Africa.

Then the Hellenic civilization assured a wide dissemination of art, literature, and science. The Greek culture faded under the impact of imperial Rome, which grew in everwidening circles, overwhelming the Greeks and destroying Carthage and making the Mediterranean area one unit. The people of Europe reacted, however, and, under the impact of Goths and Vandals, with the Arabs advancing along the southern shores of the Mediterranean, Rome went down. From Asia Minor new armies appeared to menace the Levantine coast, and the Turks advanced both into Europe and down the coasts of Syria and Egypt.

A study of history in the lands surrounding the Mediterranean shows that a period of splendour was always followed by confusion and outburst, and then a new grouping presented itself.

#### HISTORY OF SCIENTIFIC STUDY

Although well known to the geographers of antiquity and the Middle Ages, the Mediterranean Sea was scarcely subjected to any thorough modern study until the Danish expedition in the "Thor" undertook such a task in 1908–10. The investigations carried out covered as much of the Mediterranean Sea as possible with regard to pelagic (open-sea) animal life and its dependence on hydrographical (flow) conditions and also studied the seasonal circulation between the western and eastern basins and between the Balearic and Tyrrhenian seas.

The expedition of the "Thor"

Not until the end of World War II were major scientific surveys resumed when, in 1948, several surveys were made in the western basin. More systematic studies were carried out there (by the French) from 1957 to 1963.

The eastern basin has received less attention. Mention should be made, however, of investigations into the sources of the formation of deep water in the eastern basin (1957), studies of the vertical circulation of the Mediterranean Sea (1960, 1961), and studies of the hydrographic conditions of the bottom water during summer, using the observations of the French vessel "Calypso" (1955-60).

Cooperative investigations in the Mediterranean were initiated in 1969 by the Intergovernmental Oceanographic Commission (IOC/UNESCO), the International Commission for the Scientific Exploration of the Mediterranean Sea (ICSEM), and the General Fisheries Council for the Mediterranean (GFCM/FAO). Twenty-four nations agreed to cooperate in implementing these programs that cover physical, chemical, geophysical, biological, and fisheries research. Operations were started in 1969 by the German research vessel "Meteor." These operations covered seismic research, continuous seismic reflection measurements, geothermal measurements, radiological and petrophysical investigations, bathymetric measurements, volcanological studies, investigations of marine geology, biological investigations, studies regarding recent ore formation, and analysis for cosmic dust. The Mediterranean Sea, in which the continental transition between Europe and Africa takes place, still poses many unsolved geological problems, and it is hoped that Mediterranean scientific institutions can take part in tackling them within the IOC framework.

## Meghalaya

Meghalaya, literally Abode (*ālaya*) of the Clouds (*megha*), situated in the northeast corner of India, was inaugurated as a full-fledged state of the Indian Union in 1972. Occupying a mountainous plateau of great scenic beauty, it is bounded on the south and west by Bangladesh (formerly East Pakistan) and on the north and east by the Indian state of Assam.

The area of Meghalaya is 8,666 square miles (22,445 square kilometres). Its population in 1971 was about 1,000,000. Its capital is the beautiful hill town of Shillong, which is also the temporary capital of Assam, from which Meghalaya was formed. (For an associated physical feature, see BRAHMAPUTRA RIVER.)

**History.** Meghalaya consists of two districts, the Gāro Hills and the Khāsi and Jaintia Hills. It is inhabited mainly by tribal people, many of whom trace their origins to pre-Aryan times in India. Though the Aryan invaders drove the inhabitants from the plains to the surrounding hills, these people never really came under the rule of any alien group and largely managed to preserve their way of life in seclusion. Even the British, who established their sway over all of India, did not really conquer them and, in return for acceptance of overall British control, left the tribes alone. After Indian independence, the control and rule of the central government was slowly extended and expanded. But India's first prime minister, Jawaharlal Nehru, evolved a policy to preserve and protect the way

of life of the tribal peoples. With other tribal areas, the Gāro Hills and the Khāsi and Jaintia Hills were given special protection in the Indian constitution, and, while included within the state of Assam, the two districts retained a great deal of autonomy.

Even this did not prove enough, however, and when Assam, in 1960, introduced Assamese as the state's official language, agitation for autonomy and self-rule gathered strength. After several commissions and committees had studied the question, in April 1970 the government of India created Meghalaya as an autonomous state within Assam, and in December 1971 the Indian Parliament enacted a law making the area a separate state and bringing within its ambit the town of Shillong.

**Physical geography.** Geologically, Meghalaya is a detached extension of the Indian plateau. From west to east, the Gāro Hills rise abruptly from the Brahmaputra Valley to about 1,000 feet and merge with the Khāsi Hills and Jaintia Hills, two adjacent highland systems that form a single massif consisting of a series of eastward-trending ridges with tablelands between. The massif rises to 4,000-6,000 feet, declining toward the east. There are steep slopes on the southern faces of the plateau and comparatively gentle slopes toward the Brahmaputra Valley in the north. The central plateau acts as a watershed for the many rivers and streams traversing the state, the most important being the Umiām-Barapani, which is the source of hydroelectric power for the whole of Assam and Meghalaya.

One of the world's wettest regions is found in the state—Cherrapunji, with an average of 500 inches (13,000 millimetres) of annual rainfall, is, however, outclassed by Mawsynram, with an average of 700 inches (18,000 millimetres) (previously there had been no observation station at Mawsynram and the amount of rainfall was thus unknown).

The climate is mild, with an average minimum temperature in the Gāro Hills of 39° F (4° C) and in the Khāsi and Jaintia Hills, 54° F (12° C). The average maximum temperatures are 93° F (34° C) and 74° F (23.3° C), respectively.

The state is rich in forests—pines, sals, and bamboo are plentiful. Among the other trees are oaks, birches, beeches, and magnolias. The state abounds in elephants, tigers, leopards, deer, wild pigs, wild buffalo, mithun (wild oxen), wolves, anteaters, monkeys, apes, squirrels, snakes, hares, and sambar deer. Peacocks, partridges, pigeons, hornbills, jungle fowls, mynas, parrots, and other birds are found in the forests.

**Population.** According to the 1971 census, the state had a population of 983,336. Most of the inhabitants of Meghalaya are Tibeto-Burman (Gāros) or Mon-Khmer (Khāsis) in origin, and their languages and dialects belong to these groups. Whether the Mon-Khmers originally belonged to this region and were subsequently driven away to Southeast Asia or migrated from there, they are the only people in India speaking languages of the Mon-Khmer group. The most commonly spoken languages and dialects are Khasi and Garo, followed by Pnar-Synteng, Nepali, Jaintia, and Hajjong, in addition to the plains languages of Bengali, Assamese, and Hindi.

Christianity, Hinduism, and animistic forms of Hinduism are the major religions in the area. There are also some Muslims (about 30,000) and a few Buddhists (about 1,800).

The population is predominantly rural and the state has few industries. The important urban centres are Shillong, Jowai, Nongthymmai, and Tura.

**Administration.** Like other states of the Indian Union, Meghalaya has a governor, appointed by the president of India, and a council of ministers, headed by a chief minister. The ministers are collectively responsible to the legislature, which is elected on the basis of adult franchise. Meghalaya shares with Assam a common governor, high court, and other administrative organs.

The states of Assam, Manipur, Meghalaya, Nāgāland, and Tripura, and the union territories of Arunachal Pradesh and Mizoram all belong to the Northeastern Council, which coordinates plans and schemes for economic

International  
cooperation

Rainfall

Administrative  
associations  
with other  
Indian  
states

development of the region as a whole. In Shillong, where Assam also has its temporary capital, the government of India has temporary overall control of police and law and order, to obviate any friction between Meghalaya and Assam.

**Social conditions.** The state is one of the most backward and least developed areas of the country. Only about 28 percent of the people are literate. The 1947 partition of the subcontinent into India and Pakistan disrupted the tribal populations, many of whom suddenly found themselves on different sides of the international frontier between India and what was then East Pakistan. There were also tribal migrations from East Pakistan into India. In 1971, consequent on the troubles in East Pakistan and as part of the huge refugee influx into India, refugees, who outnumbered the total population of Meghalaya, took shelter in that state, completely disrupting for 11 months the political, economic, and social fabric of the state. With the creation of the new country of Bangladesh, however, the refugees returned to their homes.

#### Mineral resources

**Economy.** Meghalaya is blessed with abundant natural but untapped resources. It has rich mineral resources—coal, limestone, kaolin, feldspar, quartz, mica, gypsum, bauxite, and other minerals. The deposits of sillimanite (a source of high-grade ceramic clay) are reputedly the best in the world. Agriculture is the mainstay of the populace—71 percent of the people are cultivators. Land is owned in common, but the primitive *jhum* form of shifting cultivation (burning of trees and planting the clearings in a cyclical operation) has left the people very poor and has eroded the soil. The main products are rice, millet, maize (corn), potatoes, pepper, chillies, cotton, ginger, jute, betelnuts, oranges, mangoes, bananas, pineapples, and other vegetables.

**Transport and communications.** There is little communication between the two districts, and within the districts many of the valleys are isolated. The state has about 600 miles of surfaced roads, 900 miles of gravelled roads, 500 miles of earth roads, and 300 miles of bridle paths. High priority is being given by the state's development plan to the building, improvement, and surfacing of roads, bridges, and other facilities.

**Cultural life.** The area is rich in tribal culture and folklore. The advent of Christianity and its strict rules of Judeo-Christian ethics and morality have disrupted many of the tribal and communal institutions, however. The folk dances and music of the area are rich and colourful. Drinking and dancing to the accompaniment of music from buffalo horn *singas*, bamboo flutes, and drums are integral parts of religious ceremonies and social functions. Marriages are exogamous. One of the most curious and extraordinary customs among the Gāros is that after marriage the son-in-law comes to live in his wife's parents' house and becomes the father-in-law's *nokrom*, or a representative of the father-in-law's clan in the mother-in-law's family. After the death of the father-in-law, the *nokrom* marries (and the marriage has to be consummated) the widowed mother-in-law, thus becoming the husband of both mother and daughter. Enlightened Gāros are now discarding this custom. The Khāsis once practiced human sacrifice, but this is no longer so.

There are no daily newspapers, though there are some weeklies. The Shillong station of All-Indian Radio serves the region.

**BIBLIOGRAPHY.** *The Tribes of Assam*, a National Book Trust publication (1969), gives in a very concise form detailed information about the various tribes of Assam and among them the Gāros and Khāsis. KAMALESHWAR SINHA, *Meghalaya* (1970), contains a great deal of information about history and other information on the state; the *Meghalaya Year Book* provides a variety of statistical and other information about the state.

(C. Ra.)

## Mehmed II

Mehmed II (1432–81), Ottoman sultan from 1444 to 1446 and again from 1451 to 1481, styled Fatih ("the Conqueror") by the Turks, was the true founder of the

Ottoman Empire and an outstanding military leader. He captured Constantinople (Istanbul) and created his empire, in Anatolia and the Balkans, around it. The territories that he conquered and organized remained for four centuries the empire's solid heartland. The conqueror reorganized the Ottoman government and, for the first time, codified the criminal law and the laws relating to his subjects in one code, whereas the constitution was elaborated in another, the two codes forming the nucleus of all subsequent legislation. In the utterly autocratic personality of the conqueror, the classical image of an Ottoman padishah (emperor) was born. He punished with the utmost severity those who resisted his decrees and laws, and even his Ottoman contemporaries considered him excessively hard.

Mehmed II, miniature by Sinan Bey, late 15th century. In the Topkapı Sarayı Museum, Istanbul.

Nevertheless, Mehmed may be considered the most broadminded and freethinking of the Ottoman sultans. After the fall of Constantinople, he gathered Italian humanists and Greek scholars at his court; he caused the patriarch *Gennadius* to write a credo of the Christian faith and had it translated into Turkish; he collected in his palace a library of works in Greek and Latin. He called Gentile Bellini from Venice to decorate the walls of his palace with frescoes as well as to paint his portrait (now in the National Gallery, London). Around the grand mosque that he constructed, he erected eight colleges, which, for nearly a century, kept their rank as the highest teaching institutions of the Islāmic sciences in the empire. At times, he assembled the *'ulamā'*, or learned Muslim teachers, and caused them to discuss theological problems in his presence. In his reign, mathematics, astronomy, and Muslim theology reached their highest level among the Ottomans. And Mehmed himself left a *divan* (a collection of poems in the traditional style of classical Ottoman literature).

**Early years and first reign.** Mehmed was born on March 30, 1432, at Edirne (Adrianople), the fourth son of Murad II by a slave girl; at the age of 12 Mehmed was sent, as tradition required, to Manisa (Magnesia) with his two tutors. The same year, his father set him on the throne at Edirne and abdicated. During his first reign (August 1444–May 1446), Mehmed had to face grave external and internal crises. The king of Hungary, the pope, the Byzantine Empire, and Venice—all eager to take advantage of the accession of a child to the Ottoman throne—succeeded in organizing a crusade. Edirne was the scene of violent rivalry between the powerful grand vizier Çandarlı Halil, on the one hand, and the viziers Zaganos and Şihâbeddin, on the other, who claimed that they were protecting the rights of the child sultan. In September 1444 the army of the crusaders crossed the Dan-

Mehmed as patron of the arts

Abdication of Murad II

ube. In Edirne this news triggered off a massacre of the Christian-influenced Hurūfī sect and conjured up an atmosphere of panic and arson. When the crusaders laid siege to Varna, the reigning sultan's father was urged to come back from retirement in Bursa and lead the army. The Ottoman victory at Varna under Murad II (November 10, 1444) put an end to the crises. Mehmed II, who had stayed in Edirne, maintained the throne, and after the battle his father retired to Manisa. Zaganos and Şihâbeddin then began to incite the child sultan to undertake the capture of Constantinople, but Çandarlı engineered a revolt of the Janissaries and called Murad II back to Edirne to resume the throne (May 1446). Mehmed was sent once more to Manisa with Zaganos and Şihâbeddin, newly appointed as his tutors. There Mehmed continued to consider himself the legal sultan.

*Second accession in 1451.* On his father's death, Mehmed ascended the throne for the second time in Edirne (February 18, 1451). His mind was filled with the idea of the capture of Constantinople. Europe and Byzantium, remembering his former reign, were then not concerned much about his plans. Neither was his authority firmly established within the empire. But he was not long in showing his stature by severely punishing the Janissaries who had dared to threaten him over the delay of the customary gift of accession. Yet he reinforced this military organization, which was destined to be the instrument of his future conquests. He devoted the utmost care to all the necessary diplomatic and military preparations for the capture of Constantinople. To keep Venice and Hungary neutral, he signed peace treaties favourable to them. He spent the year 1452 mainly in building the fortress of Boğazkesen (later Rumeli Hisarı) for the control of the Bosphorus, in building a fleet of 31 galleys, and in casting new cannon of large calibre. He made the Hungarian master gunsmith, Urban, cast guns of a size unknown as yet even in Europe. Meanwhile, the grand vizier Çandarlı argued against the enterprise and during the siege of Constantinople (April 6–May 29, 1453), the opposing views were voiced in two war councils convened at critical moments. Zaganos vehemently rejected the proposal to raise the siege. He was given the task of preparing the last great assault. The commander in chief, Mehmed II himself, on the day of the attack personally directed the operations against the breach opened in the city wall by his cannon. The day after the capture of the city, Çandarlı was arrested and soon afterwards was executed in Edirne. He was replaced by Zaganos who had become Mehmed's father-in-law. Mehmed had had to consent to a three-day sack of the city, but, before the evening of the first day after its capture, he countermanded his order. Entering the city at the head of a procession, he went straight to Hagia Sophia and converted it into a mosque. Afterward he established charitable foundations and provided 14,000 gold ducats per annum for the upkeep and service of the mosque.

One of the tasks on which Mehmed II set his heart was the restoration of the city, now called Istanbul, as a worthy capital of a world-wide empire. To encourage the return of the Greeks and the Genoese of Galata (the trading quarter of the city), who had fled, he returned their houses and provided them with guarantees of safety. In order to repopulate the city, he deported Muslim and Christian groups in Anatolia and the Balkans and forced them to settle in Istanbul. He restored the Greek Orthodox Patriarchate (January 6, 1454) and established a Jewish grand rabbi and an Armenian patriarch in the city. In addition, he founded, and encouraged his viziers to found, a number of Muslim institutions and commercial installations in the main districts of Istanbul. From these nuclei, the metropolis developed rapidly. According to a survey carried out in 1478, there were then in Istanbul and neighbouring Galata 16,324 households and 3,927 shops. Fifty years later, Turkish Istanbul had become the largest city in Europe.

*Mehmed's empire.* The capture of Istanbul bestowed on Mehmed incomparable glory and prestige and immense authority in his own country, so that he began to look upon himself as the heir of the Roman Caesars and

the champion of Islām in holy war. It is not true that he had preconceived plans for his conquests, but it is certain that he was intent upon resurrecting the Eastern Roman Empire and upon extending it to its widest historic limits. His victory over the Turkmen leader Uzun Hasan at the Battle of Bashkent in Erzincan (August 11, 1473) marked in Mehmed's life a turning point as important as the capture of Istanbul, and sealed his domination over Anatolia and the Balkans.

Mehmed had assumed the title of Kayser-i Rum (Roman Caesar) and, at the same time, described himself as "the lord of the two lands and the two seas" (*i.e.*, Anatolia and the Balkans, the Aegean and the Black seas), a designation that reflected his idea of the empire. During the quarter-century after the fall of Constantinople, he undertook a series of campaigns or expeditions in the Balkans, Hungary, Walachia, Moldavia, Anatolia, the island of Rhodes, and even as far as the Crimea and Otranto in southern Italy. This last enterprise (1480) indicated that he intended to invade Italy in a new attempt at founding a world empire. The following spring, having just begun a new campaign in Anatolia, he died (May 3, 1481) at Hünkârçayırı near Maltepe, 15½ miles (25 kilometres) from Istanbul. Gout, from which he had suffered for some time, in his last days had tortured him grievously, but, there are indications that he was poisoned.

During the autocrat's last years, his relations with his eldest son Bayezid became very strained, as Bayezid did not always obey his orders. Mehmed's financial measures resulted, toward the end of his reign, in widespread discontent throughout the country, especially when he distributed as military fiefs about 20,000 villages and farms that had previously belonged to pious foundations or the landed gentry. Thus, at his death, the malcontents placed Bayezid on the throne, discarding the Sultan's favourite son, Cem (Jem), and initiated a reaction against Mehmed's policies.

**BIBLIOGRAPHY.** FRANZ BABINGER, *Mehmed der Eroberer und seine Zeit* (1953), is the most detailed account of the subject by an authority, reviewed by HALIL İNALCIK, "Mehmed the Conqueror (1432–1481) and His Time," in *Speculum*, 35:408–427 (1960). See also *Cambridge History of Islam*, pp. 295–308 (1970); and STEVEN RUNCIMAN, *The Fall of Constantinople, 1453* (1965). The main sources on the subject are given in H. İNALCIK, "Mehmed II," in *Islam Ansiklopedisi*, 7:506–535 (in Turkish).

(H.I.)

## Mekong River

The Mekong, 2,500 miles (4,000 kilometres) long, is the longest river in Southeast Asia and the seventh longest in all of Asia. Rising in Tsinghai Province, China, it flows through the Yunnan Province, after which it forms part of the international border between Burma and Laos, as well as between Laos and Thailand, also flowing through Laos, Cambodia, and South Vietnam before draining into the South China Sea to the south of Saigon, capital of South Vietnam. Vientiane, capital of Laos, and Phnom Penh, capital of Cambodia, both stand on its banks.

About 77 percent of the drainage area of the Mekong lies within the four countries traversed by its lower basin—Laos, Thailand, Cambodia, and South Vietnam; the lower basin is inhabited by about 30,000,000 people. The four countries are cooperating in the Mekong River Development Project, which, when completed, will provide facilities for the generation of hydroelectric power, irrigation, flood control, drainage, improvements in navigation, water management, and water supply. The project, which was initiated by the United Nations Economic Commission for Asia and the Far East (ECAFE), is being carried out by the four countries with the assistance of 21 governments and 11 United Nations agencies. (For historical aspects, see CAMBODIA, HISTORY OF; LAOS, HISTORY OF; SIAM AND THAILAND, HISTORY OF; and VIETNAM, HISTORY OF.)

**The Mekong—a physical conspectus.** The Mekong River drains more than 307,000 square miles (795,000 square kilometres) of land, stretching from the Tibetan Plateau to the South China Sea. Among Asian rivers,

The Battle of Bashkent

Siege and fall of Constantinople

only the Yangtze, Ganges, and Irrawaddy have larger minimum flows. The Mekong River's small width in the first 1,150 miles of its course and the contrast between the physical conditions that prevail above and below the reach where it flows down off the Yunnan highlands, divide it into two major parts.

The Upper Mekong is a long, narrow valley comprising roughly 26 percent of the total area, cutting through the mountains and plateaus of the People's Republic of China. The Lower Mekong, below the point where it forms the border between Burma and Laos, is a stream 1,454 miles in length that claims the drainage from the Korat Plateau of Thailand, from most of Cambodia, and from the westward slopes of the Chaîne Annamitique (Annamite mountain chain) in Laos and North Vietnam before reaching the sea through the distributary channels of its delta.

Origin of the river

In its upper reaches the Mekong is one of the cluster of great streams rising in the plateau between the Salween and the Yangtze; the stream bed has cut deeply into the rugged landscape through which it flows. Where it flows between Burma and Laos, it drains about 8,000 square miles of Burmese territory, all of which consists of rough and relatively inaccessible terrain. In its more gentle lower stretches, where for a considerable distance it constitutes the boundary between Laos and Thailand, it forms a subject of both friction and cooperation among the four countries of Cambodia, Laos, Thailand, and the Republic of Vietnam.

**Physiography.** *The Upper Mekong.* The upper sources, known locally as the Pam and the Dzi Chu, rise at elevations of more than 16,000 feet in the Tibetan highlands on the southern border of Tsinghai. They flow

southeasterly through the Chamdo region of Tibet. The main stream, called the Lan Ts'ang Chiang, descends in a southerly direction across the highlands of Yunnan, which are cut by erosion into hills and valleys, to a point south of Yiin-ching Hung, where it becomes the border between Burma and China. The river then moves in a southwesterly direction; over a reach of more than 125 miles it forms the Burmese-Laotian border. Although two great roads cross it—the caravan route from the southeast to Lhasa, and the K'un-ming-to-Burma road—much of the river valley in the high plateau and in the Yunnan Mountains is extremely inaccessible and sparsely populated.

*The Lower Mekong Basin.* Below Burma, the river basin may be divided into six major sections—the northern mountains, Korat Plateau, eastern highlands, southern lowlands, southern highlands, and delta sections. All these sections have somewhat similar landforms, vegetation, and soils. Most of the vegetation in the lower basin is of the tropical broad-leaf variety, although the occurrence of individual species varies with latitude and topography.

The northern mountains section has highly folded mountains reaching elevations of about 9,000 feet above sea level, many with slopes slanting at steep angles. As far south as the latitude of Vientiane, these dissected uplands (*i.e.*, cut by erosion into hills and valleys) are covered with dense deciduous forest that has deteriorated as a result of inroads made by shifting cultivation. To the south of the east-west course of the river above Vientiane lies the Korat Plateau, which embraces almost all of the Thai portion of the basin as well as the lower parts of the Mekong's Laotian tributaries. This is an area of flat or gently rolling plains traversed by relatively flat valley bottoms. Soils and deciduous vegetation on the uplands are thin, and much of the original forest has been replaced by grassland as a result of grazing and repeated burning.

The Korat Plateau

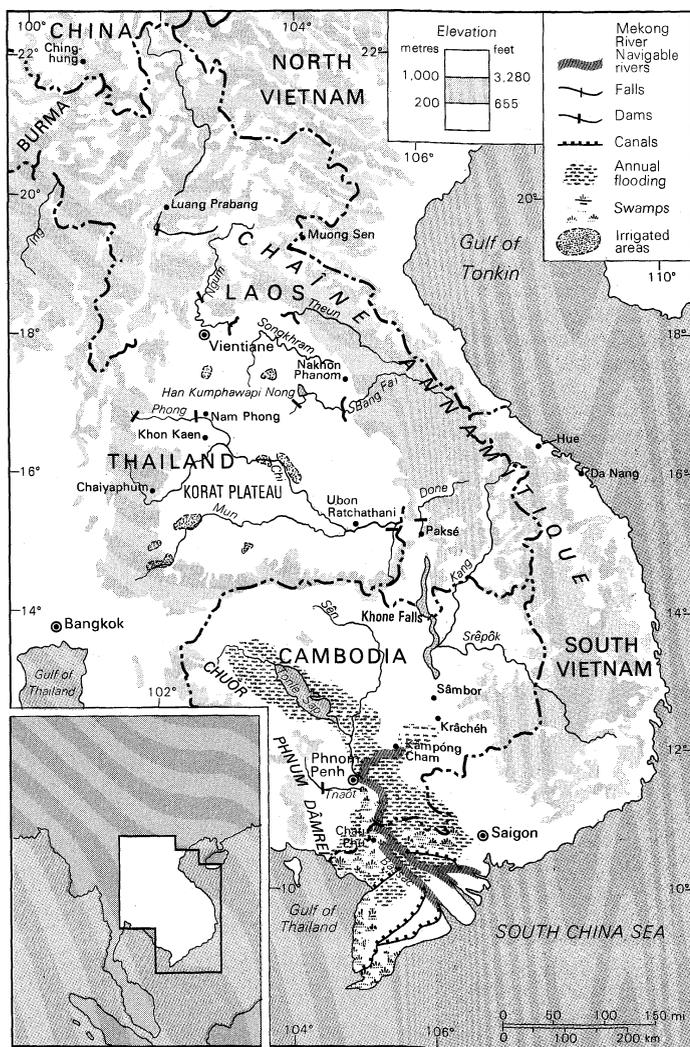

The eastern highlands form part of the Chaîne Annamitique of mountains, from which streams drain west into the Mekong. Throughout most of the distance between Muong Sen in North Vietnam and Kráchéh in Cambodia the watershed forms the border between Vietnam to the east and Laos and Cambodia to the west. There is greater relief in the northern than the southern parts of the watershed, but the highlands in general are characterized by rapid streams that flow through narrow valleys before entering the Korat Plateau or other lowlands. Forest degradation, that has resulted from lumbering, the temporary use of land for cultivation, and grazing, is widespread.

The southern lowlands border both sides of the Mekong below Paksé in Laos. The part of the river that flows through Cambodia has wide stretches of alluvium in its floodplain. Near Phnom Penh, the Cambodian capital, a junction occurs between the Mekong and the Tonle Sap river, which connects it to the Tonle Sap lake, sometimes called the Great Lake. The direction of flow of the Tonle Sap river varies to the season. In midsummer, when the Mekong is in flood, waters flow down the Tonle Sap to the lake, which at this time increases its area from about 1,000 square miles to about 3,000 square miles. In midwinter when the floods subside, the Tonle Sap reverses its flow to drain southeastward into the Mekong. Tonle Sap lake is one of the most productive fishing grounds in the world, producing as much as 26 tons of fish a year per square mile.

The Great Lake of Tonle Sap

Along the southern border of the basin in Cambodia, the Eléphant and Cardamon mountains form a string of southern highlands that drain northward into the southern lowlands.

The river divides into two streams—the Mekong and the Bassac—below Phnom Penh. From this point onward the delta spreads out to the sea. The delta, which has a total area of about 25,000 square miles, has three major sections. The upper section, above Chau Phu, has strong natural levees (embankments built on either side of the river by accumulated deposits of silt) behind which are low, wide depressions. The middle section has some

The Lower Mekong River Basin.

areas that are well drained, others that are poorly drained and swampy. Along the lower section, formed by the river mouths and by the area to the southwest, sediment is in the process of being deposited, and the flooding is less extreme than in the upper sections of the delta.

**Hydrology.** The mean annual flow of the river at Krâchéh in Cambodia is about 500,000 cubic feet per second (cusecs), making a total annual discharge for the year of about 378,000,000 acre-feet. The recorded minimum at Krâchéh is about one-twelfth of the mean, and the annual peak flow about four times the mean. Below Krâchéh the peak flows diminish as the water spreads out into the distributary channels and backswamps. Flow comes chiefly from rainfall in the lower basin and reflects the variation in seasonal rainfall caused by the monsoon winds; this variation generally forms a regular annual pattern: in April the flow is ordinarily at its lowest; in May or June the flow begins to increase, doing so most rapidly in the eastern highlands and northern mountains; the highest water levels are reached as early as August or September in the upper reaches and as late as October in the southern reaches. The northeast monsoon wind, beginning ordinarily in November in the southern areas, brings dry weather until May.

The annual sediment load is recorded as being highest at Paksé, where it amounts to 132,000,000 tons; it is about half that amount at the Burmese border and about two-thirds at Phnom Penh. The dominant hydrologic fact affecting agriculture is the long dry period in which rice cultivation is impossible without irrigation.

**The riverain populations.** In 1970 the inhabitants of the lower basin amounted to half the population of the four riparian countries, a total of 30,000,000 people. About 80 percent were engaged in agriculture, and rice was the major crop. Heaviest population concentrations are in the delta and on the Korat Plateau. The small urban population has been growing rapidly, chiefly through migration to the capital cities. There is no common ethnic tie among the basin populations. Ethnic groups range from Sino-Tibetan, including Karen and Meo mountain groups, in the Upper Mekong region, to Khmer, Cham, Tai, Mon, and Vietnamese lowland groups in the Lower Mekong Basin. The Vietnamese are heavily concentrated in the delta, and the Khmer and Tai are the most widely distributed in the lower basin.

**The river's resources.** *Irrigation and flood control.* In the lower basin the management of water offers major opportunities to increase the economic productivity of the tributary lands. Farmers practicing shifting cultivation on the uplands and the rice growers on the rain-fed lowlands are able, under normal conditions, to grow only one crop a year, taking advantage of wet season precipitation. Half the cultivated land is dependent upon some form of inundation by flood flows. Control of water, however, makes it possible to store water during the dry season, and thus permits the harvesting of a second or third crop. If irrigation is combined with flood control, the losses and delays caused by floods pouring over the river's banks can be reduced. Where storage facilities and the degree of downward slope are favourable, hydroelectric power can be generated. If navigational conditions on the Mekong's main stream and on some of its tributaries were to be improved, transport costs for landlocked areas could be reduced.

The actual development of the river's resources has, however, been modest. By 1971 only about 3 percent of the cultivated area was being irrigated. Only three small hydroelectric plants were in operation. Flood control and drainage works have been constructed in the delta to deal with smaller inundations in limited areas.

**Navigation.** In the Vietnamese part of the delta there is an elaborate system of canals. Smaller seagoing vessels can sail upstream as far as Phnom Penh and vessels drawing almost 15 feet can reach Kompong Cham during high water. Continuous water transport is blocked chiefly by the barriers of the Khone Falls and other falls between Sâmbor and Paksé, and upstream uses of the river are limited to local traffic.

In 1926, Thailand and France—which then adminis-

tered Indochina (Cambodia, Laos, and Vietnam)—entered into an agreement that neither would obstruct navigation of the river. In 1949, Cambodia, France, Laos, and South Vietnam executed a Convention on Maritime and Inland Navigation on the Mekong and on water routes to Saigon. A convention to coordinate action on navigation, river construction and other projects, and fiscal regulations affecting river commerce was signed in 1954 by Cambodia, Laos, and South Vietnam.

**The Mekong River Development Project.** After the Bureau of Flood Control of the United Nations Economic Commission for Asia and the Far East (ECAFE) had recommended study of the Lower Mekong, surveys were carried out by ECAFE and by the U.S. Bureau of Reclamation. This led to the adoption by Cambodia, Laos, Thailand, and South Vietnam of a 1957 statute creating the Committee for Coordination of Investigations of the Lower Mekong. By 1971 the four riparian countries had sponsored a series of preinvestment investigations and had undertaken construction of multiple-purpose water projects costing \$143,000,000. They had continued to cooperate despite the political stresses produced by the war in Vietnam and had enlisted the assistance of other countries. The United Nations Development Program provided assistance in the technical and administrative organization of the studies. Financial contributions toward the work had been made by 25 nations, the larger sums coming from the United States, France, Japan, and West Germany. Sixteen international specialized agencies, including the World Bank and the United Nations Food and Agriculture Organization, had also given assistance to the projects.

Investigations undertaken included basic mapping, hydrologic observations, soil surveys, fisheries studies, health studies, engineering-feasibility studies, power-market surveys, agricultural research and pilot farms, and many other inquiries. The engineering studies had provided for reconnaissance appraisal of all of the tributary basins and for more detailed examination of selected projects. Flood forecasting was begun and river navigation was improved. Mineral surveyors explored possible opportunities for bauxite and iron development.

An irrigation and hydroelectric installation was completed at Nam Pung in Thailand in 1968, and a larger irrigation and power project at Nam Phong, also in Thailand, was under construction in the early 1970s. A small power plant on the lower Done in Laos was completed in 1970. Five other water projects were under construction: on the Ngum River in Laos a power, flood-control, and irrigation scheme was under way, and Laos was negotiating with Thailand for sale of power from the 105-megawatt plant; on the Tnâot River in Cambodia, an irrigation project was being financed by the cooperation of 12 countries; a small power plant was scheduled for the Done River in Laos; and two irrigation and power projects were begun on the Dom Noi and Phrom rivers in Thailand.

Meanwhile, the focus of the Mekong Development Project as a whole was shifting to the planning of comprehensive programs for agricultural and community development in areas where water supply was available, with each country working out its individual financial arrangements with donor nations. No formal negotiations with the two upstream riparian countries, Burma and the People's Republic of China, or with adjacent countries that might be markets for power, had as yet taken place.

**Prospects for the future.** The provision of water control on the Mekong has entailed risks as well as benefits. If the engineering works are not accompanied by suitable measures to build canals, construct farm ditches, level fields, supply new seeds and fertilizers, improve farm-to-market roads, organize markets, and establish agricultural credit, no gain will be made in agricultural production, as was the case with several score small reservoirs constructed on the Korat Plateau during the 1950s. If resettlement from reservoir areas is slow or inadequate, as happened at Nam Pung, the social costs may be heavy. Water storage and irrigation may promote the spread

Ethnic  
groups

Recent  
irrigation  
and power  
projects

of schistosomiasis (a water-borne parasitic disease) and malaria or may interfere with fisheries. The Mekong Committee has been studying these problems as well as investigating other agricultural and water-management programs.

So long as military conflict continues in the region the preparation of comprehensive plans will be curtailed. Whenever that constraint is removed the countries will be obliged to consider new arrangements with their neighbours. At that time, too, the need to coordinate Lower Mekong planning with broader national programs will become more urgent.

**BIBLIOGRAPHY.** UNITED NATIONS, *Selected Bibliography: Lower Mekong Basin*, 2 vol. (1969), provides the most comprehensive list of references to the literature on the lower basin. The basic maps of resources, with descriptive text, are compiled in the UNITED NATIONS, *Atlas of Physical, Economic, and Social Resources of the Lower Mekong Basin* (1968). Two general reviews of planning for the lower basin are found in C. HART SCHAAF and RUSSELL H. FIFIELD, *The Lower Mekong: Challenge to Cooperation in Southeast Asia* (1963); and W.R.D. SEWELL and GILBERT F. WHITE, *The Lower Mekong* (1966). *Principal Rivers in Communist China*, JPRS, no. 33,880, *National Technical Information Service* (1966), contains English translations of Chinese publications describing major river systems, including the Mekong.

(G.F.W.)

## Melanchthon, Philipp

The first systematic theology of the Protestant Reformation, the Protestant public school system, and the basic Protestant creed all originated with Philipp Melanchthon, theologian and educator who, though he was for 28 years a co-worker of Martin Luther, is today often denigrated as a traitor, the source of an allegedly "alien," rationalistic element in Lutheranism.

Melanchthon, engraving by Albrecht Dürer, 1526.

Early influences and humanistic education

Born Feb. 16, 1497, in Bretten (Germany), Melanchthon inherited from his parents, Barbara Reuter and Georg Schwartzerd, a deep sense of piety that never left him. From his Bretten surroundings (where five citizens were burned as witches in 1504) he absorbed a sense of the occult that combined later with biblical references to stars, dreams, and devils to make him a firm believer in astrology and demonology. In 1508, within a period of 11 days, both his grandfather Reuter and his father died, his father after four years of invalidism.

Humanism predominated in Melanchthon's education, his studies having been directed by a great-uncle, Johannes Reuchlin, famed Hebraist and humanist. Philipp's first tutor instilled in him a lifelong love of Latin and classical literature, and, at the Pforzheim Latin school, he received further humanistic training and had his name changed from Schwartzerd ("black earth") to its Greek equivalent, Melanchthon. While at the universities of Heidelberg (1509–11, B.A.) and Tübingen (1512–14, M.A.), Melanchthon explored Scholastic thought in depth, steeped himself in the rhetoric of the Dutch humanist Rudolf Agricola and the Nominalism of the En-

glish philosopher William of Ockham and the ecclesiastical reformer John of Wesel, studied Scripture, and read classical works with a fellow student. On receiving the M.A. degree, he lectured, with conspicuous success, on the classics and soon had six books to his credit, including "Rudiments of the Greek Language" (1518), a grammar that was to go through many editions. He was praised by the great Dutch humanist Erasmus, and his name became known in England. In the best tradition of the time, Melanchthon was a humanist.

In 1518 Melanchthon accepted an invitation, relayed through Reuchlin, to become the University of Wittenberg's first professor of Greek. Only four days after his arrival, he addressed the university on "The Improvement of Studies," boldly setting forth a humanistic program and calling for a return to classical and Christian sources in order to regenerate theology and rejuvenate society.

Luther, the founder of the Protestant Reformation, and Melanchthon responded to each other enthusiastically; and their deep friendship developed, with Melanchthon committing himself wholeheartedly to the new evangelical cause, initiated the previous year when Luther nailed his Ninety-five Theses to the door of the castle church in Wittenberg. By the end of 1519 he had already defended scriptural authority against Luther's opponent Johann Eck, rejected (before Luther did) transubstantiation—the doctrine that the substance of the bread and wine in the Lord's Supper is changed into the body and blood of Christ—made justification by faith the keystone of his theology, and openly broke with Reuchlin. During this time he had also published seven more small books and had earned the Bachelor of Theology degree at Wittenberg. His energy was phenomenal. He began his day at 2 AM, with lectures, often to as many as 600 students, at 6. In addition, he found time to court Katherine Krapp, whom he married in 1520 and who bore him four children—Anna, Philipp, Georg, Magdalen.

At Luther's urging, Melanchthon lectured on Paul's Letter to the Romans and in 1521 published the *Loci communes*, the first systematic treatment of evangelical doctrine. Sin, law, and grace were the principal topics, with free will, vows, hope, confession, and other doctrines subsumed. Drawing on Scripture, Melanchthon argued that sin is more than an external act; it reaches beyond reason into man's will and emotions so that man cannot simply resolve to do good works and earn merit before God. Original sin is a native propensity, an inordinate self-concern tainting all man's actions. But God's grace consoles man with forgiveness, and his works, though imperfect, are a response in joy and gratitude for divine benevolence. Three editions of the *Loci* appeared before the end of the year, 18 editions by 1525, in addition to printings of a German translation. The last edition in 1558 was much enlarged and changed. Luther declared that the *Loci* deserved a place in the canon of Scriptures; the University of Cambridge in England later made it required reading, and Queen Elizabeth I (1533–1603) virtually memorized it so she could converse about theology.

Despite an imperial decree of death to those who supported Luther, in 1521 Melanchthon sharply answered the Sorbonne's condemnation of 104 statements of Luther with "Against the Furious Decree of the Parisian Theologasters." His "Passion of Christ and Antichrist," in the same year, utilized woodcuts by Lucas Cranach (1472–1553) in a scathing criticism of the pope's lifestyle as diametrically opposed to Christ's. When Melanchthon hesitated to publish his lectures on Corinthians, Luther stole a copy and published them in 1521 with a preface saying, "It is I who publish these annotations of yours, and send you to yourself." In 1523 Luther did the same with Melanchthon's notes on John.

While Luther was safely confined at the Wartburg after his confrontation with papal authorities at the Diet of Worms and his subsequent status as an outlaw, troubles erupted in Wittenberg over the issue of clerical marriage, granting the laity the right to use wine in the Lord's Supper, and abolition of the mass. A radical Reformer, Karlstadt (c. 1480–1541), wanted to abolish all educa-

Involvement in the Reformation

tion because Christ and the Apostles were not educated, and radical prophets of Zwickau said that God had told them to eliminate infant Baptism. Melanchthon was unable to control the mobs that demonstrated in the streets, intimidated priests, destroyed side altars, despoiled grave-stones, and broke images. Early in March 1522, Luther returned, preached eight sermons on love, and quelled the disturbances.

Although Melanchthon did not relinquish his views on justification by faith and scriptural authority, the disruptions at Wittenberg, the caustic interchange between Luther and Erasmus on free will, and the Peasants' War in 1524–1525 caused him to put more emphasis on humanism as a moderating influence in religion. This is revealed in the revised editions of the *Loci* that made more use of reason, in his educational endeavours, and in his various commentaries. In 1528 Saxony enacted into law Melanchthon's "Visitation Articles," which were guidelines for churches and schools, and established the first public school system since that of ancient Rome. At least 56 cities asked his advice in founding schools. Through him, his textbooks, and the teachers he trained, virtually the whole educational system in Germany was reorganized. He helped found the universities of Königsberg, Jena, and Marburg and reformed those of Greifswald, Wittenberg, Cologne, Tübingen, Leipzig, Heidelberg, Rostock, and Frankfurt-on-the-Oder. He believed that without education, religion would decline and mankind would be reduced to animality.

The  
Augsburg  
Confession

Melanchthon's greatest triumph was the Augsburg Confession of 1530, in which for unity's sake he sought to be as inoffensive to the Catholics as possible but forcefully stated the evangelical stance. In the ensuing negotiations over adoption of the confessional statement, he seemed to compromise, but the vigour of his Apology of the Confession of Augsburg (1531) belied any change. The Apology and Confession quickly became official Lutheran symbols (authoritative statements of faith), as did one other Melanchthon treatise, his "Appendix on the Papacy," which was an addition to the Schmalkald Articles of 1536–37, another Lutheran confessional statement. In the "Appendix," Melanchthon refuted historically and theologically any papal primacy by divine right but accepted papal jurisdiction as a human right for the sake of peace, if the Gospel were permitted.

The evangelical movement suffered setbacks in 1546 with the death of Luther and, in 1547, with the defection of Duke Maurice of Saxony to the side of the Holy Roman emperor Charles V and the military defeat of the Lutherans at Mühlberg. The University of Wittenberg was dissolved. Melanchthon and his family fled. But before the year ended, Maurice (needing the support of his Lutheran subjects) invited Melanchthon to restore the university. Recognizing that Wittenberg symbolized the evangelical cause and receiving assurances that pure doctrine would be allowed, Melanchthon returned and gathered a faculty—only to incur the hostility of theologians who regarded his actions as a betrayal. Melanchthon opposed the Augsburg Interim of 1548 (a doctrinal formula weighted toward the Catholic position, which Charles V tried to impose on Saxony to settle religious matters), but when he realized that the princes were about to adopt the nonevangelical Leipzig Interim to avoid war with Charles, he salvaged the key doctrine of justification by faith, eliminated the idea of a mass that granted merits to the worshipper, and said that the adiaphora (nonessentials, such as liturgical dress) could be accepted even though they added nothing to doctrinal integrity. His opponents protested that in time of stress nothing could be yielded and that pure forms were integral to pure biblical doctrine. Maurice, in 1552, turned against the Emperor and ended the interim with the Treaty of Passau, which was superseded in 1555, by the Peace of Augsburg with its formula of *cujus regio, ejus religio* ("whose region, his religion"), enunciating the principle that a region's religion is that of its ruler.

Melanchthon's reputation was badly tarnished, and several controversies beclouded his final years. In a controversy over the role of man as a cooperating participant

with God in the matter of salvation, Melanchthon seemed to undercut the doctrine of justification by faith alone by maintaining that three concurrent causes operate in conversion—the Word (Christ), the Holy Spirit, and man's will. Melanchthon's maintaining of the third use of the law—referring to the three uses of the law, such as the Ten Commandments, to maintain civil peace and order, show man what a sinner he really is, and serve as a guide for living—as a guideline for Christians seemed to be a return to legalism. His turning toward a spiritual view (similar to the Reformed view) of the Lord's Supper, as evidenced in the *Variata* (altered) edition of the Augsburg Confession in 1540 (Article X), seemed to be crypto-Calvinistic (*i.e.*, though Lutheran in name, apparently Calvinist, or Reformed, in tendency). These controversies diminished his influence in Lutheranism. Succeeding generations have questioned Melanchthon's approval of the death penalty for the radical Reformers, the Anabaptists, and an anti-Trinitarian, Michael Servetus; his approval of war to defend the Gospel; his condoning of polygamy for the English king Henry VIII and Philip the Magnanimous, landgrave of Hesse; and his extension of reason to support revelation.

Melanchthon died April 19, 1560, and was buried in Wittenberg beside Luther.

**BIBLIOGRAPHY.** C.L. MANSCHRECK, *Melanchthon: The Quiet Reformer* (1958), is the fullest biography to date; see also R. STUPPERICH, *Der unbekannt Melanchthon* (1961; Eng. trans. by R.H. FISCHER, *Melanchthon*, 1965). M. ROGNESS, *Philip Melanchthon: Reformer Without Honor* (1969), contains aspects of Melanchthon's thought. His basic works and letters may be found in K.G. BRETSCHNEIDER and E. BINDSEIL (eds.), *Corpus Reformatorum*, 28 vol. (1834–60); W. PAUCK (ed.), *Melanchthon and Bucer* (1969), contains the 1521 *Loci*; and C.L. MANSCHRECK (ed.), *Melanchthon on Christian Doctrine* (1965), the 1555 *Loci*. For information on Lutheran symbols, see T.G. TAPPERT (ed.), *The Book of Concord* (1959); for educational endeavours, C. HARTFELDER, *Philipp Melanchthon als Praeceptor Germania* (1889), with bibliography. W. HAMMER, *Die Melanchthonforschung im Wandel der Jahrhunderte*, 2 vol. (1967–68), has a good bibliography to 1965; for a discussion of Melanchthon's relation to patristics, see P. FRAENKEL, *Testimonia Patrum* (1961).

(C.L.Ma.)

## Melanesian Cultures

Melanesia has no firm geographical boundaries. It is generally held to include the island of New Guinea and a number of island groups to the north and east: the Bismarck Archipelago, the Solomon, New Hebrides, and Torres Straits islands, New Caledonia, Fiji, and intervening groups. All of the islands lie in the central Pacific between the Equator and the Tropic of Capricorn. (For a map of the area, see OCEANIAN PEOPLES AND CULTURES.) The term Melanesia (black islands) was introduced in 1832 by a French navigator, Dumont d'Urville, to describe those areas of the Pacific inhabited by dark-skinned peoples. There is considerable variation in skin colour, ranging from light brown in the Trobriand Islands to almost black in the northwestern Solomons.

### PEOPLES AND LANGUAGES

The people of Melanesia have been classified as belonging to the Oceanic Negroid division of mankind. Three main physical types have been distinguished: Melanesians in the anthropological and linguistic sense, Papuans, and Pygmies—the latter two only on New Guinea.

The Melanesians, who inhabit the southeast peninsula of New Guinea and the other islands eastward to Fiji, tend to have broad noses and little body hair. Their head hair is generally frizzy, although it may be wavy or curly. The Papuans are mostly of medium stature, ranging from five feet seven inches (170 centimetres) for those living at the head of the Gulf of Papua to about five feet (152 centimetres) for some mountain tribes. Their facial and body hair is often abundant and woolly in texture. Their heads tend to be long in relation to breadth; their noses are sometimes hooked and prominent; they have marked brow ridges and high, receding foreheads; and their skin colour ranges from dark to very dark.

The Pygmies inhabit the central mountains of New Guinea; two groups are the Tapiro of Irian Barat (now in Indonesia, formerly called West Irian) and the Aiome of the Trust Territories. The average height of the adult male Tapiro is four feet nine inches. The Pygmies often have abundant body and facial hair, round heads, and broad noses; their skin colour varies from yellow to dark brown. The origin of the Pygmy peoples is unclear; it has been suggested that they may have been the aboriginal inhabitants of New Guinea, driven into the mountains by invading peoples, or, alternatively, that they may derive from a Papuan stock. Several of the mountain peoples have both Pygmy and Papuan characteristics.

Micro-  
nesian and  
Polynesian  
influence

The Melanesians may also be a mixture of immigrant strains with a basically Papuan stock. Micronesian and Polynesian influence can be discerned in the culture and physical characteristics of some of them. Small islands near the Solomon and Santa Cruz groups have been colonized by Polynesians; there is a strong Polynesian influence in the Loyalty Islands and the Lau Islands of the Fiji group, and some Polynesian mixture occurs in New Caledonia and parts of the New Hebrides. Micronesian influence can be traced in certain areas of the Bismarck Archipelago.

More than 700 distinct languages are spoken in Melanesia. In the interior of the Solomons, New Britain, and New Guinea, the languages are collectively called Papuan, although their relations to one another are largely unknown. On the coasts of these islands and throughout the rest of Melanesia, the languages (usually called Melanesian) all belong to the Austronesian (Malayo-Polynesian) family, which includes the languages of Indonesia, the Philippines, aboriginal Taiwan, Malaysia, and Madagascar (see PAPUAN LANGUAGES; AUSTRONESIAN LANGUAGES). The distribution is complex, and the two major groups are often present on the same island. There is no precise correlation between language, physical type, and culture. As a rule, each language is spoken in a limited area, although some, such as Motu in Papua, are understood outside their district of origin. Pidgin English is still in use as a lingua franca.

It is not known precisely how Melanesia was first populated, although ethnologists assume that the earliest inhabitants came in successive waves from the west. No common cultural pattern is discernible today; rather, there is tremendous diversity in every aspect of social life among the peoples of Melanesia. Their societies have been described as classless, meaning that power and status are matters of individual achievement, not of inheritance or of membership in a particular group. The "big man" in Melanesian society acquires his position of leadership through his success in the acquisition of wealth and sometimes by some skill, such as oratory (as among the peoples of the Mount Hagen area in the New Guinea highlands). In this respect Melanesian society differs markedly from the Polynesian, where there is a strong emphasis on rank and chieftainship.

#### TRADITIONAL CULTURE PATTERNS

**Economic patterns.** *Settlement patterns and housing.* Village settlements are usually small, ranging between 50 and 200 inhabitants, although on river estuaries or along the seacoasts they sometimes exceed 1,000. The villages may consist of scattered hamlets, as among the Chimbu of eastern New Guinea, or they may be concentrated, as in the villages of the Orokaiva in Papua. Some villages in the Trobriand Islands are built on a circular plan, the houses facing inward to a cleared space; in the space are storehouses for yams and the chief's house. Mountain villages are often sited on easily defensible ridges; coastal villages are set back from the shore; and lowland villages are located near rivers or streams.

Houses vary in design and construction, depending on the local materials and other factors. Some have earthen floors; others are built on piles. Pile dwellings are found in various places in New Guinea and in the Bismarck Archipelago, often in locations that are subject to flooding; they are also used on dry ground, particularly where

it is uneven. The space underneath the pile house provides a useful storage area, helps to improve ventilation, and makes the house easier to defend. The height of a pile house ranges from one or two feet above the ground, as among the Mafulu of central Papua, to as much as 15 feet for men's houses—social and ceremonial centres of many villages. The ordinary village house is built for a single family; occasionally, joint or extended families occupy a single dwelling, as in the Sepik Basin and among the Kiwai of western Papua.

Some houses are circular, with a roof supported by a single central post. The more common rectangular houses have a ridgepole supported at either end and sometimes in between by central posts. Rafters stretch from the ridgepole to the top of the wall plates; the roof thatch, usually grass or palm leaves, is lashed to horizontal members running across the rafters. Kiwai communal houses have two rows of posts on each side of the centre line, supporting rafters that are joined at a ridgepole in the centre. In larger houses, tie beams are often lashed to opposite wall plates or between rafters partway up the slope of the roof to counter the outward pressure of the roof timbers.

Decoration is widely applied on men's houses, clubhouses, and chiefs' houses. In New Caledonia, chiefs' houses have carved human-shaped boards flanking the doorways. In the Trobriand Islands, the yam houses are adorned with carved and painted boards.

Most Melanesian dwellings are dark and poorly ventilated; doors are small and there are no windows. The simple furnishings include bed mats, headrests, and a few personal belongings, such as pots, baskets, tools, fishing equipment, and weapons. A fire often burns all night, the smoke escaping through the roof.

*Food.* For many Melanesians, gardening provides the main source of food. The so-called swidden type of agriculture is practiced, whereby the land, after it lies fallow for a number of years to restore its fertility, is cleared by burning off the vegetation. The system is believed to have originated in Southeast Asia. Agriculture has had a long history in New Guinea. Pig bones have been found in the remains of inhabited sites dated at about 3000 BC. The findings suggest that the pigs were domesticated and that crops must have been grown to feed them. Systems of water-control ditches existed in the western Wahgi Valley of eastern New Guinea as early as 350 BC, indicating that intensive agriculture had been established by then.

The three most important staple crops are yams, taro, and sweet potatoes. Yams are grown in the dry regions, such as the leeward slopes of high islands covered with savanna or savanna woodland; taro grows well in areas of high rainfall; and in the highlands the sweet potato predominates. The sweet potato is of South American origin and may have reached New Guinea from the Philippines after Spanish colonization. Other crops include bananas, plantains, coconuts, manioc, maize, cassava, breadfruit, pineapple, and tomatoes.

The gathering of wild and semicultivated plants and fruits, either for medicinal purposes or as a supplement to the diet, is common. The sago palm, which grows well in the freshwater swamps of New Guinea and the Solomon Islands, is one of the most important wild food plants.

Pigs provide the main supply of animal protein. Some crops are grown specifically for them, and they also scavenge around the villages and root in the gardens. Other domesticated livestock include chickens and dogs, which are sometimes eaten and are also used for hunting. Cassowary birds are sometimes caught and reared in pens. Cattle and horses have been introduced in Fiji and New Caledonia, and goat herds have been established in some places. The hunting and trapping of wild pigs, marsupials, and birds provides a small amount of additional protein.

Coastal peoples eat a lot of fish. The reefs of eastern Papua, the Torres Straits, the northern Solomon Islands, Fiji, and the areas surrounding New Caledonia yield shellfish, crabs, octopus, sea snails, and mussels; in the lagoons, mullet, bream, grouper, small sharks, and turtles can be caught. The bonito is an important food fish on the

Gardening  
and  
gathering

north coast of New Guinea and around the Solomons. Fish in river pools and lagoons are sometimes drugged with a fluid from pounded plants of the genus *Derris*. Spears, harpoons, traps, nets, and hooks are also used.

#### Dietary customs

The main meal of the day is usually cooked and eaten in the late afternoon. The Melanesians use an earth oven, consisting of a pit with hot stones. The stones are covered with a layer of leaves, on which the food is placed. Water is sprinkled over everything, and the pit is covered with leaves and earth to prevent the steam from escaping. The size of the pit depends on the quantity of food being prepared. In Fiji, the pit is sometimes 50 feet (15 metres) in circumference and up to eight feet deep. Food is also cooked on fires above ground or boiled in pots; in the interior of New Guinea it is cooked in sections of bamboo. Vegetables are usually scraped and then cut up with tools made from shell, coconut, or bamboo. The meat of coconuts is gouged out, and the liquid is expressed and added to vegetable dishes. Staples such as taro are mashed after cooking to make a kind of pudding.

The preservation of food is a problem in Melanesia. Taro can be left in the ground for fairly long periods. In the Trobriand Islands yams are stored in specially constructed houses. Breadfruit is preserved by drying it over a fire or by fermenting it in a pit covered with earth and leaves. Baskets of vegetable food are often hung on wooden hooks inside the huts.

Betel chewing is common. The chewer uses a mixture of the nut of the areca palm (*Areca catechu*), the fruit or leaves of the betel pepper (*Piper betle*), and lime made either by burning coral or shells or by grinding limestone. A small piece of nut is wrapped in a leaf of the betel pepper with a pellet of lime, or the lime may be mixed with the nut and pounded in a small mortar. Betel chewing has a mildly stimulating effect; it induces salivation, and its prolonged use stains the mouth red.

Tobacco is grown and smoked widely. Several kinds of pipes are used; in Irian Barat some have bowls made from nuts. One popular pipe in Irian Barat and New Guinea consists of a tube of bamboo closed at one end, near which a hole is bored. Tobacco in a piece of leaf or a wooden bowl is fitted in the hole. Cigarettes are made with banana leaves.

In eastern Melanesia, where betel is not chewed, an infusion is made from the root of the pepper plant *Piper methysticum*. It is known as kava and has a mildly stimulating effect like that of betel. The root is grated, and the pulp is placed in a bowl. Water is added, and the solution is put into a strainer of hibiscus fibre, which is wrung out like a sponge into a coconut kava cup. Drinking is usually ceremonial, every stage regulated by a precise code of behaviour.

Food taboos are numerous for nursing mothers, young children, fighting males, and others. The Tsembaga of the Bismarck Range in New Guinea eat a large quantity of heavily salted pig fat before fighting; this, together with a taboo on drinking, has the effect of shortening the fighting day because after a certain period everyone becomes unbearably thirsty.

*Division of labour.* Men do the heavy work of clearing, planting, and fencing. Women generally do the weeding, tending, and digging; they also collect wild food plants and shellfish and feed the pigs. Women prepare the everyday family meals, but the men dig earth ovens and often do large-scale cooking for feasts. Both sexes make their own tools and utensils, men producing axes and adzes and the women making baskets, mats, armbands, ornaments, or shell disks for currency.

#### Work roles of children

Children start to help their parents from a very young age. In Wogeo, boys participate in fishing expeditions from the age of about four or five. Small girls often begin by carrying vegetables home from the gardens, and by the age of 10 or so they may be entrusted with their own garden areas.

The crafts are not highly specialized. In some areas, however, certain work is undertaken by specialists. The *malanggan* carvings of New Ireland, used in mortuary rituals, are made by specialist carvers; the rights to individual designs are transferable property. The builders of

large seagoing canoes in Fiji are a distinct group with their own chief. In fields such as dentistry and medicine, particular individuals tend to acquire a reputation for competence. Most specialization is on the level of the village or area. Extensive trading networks exist throughout Melanesia, and goods produced in one part are often to be found far away from their place of manufacture.

Where larger work forces are needed for specific tasks such as building houses, an individual has a special call on his kin. Most labour is provided reciprocally, with a good deal of cooperation at the village level. In a few areas, such as parts of the central highlands of New Guinea, labour is a salable commodity, and a man may hire himself out for a specific task, such as building a fence.

*Tools.* While a Bronze Age culture existed prehistorically in Melanesia, by the time the Europeans came the Melanesians were not using metal. Tools are made of stone and shell. The adze (in which the blade is set at right angles to the haft) and the axe are used in woodworking. Their blades are made from fine-grained tough stone, ground on sandstone. They are hafted in various ways; one typical form is the elbow haft: a handle-length piece of wood is cut from the fork of a tree and the blade lashed to the shorter, stubby end from the major limb, the longer, slimmer branch forming the handle. Axe and adze blades are also fashioned from the shell of the giant clam *Tridacna*.

Knives are made from bamboo all over Melanesia. Cutting implements are also made from stone in Irian Barat and from obsidian in the Admiralty Islands; many groups simply use sharp-edged flakes without refining them. Drills are made of stone. Other tools include stone or shell blades hafted as chisels and pigs' tusks used for burnishing wood or, when sharpened, as chisels. Engraving tools are made from the incisor teeth of rodents; the jawbones serve as handles. Rasps are made from the skin of sharks and rays, and awls and needles from the bones of birds or rodents.

*Clothing and ornament.* Everyday clothing is fairly simple. Men wear a strip of bark cloth, vegetable fibre, or pandanus leaf between their legs. This can be looped under a waistband and may be painted or decorated. Penis wrappers and sheaths made from bamboo or gourd are worn in the northern New Hebrides, Irian Barat, and New Caledonia. On the border of Papua and New Guinea, the common dress is a bark-cloth apron hanging down the back and a series of triangular fibre fringes in front.

Women's dress is most commonly a skirt made from shredded leaf or string attached to a waist cord. The skirt may be only a few inches long as in the Loyalty Islands or ankle length as in parts of the New Hebrides, but it usually reaches to about the knees. Skirts of fine matting are worn in the New Hebrides, and in parts of inland Papua women wear a band of bark cloth or matting similar to that of men. Women often remove their skirts while working and wear only a few leaves tucked into a waist cord. For both men and women in parts of New Guinea, bark-cloth cloaks protect them from the rain and provide warmth at night. Belts made from long strips of bark are also worn.

Ornaments of some kind are worn by all Melanesians. Generally, those worn by males and females are distinct. Leg bands and armbands made of plaited vegetable fibre are widely distributed in New Guinea, the Bismarck Archipelago, and the Solomon Islands and are worn by both sexes. Head ornaments include combs, some of which are fairly elaborate, such as those of the Admiralty Islands that have handles of red-painted resin with geometric patterns. Feather headdresses are worn for ceremonial occasions in many parts of New Guinea. An ornament known as a *kap-kap*, of the Solomon Islands and the Bismarck Archipelago, consists of a piece of fretwork carving, sometimes painted, attached to a disk of white shell and worn on the forehead or breast. Ears and noses are commonly pierced to take ornaments of carved bone, shell, bamboo, wood, and vegetable fibre. Necklaces are made from shells, teeth, bone, seeds, and vegetable fibre. Shell arm rings have a wide distribution; in some areas

#### Women's clothing

they are narrow and are worn in sets. Wooden arm rings are made in the New Hebrides.

Some ornaments indicate status; thus, breast ornaments of shell and cachalot ivory are worn by Fijian chiefs, while other types show that a man has taken a life or accomplished a certain number of ceremonial exchanges.

Hairdress varies. It may be allowed to grow in ringlets, as in New Guinea and parts of the Solomons. It is shaved off as a sign of mourning in the Trobriand Islands. Some coastal peoples in New Guinea draw their hair through a tapering cylinder of plaited cane, decorated with shells and teeth. Hair may also be decorated with lime or flowers.

Body painting and tattooing

Elaborate body painting is undertaken for ceremonial occasions. The practice of tattooing is widespread. Cicatrization, or the production of scar tissue, is common in New Guinea and the Solomons, where cuts are emphasized by rubbing some foreign matter into the wound. The heads of children are constricted to make them longer in parts of southern New Britain and in southern Malekula.

*Handicrafts.* Many articles are made from string, produced by rolling vegetable fibres in the palm of the hand or on the thigh. Before the fibres are twisted they may be prepared by soaking, scraping, or chewing. For thicker string or rope, several strands are twisted or plaited together. The string is used for nets, bags, bowstrings, and for lashing adze blades. It also has many constructional purposes; e.g., in house or canoe building and rigging.

Weaving is not common in Melanesia except where there is some Polynesian or Micronesian cultural influence, as in the small islands stretching from the Bismarck Archipelago to the Santa Cruz group. It is done with the single-tension loom, with no frame.

Use of bark cloth, however, is widespread. Fijian bark cloth, the finest, is made by soaking the inner bark of the paper mulberry (*Broussonetia papyrifera*) and beating it. It may be painted, rubbed with pigment, or stencilled. The bark cloth produced in the rest of Melanesia is generally coarser than that of Fiji.

Baskets are woven by practically all groups. The materials used include coconut leaves, pandanus, grass, rushes, and rattan. In the Admiralty Islands baskets are waterproofed with crushed putty nut. Mats, made from similar materials, provide bed and floor coverings, clothing, currency, canoe sails, and even house walls.

Pottery is made in all the main island groups and in most areas of New Guinea. No wheel is used. Firing is done in the open, without kilns or ovens. Pots are decorated in various ways, without glazing. Fijian pots are rubbed with resin while they are hot, giving them a shiny appearance.

Melanesian water craft

*Transportation.* The lack of roads, vehicles, and pack animals in Melanesia means that travelling in the interior is usually done on foot. Dugout canoes made from tree trunks carry people and goods on rivers and streams. Oceangoing outrigger canoes ply between islands. Canoes from the Santa Cruz Islands have a balancing platform on the side opposite the outrigger. Double-outrigger craft, with a float on each side of the hull and generally held to be an Indonesian type of craft, are to be seen in western Irian Barat, in the Torres Straits islands, and in the Nissan group. Catamarans, consisting of two hulls side by side, are made in the Fiji group, New Caledonia, and on the south coast of Papua. The Fijian catamaran sometimes exceeds 100 feet in length and can carry 200 men. The *lakatoi* of the Port Moresby area of New Guinea is a large cargo-carrying craft composed of a number of dugout hulls lashed side by side, with a deck covering them.

Some boats in the Solomon Islands and in southern New Ireland are constructed of planks, which are hand hewn by splitting tree trunks and adzing the surfaces. They are lashed together, held in place by U-shaped ribs, and the seams caulked with crushed putty nut. They are often lavishly decorated; the bows and sides are covered with pearl shell inlay, and a carved figurehead of a guardian spirit is attached to the bow.

Canoes for sailing generally have one mast, although

two-masted forms occur in New Guinea. Sails were formerly made of vegetable fibre or matting, now replaced in most areas by canvas. Paddles are manned both for moving and steering the canoes. Some are decoratively carved or painted.

*Property and exchange.* In Melanesia, property is usually vested in kinship groups rather than individuals. These groups tend to be either patrilineal (descent traced through the male line) or matrilineal (descent traced through women; for example, from a mother's brother to her son). Among the Trobriand Islanders, landholdings are vested in matrilineal subclans. The head of the subclan, who has the formal title of ownership, is the eldest male of the eldest lineage in the subclan. All members of the subclan have a share in the joint ownership and work as much of the land as they need or are able to use. They may pass on plots to their heirs but have no rights of disposal outside the subclan. Groups may also have vested rights to areas of beach for fishing or storing canoes, and rights to areas of uncultivable bush and even to particular trees. Patterns of kinship are not always rigid, and in a patrilineal society an individual may also have claims on his matrilineal kin; in certain circumstances he may exert his right to work land owned by his matrilineage.

Kinship basis of property

Some kinds of property are held individually, as personal possessions: tools, weapons, artifacts of all kinds, and garden produce. A man's wealth is usually distributed on his death. His pigs may be slaughtered for his funeral rites, leaving very little to his immediate heirs.

The exchange of goods is an important part of life in Melanesia. Great emphasis is placed upon reciprocity. Within any local group the bartering of such small objects as baskets and pots goes on continually. More formalized exchanges occur both within and between communities. Among the people of Mount Hagen in New Guinea, ceremonial exchange is one of the means by which status is achieved. The transactions take place between partners (usually of different subclans), who exchange pigs and pearl shells. It is status enhancing to give back more than one has received, so that if a man gives his partner two pearl shells and one pig (worth four pearl shells), he may expect to receive eight to 10 pearl shells in return. Wealth is thus kept in circulation.

Exchanges between relatives are common; a man is under an obligation to give a clansman an object he may need or covet, but there is an understanding that a reciprocal gift will be made at some future date. One way of celebrating a marriage is by an exchange of goods between the prospective in-laws.

At feasts and on ceremonial occasions, gifts of food and valuables are brought and then redistributed, often by a chief or big man. At these times specific obligations may be discharged. The settlement of disputes between warring groups frequently involves gift exchange, in addition to any compensation paid for death or injury.

Exchanges also take place with more distant communities. Elaborate trade networks have been established in the interior of New Guinea. The Kapauku of the central highlands form an important link in a trade route that originates at the coast and goes northward and then east into the mountains. Cowrie-shell necklaces, steel axes, and machetes move from the coast to the interior; red ochre, stone axes and knives, decorated net bags, and palm wood move in the opposite direction. Traders in each region acquire the goods, carry them a certain distance, and sell them to the next group in the chain.

Trade networks of New Guinea

The famous *kula* networks that cover a large area of the Massim district of eastern Papua handle two classes of goods. Each class always travels in the same direction around the *kula* area; thus, arm rings go counterclockwise and necklaces clockwise, so that a man receives necklaces from his partners in one direction and gives them arm rings he has received from the other direction. The valuables are highly prized, particularly old and finely made ones that have completed many circuits. A *kula* expedition requires a great deal of preparation, including magical ceremonies to ensure that all goes well. The canoes travel in fleets, carrying ordinary goods as well as valu-

able ones, although prestige and status come with the acquisition of *kula* objects.

Numerous objects serve as currency. To qualify for such use, an object must have a relatively stable value for all who use it, and the value of other objects must be easily calculable in terms of it. Some currency objects, such as tobacco and pigs, have an intrinsic practical use; others are employed only in transactions, and some are limited to particular kinds of transactions, such as the marriage payment. The stylized ornamental fishhooks of the Torres Straits islands fall into the last category. Shell disks, shell ornaments, pigs, pig tusks, mats, teeth, and many other objects serve as currency.

**Social and political life.** *Kinship.* Clan membership is determined by descent from a common ancestor. Some clans are fairly loose in organization, but most are exogamous—that is, marriage to another clan member is forbidden. Clansmen do not necessarily live in the same village; they cooperate with each other in various ways but tend to meet only on ceremonial occasions.

Some clans are totemic, believing themselves to be mystically associated with or descended from a particular animal or vegetable species; taboos may prohibit the killing or eating of one's totem. Some totemic clans believe they are able to increase or control the totem species.

Certain types of marriage are often preferred. A common preference is for marriage with a cross-cousin. (Cross-cousins are the children of siblings of the opposite sex; for example, one's cross-cousins are the children of one's mother's brother or one's father's sister.) Marriage with the children of the mother's brother is generally preferred, especially if they are also the children of the father's sister—which may be the case if cross-cousin marriage has been practiced over several generations.

The customs of kinship and marriage vary greatly in Melanesia. In some societies certain relationships are characterized by avoidance, notably that between a man and his mother-in-law. The man will aim to reduce all contact with his mother-in-law as far as possible. The degree of avoidance may depend on how closely he is related to her in other ways; it becomes attenuated with genealogical distance, so that avoidance is characteristically strongest where a man's mother-in-law is also his father's sister.

Many kinship systems are of the classificatory type in which a person calls various relatives by the same name. Thus, the term father may be used in addressing all of one's father's relatives of the same generation, such as his brothers and cousins. The children of these classificatory fathers then become "brothers" and "sisters." This is presumably an expression of the social ties and obligations that exist between kin and does not imply any confusion on the part of the Melanesians.

Polygyny is widespread. Since it is the wives who tend the gardens, such marriages have economic advantages. Although a particular group may be strongly patrilineal (as the Fijians) or matrilineal (as the Trobriand Islanders), it may stress kinship ties on both sides in different contexts. A man may wish to call on supporters or helpers in a range of situations—*e.g.*, to help him pay for a wife or clear a patch of forest—and his kin are under a special obligation to him. In societies where matrilineal ties are particularly important, a man can expect to inherit from his mother's brother. Tensions may arise in such cases if the father favours his own children rather than those of his sister.

*Political leadership.* Hereditary chieftainship is the rule in certain areas (for example, in Fiji and the Trobriand Islands), but it is not a typical institution in Melanesia. A big man or chief acquires his position by achieving prestige in his society. This may be done in a variety of ways, not merely by the accumulation of wealth; skill in oratory may be one requirement. Theoretically, the way to leadership is open to anyone with sufficient perseverance. Informal government by old men is common in much of Melanesia, the elders deciding group policy and arbitrating in internal and external disputes. It is recognized, however, that no individual has the right to compel anyone to do anything against his will.

Fiji, where there has been Polynesian influence, has powerful chiefs, and its society can be called highly stratified. Even there, however, sanctions curb the abuse of power, and commoners may withhold their cooperation in communal enterprises.

Political units are generally small and do not always have a specific head, although the leaders of component groups may confer together. Men's organizations constitute an important social institution. The men's house, usually a large building in the village, serves as a social centre where men meet, sleep, eat, and talk; it may also have political, religious, or economic functions. Membership is often based on the clan. The senior and most influential members tend to be lineage elders who have prestige in the society as a whole. Ceremonial and sacred objects are prepared and stored in the men's house to keep them away from the gaze of women and uninitiated males. When members give feasts, they distribute food and goods to each other. Some clubs are graded, as in the northern New Hebrides: an entrance fee has to be paid, and promotion through the grades is gained by purchase and by giving feasts. Most men join the clubs. There are also various secret societies whose members wear masks and impersonate spirits. A man may belong to several of them.

*The life cycle.* Ideas about conception vary in Melanesia, and it has been suggested that some peoples are ignorant of the nature of the relationship between sexual intercourse and pregnancy. In most of the societies, however, it is understood that both parents play a part in the process. On the island of Wogeo the man is likely to suffer morning sickness; he is treated as an "expectant father." Pregnant women observe various taboos such as restraining from sexual intercourse to ensure the health of the child. During birth a woman may go into seclusion, perhaps in a specially built hut. Female relatives assist with the process.

The weaning of children takes place late by Western standards, sometimes delayed until the end of the third year, although supplementary solid foods are given at an early stage. It is common for a mother to take her baby to the garden with her, carrying it in a bag on her back or suspending it from a tree in a basket while she works. Older children are left in the village with relatives and friends. Babies in Wogeo are discouraged from crawling, as the parents feel they should be old enough to look after themselves before having freedom of movement. Small children of both sexes play together but normally form separate groups at puberty or earlier. By the early teens young people tend to be preoccupied with adult concerns. The Wogeo people set aside property for a child, such as a garden plot, and both boys and girls are expected to assist their elders according to their capacity. The education of children is taken seriously. Much time and trouble are expended on imparting knowledge and teaching technical skills. Moral training is also emphasized, including learning to cooperate with others. Myths and stories are used in teaching.

Initiation rites are held for both boys and girls, although they are generally of greater significance for boys. The boys may spend a period in seclusion, where they learn about the male role in society or are given secret knowledge not available to women and uninitiated males. Initiation is often done in fairly large groups; it may involve circumcision or some other form of physical marking.

Ceremonies at birth, initiation into manhood, marriage, and death usually include a feast and the exchange of gifts. Sometimes ceremonies are combined, as in New Ireland, where funeral rites may include the initiation of a group of boys.

Some ceremonies take place regularly every year, notably those connected with gardening. In the Trobriand Islands the garden magician is an important figure at every stage of the horticultural cycle. At harvest time piles of yams are displayed, the storehouses are filled, and feasting and distribution of food take place.

*Law and justice.* In many Melanesian societies, certain offenses are thought to be punished automatically by spirits or ancestral ghosts. Other punishment takes different

Functions  
of the  
men's  
house

Totemic  
clans and  
taboos

Weaning  
and care  
of young  
children

forms, depending on the seriousness of the offense. Failure to cooperate with one's kin and fellow villagers may lead to ostracism. For more violent offenses such as homicide, the culprit may be required to leave the community for a space of time. "Big men" sometimes act as arbitrators in disputes, using their position and influence to encourage the parties to settle their differences. Such a settlement may be marked by an exchange of goods to show that the parties have resumed relations. Members of the same lineage tend to support each other in disputes with those of other groups. In general, within political units the tendency is to settle quarrels; if skirmishes occur, nonlethal weapons are used.

Warfare between groups was formerly endemic in Melanesia and still persists in some areas. The situation among the Siane of the eastern highland of New Guinea may be taken as fairly typical. A clan normally maintains friendly relations among its members and is formal or hostile with members of other clans. But since other groups are possible sources of husbands or brides, alliances are made between clans. Disputes usually concern such matters as the seduction of a wife, theft of a pig, or perhaps a death blamed on sorcery. Resort to force may take the form of ambush and murder of a single victim from the offending clan, or it may involve a bout of ceremonial warfare. Neutral clans may be brought in to mediate in the settlement of hostilities; they estimate on which side the balance of damages lies, so that compensation can be made. A peacemaking feast usually follows the settlement.

Headhunting was formerly practiced in western Papua, in large areas of Irian Barat, in the Sepik River basin, and in the central Solomon Islands. It usually had some ritual significance. In some cases a male had to obtain a head before he could be initiated into manhood. The Kiwai of southwest Papua took heads as a sign of achievement and kept them as trophies.

Warfare on a large scale occurred only in Fiji, where mercenaries from Tonga took service with the Fijian chiefs.

**Religion and art.** *Beliefs.* Melanesians believe in a wide range of supernatural phenomena. These include spirit beings, non-personalized forces, and sometimes totems. It is often difficult to make a distinction between magic and religion.

Spirit beings are of various kinds. There are spirits of the dead, both remote and recent. There are spirits that have some creative or regulative function and others that have no such function, including demons or tricksters. The latter two groups are often associated with a particular place, such as a river or sea. Totems, which are species of animals or vegetables, fall into two categories: they may be believed to be ancestors of a particular descent group, or they may be regarded as symbols for such groups.

All Melanesians perform rituals to coerce or propitiate the dead. The Mae Enga of the western New Guinea highlands often dedicate the pigs they kill to potentially dangerous ancestors. If a man falls ill or is injured, a pig is killed immediately; if the patient fails to recover, divination is made by specialists to see where the ritual was at fault.

Ancestors, souls of the dead, and spirits are often thought to inhabit a world similar to that of living beings. Existing social customs are generally validated through myths about ancestors or spirit beings, including how they set the precedents for current forms of behaviour.

The concept of mana, or supernatural power, is a recurrent theme in Melanesian religion, particularly among the eastern groups. Mana can benefit a man or be dangerous to him; it may be contained in inanimate objects or be infused into them by experts. It seems to originate from spirits or ghosts of the dead.

Magical techniques are used to achieve health, wealth, good looks, or resistance to alien sorcery. Most persons possess a few charms and spells, but there are also specialists who practice the more important kinds of magic such as garden or healing magic, sometimes for a fee. Serious illness or death is often ascribed to sorcery within or outside the group, and sorcerers are greatly feared.

*Art and music.* The Melanesians have a rich and varied artistic life. The principal medium of the artist is wood; other materials include seashells, turtle shells, vegetable fibres, feathers, flowers, leaves, and string. In most areas a great many masks, figures, and other ceremonial objects are produced. They may be made of carved wood, bark cloth, or basketry and are painted with red, white, and black earth pigments. Houses are often decorated; in New Caledonia, chiefs' houses are carved and painted in black and red, the designs incorporating enormous human faces. A lot of decorative work is done on everyday objects such as lime boxes, spatulas, and food bowls. In the Massim district of eastern Papua, the curvilinear patterns carved in low relief on canoe prows, dance ornaments, ornamental boards for yam houses, and war clubs are derived from birds (especially the frigate bird) and other natural objects. The human figure is a dominant theme in many areas. The *malanggan* carvings of northern New Ireland, made for funeral rituals, are complex wooden figures in the shape of men, pigs, birds, snakes, and fish, painted in various colours, often with areas of openwork.

Music and dancing are practiced both ceremonially and for amusement. Learning dances is sometimes part of a young man's initiation. Men and women tend to dance separately. Dancing is accompanied by skin drums beaten by hand and wooden slit gongs played with sticks. Rhythm is also supplied by seed rattles attached to the wrists or ankles. Panpipes, mouth harps, and bamboo or reed flutes are widely used. Bull-roarers are whirled to simulate the voices of the spirits. In the New Hebrides, enormous slit gongs are played for elaborate ballet-type dances.

Singing and storytelling are important in many ceremonies. The songs are made up, often describing recent events, with the audience singing a refrain. The impersonation of spirits, mythological characters, and ancestors is widespread. The Elema of the Gulf of Papua region have a dramatic cycle taking 20 to 30 years to complete. It involves much complex ritual; central to it is the production of masks, which are ritually killed after the ceremonies are completed. A segment of dancing and drama may last a month, during which the characters and actions of a number of sea spirits are portrayed to the accompaniment of drums.

Children's games such as hide-and-seek, cat's cradle, "hunt the nut," and chasing games are played. One adult game in the New Hebrides is played by throwing reeds on the ground so that they rise in the air and fly some distance; the winner is the one whose reed goes the farthest. Contests between villages often end in blows.

#### MODERN MELANESIA

European settlers, chiefly missionaries at first, came to Melanesia in the 19th century. The Dutch took possession of western New Guinea in 1828; the French gained New Caledonia in 1853; Fiji was ceded to the British in 1874; the British and Germans partitioned New Guinea and the Bismarck Archipelago in 1884; a British protectorate was established over the Solomon Islands, with the exception of Buka and Bougainville, in 1893; Anglo-French competition for influence in the New Hebrides led to the establishment of a condominium there in 1906; the Australians began to administer Papua in 1909 and all of eastern New Guinea after World War I. West New Guinea (Irian Barat) became part of Indonesia in 1969.

Europeans and their civilization had a powerful impact upon the Melanesians. The Europeans introduced plantation agriculture and indentured labour, metal tools, and many new crops. They also introduced various infectious diseases, including measles, from which many people died. Another product of the European influx was the cargo cult. It was based on the idea of a coming millennium. One of the early cargo cults was the Tuka movement in Fiji, first observed in 1885. Ndugumoi, a hereditary priest, claimed to have received word that all ancestors would soon return, the whites would be driven away, and quantities of goods would be provided for everyone. He rallied many followers, but the government arrested

Music and dancing

Spirit beings

The European impact on traditional Melanesia

him and he died in exile. The Tuka movement lasted until after World War I.

There have been numerous other cargo cults, all arising out of the Melanesian astonishment at the vast amount of goods available to the white men, which they assume to be provided by some supernatural agency. One version of the central myth is that God (or Jesus or angels) has been sending goods to the Melanesians but that the white people have been intercepting them. In some of the cults that developed after World War II, the participants even built airstrips and warehouses to receive the cargo. In recent times the cults have acquired political overtones, and some observers have suggested that they represent emergent nationalist movements.

In the 1970s Melanesia seemed to be moving rapidly into the modern world. Fiji had become independent; the Solomon Islands had a Governing Council with a Melanesian-elected majority, and nationalist movements were becoming stronger in the territories of Papua, New Guinea, New Caledonia, and the New Hebrides. Melanesians were being increasingly employed in jobs formerly held by Europeans. Education was continually increasing; there were universities at Port Moresby (in eastern New Guinea) and on Fiji.

The culture of Melanesia as described is disappearing; only in areas without intensive contact with Europeans do the old ways continue without much change.

**BIBLIOGRAPHY.** Not many books deal with the Melanesian region as a whole. LEWIS L. LANGNESS and JOHN C. WESCHLER (eds.), *Melanesia: Readings on a Culture Area* (1971), includes materials dealing with a range of Melanesian societies. A comprehensive treatment of the region and its geography is H.C. BROOKFIELD with DOREEN HART, *Melanesia: A Geographical Interpretation of an Island World* (1971). The Melanesian economy is treated in JACQUES BARRAU, *Subsistence Agriculture in Melanesia* (1958), which correlates different types of subsistence economies with five ecological zones. LEOPOLD POSPISIL, *Kapauka Papuan Economy* (1963), is a description of the economy of the West New Guineans. BRONISLAW MALINOWSKI's works on the Trobriand Islands are classics; his *Argonauts of the Western Pacific* (1922), contains a full account of the *kula* exchange of eastern Papua. B.A.L. CRANSTONE, *Melanesia: A Short Ethnography* (1961), is a clear, concise, and well-illustrated treatment of all aspects of material culture and technology. Recent economic changes are discussed in RICHARD F. SALISBURY, *From Stone to Steel: Economic Consequences of a Technological Change in New Guinea* (1962). There are numerous monographs and articles dealing with social organization in various parts of the Melanesian region. J.A. BARNES, "African Models in the New Guinea Highlands," *Man*, 62:5-9 (1962), is an important essay. M.J. MEGGITT, *The Lineage System of the Mae-Enga of New Guinea* (1965), describes a Melanesian segmentary lineage system but has led to much controversy. Another recent view of patterns of kinship is PHYLLIS M. KABERRY, "The Plasticity of New Guinea Kinship," in MAURICE FREEDMAN (ed.), *Social Organization: Essays Presented to Raymond Firth* (1967). A description of the way in which "big men" achieve their status in the Hagen area of New Guinea is ANDREW STRATHERN, "Despots and Directors in the New Guinea Highlands," *Man*, 1:356-367 (1966). H. IAN HOGBIN's studies of socialization among the Wogeo include "A New Guinea Infancy: From Conception to Weaning to Wogeo," *Oceania*, 13:285-309 (1942-43); "A New Guinea Childhood: From Weaning till the Eighth Year in Wogeo," *ibid.*, 16:275-296 (1945-46); and "Puberty to Marriage: A Study of the Sexual Life of the Natives of Wogeo, New Guinea," *ibid.*, 16:185-209. Some general characteristics of Melanesian religions are examined in PETER LAWRENCE and M.J. MEGGITT (eds.), *Gods, Ghosts, and Men in Melanesia: Some Religions of Australian New Guinea and the New Hebrides* (1965). For a historical and analytical account of cargo cults in Melanesia, see PETER WORSLEY, *The Trumpet Shall Sound* (1957). Useful books on Melanesian art include P.H. LEWIS, *The Social Context of Art in Northern New Ireland* (1969); DOUGLAS NEWTON, *Art Styles of the Papuan Gulf* (1961); and FRANCIS E. WILLIAMS, *Drama of Oroko: The Social and Ceremonial Life of the Elema* (1940).

## Melbourne

Although the officially defined city was the home of only some 75,000 people in the early 1970s, Melbourne

is the core of an extensive metropolitan area and the world's most southerly multimillion-peopled urban area. It is situated on the southeastern coast of Australia, at the head of Port Phillip Bay and is the capital of the state of Victoria; from 1901 until 1927 it was the capital of the Commonwealth of Australia. In Australia, it is second only to Sydney in size, and there is an intense rivalry between the two cities, to whom history and geography have bequeathed quite diverse characteristics. Though Melbourne's flat site has led to the regular development of a rectangular pattern of streets, the city has many beautiful parks, and the person with an eye for architectural detail and history can find much that is varied and attractive. Melbourne also has a reputation for conservatism and financial soundness—attributes that many feel were revealed in the early 1970s by the burgeoning skyline of the central city and the rapidly expanding eastern suburbs. Related information may be found under VICTORIA; AUSTRALIA, HISTORY OF.

**History.** Melbourne is distinguished from the other state capitals by the fact that it was founded unofficially, by individual enterprise. The site of Melbourne was discovered in February 1803, but settlement was delayed until 1835, when the pioneer settler and entrepreneur John Batman and his associates purchased 600,000 acres on the northern shores of Port Phillip Bay from aboriginal groups. Before returning to Tasmania, Batman left a party to protect this new interest near Geelong. A second, independent party from Tasmania, organized by another pioneer land speculator, John Fawkner, arrived two months later and established stores and houses. Though there was disagreement between the two early groups, they were both agreed that the New South Wales government should recognize the settlement. One year later, the first administrator of Port Phillip arrived, and in 1837 the new settlement between the Yarra River and the Maribyrnong River was named Melbourne, after the British Prime Minister, Lord Melbourne.

The first settlement measured one mile in length along the north bank of the river and half a mile in width; it became a town in 1842 and a city in 1847, but the first spurt in development followed the discovery (1857) of gold around Bendigo and Ballarat, less than 100 miles away. These discoveries at first depopulated the city, but immigrants from overseas soon began to arrive, and good business was done in satisfying their needs. In 1852 alone, 100,000 people arrived at the gold fields, and in three years the population of the city itself had increased fourfold to 80,000. Melbourne quickly capitalized on its central position and port facilities to capture most of the region's trade: railways were built to other important centres such as Geelong (1856); Ballarat and Bendigo (1862); Echuca (1864); and Wodonga (1873); a link with the New South Wales system at Albury was made in 1883. In recognition of the importance of the city's port facilities the Melbourne Harbour Trust was created in 1887, and the course of the lower Yarra was redirected through the Goode Canal to the south to improve navigation and reduce silting problems. During the 1870s manufacturing industries flourished under the protection of a high tariff wall, and progress in most areas continued until 1889 when financial problems and the collapse of many firms began to shake public confidence. In the decade before 1891 the population of the city increased by nearly 200,000; in the following decade only 6,000 were added.

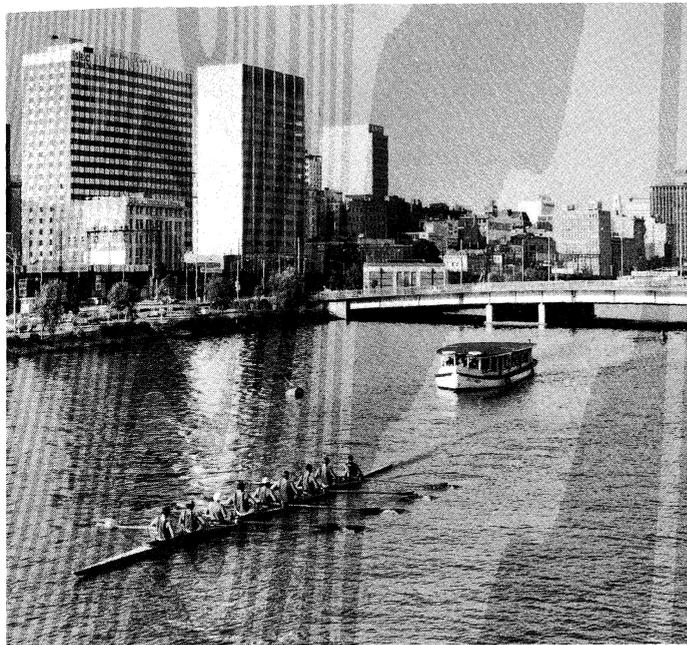

The 20th century, however, brought new confidence with the establishment of the Commonwealth of Australia and the short-lived selection of Melbourne as the national capital. During the two World Wars, and in the period after 1945, manufacturing industry in Melbourne increased dramatically. The expansion in the latest period was accompanied by the influx of thousands of British and European immigrants.

**The contemporary city.** For census and planning purposes the Melbourne of the 1970s has two boundaries. The outer boundary, defining the Melbourne Statistical Division, includes all areas in close economic and social contact with the central city. It begins on the west shore

Charles May—Black Star

of Port Phillip Bay and arches north and east of the bay to the north shore of Western Port Bay; the area enclosed is 2,368 square miles (6,133 square kilometres). The inner boundary encloses the Melbourne metropolitan area; *i.e.*, those areas, which, at the time of a census, have a density of at least 500 persons per square mile. By 1966, this area occupied 21 percent of the statistical division.

The metropolitan area occupies a flat site at the northern end of Port Phillip Bay. Most of it is less than 400 feet high. The shape of the area displays a strong correlation with the geology and drainage of the site. The central city is built close to the Yarra River on firm foundations of ancient sandstones and mudstones. Similar rocks underlie some of the higher eastern areas that command the best views and are occupied by more expensive housing. To the north and west, a plain underlain by basalt rocks encouraged the early establishment of low-cost housing and industry but has proved less attractive in recent times. To the south, the mouth of the Yarra and Maribyrnong rivers consists of soft alluvium, which has been easily excavated to provide excellent docks and industrial sites close to the city centre. The metropolitan area is drained by the River Yarra and its main tributaries—the Maribyrnong River, and the Merri, Darebin, Diamond, and Gardiner creeks. These watercourses interrupt the urban areas, and their valleys are used mainly for drainage, sports grounds, parks, and principal railways and highways. The city has developed in an asymmetric pattern around the bay. The western shores of the bay are comparatively underdeveloped, while most of the eastern shores have been subdivided for commuters' homes in Frankston, and for holiday homes in Mornington and Flinders. Development toward building sites in the eastern hills at Eltham, Lilydale, and Sherbrooke was further distorting the shape of the city in the early 1970s.

**Demographic trends.** At the start of the 1970s, the population of the Melbourne Statistical Division was estimated to be over 2,380,000, or almost 70 percent of the population of the entire state of Victoria. Even as far back as 1921, Melbourne had contained more than half the state's population. Ninety-five percent of Melbourne's population lives in the metropolitan area and the city's population is growing at an annual rate of about 2 percent. This is slower than it was in the decade following the 1954 census, when immigration accounted for well over half the annual increase. Immigration and natural increase were making equal contributions to population growth in 1970. The distribution of population within the

metropolitan area is slowly changing. Some rehabilitation of the poorer residential inner areas has occurred. The Housing Commission supervises the completion of about 1,500 houses and apartments each year.

**Economic life.** That Melbourne dominates the economic life of Victoria is not surprising in view of the fact that the city is at the centre of the communications network linking the rest of the state to Australia and the world, that it contains the bulk of the state's population, and is the seat of government and of major financial institutions.

Melbourne port occupies 10½ square miles of level, easily excavated land at the mouth of the Yarra River. Particular sections of the port specialize in different types of cargo, using the most modern loading and unloading techniques. Main imports are bulk oils, newsprint and paper, phosphatic rock, iron and steel, chemicals, timber, and coal. Main exports are wool, scrap metal, meat, fruit, flour, and dairy products. Passenger terminals handle some 100,000 travellers each year.

The Melbourne Statistical Division includes three-quarters of the state's factories, employing 83 percent of its industrial workers. Although 60 percent of the factories employ fewer than ten people, 55 percent of the work force is employed in large factories with more than 100 employees. The earliest clothing and metal factories were established in the inner suburbs of Collingwood, Richmond, Fitzroy, Brunswick, Melbourne, and Footscray. Newer and larger industries—producing motor cars, rubber goods, chemicals, and refined oils—are being established in such outer suburbs as Moorabbin, Altona, Broadmeadows, and Dandenong, areas which offer cheaper land in more extensive sites, an increasing population, and fewer traffic congestion problems. The most important Melbourne industries, in terms of numbers employed, are: metal processing; textile and clothing manufacture; food preparation; and paper making and printing. The reduced industrial importance of the inner city is paralleled by its declining share of the retail trade. New, large, regional shopping centres have been established in the rapidly growing eastern and southern suburbs.

**Administration and services.** The Melbourne Statistical Division consists of 41 cities and 13 shires, each with its own council. The councils have the responsibility of collecting taxes (rates) and using these and other funds to provide local services, notably the maintenance of roads and the provision of libraries. While uniform building regulations apply to the Melbourne Statistical Division, local councils may make specific bylaws dealing with such subjects as subdivisions and apartment building. There are also certain statutory authorities that control aspects of metropolitan government. The Melbourne and Metropolitan Board of Works is responsible for a master planning scheme, the construction of main roads and bridges, the provision of water, and the disposal of sewage. A Tramways Board controls tram and bus services; a Harbour Trust is responsible for the large port area; and a Housing Commission, created in 1938, coordinates slum clearance and urban renewal.

Melbourne is well equipped to provide the services expected of a major city. Adequate public transport is provided by electric trains, buses, and old-fashioned—but nevertheless efficient—tramcars. Increasing numbers now travel by car, however, and all three services were showing declining numbers of passengers and rising deficits at the beginning of the 1970s. The emphasis on car travel has created problems of road congestion at peak hours, and efforts were being made by the 1970s to provide a system of freeways, clear ways, and a major high-level bridge over the lower Yarra to link the eastern and western industrial areas. An international airport near suburban Tullamarine opened in 1970, and a well-equipped port serves overseas passengers. Melbourne maintains excellent telecommunication links with the world's major cities.

**Cultural life.** Opportunities to appreciate all forms of art and culture and to enjoy other types of recreation are plentiful in and around Melbourne. The Victorian Arts Centre, opened in 1968, houses art galleries, theatres,

Local  
government

Central Melbourne and (inset) the Port Phillip Bay area.

auditoriums, studios, and study areas on a central site. Each year seasons of opera, ballet, and concerts include performances by international artists. Live theatres and cinema complexes present contemporary and popular plays and films. There are hundreds of sports grounds, tennis courts, swimming pools, and golf courses for active sportsmen, while spectators find good accommodations at the famous Melbourne Cricket Ground, which holds crowds of more than 110,000, and at the Kooyong tennis

courts. Sailing and fishing on the bay and surfing on the ocean beaches are also available, and the winter ski fields around Buller are within easy reach.

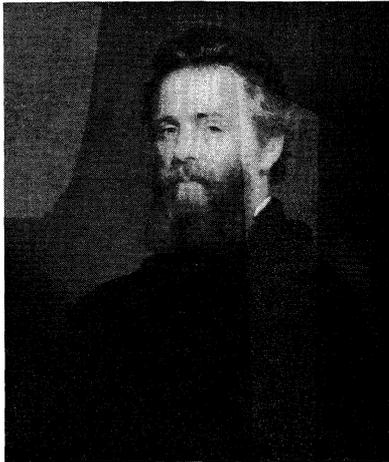

**BIBLIOGRAPHY.** W.H. NEWNHAM, *Melbourne* (1956), a good, general, historical account; MELBOURNE, COMMONWEALTH BUREAU OF CENSUS AND STATISTICS, *Victorian Year Book* (annual), invaluable for recent statistics and developments; also contains a detailed bibliography.

## Melville, Herman

In his life as well as his work, Herman Melville was a symbol of the conflicts inherent in the new American nation in which he wrote. He was a man at odds with the heady idealism of his age, which saw the young nation as an image of moral regeneration, liberated from the corrupting traditions of Europe. He wanted to believe, with Ralph Waldo Emerson, in the greatness of America's and humanity's future, and, unlike his friend Nathaniel Hawthorne, he longed to cling to an idealistic vision of the human being. But he was unable to reconcile such ideals with the reality he experienced. Instead of finding in the explosive growth of the country in the 19th century a sign of regeneration, he saw the brutal acquisitiveness of its commerce, the misery of the exploited immigrants, and the contrast between human profession and human act.

**Heritage and youth.** Melville's heritage and youthful experiences were perhaps crucial in forming the conflicts underlying his artistic vision. He was born on August 1, 1819, in New York City, the third child of Allan and Maria Gansevoort Melvill, in a family that was to grow to four boys and four girls. His forebears had been among the Scottish and Dutch settlers of New York and had taken leading roles in the American Revolution and in the fiercely competitive commercial and political life of the new nation. One grandfather, Maj. Thomas Melvill, was a member of the Boston Tea Party in 1773, and subsequently a New York importer. The other, Gen. Peter Gansevoort, was a friend of James Fenimore Cooper and famous for leading the successful defense of Ft. Stanwix, in upstate New York, against the British.

In 1826 Allan Melvill wrote of his son as being "very backward in speech and somewhat slow in comprehension . . . of a docile and amiable disposition." In that same year, scarlet fever left the boy with permanently weakened eyesight, but he attended Male High School. When the family import business collapsed in 1830, the family returned to Albany, where Herman enrolled briefly in Albany Academy. Allan Melvill died in 1832, leaving his family in desperate straits. The eldest son, Gansevoort, assumed responsibility for the family and took over his father's felt and fur business. Herman joined him after two years as a bank clerk and some months working on the farm of his uncle, Thomas Melvill, in Pittsfield, Mass. About this time, Herman's branch of the family altered the spelling of its name. Though finances were precarious, Herman attended Albany Classical School in 1835 and became an active member of a local debating society. A teaching job in Pittsfield made him unhappy, however, and after three months he returned to Albany.

**Wanderings and voyages.** Young Melville had already begun writing, but the remainder of his youth became a quest for security. A comparable pursuit in the spiritual

realm was to characterize much of his writing. The crisis that started Herman on his wanderings came in 1837, when Gansevoort went bankrupt and the family moved to nearby Lansingburgh (now Troy). In what was to be a final attempt at orthodox employment, Herman studied surveying at Lansingburgh Academy to equip himself for a post with the Erie Canal project. When the job did not materialize, Gansevoort arranged for Herman to ship out as cabin boy on the "St. Lawrence," a merchant ship sailing in June 1839 from New York for Liverpool. The summer voyage did not dedicate Melville to the sea, and on his return his family was dependent still on the charity of relatives. After a grinding search for work, he taught briefly in a school that closed without paying him. His uncle Thomas, who had left Pittsfield for Illinois, apparently had no help to offer when the young man followed him West. In January 1841 Melville sailed on the whaler "Acushnet," from New Bedford, Mass., on a voyage to the South Seas.

In June 1842 the "Acushnet" anchored in the Marquesas Islands in present-day French Polynesia. Melville's adventures here, somewhat romanticized, became the subject of his first novel, *Typee* (1846). In July Melville and a companion jumped ship and, according to *Typee*, spent about four months as guest-captives of the reputedly cannibalistic Typee people. Actually, in August he was registered in the crew of the Australian whaler "Lucy Ann." Whatever its precise correspondence with fact, however, *Typee* was faithful to the imaginative impact of the experience on Melville. Despite intimations of danger, Melville represented the exotic valley of the Typees as an idyllic sanctuary from a hustling, aggressive civilization.

Although Melville was down for a 120th share of the whaler's proceeds, the voyage had been unproductive. He joined a mutiny that landed the mutineers in a Tahitian jail, from which he escaped without difficulty. On these events and their sequel, Melville based his second book, *Omoo* (1847). Lighthearted in tone, with the mutiny shown as something of a farce, it describes Melville's travels through the islands, accompanied by Long Ghost, formerly the ship's doctor, now turned drifter. The carefree roving confirmed Melville's bitterness against colonial and, especially, missionary debasement of the native Tahitian peoples.

These travels in fact occupied less than a month. In November he signed as a harpooner on his last whaler, the "Charles & Henry" out of Nantucket, Mass. Six months later he disembarked at Lahaina, in the Hawaiian Islands. Somehow he supported himself for over three months, then in August 1843 he signed as an ordinary seaman on the frigate "United States," which in October 1844 discharged him in Boston. *White-Jacket* (1850) conveys an idea of the tensions embodied for Melville in that voyage home, among them his feeling for the democratic fraternity of the seamen, about which he had mixed feelings, and his opposition to savage shipboard discipline. (Over 160 floggings were recorded on that voyage of the "United States.") The book demonstrated comradeship undermined by alienation and a faith in human perfectibility that was unsettled by an awareness of human corruption.

**The years of acclaim.** Melville rejoined a family whose prospects had much improved. Gansevoort, who after James K. Polk's victory in the 1844 presidential elections had been appointed secretary to the U.S. legation in London, was gaining political renown. Encouraged by his family's enthusiastic reception of his tales of the South Seas, Melville wrote them down and attempted to publish them. Harper and Brothers, skeptical of their authenticity, rejected the manuscript. Gansevoort had more success; though also dubious, the London publisher John Murray accepted it. Wiley and Putnam agreed to an American edition. The years of acclaim were about to begin for Melville.

*Typee* provoked immediate enthusiasm and outrage. Was it to be believed? The companion of Melville's Polynesian idyll appeared and verified its truth, but his corroboration was poorly detailed. Doubts persisted. Missionaries protested loudly against the criticism of their

*Typee*

Early novels

activities, and the second edition deleted offensive passages. But for Melville it was unquestionably fame, confirmed by the identical response to *Omoo*, published by a still uneasy Murray. Gansevoort, dead of a brain disease, never saw his brother's career consolidated, but the bereavement left Melville head of the family and the more committed to writing to support it. Another responsibility came with his marriage in August 1847 to Elizabeth Shaw, daughter of the chief justice of Massachusetts. He tried unsuccessfully for a job in the U.S. Treasury Department, the first of many abortive efforts to secure a government post.

In 1847 Melville began a third book, *Mardi*, and, through Evert Duyckinck, a Wiley and Putnam editor, was introduced into the literary and artistic circles of New York City. He became a regular contributor of reviews and other pieces to a literary journal. To his new acquaintances he appeared the character of his own books—extrovert, vigorous, “with his cigar and his Spanish eyes,” as one writer described him. Melville resented this somewhat patronizing stereotype, and in her reminiscences his wife recalled him in a different aspect, writing in a bitterly cold, fireless room in winter. He enjoined Murray not to call him “the author of *Typee* and *Omoo*,” for his third book, *Mardi* (1849), was to be a different cast.

*The quests begun.* When *Mardi* appeared, public and critics alike found its wild, allegorical fantasy and medley of styles incomprehensible. It began as another Polynesian adventure but quickly set its hero in pursuit of the mysterious Yillah, “all beauty and innocence,” a symbolical quest that ends in anguish and disaster. Concealing his disappointment at the book's reception, Melville wrote to Richard Bentley, now his English publisher, that the book, “judged only as a work meant to entertain,” had been misapprehended by the critics and added, darkly, that “*Mardi*, in its larger purposes, has not been written in vain.”

Financially it had been. To repair his popular reputation, Melville quickly wrote *Redburn* (1849) and *White-Jacket* (1850) in the manner expected of him. Richard Bentley in England and Harper and Brothers in New York brought out *Redburn*, which was an elaboration of Melville's 1839 voyage on the “St. Lawrence,” with an invented melodramatic sequence in England. In October 1849 Melville sailed to England to resolve Bentley's doubts about *White-Jacket*. Rewarded by Bentley's acceptance of *White-Jacket*, he visited the Continent, kept a journal, and arrived back in America in February 1850. The critics acclaimed *White-Jacket*, and its powerful criticism of abuses in the U.S. Navy won it strong political support.

But both novels, however much they seemed to revive the Melville of *Typee*, had passages of profoundly questioning melancholy. It was not the same Melville who wrote them. He had been reading Shakespeare with “eyes which are as tender as young sparrows,” particularly noting sombre passages in *Measure for Measure* and *King Lear*. This reading struck deeply sympathetic responses in Melville, counterbalancing the Transcendental doctrines of Emerson, whose general optimism about human goodness he had heard in lectures and some of whose attitudes pervaded *White-Jacket*. A fresh imaginative influence was supplied by Hawthorne's *Scarlet Letter*, a novel deeply exploring good and evil in the human being that Melville read in the spring of 1850. On Duyckinck's encouragement, he made Hawthorne's *Mosses from an Old Manse* the basis of a eulogistic essay that was published in a journal. That summer, Duyckinck introduced him to Hawthorne, who was living near Pittsfield. Melville bought a nearby farm, which he christened “Arrowhead,” and the two men became neighbours physically as well as in sympathies.

*Moby Dick* and *Pierre*. Melville had promised his publishers for the autumn of 1850 the novel first entitled *The Whale*, finally *Moby Dick*. His delay in submitting it was caused less by his early-morning chores as a farmer than by his explorations into the unsuspected vistas opened for him by Hawthorne. Their relationship reani-

mated Melville's creative energies. On his side, it was dependent, almost mystically intense—“an infinite fraternity of feeling,” he called it. To the cooler, withdrawn Hawthorne, such depth of feeling so persistently and openly declared was uncongenial. The two men gradually drew apart. They met for the last time, almost as strangers, in 1856, when Melville visited Liverpool, where Hawthorne was American consul.

*Moby Dick* was published in London in October 1851, and a month later in America. It brought its author neither acclaim nor reward. Basically its story is simple. Captain Ahab pursues the white whale, Moby Dick, which finally kills him. At that level, it is an intense, superbly authentic narrative of whaling. In the perverted grandeur of Captain Ahab and in the beauties and terrors of the voyage of the “Pequod,” however, Melville dramatized his deeper concerns: the equivocal defeats and triumphs of the human spirit and its fusion of creative and murderous urges. In his private afflictions, Melville had found universal metaphors.

Increasingly a recluse to the point that some friends feared for his sanity, Melville embarked almost at once on *Pierre*. It was an intensely personal work, revealing the sombre mythology of his private life framed in terms of a story of an artist alienated from his society. In it can be found the humiliated responses to poverty that his youth supplied him plentifully and the hypocrisy he found beneath his father's claims to purity and faithfulness. His mother he had idolized; yet he found the spirituality of her love betrayed by sexual love. The novel, a slightly veiled allegory of Melville's own dark imaginings, was rooted in these relations. When published in 1852, it was another critical and financial disaster. Only 33 years old, Melville saw his career in ruins.

*The losing of faith.* Near breakdown, and having to face in 1853 the disaster of a fire at Harper's that destroyed most of his books, Melville persevered with writing.

*Israel Potter*, plotted before his introduction to Hawthorne and his work, was published in 1855, but its modest success, clarity of style, and apparent simplicity of subject did not indicate a decision by Melville to write down to public taste. His other contributions to *Putnam's Monthly Magazine*, “Bartleby the Scrivener” (1853), “The Encantadas” (1854), and “Benito Cereno” (1855), reflected the despair and the contempt for human hypocrisy and materialism that possessed him increasingly following the failure of *Pierre*. The clerk Bartleby was typical. The germ of his experience—isolating himself from his duties, from society, in the end from life itself—was Melville's own. Bartleby was the casualty of a society indifferent to his mute, passive protest. The tormented writer knew that these stories were not the way back to his audience but a private pursuit. As he wrote to Hawthorne, “What I feel most moved to write will not pay.”

In 1856 Melville set out on a tour of Europe and the Levant to renew his spirits. The most powerful passages of the journal he kept are in harmony with *The Confidence-Man* (1857), a despairing satire on an America corrupted by the shabby dreams of commerce. This was the last of his novels to be published in his lifetime. Three American lecture tours were followed by his final sea journey, in 1860, when he joined his brother Thomas, captain of the clipper “Meteor,” for a voyage around Cape Horn. He abandoned the undertaking in San Francisco.

**The years of withdrawal.** Around these years Melville abandoned the novel for poetry, but when he came home the prospects for publication were not favourable. With two sons and daughters to support, Melville sought government patronage. A consular post he sought in 1861 went elsewhere. On the outbreak of the Civil War, he volunteered for the Navy, but was again rejected. He had apparently returned full cycle to the insecurity of his youth, but an inheritance from his father-in-law brought some relief and “Arrowhead,” increasingly a burden, was sold. By the end of 1863, the family was living in New York City. The war was much on his mind and furnished the subject of his first volume of poetry, *Battle-Pieces* and

Mardi

Meeting  
with  
Hawthorne

*Aspects of the War* (1866), published privately. Four months after it appeared, an appointment as a customs inspector on the New York docks finally brought him a secure income.

Despite poor health, Melville began a pattern of writing evenings, weekends, and on vacations. In 1867 his son Malcolm shot himself, accidentally the jury decided, though it appeared that he had quarrelled with his father the night before his death. His second son, Stanwix, who had gone to sea in 1869, died in a San Francisco hospital in 1886 after a long illness. Throughout these griefs, and for the whole of his 19 years in the customs house, Melville's creative pace was understandably slowed from the amazing fertility of the 1840s.

Final  
writings

His second collection of verse, *John Marr, and Other Sailors; With Some Sea-Pieces*, appeared only in 1888, again privately published. By then he had been in retirement for three years, assisted by legacies from friends and relatives. His new leisure he devoted, he wrote in 1889, to "certain matters as yet incomplete." Among them was *Timoleon* (1891), a final verse collection. More significant was the return to prose that culminated in his last work, the novel *Billy Budd*, which remained unpublished until 1924. Provoked by a false charge, the sailor Billy Budd accidentally kills the satanic master-at-arms. In a time of threatened mutiny he is hanged, going willingly to his fate. Evil has not wholly triumphed, and Billy's memory lives on as an emblem of good. Here there is, if not a statement of being reconciled fully to life, at least the peace of resignation. The manuscript ends with the date April 19, 1891. On the following September 28, Melville died.

Melville's was a life neither happy nor, by material standards, successful. By the end of the 1840s he was among the most celebrated of American writers, yet his death evoked but a single obituary notice.

In the internal tensions that put him in conflict with his age lay a strangely 20th-century awareness of the deceptiveness of realities and of the instability of personal identity. Yet his writings never lost sight of reality. His symbols grew from such visible facts, made intensely present, as the dying whales, the mess of blubber, and the wood of the ship, in *Moby Dick*. For Melville, as for Shakespeare, man was ape and essence, inextricably compounded; and the world, like the "Pequod," was subject to "two antagonistic influences . . . one to mount direct to heaven, the other to drive yawingly to some horizontal goal." It was Melville's triumph that he endured, recording his vision to the end. After the years of neglect, modern criticism had secured his reputation with that of the great American writers.

#### MAJOR WORKS

NOVELS: *Typee: A Peep at Polynesian Life* (1846); *Omoo: A Narrative of Adventures in the South Seas* (1847); *Mardi and a Voyage Thither* (1849), a political and philosophical allegory; *Redburn, His First Voyage* (1849); *White-Jacket; or, The World in a Man-of-War* (1850); *Moby Dick; or, The Whale* (1851, as *Moby Dick; or, The White Whale* in some later-19th-century editions); *Pierre; or The Ambiguities* (1852); *Israel Potter: His Fifty Years of Exile*, (1855), a historical novel of the American Revolution; *The Confidence-Man: His Masquerade* (1857), a satirical allegory; *Billy Budd, Foretopman*, a short novel written 1888-91 and found after Melville's death; first published in *Billy Budd, and Other Prose Pieces* (1924).

SHORT STORIES, SKETCHES, AND JOURNALS: *The Piazza Tales* (1856), includes "The Piazza," "Bartleby the Scrivener," "Benito Cereno," "The Encantadas, or, Enchanted Isles," and "The Lightning-Rod Man"; *The Apple-Tree Table and Other Sketches* (1922), contains 10 sketches first published in periodicals, 1850-56; *Journal up the Straits, October 1, 1856-May 5, 1857* (1935); *Journal of Melville's Voyage in the Clipper Ship, "Meteor"* (1929).

VERSE: *Battle-Pieces and Aspects of the War* (1866); *Clar-el: A Poem and Pilgrimage in the Holy Land* (1876); *John Marr, and Other Sailors; With Some Sea-Pieces* (1888); *Timoleon* (1891), a collection. Poems unpublished during Melville's lifetime are included in later collections and selections.

#### BIBLIOGRAPHY

*Editions:* The standard edition is *The Works of Herman Melville*, 16 vol. (1922-24); Hendricks House undertook a

new complete edition in 1947; the Northwestern-Newberry edition, ed. by HARRISON HAYFORD, HERSHEL PARKER, and G. THOMAS TANSSELLE, began in 1968; *Collected Poems of Herman Melville*, ed. by HOWARD P. VINCENT (1947); *Melville's Billy Budd*, ed. by F. BARRON FREEMAN, corrected by ELIZABETH TREEMAN (1956); *The Complete Stories of Herman Melville*, ed. by JAY LEYDA (1949); *Journal of a Visit to London and the Continent, 1849-1850*, ed. by ELEANOR MELVILLE METCALF (1949); *Journal of a Visit to Europe and the Levant, 1856-1857*, ed. by HOWARD C. HORSFORD (1955); *Letters*, ed. by MERRELL R. DAVIS and WILLIAM H. GILMAN (1960).

*Biographical:* RAYMOND M. WEAVER, *Herman Melville: Mariner and Mystic* (1921), interesting as the first biographical study; LEWIS MUMFORD, *Herman Melville* (1929), an early life, now a little outmoded, but still a sensitive appreciation of the man; NEWTON ARVIN, *Herman Melville* (1950), a critical biography, judiciously combining life and works; LEON HOWARD, *Herman Melville: A Biography* (1951), the most complete factual account of Melville's life, perceptively analytic; JAY LEYDA, *The Melville Log: A Documentary Life of Herman Melville* (1951), a fascinating collection of documents, photographs, and letters; WILLIAM H. GILMAN, *Melville's Early Life and Redburn* (1951), a thorough record of Melville's youth and the relationships between fact and fiction in *Redburn*.

*Critical:* F.O. MATTHIESSEN, *American Renaissance* (1941), a brilliant short analysis of Melville in relation to his contemporaries and his times; WILLIAM E. SEDGWICK, *Herman Melville: The Tragedy of Mind* (1944), one of the best studies of Melville's ideas as they appear in his novels; VAN WYCK BROOKS, *The Times of Melville and Whitman* (1947), useful for general historical background; RONALD MASON, *The Spirit Above the Dust* (1951), straight, interpretive criticism, illuminating on *Pierre* and *Moby Dick*; LAWRENCE THOMPSON, *Melville's Quarrel with God* (1952), an interesting case for Melville's Christian unorthodoxy; ELEANOR MELVILLE METCALF, *Herman Melville: Cycle and Epicycle* (1953), an important addition to Melville studies; RICHARD CHASE, *Herman Melville: A Collection of Critical Essays* (1962), a well-chosen selection of criticism; A.R. HUMPHREYS, *Melville* (1962), an excellent introductory study; D.E.S. MAXWELL, *Herman Melville* (1968), representative excerpts from the works, with explanatory and critical comment.

(D.E.S.M.)

## Membrane, Biological

Biological membranes are the thin layers of material that form the outer limits of living cells and their various inner components. Membranes are ubiquitous structures in living matter. They differ greatly in structure and properties, however, and statements on membranes may be generalized only to a certain limited degree.

Every cell, including the most primitive micro-organism, is surrounded by a membrane called the plasma membrane. This membrane separates the cell from its environment, thereby fostering the maintenance of a constant milieu in which intracellular reactions occur. The plasma membrane, however, does not isolate the cell completely from the external world. Instead, it allows a highly controlled exchange of matter across the barrier it poses; some special compounds are able to pass through the membrane easily; others are completely blocked. This screening effect on the substances that enter and leave the cell is perhaps the most important function of the cell membrane.

Within cells, many additional membranes can be distinguished. These membranes surround, or themselves comprise, the various structural units, called, as a group, organelles. Prominent among these are the nucleus, or central body of the cell, and the mitochondria, or energy-storing units. Photographs taken with an electron microscope reveal that membranes from different cell types have certain common structural features (see Figure 1). Most prominent of these is a three-layered structure, which, after staining by a chemical agent, becomes visible as two dark layers separated by an intermediate light one. This three-layered structure appears to be a fundamental feature of almost all biological membranes. Both the plasma membrane and some of the intracellular membranes are believed to be parts of a continuous membrane system that extends through much of the body of the cell.

Certain biochemical processes are known to occur in

External  
and  
internal  
mem-  
branes

close association with membranes. This is especially true of those sequences of reactions associated with energy production in the mitochondria. In bacteria, the protein-synthesizing units (ribosomes) and the genetic material (DNA) are attached to the plasma membrane.

Comparison of the cells of a series of organisms of increasing complexity—such as bacterial, yeast, plant, and animal cells—reveals that the number of cellular structures containing membranes increases with the increasing complexity of the organism. In the cells of the bacterium *Escherichia coli*, the chromosomes are simply embedded in the cytoplasm, whereas in yeast cells they are enclosed in a nuclear membrane. Such membrane-containing organelles as mitochondria and chloroplasts, photosynthetic structures occurring in plant cells, are found only in the more highly organized cells of animals and plants.

During the lifetime of every multicellular organism, primitive cells undergo differentiation and specialization, with the result that a diverse population of highly differentiated and specialized cells is formed; associated with this process is the development of different kinds of membranes in the differentiated cells. The degree of development in embryonic liver cells of the complex membrane structure called the endoplasmic reticulum may, for instance, be correlated with the stage of growth of the cells. In some cases, highly specialized membrane structures are formed in specialized cells; examples are the brushlike membrane surface (brush border) of certain epithelial cells and the membrane structures (myelin sheaths) wound round the extensions (axons) of nerve cells.

Surrounding the membranes of bacterial and plant cells is an additional structure, the rigid cell wall, whose chemical composition is quite different from that of the proper cell (cytoplasmic) membranes. The walls of these cells appear to play chiefly a protective and structural role, leaving to the cell membrane the task of regulating the passage of materials into and out of the cell. This conclusion is supported by the finding that removal of the cell wall does not increase the permeability of the cell membrane to various materials.

### The nature of membranes

#### BIOCHEMICAL CONSTITUENTS OF MEMBRANES

Most of current knowledge about the biochemical constituents of membranes originates in studies of red blood cells (erythrocytes) of animals. Less is known about the

molecular composition of bacterial and plant cells. The chief advantage of red blood cells for experimental purposes is that they may be obtained easily in large amounts. In addition, the red blood cells contain no typical membrane structures other than the plasma membrane, a situation that facilitates study of that structure. Generally speaking, the chief biochemical components of membranes are fats (lipids) and proteins; lesser amounts of carbohydrates and nucleic acids are found in certain membranes.

**Lipids.** The amount of lipid in the cell membrane varies considerably among different cell types. For example, the lipid content of the myelin sheath of the nerve cells is about 70 percent of the total membrane material; whereas that of the liver mitochondrial membrane is about 30 percent, and that of the liver endoplasmic reticulum is about 50 percent.

The composition of the lipids in the membranes of various kinds of cells also differs greatly. For example, cholesterol, a lipid material that is not a true fat, is a major component of most varieties of animal-cell membranes; whereas in several internal membranes of liver cells, it is present in only minor amounts, and it is almost entirely absent from bacterial membranes. Even the lipid composition of red-blood-cell membranes varies among different animal species. There are, however, some common features: on the average, cholesterol makes up about 27 percent of the total lipids, and the lipids bearing phosphate groups (phospholipids) account for about 60 percent. The amount of a particular phospholipid, lecithin, shows considerable variation among red-cell membranes of different species: it is hardly detectable in red-cell membranes of the sheep, whereas its content in those of the pig is about 25 percent, and in those of the rat 50 percent. Lipids containing carbohydrates (glycolipids) have not been found in intracellular membranes; they appear to occur exclusively in plasma membranes. The pattern of the fatty acids incorporated in the fats of biological membranes also varies within a wide range. More than three quarters of the total of fatty acids in human erythrocytes are made up by the following five species: palmitic acid (30 percent of the total), oleic acid (17 percent), stearic acid (16 percent), linoleic acid (10.5 percent), and arachidonic acid (10 percent).

A number of external factors have been found to affect the lipid content of membranes. In the micro-organism *Mycoplasma laidlawii*, for example, cholesterol may or may not be present depending on the composition of the growth medium. Within mammalian cells of any one type, the ratio between the amounts of the different lipid classes is relatively constant, but the pattern of fatty acids they contain may vary with such factors as diet and the external temperature.

**Proteins.** Evidence suggests that a protein layer covers the lipid core of the membrane on each side. Less is known about the composition of the protein than about that of the lipid fraction of the membrane. The proteins probably account for special biological functions of the membrane, such as transport of material into and out of the cell. Both the stability and the flexibility of biological membranes are maintained by special lipid-lipid and lipid-protein interactions, but little is known about the specific forces involved.

**Carbohydrates.** The carbohydrates found in membranes are bound chemically to the lipids (producing glycolipids) and to the proteins (giving glycoproteins). Glycoproteins appear chiefly in the outer protein layer of the membrane.

**Nucleic acids.** Although adsorption of foreign ribonucleic acid (RNA) to membranes during laboratory separations cannot be excluded, it appears that some RNA is a genuine component of the plasma membranes of rat liver cells. The amount present seems to be very small, of the order of five micrograms for every milligram of protein. Larger amounts of RNA have been found in bacterial membranes.

**Arrangement of the biochemical constituents.** Ideas concerning the molecular arrangement of the membrane components are based to a considerable extent on obser-

Variable compositions of lipid membranes

Layered  
models of  
mem-  
branes

variations of the behaviour of similar molecules at the surface of a water solution exposed to air. Experiments of this kind suggest that the lipid molecules are packed together as closely as possible, like pickets in a picket fence. Since the minimum surface area occupied by all lipids extractable from erythrocytes exceeds the surface of the cells, the lipids are assumed to be present in a double layer. The concept of a double lipid layer, covered on both sides by proteins, was put forward in 1935 as the first significant model of membrane architecture, and has subsequently come to be known as the unit-membrane concept. Since membranes may be isolated without alteration of the molecular arrangement, the organization of the biological membrane appears to be more stable than that of a lipid film at a water surface.

Studies of various membranes (such as those of the myelin sheath) by means of the electron microscope have revealed a three-layered structure, in agreement with the proposed membrane model. The thickness of plasma membranes is of the order of 70–90 angstrom units, the double-layered lipid core alone being about 50 angstroms. Later modifications of the original membrane model included the ideas that the proteins were spread out over the lipid surfaces and that those on the inside of the cell membrane differ from those on the outside (see Figure 2).

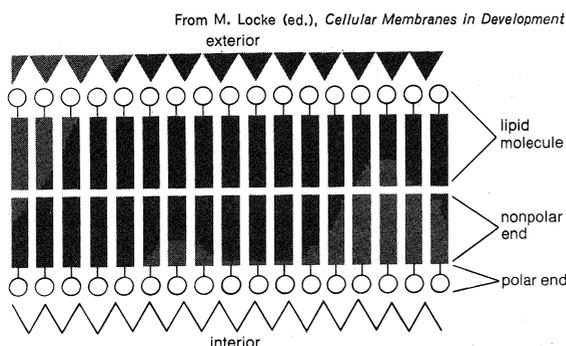

Figure 2: Unit membrane concept (see text).

Many results of recent experiments are difficult to reconcile with the concept of the unit membrane. Consequently, alternative models of membrane structure have been proposed. According to some of these, called "subunit models," the membrane may be considered as a two-dimensional aggregation of separate lipoprotein subunits, rather than discrete layers of lipid and protein. For 30 years concepts of membrane structure have been dominated by the unit-membrane model, but some of the early arguments supporting it have lost much of their force, and subunit models now are likely to receive more serious consideration.

#### PROPERTIES OF MEMBRANES

**Properties attributable to lipid components.** At the end of the 19th century it was postulated that lipids were located at the cell surface. This assumption was based on studies of the penetration into cells of compounds known to be readily dissolved in lipid materials. Extension of these studies established a close correlation between the lipid solubility of substances and their ability to penetrate the plasma membrane. On the other hand, a negative correlation could be established between the ability of substances to form hydrogen bonds (secondary associations involving hydrogen atoms) with suitable materials and their ability to penetrate the cell membrane. Lipid materials generally do not form hydrogen bonds. Thus, although lipids are no longer considered to form the surface of the cell membrane, they do nonetheless appear to be involved in the process that admits or excludes materials from the cell.

Largely because of the lipid component of the cell membrane, its electrical resistance is high. The electrical resistance may be lowered by special substances, for instance, certain antibiotics and detergents. The antibiotics are

known to interact with cholesterol and possibly with other membrane components. The detergents generally appear to weaken protein–lipid interactions.

**Properties attributable to protein components.** Even after almost all lipids have been removed from mitochondrial membranes, the membranes do not collapse. It has been assumed, therefore, that protein bridges cross the lipid core to connect the outer and inner protein layers and maintain the membrane structure with or without the lipid materials.

The physical properties of the cell surface appear to be due largely to the effect of the membrane proteins. The surface tension of cells suspended in an aqueous medium, for example, is very low compared to the tension of a water–air or of a water–oil interface. Since the adsorption of proteins onto oil droplets considerably decreases the surface tension, it was initially concluded that a lipid layer covered by proteins would best account for the low surface tension of the cell membrane. But this conclusion does not take into consideration the fact that for a double layer of lipids only the difference between two opposing surface tensions is measured; this should be much lower than that of any single layer measured separately, and therefore the introduction of protein to explain the result may not be necessary. A bimolecular layer of pure lipid, however, cannot account for the structural elasticity of the cell surface. The presence of an elastic protein in this region is considered the likely explanation.

Membranes, especially the plasma membrane, incorporate various specific proteins, such as enzymes and antibodies, that play active and specific roles in the functioning of the cell. The enzyme pattern of the cell membrane varies greatly from cell type to cell type. Proteins at the surface of cell membranes also are believed to be involved in the transport across the membrane of specific chemical substances, such as amino acids, sugars, and ions of various kinds. Partial disruption of the cell membrane leads to the separation of specific "binding" proteins that manifest the properties expected of such transport materials.

Various glycolipids and glycoproteins seem to be located at the cell surface. This is known to be true of the blood-group substances, specific materials that are responsible for the existence of the various blood types. Similar substances can be isolated from bacteria. As shown by immunological techniques, plasma membranes of rat liver cells have a structural pattern different from that of other membranes within the same cell, and also from the plasma membranes of liver cells of other animal species.

**Electrical properties.** Most, possibly all, membranes of living cells manifest a difference in electrical potential between the two sides of the membrane. With suitable electrodes a fairly constant electrical current can be drawn from such membranes. The electrical activity of biological membranes clearly depends upon active metabolism in the cell, because it disappears upon chemical inhibition of metabolism and after the death of the cells. Electrical activity also appears to be associated closely, either directly or indirectly, with the active transport of ions, such as sodium and potassium, across the membrane.

There are two ways in which an electromotive force might be produced in a biological membrane: (1) by the maintenance of an unequal distribution of one or more ions on the two sides of the membrane, or (2) by the action of a so-called ion pump, which moves a single ion type directly across the membrane. Some insight into the first possibility has been obtained from observations with artificial membranes, such as collodion, or cellophane, separating two solutions of the same salt, at varying concentrations. Such studies show that a difference in electrical potential between the two sides of the membrane will appear if the concentration of the salt on both sides of the membrane is unequal and if the membrane is preferentially permeable (selectively permeable) to either positively charged ions (cations) or negatively charged ions (anions).

The electrical potentials associated with many biological

Surface  
tension  
and  
elasticity

Potential  
difference  
across the  
cell  
membrane

membranes can be partly accounted for by the maintenance of unequal distributions of ions and by the selectively permeable nature of the particular membrane. Since biological membranes are not "ideally" selectively permeable, this kind of potential difference is a nonequilibrium condition; *i.e.*, it will tend to cancel, unless the unequal ion distribution is maintained by the metabolic activity of the cell. Thus the electrical potential disappears upon metabolic inhibition.

Figure 3 shows the relationship between potassium ions ( $K^+$ ) and sodium ions ( $Na^+$ ) on either side of a semi-permeable membrane, such as occurs in cells, in a resting state. It can be seen that potassium ions have a greater tendency to diffuse outward through the membrane (top channel with arrow directed to the exterior—to the left). Sodium ions, however, tend to diffuse inward through the membrane (bottom channel with arrow directed to the interior—to the right). The steepness of the sodium-ion channel, from exterior to interior, indicates the relative ease with which sodium ions would pass inward through the membrane in the absence of the  $Na^+-K^+$  pump, whose directional nature is shown by the arrows in the circle. The mechanism of operation of the pump is indicated by the arrows in the channels directly above the pump (for potassium) and below it (for sodium). Thus, the pump, which requires metabolic energy to function, actively pumps the inward-diffusing sodium outward and, by pumping some potassium inward, helps to maintain a relatively constant interior potassium-ion concentration. This concentration is responsible for the so-called resting potential of cell membranes. (The widths of the channels indicate the relative quantities of ions passing through the membrane either by diffusion or by the operation of the pump.)

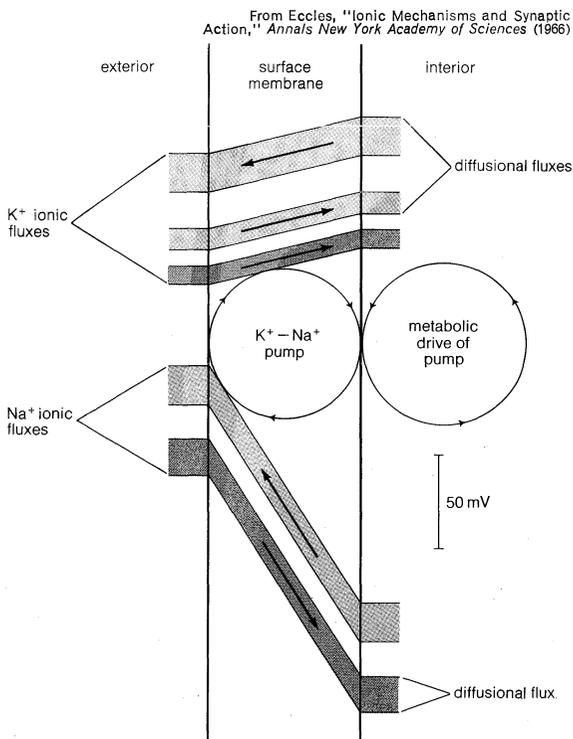

Figure 3: Potassium ( $K^+$ ) and sodium ( $Na^+$ ) fluxes through the surface membrane in the resting state (see text).

In biological systems special potential differences occur because of an unequal distribution of the proteins, which as a rule are polyanions unable to penetrate the cellular membranes. These potential differences also contribute to the overall potential difference measured between the intercellular fluid and the external medium. They often persist after metabolic inhibition or death. Their contribution to the overall potential difference, however, is small compared to the previously mentioned potential differences.

In addition to the potential differences mentioned above, which primarily depend on the unequal distribution of ions, an electrical potential difference also may be directly produced by the active transport of a single ion type, even in the absence of unequal distribution of ions. Such an ion pump is unidirectional; *i.e.*, it pumps only one ion species in one direction. This is different from the exchange of ions associated with the maintenance of the unequal distribution. The potential difference produced by an ion pump in a membrane between identical electrolyte solutions depends on the power of the pump to move ions and on the general ability of the membrane to carry ions of all types.

Generally it is difficult to decide whether a potential difference observed in a biological membrane is due to the combined effect of an unequal distribution of ions and a selectively permeable membrane, or to the operation of a unidirectional ion pump.

## Functions of membranes

### COMPARTMENTALIZATION OF CELLS

Cells contain various internal structures, or organelles, each of which is enclosed by a membrane. Functionally, these organelles are separate metabolic compartments, specialized to carry out distinct sequences of enzyme-catalyzed reactions. They are protected from one another's enzymatic activities, and those of the ground substance of the cell, by membranes of limited permeability.

A compartmentalization of the cell seems to be required for many cellular functions, including uptake and conversion of nutrients, synthesis of new molecules, production of energy, and regulation and coordination of metabolic sequences. The subcellular particles generally are visible in the electron microscope after appropriate treatment of the cell. The best known of these particles are: (1) the nucleus, (2) the mitochondria, (3) the lysosomes, and (4) the microbodies. (Each of these is discussed briefly below.) Bacterial cells lack some of these organelles; *e.g.*, the nucleus and the mitochondria. Recently, however, other highly organized membrane structures, the mesosomes, have been detected in bacteria; their metabolic functions are not yet known.

**The nucleus.** Because the nucleus of the cell has the highest specific density of all subcellular particles, it can be isolated easily by differential centrifugation (a separation method based on spinning a solution in a centrifuge). The nucleus may occupy anywhere from 10 percent to nearly 100 percent of the total volume of the cell. It contains the genetic material of the cell, or DNA (deoxyribonucleic acid), as well as the associated basic proteins, glycolytic enzymes, and several varieties of cation. The nucleus is surrounded by a double membrane, the outer layer of which is connected with the membranes of the endoplasmic reticulum (the membrane material that traverses the cytoplasm of the cell). The nuclear membrane disappears during cell division. It apparently does not represent a real barrier to most of the cellular and nuclear substances; pores as large as 500 angstroms in diameter have been observed in this membrane, but the size varies with the condition of the cell. Thus, the interior of the nucleus is in complete communication with the cytoplasm during cell division (when the nuclear membrane is gone) and partially so at other times (by way of pores in the membrane).

**Mitochondria.** Mitochondria are constituents of most cells that undergo respiration (oxygen uptake). They are enclosed by an outer membrane; the interior contains two compartments, a granular matrix, which is surrounded by a folded membrane (the inner membrane) and an intermembrane space or outer compartment. In mitochondria, many substances are oxidized, and adenosine triphosphate (ATP), the energy-storing chemical of the cell, is produced. These biochemical functions are carried out chiefly by enzyme complexes situated in (or in close association with) the mitochondrial membranes. The outer membrane is readily permeable to substances of low molecular weight, with the result that the outer compartment is in equilibrium with the cytoplasm with respect to these substances. Evidence has been presented that distinct

Organelles

Compartmentalization

translocating systems for ions and metabolites (biochemical transformation products) are constituents of the inner membrane. The compartment enclosed by this membrane contains all the enzymes responsible for the energy-producing metabolic transformations associated with cellular oxidation processes. It is evident that the high efficiency of the energy-generating enzyme complexes is made possible by the special organization of the inner mitochondrial membrane.

**Lysosomes.** A distinct variety of subcellular organelles in the cells of various tissues, because it serves a degradative function, has been given the designation lysosome (Greek: *lysis*, dissolve; *sōma*, body). These particles contain enzymes that are able to degrade nearly all cellular macromolecules, such as nucleic acids, proteins, and polysaccharides. That lysosomes are not structurally uniform is indicated by the fact that they sediment at different rates in an ultracentrifuge (a device that separates materials on the basis of their weight and shape). Each lysosome is surrounded by a single membrane of low permeability, which protects the other cellular material from the degrading enzymes of the lysosomes. Lysosomes play a role in the decomposition of cell components after the death of the cell (autolysis), and they are also involved in the degradation of small particles that have been taken up by pinocytosis (see below *Pinocytosis*).

**Microbodies.** Another group of membranous subcellular particles has been isolated from mammalian cells and named microbodies or peroxysomes. These particles are minute spheres composed of a granular matrix enclosed by a single membrane. Peroxysomes are characterized by their content of a series of enzymes that produce hydrogen peroxide, as well as the enzyme catalase, which splits the peroxide produced by the other enzymes to give oxygen and water. The peroxysomes obtained from animal liver or kidney cells are closely related to similar particles isolated from protozoans, yeasts, and plant cells. They all have similar sedimentation constants and similar structures. They also contain, as a rule, catalase and other enzymes. In some cases, microbodies contain enzymes of the glyoxylic acid cycle, which plays an important role in cellular metabolism. Hence the name glyoxysome also has been proposed for this group of organelles.

#### MOVEMENT OF WATER ACROSS CELL MEMBRANES

All biological membranes appear to be permeable to water, but permeability varies widely among different membranes. The flow of water across biological membranes, as compared to the flow of dissolved materials (solutes), shows certain peculiarities that result from the continuous and semicrystalline arrangement of the water molecules. In dilute solutions, the solute particles are far enough apart not to influence each other's movements. Consequently, their behaviour follows the laws that govern the behaviour of gas molecules in free space. In contrast, the molecules of water form a continuum, each molecule remaining in immediate contact with its neighbours in a semicrystalline lattice. Though this lattice tolerates distortions and rearrangements, contact between the molecules is always maintained. At the boundary with air, vacuum, or other, immiscible liquids, single water molecules may leave the continuum to pass into the contiguous phase. Hence water may penetrate a membrane in two different ways: (1) as a continuum, by bulk flow, or (2) as a solute—that is, molecule by molecule, by diffusional flow. Diffusional flow occurs if water molecules pass across a lipid membrane or into a gaseous phase. Bulk flow, on the other hand, predominates if water moves through pores or through a membrane made of material easily penetrated by water. Diffusional flow is very slow as compared to bulk flow. Across artificial nonlipid membranes, such as collodion or cellophane membranes, water has been shown to move almost exclusively by bulk flow, no matter what drives it across the membrane. Across purely lipid membranes, which presumably lack pores, bulk flow should not occur at all. Across biological membranes, which consist of both lipid and, possibly porous, nonlipid material, both bulk and

Bulk flow  
and  
diffusional  
flow

diffusional flow are believed to occur in parallel. Bulk flow may be considerably influenced by interaction with solutes, owing chiefly to frictional forces between the flowing water and the solute molecules. Accordingly, water passing through narrow pores will tend to drag solute molecules along with it, and the flow of water may be slowed down if the solute particles penetrate the pores less readily because of their size or electric charge. Conversely, solutes diffusing through narrow pores will tend to carry water with them in the direction opposite to that in which it would normally move.

The flow of water across the cell membrane is determined by two factors: the osmotic pressure and the hydrostatic pressure. The former is an effect brought about by different concentrations of dissolved substances on the two sides of the membrane. In effect, this results from the replacement of water molecules by solute molecules on the side of the membrane with the more concentrated solution. The flow of water across the membrane acts to neutralize this concentration difference. The flow of water also is proportional to the difference between the hydrostatic pressure on the two membrane sides. In this respect, the behaviour of water differs from that of solutes, since the immediate influence of a hydrostatic pressure difference on the diffusion of solutes is negligible. The two driving forces, the osmotic and the hydrostatic pressure differences, are additive, so that the movement of water between two solutions of the same solute across a membrane is almost proportional to the sum of the two effects.

The modification of the water flow due to interaction with the flow of solute depends on the permeability of the membrane for the solute. This may be illustrated for some extreme cases by a simplified model, consisting of two solutions of the same solute separated by a membrane. In a highly selective, so-called semipermeable membrane, which permits the passage of water, but not that of any solute present, the flow of water, which cannot interact with any solute flow, is proportional simply to the sum of the hydrostatic and osmotic effects. A directly opposite situation would be represented by a coarse membrane, which owing to the width of its pores lets all solutes penetrate as easily as water. In this case no osmotic pressure difference would develop and any volume flow of water would have to be attributed to the hydrostatic pressure difference only. More interesting and relevant are the intermediate cases, represented by selectively permeable or "leaky" membranes. These are permeable to solutes but less so than to water; consequently, frictional forces between water and solute within the pores will greatly alter the rate of movement of both. Thus, the osmotic pressure difference, which will steadily decrease, can at no time exert its full effect in these cases. The effect of leaky membranes may be different for different solutes, because the same membrane may be more permeable to one solute than to another. The concept of selective permeability is especially important in the study of biological membranes.

#### MOVEMENT OF SOLUTES THROUGH MEMBRANES IN RESPONSE TO A CONCENTRATION GRADIENT

**Methods of studying permeability.** The rate of uptake of solutes by a cell or a cellular tissue is usually obtained either from the rate of disappearance of the solute in the medium, or from the rate of its appearance in the cellular mass. The exit of solutes from cells is studied in an analogous way—that is, by the rate of their appearance in the medium, or the rate of their disappearance from the cell. In special cases the entry of solutes is measured indirectly by the changes in the cell volume brought about as water follows the solute by osmosis. Most of the methods do not tell reliably whether the substance has truly entered the cells or whether it is adsorbed to the cellular surface. Adsorption may be significant with very large molecules, like those of certain dyes, but not with such small molecules as inorganic ions, sugars, and amino acids (as has been shown by fluorescence and studies with radioactive isotopes). If these substances disappear from the medium or appear in the cellular mass, it usually can be taken for

Osmotic  
and  
hydrostatic  
pressure

granted that they have entered the cell. Measuring the disappearance from the medium has the disadvantage that the medium is often of greater volume than the cellular mass, so that changes in concentration of the solute there may be small. On the other hand, the rate of appearance of a solute inside the cell may be misleading if the solute is metabolized or otherwise altered inside the cell. In special cases, however, if the reaction is rapid enough and the product can be measured easily, the alteration may be useful as an indirect determination of the rate of entry of the original material. For example, the rate of entry of sugar into muscle cells can be estimated satisfactorily by the appearance of the transformation product, lactic acid.

Theoretically, the rate of uptake should be referred to the total cellular surface area. The assessment of this surface area, however, is very difficult, especially if, for example, the cellular shape is not spherical. For this reason, the rate of penetration is usually related either to volume of water in the cells or their dry weight. Relating it to the cellular water volume may be ambiguous, because the water content of a cell can change during the penetration of the solute. If such volume changes are not taken into account, the true entry (or exit) rates may be greatly obscured. Its relation to cellular dry weight, therefore, often is more meaningful than its relation to cellular water. The dry weight presumably stays constant during the experiment and also may have a constant relation to the total cellular area or to the total number of transport sites or permeability channels in the cell membranes.

The rate at which a solute enters or leaves a cell is called a flux (influx and efflux, respectively). It is important to distinguish between net, or overall, flux and unidirectional flux, either influx or efflux. The net flux is the total observed shift of a given solute from the extracellular into the intracellular compartments, or *vice versa*. Unidirectional fluxes, of a given substance, can be measured only by the use of radioactive isotopes that behave just as the ordinary atoms of an element do, but are easily detected because of their radioactivity. The movement of molecules carrying such atoms (called labelled molecules) can be followed by means of the radioactivity. The difference between influx and efflux, as determined by labelling experiments, must be equal to the net flux as measured by chemical means. Knowledge of unidirectional fluxes may be helpful, for instance, in testing for active transport (see below). Furthermore, the unidirectional fluxes may reveal special phenomena, which may give relevant information concerning the mechanism by which transport occurs (see below *Facilitated diffusion* and *Exchange diffusion*). Unidirectional fluxes may be determined even in the absence of net transport—for example, when the rates of influx and efflux are exactly in balance.

To study the transport rates, or kinetics, of rapidly penetrating substances, the time allowed for transport to occur must be short and sharply terminated, circumstances that can be provided, for instance, by separating the cells rapidly from the extracellular medium. To carry out such separations in a short enough period compared to the incubation time is often very difficult, if not impossible. Many bacteria, because of their stiff walls, can be filtered through membrane filters and subsequently washed. In such cases separation between cells and incubation medium is complete in a few seconds. Many mammalian cells, however, cannot be filtered and, therefore, must be centrifuged, a procedure that may take a minute or more. The transport experiment usually is terminated by the sudden cooling of the incubated cells or by the addition of certain chemicals, usually mercury salts, that supposedly stop all transport. Other methods to allow a more rapid termination of the experiments and hence shorter incubation times are under development.

The problems just mentioned refer chiefly to suspensions of cells, such as red blood cells, or bacteria. Other problems arise if whole tissue or tissue fragments are studied. Such tissue always contains some extracellular space, enclosed within the tissue but actually between the

cells. In order to determine the exact cellular content of the tissue, the fraction of the trapped extracellular space must be precisely determined. This can be done with the help of materials that do not penetrate the cell, such as iodinated proteins or certain higher polysaccharides (complex sugars). Determining the concentration of such substances in the tissue mass and assuming that their concentration in the trapped extracellular space equals that in the external medium makes it possible to estimate the size of the trapped extracellular space.

**Factors that influence permeability.** The permeability of the plasma membrane to various solutes ranges widely, from extremely high permeability to complete impermeability. It often is difficult to state a reliable correlation between the permeability and the chemical and physical properties of the solute. Usually, however, lipid-soluble substances penetrate cellular membranes easily. The rate at which these substances move through the membrane seems to be directly related to their solubility in lipids relative to that in water (partition coefficient) and to their molecular size. For many water-soluble substances the penetration seems to depend greatly on the molecular weight and, in the case of ions, on the number of electrical charges per ion. For neutral substances the ease of penetration decreases with increasing molecular size. It is assumed, therefore, that water-soluble substances (neutral and ionic) penetrate the cellular membrane through charged pores of an appropriate size. Very often there is a sharp limit of molecular size, above which solutes are quite unable to penetrate the cellular membrane. Water-soluble organic compounds containing more than three to five carbon atoms, for example, seem to be unable to penetrate the membrane of the red cell. On the basis of these results, it would seem that there are two major channels for passive penetration of cell membranes, one through the lipid part of the membrane (used by lipid-soluble substrates) and the other across preformed pores (used by water-soluble substances). There is, however, a great number of organic compounds to which the above rules do not apply; *e.g.*, many substances of physiological importance, such as sugars, amino acids, nucleotides, and other materials. These substances are not soluble in lipids, and their size exceeds by far the limit of permeability mentioned above. For these and other reasons, it is generally assumed that such compounds penetrate the plasma membrane by special transport mechanisms.

As a rule, the presence of more than one electrical charge per molecule seems to hinder penetration; hence polyvalent ions, such as calcium ions and sulfate ions, appear to penetrate cells very slowly, if at all. With monovalent ions, oppositely charged particles often behave very differently. It is well established, for instance, that the red-blood-cell membrane is selectively permeable for anions, but not cations. Small anions, such as chloride and bicarbonate, penetrate the membrane about a million times faster than cations of similar size. The ability of the membrane to discriminate between positively and negatively charged solutes is reportedly due to the presence of fixed positive charges inside the membrane, perhaps on the surfaces of water-filled pores. Such regions of high positive-charge density could act as barriers to cations but, at the same time, could favour the penetration of anions. The positive charges in membranes could result from the attachment of protons (positively charged hydrogen ions) to basic amino-acid residues in membrane proteins. As a consequence of the presence of fixed charges, equilibria will be established between the membrane proteins and the suspension fluid. Because of these equilibria, it might be expected that the passage of anions through the red-cell membrane would be highly dependent upon the acidity and the ionic strength of the suspending medium. In fact, the flux of the sulfate ion has been shown to increase as the hydrogen-ion concentration in the medium is increased, as could be expected on the basis of the expected equilibrium.

**Facilitated diffusion.** As has been mentioned, certain substances, including sugars and amino acids, easily penetrate the plasma membrane of many, or all, cells, al-

Effect of molecular size and charge

Influx and efflux

Effect of fixed charges

though they are neither soluble in lipids nor small enough to penetrate the membrane pores. It is therefore assumed that the transport of these substances across the plasma membrane is brought about by a special mechanism. This mechanism, called facilitated diffusion, has the following characteristics not found in free diffusion:

1. It can be saturated; *i.e.*, the rate of penetration does not increase with the concentration difference but tends toward a maximum value, which cannot be exceeded by a further increase of the concentration gradients. In other words, the mechanism behaves as if the membrane had only a limited number of transport sites which, once occupied, cannot accommodate other molecules.

2. It is subject to competitive inhibition; *i.e.*, closely related molecules seem to compete with each other for the available sites, because the transport rate of any one substance is depressed in the presence of the other.

3. It shows a considerable degree of specificity; *i.e.*, a limited number of compounds are "recognized" and admitted, and others are rejected. This selection is not on the basis of gross chemical or physical properties, because molecules that greatly resemble one another may be treated quite differently. For instance, D-glucose (a common sugar) readily enters red blood and muscle cells, whereas its isomer, L-glucose, which is hardly distinguishable from it by chemical or physical means, enters these cells hardly, if at all.

4. Some systems of facilitated diffusion undergo the peculiar phenomenon of counterflow or countertransport. In this phenomenon, the movement of a certain substance across the membrane is accelerated by the presence of a closely related substance on the other side of the membrane. Such behaviour has been shown by amino acids and sugars in various cells. Often a compound that competitively inhibits the transport of another compound when it is on the same side of the membrane may enhance it when it is on the other side.

All these characteristics, or at least the first three, are very similar to those of enzymatic reactions and are best explained in terms of a carrier substance, which combines with the transported substrate on the one side of the membrane, carries it through the membrane, and delivers it on the other side. Nearly all observations that have been made are compatible with this concept. But only speculations as to the nature of such a carrier are possible. The fact that it enables a substance to penetrate a lipid membrane has led some authors to believe that any such carrier is of a lipid nature. On the other hand, the high degree of specificity toward the transportable substance can only be accounted for by a protein, because only a protein molecule could show the required specificity of shape that would permit it to function as required. Many investigations assume that such a carrier must be a lipoprotein.

**Exchange diffusion.** Exchange diffusion may be considered a special case of facilitated diffusion with the additional feature that the solute molecule penetrates the membrane only in exchange for another molecule, either of the same species (homoexchange) or of a different but closely related one (heteroexchange). The second molecules cross the membrane in a direction opposite to that of the first. Obviously homoexchange does not permit net transport of the solute concerned; it can be detected, therefore, only by isotopic labelling of the solute on one side of the membrane. Exchange diffusion is not to be confused with electrostatic exchange, in which one ion species cannot penetrate a membrane for electrostatic reasons, unless another charged particle of the same charge moves in the opposite direction. Electrostatic exchange is unspecific, whereas true exchange diffusion shows a high degree of specificity with respect to both exchange partners.

Pure exchange diffusion is rare. A typical example is the penetration of phosphate ions into the cells of staphylococci, a process that requires exchange by another phosphate ion or, specifically, the similar arsenate ion. More frequently, there occurs a so-called partial exchange diffusion, in which a solute can penetrate without an exchange partner but does so much more readily in the

presence of one. Such instances are found in the transport of sugars and amino acids into various cells. Partial exchange diffusion can lead to the temporary movement of one solute from a volume of low concentration into one of high concentration but such a concentration gradient of the other solute must be present, if the process is to occur at all.

Exchange diffusion is usually interpreted in terms of a carrier substance, which is mobile only when it carries a solute molecule (and, therefore, immobile in the empty form). In explanation, it can be hypothesized that the unloaded carrier is loosely bound to some membrane constituent, and is released upon the attachment of a solute molecule. In partial exchange diffusion the unloaded carrier is thought to be not entirely immobile, merely less mobile than the loaded one.

**Comparison of permeability properties of different kinds of cells.** The permeability properties of biological membranes vary widely among the different classes of cells and tissues, but many features seem common to the membranes of all cells. The variations may be due partly to differences between membranes with respect to their basic structure—for example, size of pores, presence or absence of fixed electrical charges, and the nature of the lipid components. Other differences may concern the presence or activity of special transport systems. As mentioned above, the red-cell membrane is almost impermeable to cations but highly permeable to anions. For certain cancer cells the opposite is true. These differences are attributed to fixed electrical charges of the membrane. Within the same organism variations among the membranes of various cells also are observed; for example, liver cells supposedly are far more permeable to almost all solutes than are other cells. The activity of the different transport systems may change during the development of a given cell. The red cell, for instance, loses some of its transport systems for amino acids during maturation. During cell division, membrane permeability also changes. In addition, it would appear that a normal cell becomes more permeable to certain amino acids, and possibly other solutes, after infection with cancer-producing virus. Many transport systems in various cells also can be controlled by hormones, metabolites, and other physiological substances, as has already been mentioned.

The permeability pattern of the membranes of subcellular organelles greatly differs from that of the plasma membrane of the same cell. For instance, the mitochondrial membrane is impermeable to chloride ions, but permeable to phosphate ions and to the coenzyme adenosine triphosphate, whereas the opposite is true for the cellular membrane. Furthermore, the mitochondria and also the sarcoplasmic reticulum of muscle cells are able to transport calcium ions (the former one in exchange for hydrogen ions), whereas the plasma membrane is practically impermeable to calcium ions.

#### MOVEMENT OF SOLUTES INDEPENDENT OF CONCENTRATION GRADIENTS: ACTIVE TRANSPORT

**Requirements.** Transport of a solute across a membrane is called active if it occurs "uphill"—that is, against a concentration gradient and if the solute is electrically charged (ionic), against an electric field. In chemical terms "uphill" means from a lower to a higher thermodynamic potential—that is, from a system of lower energy to one of higher content. The true significance of active transport, then, is that it occurs in seeming violation of simple chemical and physical laws; it is a process made possible only by the active participation of processes occurring within the cell.

The difference in the thermodynamic potential of a solute on two sides of a membrane (a comparison that makes it possible to judge whether transport processes are active or passive) is the sum of a chemical and an electrical term and, therefore, is also called the electrochemical potential difference. The chemical term contributing to the electrochemical potential difference is given by multiplying a constant factor (the gas constant) by the absolute temperature and by the natural logarithm of the ratio of the concentrations of the solute on the two sides of the

"Uphill"  
transport

Partial  
exchange  
diffusion

membrane. The electrical term is equal to another constant (the Faraday constant) multiplied by the electrical potential difference across the membrane. In equation form, these relationships are written as:

$$\Delta\mu = RT \ln (C_2/C_1) + FE,$$

in which  $\Delta\mu$  is the electrochemical potential difference (the Greek letter delta,  $\Delta$ , indicating difference, and the Greek letter mu,  $\mu$ , representing potential);  $R$  is the gas constant;  $T$ , the absolute temperature;  $\ln$  indicates natural logarithm;  $C_1$  and  $C_2$  are the concentrations of solute on the two sides of the membrane;  $F$  is the Faraday constant; and  $E$  is the electrical potential difference across the membrane.

If the electrochemical potential difference ( $\Delta\mu$ ) is positive, the flow of the solute in the direction from side one to side two is uphill, or, by definition, active. This is so because an additional driving force not expressed in the equation, but greater than the electrochemical potential difference, must be present to enforce the uphill flow of the solute. If the electrochemical potential difference is negative, the flow of solute is "downhill" and may be passive. Active transport would, however, not be excluded, for an active force could still be present, and, according as it is directed parallel to, or against, the electrochemical potential difference, accelerate or retard the flow. One way to test for the presence of such a force would be to vary the electrochemical potential difference arbitrarily and see whether uphill transport does occur. If such variations are not feasible, the ratio of unidirectional fluxes may be determined and related to the electrochemical potential difference. To do this, however, the influx and efflux must be determined separately using different radioactive isotopes. Fortunately, in biological transport, this problem rarely arises since the question usually is whether a clear difference in concentration or in electrochemical potential of a given solute is, or is not, due to active transport.

In true active transport the necessary energy to drive the process uphill is derived directly or indirectly from a chemical reaction of cellular metabolism, most likely from the splitting of energy-rich compounds (such as ATP). Accordingly, active transport should have an additional criterion, namely the dependence of the transport rate, or of the accumulation of solute on one side of the membrane, on metabolism. This dependence usually is tested by withholding oxygen (anoxia) or cellular nutrients from the cells, or by adding metabolic inhibitors. To the extent that transport or accumulation is independent of metabolism, active transport can be excluded. Dependence on metabolism, on the other hand, suggests, but does not prove, active transport.

It follows from the foregoing that active transport involves an energetic coupling between the movement of the solute and a chemical reaction. In some systems this coupling between the two processes appears to be direct. In that case the active transport is said to be "primary." On the other hand, there are systems of active transport in which the coupling is indirect, the uphill transport being driven not immediately by metabolism but by the gradient of another solute. In these cases, the actively accumulated solute is, in effect, dragged along with the downhill movement of the other solute. In this case the active transport is said to be "secondary." A typical example of secondary active transport is the accumulation of amino acids and sugars in animal cells, a process that requires that the electrochemical potential difference ( $\Delta\mu$ ) of sodium ions be higher outside the cell than inside. In order to maintain this relationship sodium ions must be actively extruded from the cells by the so-called sodium-ion pump, a metabolic process leading to transfer of sodium ions across the membrane. Hence, secondary active transport ultimately also depends on metabolism, unless the appropriate electrolyte gradient is artificially maintained.

The kinetics of active transport closely resembles that of facilitated diffusion (see above) except for the capability of uphill movement (pumping). Both systems show saturation kinetics, competitive inhibition, specificity toward

the transported substrate, and, in some cases, counter-transport phenomena. Each may be considered a special case of a more general process called "mediated transport."

**Substances transported.** Active transport of inorganic and organic solutes occurs in all living cells and tissues. It may serve several purposes, one of them being to maintain a constant composition of solutes inside the cell (homocellular transport). This may be achieved by replacing solutes lost by metabolism and leakage, or by removing solutes entering the cell in excess. A typical example is the maintenance of a high level of potassium ions and a low level of sodium ions inside the cell. Another purpose of active transport is to move large amounts of certain solutes through cellular layers, as in reabsorption and excretion (transcellular transport) by the epithelial layers of the intestine, the kidney tubules, and the various secretory glands. Both homocellular and transcellular transport are believed to operate according to the same general principles, because in either case the essential process takes place in the cellular membrane. In transcellular transport, however, unlike homocellular transport, the transporting cell membrane must be "polar"; that is, the transport capacities in one region of the membrane must be different from those in different regions of the membrane. For example, the epithelial cell of the intestine seems to reabsorb sugars or amino acid actively only at the part of the cell next to the space through which the food moves (lumen), whereas the movement of these solutes across the part of the cell membrane facing the body interior (serosa) seems to be passive, following the concentration gradient. For the active extrusion of sodium ions the opposite behaviour seems to be the case, the active pump being isolated only in the serosal border, whereas across the luminal border sodium ion enters passively. In essence, then, transcellular transport also is homocellular.

**Sodium and potassium ions.** One of the longest known and most extensively studied transport systems is the sodium-ion-potassium-ion pump, which accounts for the homocellular transport of potassium ions into, and sodium ions out of, the cell. This pump is present in all cells of animals, plants, and micro-organisms, in which it maintains the typical distribution of these ions: high cellular potassium; low cellular sodium. Even in the few apparent exceptions, such as the red blood cells of some animal species, which have a higher level of sodium ions than of potassium ions, the sodium-ion-potassium-ion pump is present, only it is much less effective than in other cells.

The uptake of potassium ions seems to be linked with the extrusion of sodium ions, but the nature of the linkage is not completely understood. Accordingly, the uptake of potassium ions is greatly enhanced by an increase in intracellular sodium ions, and the extrusion of sodium ions by an increase in extracellular potassium ions. It has been assumed that a single pump is responsible for both movements, a so-called exchange pump. To the extent that this pump exchanges one potassium ion for one sodium ion, it does not cause a net shift of electric charges. Some authors postulate two separate pumps, which are linked to each other in an unknown way. In some cells, such as those of muscle and nerve tissue, a potassium-ion pump need not be postulated, since the accumulation of potassium ions is almost entirely accounted for by the electric potential difference as measured across the cell membrane. This potential difference would then have to be attributed to a sodium-ion pump. In other words, the electrochemical potential of potassium is about equal on both sides of the membrane. This does not entirely rule out a potassium-ion pump or a sodium-ion-potassium-ion exchange pump. In this case, however, active potassium-ion transport, if it occurs, is abortive, for it does not show any effects.

Perhaps the passive permeability of the muscle-cell membrane to the potassium ion is so great as to prohibit any sizable electrochemical potential difference for potassium ions to be established. In other cell types, such as red cells, cancer cells, and others, the assumption of active

transport of both potassium and sodium ions seems inescapable.

Transcellular transport of sodium ions occurs in the reabsorption of this ion by the intestine and by the kidney tubules. As has already been mentioned, the transcellular transport of sodium ions seems essential for the net movement of water across tissue membranes of animals. In animal cells, the same pump mechanism seems to be involved in homocellular distribution of both sodium and potassium ions as well as for the net transport of sodium ions, potassium ions, and water in the intestine and the kidneys.

As to the energy requirements of the sodium-ion-potassium-ion pump, a direct coupling with metabolism is suggested by considerable evidence. In all cellular material containing membranes with sodium-ion pumps so far investigated, an enzyme has been found that splits ATP into ADP (adenosine diphosphate) and inorganic phosphate, thus catalyzing the reaction generally assumed to supply energy for transport. The behaviour of this enzyme has many features in common with the transport of sodium and potassium ions; it is activated, for instance, by sodium and potassium ions, and it is inhibited by certain substances such as digitalis and strophanthin. It is therefore assumed that this enzyme, the so-called transport adenosine triphosphatase, is an essential component of the transport systems concerned, or of their coupling to metabolism. Although details of the molecular mechanism of the enzyme reaction have been elucidated, the nature of its connection with the transport process itself is still a matter of controversy. Some investigators believe that the enzyme itself is the carrier of sodium ions, but this opinion is not shared by all workers in the field.

**Other inorganic ions.** By contrast to the transport of sodium and potassium ions, that of other ions is quantitatively less conspicuous and mostly restricted to special tissues or cells. An active transport of magnesium and sulfate ions in many cells is considered likely in view of the high concentration of these ions in most cells, but this has not been proven. Nor is it known why calcium ions have a much lower concentration in most cells than in the extracellular fluid. That the ions magnesium, sulfate, and calcium, because of their double electric charge, penetrate cellular membranes less readily than do singly charged ions, such as sodium and potassium ions, may be of importance, but the calcium ion seems indisputably transported actively during its reabsorption from the intestine. This transport seems to be promoted by vitamin D, but this vitamin seems to act by an indirect and obscure mechanism. Of special physiological importance is the active transport of calcium ion in subcellular particles, such as mitochondria and the endoplasmic reticulum (see above). The latter system of fine tubular vesicles within muscle cells is able to accumulate calcium ions from the cytoplasm, thereby causing relaxation of the muscles. Conversely, during muscle contraction, calcium is released from these vesicles, and the resulting rise in cytoplasmic level of calcium seems to initiate the contraction of muscular protein. Here also a special enzyme, an adenosine triphosphatase activated by calcium ions, appears to be involved.

Active transport of hydrogen ions (protons) is involved in the formation of acidic fluids, such as gastric juice and urine. The active transport of hydrogen ions in the gastric mucosa is extremely powerful. The power of gastric acid secretion is very high, of the same order as that of the heart muscle in its most active state. The acidification of the urine is very important for the maintenance of the acid-base balance in the organism—*e.g.*, during excessive acid formation.

Transport of anions (negatively charged ions) is less frequent in animal cells than is cation (positively charged ion) transfer. Chloride ion, however, is actively transported by stomach cells in connection with the formation of gastric acid. It also seems to occur in the cornea of the eye, and possibly in other tissues. Active transport of sulfate ion is found in certain bacteria, such as *Salmonella typhimurium*, in which the sulfate ion serves as a precursor for the synthesis of sulfur-containing amino

acids. Anion transport seems to have a paramount transport function in the absorption of water by plant roots. In this case, nitrate ions are thought to be the predominant ions. While nitrate ions are being absorbed by the surrounding fluid into the inner parts of the root, water also moves there, following an osmotic gradient between the root sap and the extracellular fluid. Very high hydrostatic pressures within the root can be produced in this way and may cause the flow of water from the roots to the upper parts of the plant. The transport of nitrate ions, and other anions, is closely connected with the respiration of the root (anion respiration). This is in accord with the assumption that the transport of these ions, depending on energy supply, is linked to cellular metabolism.

**Organic substances.** In addition to inorganic ions, various organic solutes are actively transported by many cells and tissues. Sugars, however, usually enter mammalian cells, such as muscle cells and red blood cells, merely by facilitated diffusion. Only in the intestine and in the kidney tubule does active accumulation of sugar occur, probably driven by a sodium-ion concentration gradient, as has been mentioned above. Various amino acids are accumulated by single cells, as well as by the intestinal mucosa and by the kidney tubules. The mechanism in all cases seems to be based on the same principle. Apparently there are different systems of amino-acid transport, with differing—but overlapping—specificities. This transport is also, at least in part, driven by a sodium gradient. Various other organic solutes, such as nucleotides, also seem to be accumulated by cells by the intestine, or by the kidney tubules. Knowledge of the properties of such transport processes is very scanty.

**Mechanisms of active transport.** The mechanism of active transport has not been elucidated. The most common view is that a mobile carrier is involved, just as in facilitated diffusion. In order to perform active transport, however, the carrier, after having delivered solutes to the final compartment, must undergo a change of such type that it can no longer bind the transported solute. Then, on its return trip it somehow must be reactivated, possibly with the expenditure of metabolic energy. This may be illustrated in Figure 4. In this figure, X is the carrier in

Transport of organic solutes

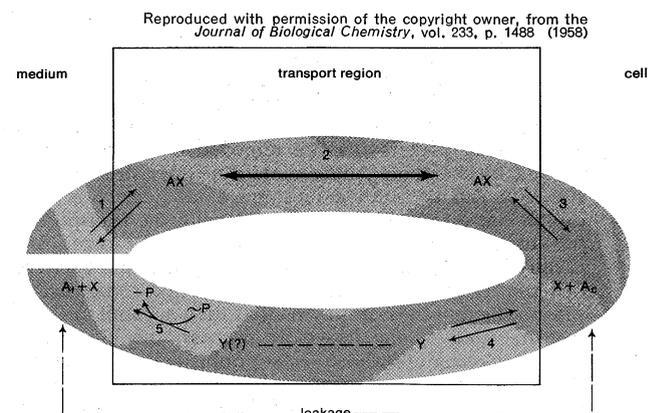

Figure 4: Schematic model of active transport, associated with exchange diffusion (see text).

the activated and Y the carrier in the inactivated form. Only X binds the substrate A; it carries A across the membrane and after delivering it at the other side, X itself is catalytically transformed into Y. Later Y must be reactivated by a reaction that presumably involves energy-rich phosphates. Even though most observations can be easily reconciled with this model, it has not yet been proven by direct experimental evidence. The model does not necessarily imply that the carrier as a whole moves freely within the transport region; it would suffice if only a binding group of the carrier molecules were shuttled back and forth across the osmotic barrier. Other models have been based on immobile systems, with the assumption of binding sites lining the transport pores. If the affinity of these binding sites is shifted, the molecule to be transported may be moved across the channel. Such a

Transport of anions

model would account for many observations in connection with active transport and facilitated diffusion. It would, however, not be easily compatible with the phenomena of countertransport and exchange diffusion. The principle of such a schematic model is also depicted in Figure 4.

Sugar transport in bacteria

A transport system of a special kind seems to be involved in the transport of sugars in certain species of bacteria. In these bacteria, the sugar is not transported as such but as a phosphate ester. The phosphorylation reaction appears to take place simultaneously with transport, for it can be shown with isotopic labelling that the sugar portion of the phosphate esters derives exclusively from the extracellular sugar, whereas the phosphate unit is entirely of intracellular origin. Presumably, an enzyme located in the membrane catalyzes the reaction between the sugar and the phosphoryl donor, thereby pulling the sugar molecule across the membrane. It is difficult to characterize the driving force in such a system.

This special sugar-transport system also is called a phosphotransferase system, because it involves the transfer of a phosphoryl group from an energy-rich phosphate compound (in this case phosphoenolpyruvate, an intermediate of sugar metabolism) to the sugar. Some of the enzymatic components of this system have already been isolated, including two enzymes (transferases), one catalyzing the transport of phosphate from phosphoenolpyruvate to a protein, and the second catalyzing the phosphorylation of the sugar on the outside of the cell by the phosphorylated protein on the inside. The second enzyme may come close to the concept of a transport carrier, though it need not be mobile for its action.

The discovery of this particular transferase system is undoubtedly an important step toward the elucidation of the mechanism of transport systems, but it does not explain all transport systems, not even all microbial systems for the transport of sugars. It is unlikely that the same mechanism applies to sugar transport in animal cells. It is even less likely that a similar system is responsible for amino-acid transport in any cell. Here the traditional carrier model seems to account best for all recorded observations.

Experimental data concerning the chemical basis of carrier systems are scarce. Certain proteins that bind amino acids and other transportable solutes have been isolated from various bacteria and from intestinal mucosa. With respect to its affinity and specificity, the binding is closely related to the transport of the corresponding substrates. The binding proteins can be removed from the cellular surface by shock procedures, and thus their structure and function can be studied in some detail. There is little doubt that these proteins must deal with the transport of the substances they bind, but it has not been shown—and it may be difficult to do so—that they are real carriers; *i.e.*, that they are able to move the bound solute across plasma membranes. It may be that they account only for the first step of the transport process, the binding or so-called recognition step. It is doubtful that an adenosine triphosphatase mechanism, such as that which seems to work in the transport of sodium, potassium, and chloride ions, is involved in amino acid and sugar transport. No such adenosine triphosphatase has been shown to be activated by amino acids, sugars, or any other of the transported organic solutes.

Oxidation-reduction models

Little is known about the underlying mechanism of electrolyte transport, as has already been mentioned, apart from the likely participation of the transport adenosine triphosphatase. An older but revived hypothesis is that of an oxidation-reduction (redox) pump. It is known that, in oxidation-reduction reactions within the respiratory chain, electrons are transferred between reacting molecules or ions. It has been surmised that this electron transfer is spatially orientated in membranes so that the resulting shift of electrical charges may entail the equivalent movement of oppositely charged ions, such as sodium and potassium ions or hydrogen ions. The direct linkage between electron transfer and active ion transport, thus postulated, is hardly compatible with the concept of an adenosine triphosphatase. For this reason the

older versions of the redox models, formerly much in vogue, have been abandoned. With additional assumptions, however, the implementation of redox processes in electrolyte transport can still be defended. In this connection, however, it is not known whether the transfer of energy from a chemical reaction, such as the splitting of an energy-rich phosphate bond, to a transport process is reversible. It is possible that such a reversible transfer may be involved (according to the so-called chemi-osmotic hypothesis) in oxidative phosphorylation; *i.e.*, in the synthesis of energy-rich phosphates in connection with the oxidative degradation of metabolites in the respiratory chain.

**Pinocytosis.** Pinocytosis, which means "cell drinking," is often considered to be a special device for the transport of material into and across cells, which is used by the cells in addition to, or even instead of, active transport. In this process single molecules or ions alone are not transported, but rather a droplet of the medium surrounding the cell is caught and engulfed by the cellular membrane and taken as a vesicle into the cell. The appearance of little vesicles within leucocytes, and their movements there, were observed about forty years ago. Later it was shown that the formation of these vesicles is initiated by prior binding or absorption of a solute or protein to the cellular surface, which then invaginates and forms the little vesicles. These remain, apparently floating freely in the cytoplasm. The borders of these vesicles are thought to be similar to the cellular membranes, with the result that the material trapped in them has not really mixed with the cellular contents. The further fate of these vesicles is uncertain. They may serve to carry a part of the extracellular fluid across the cell, finally being emptied on the opposite side by reverse pinocytosis. In this way extracellular fluid could be moved across a cellular layer without actually entering the cytoplasm. Such a process might be involved in the reabsorption of certain insoluble materials from the intestine or in the movement of plasma across the capillary membranes. On the other hand, all or part of the solutes present in the vesicular fluid could be transported across the vesicular membrane into the cell. This would, of course, be a real transport process, such as has been discussed above. It has been suggested that the cellular membrane, once it has been transformed into the boundaries of the pinocytosis vesicle, changes its permeability so as to become more permeable to otherwise nonpermeating solutes. A sugar molecule, for example, could be taken up by the cell in two steps, first by pinocytosis, and second by modified transport from the vesicle into the cytoplasm. It has been shown that pinocytosis is an energy-consuming process and that it is involved in the secretion of large molecules and particles, such as proteins, lipid droplets, micelles, and crystallites, from the cell. It probably is not involved in the transport and uptake of small molecules and ions, such as sugars, amino acids, and electrolytes. Thus, pinocytosis and membrane transport may exist side by side and serve different purposes.

## Memling, Hans

Hans Memling (Memlinc) was one of the most prolific and accomplished masters of Flemish painting at the end

"Diptych with Madonna and Martin van Nieuwenhove" (left wing), oil on panel by Hans Memling, 1487. In the Memling-Museum, Brugge, Belgium. 44.1 x 33 cm.

By courtesy of the Memling-Museum, Brugge, photograph, © A.C.L., Brussels

of the 15th century. Though heavily influenced by contemporary painters, Memling's art displays better than that of any other Flemish master (except his follower Gerard David) the general tenor of that interlude in Netherlandish art known as the *détente*, the mellowing and relaxation of expression that followed the first generations of painters and provided a bridge to the new Italianizing styles of the 16th century in the north. Memling painted portraits and devotional pictures—well-balanced, restrained compositions, often full of charm and colourful detail. Rather than displaying drama or pathos, Memling's paintings render figures that are withdrawn into calm idealism, with faces demonstrating gentle, sweet piety.

Memling was born about 1430/35 in or near Seligenstadt in the region of the Middle Rhine. He was apparently first schooled in the art of Cologne and then travelled to the Netherlands (c. 1455–60), where he probably trained in the workshop of the painter Rogier van der Weyden. He settled in Bruges (modern Brugge) in 1465; there he established a large shop and executed numerous altarpieces and portraits. Indeed, he was very successful in Bruges: it is known that he owned a large stone house and by 1480 was listed among the wealthiest citizens on the city tax accounts. By 1484 he had enrolled at least three apprentices, and the number of his imitators and followers testifies to his widespread popularity throughout Flanders. Sometime between 1470 and 1480 Memling married Anna de Valkenaere (died 1487), who bore him three children.

A number of Memling's works are signed and dated, and still others allow art historians to place them easily into a chronology on the basis of the patron depicted in them. Otherwise it is very difficult to discern an early, middle, and late style for the artist. His compositions and types, once established, were repeated again and again with few indications of any formal development. His Madonnas gradually become slenderer, more ethereal and self-conscious, and a greater use of Italian motifs such as putti, garlands, and sculptural detail for the settings marks the later works. His portraits, too, appear to develop from a type with a simple neutral background to those enhanced with a loggia or window view of a landscape, but these, too, may have been less a stylistic development than an

adaptation of his compositions to suit the tastes of his patrons.

A good example of the difficulties of dating encountered by scholars is the triptych of "The Virgin and Child with Saints and Donors" that Memling executed for Sir John Donne (National Gallery, London), which until recently had been dated very early—around 1468—because it was believed that the patron commissioned the work while visiting Bruges for the wedding of Charles the Bold (duke of Burgundy) to Margaret of York and that he died the following year (1469) in the Battle of Edgecote. It is now known that Sir John lived until 1503 and that it is probably his daughter Anne (born 1470 or later) who is portrayed as the young girl kneeling with her parents in the central panel, thus indicating that the painting was commissioned about 1475.

Memling's art clearly reveals the influence of contemporary Flemish painters. He borrowed, for example, from the compositions of Jan van Eyck, the famed founder of the Bruges school. The influence of Rogier van der Weyden and Hugo van der Goes can also be discerned in his works—for example, in a number of eye-catching details such as glistening mirrors, tile floors, canopied beds, exotic hangings, and brocaded robes. Above all, Memling's art reveals a thorough knowledge of, and dependence on, compositions and figure types created by Rogier van der Weyden, the painter with whom he had probably apprenticed. In Memling's large triptych (a painting in three panels, generally hinged together) of the "Adoration of the Magi" (Prado, Madrid), one of his earliest works, and in the altarpiece of 1479 for Jan Floreins (Memling-Museum, Brugge), the influence of Rogier's last masterpiece, the "Columba Altarpiece" (1460–64; Alte Pinakothek, Munich), is especially noticeable. Some scholars believe that Memling himself may have had a hand in the production of this late work while still in Rogier's studio. He also imitated Rogier's compositions in numerous representations of the half-length Madonna with the Child, often including a pendant with the donor's portrait (the "Madonna and Martin van Nieuwenhove"; Memling-Museum, Brugge). Many devotional diptychs (two-panel paintings) such as this were painted in 15th-century Flanders. They consist of a portrait of the "donor"—or patron—in one panel, reverently gazing at the Madonna and Child in the other. Such paintings were for the donor's personal use in his home or travels.

Most of Memling's patrons were those associated with religious houses, such as the Hospital of St. John in Bruges, and wealthy businessmen including burghers of Bruges and foreign representatives of the Florentine Medicis and the Hanseatic League (an association of German merchants dealing abroad). For Tommaso Portinari, a Medici agent, and his wife, Memling painted portraits (Metropolitan Museum of Art, New York) and an unusual altarpiece that depicts over 22 scenes from the Passion of Christ scattered in miniature in a panoramic landscape encompassing a view of Jerusalem (Galleria Sabauda, Turin). Such an altarpiece, perhaps created for new devotional practices, became very popular at the end of the 15th century. His best known work with extensive narration is the sumptuous Shrine of St. Ursula in the Hospital of St. John. It was commissioned by two nuns, Jacosa van Dudzele and Anna van den Moortele, who are portrayed at one end of the composition kneeling before Mary. This reliquary, completed in 1489, is in the form of a diminutive chapel with six painted panels filling the areas along the sides where stained glass would ordinarily be placed. The narrative, which is the story of Ursula and her 11,000 virgins and their trip from Cologne to Rome and back, unfolds with charm and colourful detail but with little drama or emotion. Other patrons of the same hospital commissioned Memling to paint a large altarpiece of St. John with the mystical marriage of St. Catherine to Christ as the central theme (Memling-Museum, Brugge). Elaborate narratives appear behind the patron saints John the Baptist and John the Evangelist painted on the side panels, while the central piece is an impressive elaboration of the enthroned Madonna between angels and saints (including Catherine) that one

Altarpieces and portraits

Difficulties of dating Memling's works

finds in innumerable other devotional pieces attributed to Memling. His last great monumental commission that is recorded is the "Passion Triptych", including the Crucifixion Panel (St.-Annen-Museum, Lübeck), a work executed in 1491 for Heinrich Greverade, a merchant of Lübeck, and widely copied.

Because Memling's work was so strongly influenced by that of other painters, it often has been harshly dealt with by 20th-century critics. Yet in his own lifetime he was acclaimed. Recording his death on August 11, 1494, the notary of Bruges described him as "the most skillful painter in the whole of Christendom."

#### MAJOR WORKS

"The Martyrdom of St. Sebastian" (c. 1470; Musées Royaux des Beaux-Arts, Brussels); "Portinari Triptych" (c. 1470; Metropolitan Museum of Art, New York); "Portrait of Gilles Joye" (1472; Sterling and Francine Clark Art Institute, Williamstown, Massachusetts); "The Last Judgment" (c. 1473; Marienkirche, Danzig); "Triptych: The Virgin and Child with Saints and Donors" (c. 1475; National Gallery, London); "The Deposition" (c. 1475; Museo de la Capilla Real, Granada, Spain); "The Virgin and Child" (c. 1475; Museo de la Capilla Real, Granada, Spain); "The Mystic Marriage of St. Catherine of Alexandria" (c. 1475; Louvre, Paris); "Christ Surrounded by Angel Musicians" (c. 1475; Musée Royal des Beaux-Arts, Antwerp); "Mystic Marriage of St. Catherine of Alexandria" (1479; Memling-Museum, Brugge); "Adoration of the Magi" (1479; Memling-Museum, Brugge); "The Descent from the Cross" (1480; Memling-Museum, Brugge); "Scenes from the Life of Christ and the Virgin" (c. 1480; Alte Pinakothek, Munich); "Madonna and Child with Angels" (c. 1480-85; National Gallery of Art, Washington, D.C.); "Moreel Triptych" (1484; Groeninge Museum, Brugge); "Bathsheba" (c. 1485; Staatsgalerie, Stuttgart); "Diptych with Madonna and Martin van Nieuwenhove" (1487; Memling-Museum, Brugge); "St. Benedict" (1487; Uffizi, Florence); "Portrait of Benedetto Portinari" (1487; Uffizi, Florence); "The Virgin and Child" (1487; Staatliche Museen Preussischer Kulturbesitz, Berlin); St. Ursula Shrine (1489; Memling-Museum, Brugge); "Resurrection" (c. 1490; Louvre, Paris); "Passion Triptych" (Crucifixion Panel, 1491; St.-Annen-Museum, Lübeck).

**BIBLIOGRAPHY.** Lengthy bibliographies on the artist appear in A. WURZBACH, *Niederländisches Künstler-Lexikon*, vol. 2 (1909); and V. DENIS, *Encyclopedia of World Art*, vol. 9, col. 729-735 (1964). Among the earlier studies of Memling, see especially J.A. CROWE and G.B. CAVALCASELLE, *The Early Flemish Painters* (1857); L.J. KRAMMERER, *Memling* (1899); F. BOCK, *Memling Studien* (1900); W.H.J. WEALE, *Hans Memling* (1901); and K. VOLL, *Memling* (1909). For the relationships with Rogier van der Weyden, see especially G. HULIN DE LOO "Hans Memling in Rogier van der Weyden's Studio," *Burlington Magazine*, 52:160-177 (1928); and M.J. FRIEDLANDER, "Noch etwas über das Verhältnis Roger van der Weydens zu Memling," *Oud-Holland*, 61:11-19 (1946). The standard references are L. VON BALDASS, *Hans Memling* (1942); and M.J. FRIEDLANDER, *Memling* (1950); and his *Die Altniederländische Malerei*, vol. 6 (1928; Eng. trans., *Early Netherlandish Painting*, vol. 6, 1971). Also very useful are the discussions of Memling's works that have appeared in the series *Les Primitifs flamands*, especially vol. 9, J. BIALOSTOCKI, *Les Musées de Pologne* (1966); and vol. 11, M. DAVIES, *The National Gallery-London-III* (1970).

## Memory, Abnormalities of

Disorders of memory must have been known to the ancients and are mentioned in several early medical texts; but it was not until the closing decades of the 19th century that serious attempts were made to analyze them or to seek their explanation in terms of brain disturbances. Of the early attempts, the most influential was that of a French psychologist, Théodule Armand Ribot, who, in his *Diseases of Memory* (1881, English translation 1882), endeavored to account for memory loss as a symptom of progressive brain disease by embracing principles describing the evolution of memory function in the individual, as offered by an English neurologist, John Hughlings Jackson. Ribot wrote:

The progressive destruction of memory follows a logical order—a law. It advances progressively from the unstable to the stable. It begins with the most recent recollections, which, being lightly impressed upon the nervous elements,

rarely repeated and consequently having no permanent associations, represent organization in its feeblest form. It ends with the sensorial, instinctive memory, which, having become a permanent and integral part of the organism, represents organization in its most highly developed stage.

The statement, amounting to Ribot's "law" of regression (or progressive destruction) of memory, enjoyed a considerable vogue and is not without contemporary influence. The notion has been applied with some success to phenomena as diverse as the breakdown of memory for language in a disorder called aphasia and the gradual return of memory after brain concussion. It also helped to strengthen the belief that the neural basis of memory undergoes progressive strengthening or consolidation as a function of time. Yet students of retrograde amnesia (loss of memory for relatively old events) agree that Ribot's principle admits of many exceptions. In recovery from concussion of the brain, for example, the most recent memories are not always the first to return. It has proved difficult, moreover, to disentangle the effects of passage of time from those of rehearsal or repetition on memory.

A Russian psychiatrist, Sergey Sergeevich Korsakov, (Korsakoff), may have been the first to recognize that amnesia need not necessarily be associated with dementia (or loss of the ability to reason), as Ribot and many others had supposed. Korsakov described severe but relatively specific amnesia for recent and current events among alcoholics who showed no obvious evidence of shortcomings in intelligence and judgment. This disturbance, now called the Korsakoff syndrome, has been reported for a variety of brain disorders aside from alcoholism and appears to result from damage in a relatively localized part of the brain.

The neurological approach may be combined with evidence of psychopathology to enrich understanding of memory function. Thus, a French neurologist, Pierre Janet, described amnesia sufferers who were apparently very similar to those observed by Korsakov but who gave no evidence of underlying brain disease. Janet also studied people who had lost memory of extensive periods in the past, also without evidence of organic disorder. He was led to regard these amnesias as hysterical, explaining them in terms of dissociation: a selective loss of access to specific memory data that seem to hold some degree of emotional significance. In his experience, reconnection of dissociated memories could as a rule be brought about by suggestion while the sufferer was under hypnosis. Freud regarded hysterical amnesia as arising from a protective activity or defense mechanism against unpleasant recollections; he came to call this sort of forgetting repression, and he later invoked it to account for the typical inability of adults to recollect their earliest years (infantile amnesia). He held that all forms of psychogenic (not demonstrably organic) amnesia eventually could resolve after prolonged sessions of talking (psychotherapy) and that hypnosis was neither essential nor necessarily in the amnesiac's best interest. Nevertheless, hypnosis (sometimes induced with the aid of drugs) has been widely used in the treatment of hysterical amnesia, particularly in time of war when only limited time is available.

#### ORGANIC DISORDERS OF MEMORY

Defect of memory is one of the most frequently observed symptoms of impaired brain function. It may be transitory, as after an alcoholic bout or an epileptic seizure; or it may be enduring, as after severe head injury or in association with brain disease. When there is impaired ability to store memories of new experiences (up to total loss of memory for recent events) the defect is termed anterograde amnesia. Retrograde loss may progressively abate or shrink if recovery begins, or it may gradually enlarge in scope, as in cases of progressive brain disease. Minor grades of memory defect are not uncommon after-effects of severe head injury or infections such as encephalitis; typically they are shown in forgetfulness about recent events, in slow and insecure learning of new skills, and sometimes in a degree of persistent amnesia for events preceding the illness.

Ribot's  
"law"

Repression

*Transient global amnesia.* Apparently first described in 1964, transient global amnesia consists of an abrupt loss of memory lasting from a few seconds to a few hours, without loss of consciousness or other evidence of impairment. The individual is virtually unable to store new experience, suffering permanent absence of memory for the period of the attack. There is also a retrograde loss that may initially extend up to years preceding the attack. This deficit shrinks rapidly in the course of recovery but leaves an enduring gap in memory that seldom exceeds the three-quarters of an hour before onset. Thus the person is left with a persisting memory gap only for what happened during the attack itself and in a short period immediately preceding. Such attacks may be recurrent, are thought to result from transient reduction in blood supply in specific brain regions, and sometimes presage a stroke.

*Traumatic amnesia.* On recovery of consciousness after trauma, a person who has been knocked out by a blow on the head at first typically is dazed, confused, and imperfectly aware of his whereabouts and circumstances. This so-called posttraumatic confusional state may last for an hour or so up to several days or even weeks. While in this condition, the individual appears unable to store new memories; on recovery he commonly reports total amnesia for the period of altered consciousness (posttraumatic amnesia). He also is apt to show retrograde amnesia that may extend over brief or quite long periods into the past, the duration seeming to depend on such factors as severity of injury and the sufferer's age. In the gradual course of recovery, memories are often reported to return in strict chronological sequence from the most remote to the most recent, as in Ribot's law. Yet this is by no means always the case; memories seem often to return haphazardly and to become gradually interrelated in the appropriate time sequence. The amnesia that remains seldom involves more than the events that occurred shortly before the accident though in severe cases careful inquiry may reveal some residual memory defect for experiences dating from as long as a year before the trauma. It is thought by some that, after recovery, the overall period of time for which there is no recollection may indicate the degree of severity of the head injury.

*Traumatic automatism.* Posttraumatic amnesia sometimes is observed after mild head injury without loss of consciousness and with no apparent change in ordinary behaviour. A football player who is dazed but not knocked out by a blow on the head, for example, may continue to play and even score a goal. But he may be going through these motions automatically and may later have no memory whatever of the part of the game that followed his injury. The phenomenon is known as traumatic automatism and seems similar to, if not identical with, transient global amnesia.

*Memory defect after electroconvulsive therapy.* Electroconvulsive treatments have been widely used in psychiatry, particularly for depressed people. A seizure or convulsion is induced by passing current through electrodes placed on the forehead. Each treatment is followed by a period of confusion for which the person is subsequently amnesic; at this time there is also a rapidly abating amnesia of some seconds for events that immediately preceded the shock. After a number of treatments, however, some individuals complain of more persistent memory defect, shown mainly in exaggerated forgetfulness for day-to-day events. These difficulties nearly always clear up within a few weeks after treatment ends. Experimental evidence tentatively suggests that electroshock administered to only one side of the head produces therapeutic results equal to those of the standard procedure but with significantly reduced impairment of memory.

*Korsakoff syndrome.* First described in cases of chronic alcoholism, Korsakoff's psychosis, or syndrome, occurs in a wide variety of toxic and infectious brain illnesses, as well as in association with such nutritional disorders as deficiency of the B vitamins. The syndrome also has been observed among people with cerebral tumours, especially those involving the third ventricle (one of the fluid-filled cavities in the brain). The main psychological feature is

gross defect in recent memory, sometimes so severe as to produce "moment-to-moment" consciousness; such people can store new information only for a few seconds and report no continuity between one experience and the next. They seem incapable of learning, even after many trials or repetitions. Although cases of such severity are relatively rare, the ability to store experience only briefly is quite characteristic of the Korsakoff syndrome.

In addition, sufferers almost always show evidence of retrograde amnesia that can span as little as a few weeks past to as much as 15 or 20 years before onset of the disorder. These extensive retrograde amnesias are seldom total or uniform, and "islands" of memory often can be found by persistent interrogation. The person's memory function depends heavily on circumstances; for example, a man with Korsakoff's syndrome who recognizes his wife instantly when she visits may in her absence vehemently deny that he is married. Commonly, there is disorientation in place and time; the individual often underestimates his own age, sometimes grossly. Some sufferers characteristically confabulate; *i.e.*, they remember experiences they never personally had or they falsely localize their memories in time. Not uncommonly, these people deny being ill or that their memory is in any way affected. Otherwise, they can exhibit good intelligence and, apart perhaps from some lack of spontaneity, may show little or no personality change.

While Korsakoff's syndrome is commonly encountered as a transitory sign of brain disorder, it can be chronic, remaining effectively unimproved over many years. Even with improvement, however, an appreciable weakness in recent memory, particularly in regard to sequence in time, is quite apparent.

*Persistent defect after encephalitis.* Attention repeatedly has been drawn to severe and persistent memory defect following attacks of a form of brain inflammation called acute inclusion body encephalitis. The individual's behaviour closely resembles that of Korsakoff's syndrome except that his insight into the memory disorder is usually good and confabulation is infrequent or absent. Indeed, the memory disorder is sometimes so limited and specific as to raise the possibility of a psychogenic (*i.e.*, hysterical) amnesia. In cases of this kind there may be little or no impairment of intelligence or judgment.

*Defect following brain surgery.* Surgical operations on the sides of the brain (the temporal lobes) to remove tissues that produce symptoms of epilepsy are routine. While good results are often achieved, a degree of memory defect ensues. Operations on the dominant (usually left) temporal lobe tend to hamper one's ability to learn verbal information by hearing or reading. Usually observable even before surgery, the defect tends to be more marked after operation and has been reported to persist for up to three years before eventual recovery. Operations on one temporal lobe when there is unsuspected damage to its fellow on the other side of the brain (or on both lobes, in surgery very rarely undertaken) produce severe and persistent general memory defect, altogether comparable to postencephalitic amnesia. There is gross defect in recent memory and in learning (except perhaps in motor learning), with retrograde amnesia that initially may involve several years of the person's past. Intelligence otherwise appears to be well preserved; the individual shows insight into his memory difficulty, and seldom, if ever, confabulates.

*Diffuse brain diseases.* Some memory failure is almost universal during old age, particularly in forgetfulness for names and in the reduced ability to learn. Many people of advanced age, nevertheless, show adequate memory function if they suffer no brain disease. Impairment of memory is a characteristic early sign of senility, as well as of hardening of the brain arteries (cerebral arteriosclerosis) at any age, with exaggerated forgetfulness for recent events and progressive failure in memory for experiences that preceded the disorder. As arteriosclerotic brain disease progresses, amnesia tends to extend further into the past, embracing personal experience and general or common information. When the symptoms are almost those of the Korsakoff syndrome, the disturbance is called pres-

Haphazard  
recovery  
of memory

Extensive  
retrograde  
amnesia

Senility

byophrenia. In most cases the amnesia is complicated by failure in judgment and changes in character. It has been suggested that severe memory defect in an elderly person carries a poor prognosis, being related to such factors as a shortened survival time and an increased death rate.

A Swiss psychiatrist, Eugen Bleuler, held that amnesia results only from a diffuse disorder of the outer layers (cortex) of the brain and suggested that memory depends on the integrity of the cortex as a whole. Indeed, the removal of brain tissue from rats and monkeys in experimental studies has indicated that retention of complex habits by the animals depends on the total amount of cortex that remains. It was claimed that the degree to which memory is lost depends not on where the brain is injured but on the extent of the damage. (This is the "law" of mass action, which asserts that the brain functions in a unitary manner; *i.e.*, as a whole.) While the extent of diffuse brain damage is roughly related to the severity of memory defect, the principle of mass action is nevertheless manifestly inadequate. It would seem that, whatever its physical basis, memory depends on the integrity of relatively limited parts of the brain, rather than on that organ (or even the cortex) as a whole.

Severe and highly specific amnesic symptoms principally stem from damage to such brain structures as the mammillary bodies, circumscribed parts of the thalamus, and of the temporal lobe (*e.g.*, the hippocampus). (For illustrations and descriptions of these structures, see NERVOUS SYSTEM, HUMAN.) While the ability to store new experience (and perhaps in some degree to retrieve well-established memories) appears to depend on a distinct neural system involving the temporal cortex and limited parts of the thalamus and hypothalamus, understanding of the neuroanatomy of memory remains sketchy enough to generate major differences of opinion. French and German workers tend to stress the role of the mammillary bodies, while United States investigators are more prone to implicate the thalamus. It has been pointed out that circumscribed damage to the mammillary bodies is not invariably associated with memory defect; cases of amnesia evidently occur in which these structures are spared. Nevertheless, implication of the mammillary bodies in a large number of verified cases of Korsakoff's syndrome seems incontrovertible. Injury to other neural tissues (*e.g.*, the so-called fornix bundle deep within the brain) that anatomically might be expected to produce severe memory disorder rarely does so. While evidence for amnesia as a sign of localized brain damage is impressive, much remains to be understood about the physical system that sustains memory.

Brain structures in amnesia

#### PSYCHOLOGICAL STUDIES OF AMNESIA

*Short-term memory.* It has long been known that so-called short-term memory (see MEMORY: RETENTION AND FORGETTING) is typically intact among amnesia sufferers. Such victims usually can repeat a short phrase or a series of words or numbers from immediate memory as adequately as anyone of comparable age and intelligence. Such an amnesic person can retain the gist of a question or request long enough to respond appropriately, unless, of course, there is enough delay in performance or attention is diverted. Evidently the ability to register information is intact, if this means availability of data in short-term memory. For this reason, experimental psychologists who favour a sharp distinction between short-term and long-term storage systems contend that the primary deficit in amnesia is an inability to transfer information from short-term to long-term storage.

*Associative learning.* It has been argued that the basic deficit in the amnesic state is a loss of learning ability. In a series of experiments with amnesic patients, using, for the most part, verbal material, the subjects evidenced failure to link new with old associations, rapid fading of new associations, and great difficulty in reproducing whatever associations might have been formed. These findings have been amply confirmed by later work; in one view, however, the weakness resides less in the failure to establish new associations than in their rapid decay (*i.e.*,

accelerated forgetting). On the other hand, it has often been noticed that if a Korsakoff patient can once succeed in learning an item, he may be able to reproduce it correctly after an appreciable interval of time. Further experiments, using a variety of techniques for assessing learning and retention, have suggested that it is retrieval rather than learning that is at fault.

*Motor skill.* Attention has been drawn to the fact that the acquisition of manual skill in Korsakoff patients is less impaired than either verbal learning or the solution of puzzles or mazes. This is confirmed in the observation that a severely amnesic patient who had undergone an extensive operation on the temporal lobes could perform rotary-pursuit and tracking tasks at a level not greatly inferior to that of healthy control subjects. A second case of the same kind has recently been described, in which memory for motor tasks such as maze learning or the rendering of new compositions on the piano is said to have been completely preserved. These observations suggest that the acquisition of motor skill may remain relatively unaffected by lesions that give rise to a severe defect of general memory. What is commonly called global or generalized memory defect may, therefore, become increasingly subject to fractionation.

*Residual learning capacity.* Korsakov himself pointed out that a patient who consistently denies that he has seen his doctor before does not necessarily react to him on each successive encounter as a total stranger. It would thus appear that, in spite of gross amnesia, some learning, perhaps implicit, can still take place. This view has gained considerable support from both clinical and experimental studies. About 1900 it was reported that even severely affected Korsakoff patients show appreciable savings in relearning verbal material after an interval of several hours or days, thus indicating minimal retention. Some Korsakoff patients, in spite of gross amnesia, eventually learn their way about the hospital. Again, some patients who disown any knowledge of their whereabouts may nevertheless give the correct name of the hospital, when asked to guess or to select it correctly from a list containing the names of several hospitals. Thus, while learning capacity is seldom, if ever, wholly destroyed, there is failure to integrate new knowledge within the total personality. It is apparently a lack of mental coherence that lies at the basis of Korsakoff's psychosis.

*Forgetting.* While some clinicians have attributed memory defect largely, if not exclusively, to defective registration of experience (*i.e.*, failure to form memory traces), the widely accepted view is that it results primarily from a greatly increased rapidity of forgetting (*i.e.*, rapid decay of memory traces). With some exceptions, this view has also been held by the great majority of experimental psychologists who have worked with amnesic people. The consensus is that amnesia sufferers characteristically lose much of the memory they once had. This conclusion finds support in the very rapid extinction of conditioned eyeblink responses to a buzzer. It is notable that, in Korsakoff states, forgetting appears to be due to the passage of time (oblivescence) rather than to retroactive inhibition or some kindred interference effect (see LEARNING THEORIES).

*Time disorders.* Estimation of time is typically poor in amnesic states. The individual is prone to underestimate grossly the duration of an interview or the time in which he has been engaged on any particular activity. Conversely, he may equally grossly overestimate the time that has elapsed since a particular event (*e.g.*, the visit of a relative) of which he has preserved some recollection. Indeed, amnesic patients exhibit a remarkable want of coherence in their thought processes, suggesting that a lack of temporal synthesis underlies, and may indeed in large part explain, the defect of memory. Nevertheless, although difficulties in dating particular past events and in building a coherent time framework are quite characteristic of amnesic states and may persist after otherwise good recovery, an explanation couched wholly in terms of time disturbance is scarcely convincing.

*Retrograde amnesia.* Inasmuch as retrograde amnesia relates to memory for events that took place at a time

Generalized versus specific memory loss

Consolidation of the memory trace

when brain function was unimpaired, it clearly cannot be ascribed to failure of registration—with the exception, perhaps, of the very brief permanent amnesias following electroconvulsive shock or head injury. Retrograde amnesia otherwise would appear to be wholly due to a failure of retrieval, though this failure is evidently selective. That recent memories are generally harder to evoke than those more remote is usually explained on the basis of consolidation; *i.e.*, progressive strengthening of memory traces with the passage of time. Yet, recency is not the only factor governing the vulnerability of memory traces, and in some cases memory for a relatively recent event may still be preserved while that for one more remote is inaccessible. Much depends, too, on the method used to test retrieval; recognition, for example, may succeed when voluntary recall entirely fails. By and large, the availability of information in memory would seem to depend to a considerable extent on its relation to the person's current interests and preoccupations. When these are severely curtailed by an amnesic state, the links connecting present and past are severed, with a consequent failure of reproduction.

#### PSYCHOGENIC AMNESIA

It long has been known that some forms of amnesia appear to be quite different from those associated with detectable injury or disease of the brain. These comprise, first, amnesias that can be induced in apparently normal individuals by means of suggestion under hypnosis; and secondly, amnesias that arise spontaneously in reaction to acute conflict or stress, and which are commonly called hysterical. Such amnesias are effectively reversible and have been explained wholly in psychological terms. Nevertheless, organic factors are not infrequently involved to some extent, and the distinction between organic and psychogenic amnesia may well turn out to be a good deal less absolute than has been traditionally supposed.

*Hypnotic amnesia.* Memory of a hypnotic trance is often vague and fragmentary, as in awakening from an ordinary dream. This may be due in part to defect of registration during the period of altered consciousness. At the same time, very much more complete posthypnotic amnesia can be induced if an individual is told that, when he awakens, he will remember nothing of what went on during the period of hypnosis. This is clearly a psychogenic phenomenon; memory is fully regained if the patient is rehypnotized and an appropriate counter-suggestion given. It may also be regained if the person is persistently interrogated in the waking state, again suggesting that the amnesia is apparent rather than real. This observation led Freud to seek access to ostensibly forgotten (repressed) memories in his patients without the use of hypnosis.

*Hysterical amnesia.* Hysterical amnesia is of two main types. One involves the failure to recall particular past events or those falling within a particular period of the patient's life. This is essentially retrograde amnesia but it does not appear to depend upon an actual brain disorder, past or present. In the second type there is failure to register—and, accordingly, later to recollect—current events in the patient's ongoing life. This is essentially anterograde amnesia and, as an ostensibly psychogenic phenomenon, would appear to be rather rare and almost always encountered in cases in which there has been a pre-existing amnesia of organic origin. Very occasionally, amnesia appears to cover the patient's entire life, extending even to his own identity and causing him to fail to recollect all particulars of his whereabouts and circumstances. Although most dramatic, such cases are extremely rare and seldom wholly convincing. They usually clear up with relative rapidity, with or without psychotherapy.

Hysterical amnesia differs from organic amnesia in a number of important respects. As a rule it is sharply bounded, relating only to particular memories, or groups of memories, often of direct or indirect emotional significance. It is also usually motivated in that it can be understood in terms of the patient's needs or conflicts; *e.g.*, the need to seek financial compensation after, say, a

road accident causing a mild head injury or to escape from the memory of an exceptionally distressing or frightening event. Hysterical amnesia also may extend to cover basic school knowledge, such as spelling or arithmetic, which is never seen in organic amnesia unless there is concomitant aphasia or a very advanced state of dementia. A most distinctive feature of hysterical amnesia is that it can almost always be relieved by such procedures as hypnosis. Although the task of distinguishing organic and psychogenic amnesia is not always easy, it can usually be achieved on the basis of such criteria, especially when there is no reason to suspect actual damage to the brain.

*Legal implications.* The differentiation of organic from functional amnesia not uncommonly assumes legal importance, as in cases in which compensation is sought for disability held to be due to industrial or road accidents causing head injuries. If there is a complaint of defective memory, it is legally important to ascertain what part of it can be ascribed to the aftereffects of the head injury and what part of it to subsequent psychogenic elaboration. Similar issues may also arise on occasion in criminal cases, as in a trial in England (1959) in which it was contended that the accused man had a total amnesia for the circumstances of his alleged offense—the murder of a police officer—and should therefore be regarded as unfit to plead. After much discussion as to whether the amnesia was organic, hysterical, or feigned, the jury found it not to be genuine and the trial proceeded to conviction.

*Mixed amnesic states.* Students of amnesia have been increasingly impressed by the frequency with which psychogenic factors appear to reinforce, prolong, or otherwise complicate an organic memory defect. Hysterical reactions appear to be far from uncommon in brain-damaged patients: conversely, there is little or nothing in the pathology of hysterical amnesia that has not been observed in the organic syndrome. A particularly interesting case reported in the German literature in 1930 aroused great controversy. This was the case of a young man who developed severe and persistent amnesia following accidental carbon monoxide poisoning. His consciousness was virtually restricted to a second or two and no lasting memory traces could apparently be formed. While the original defect of memory may have been largely, if not wholly, organic, it was sustained thereafter on a hysterical basis. Conversely, a case has been reported in which the diagnosis, originally hysterical amnesia, had to be altered in light of the discovery that the patient had suffered from progressive disease of the brain. In such cases, organic and psychogenic factors appear to interact to produce complex and atypical symptoms.

*Fugue states.* The fugue is a condition in which the individual wanders away from his home or place of work for periods of hours, days, or even weeks. One celebrated case was that of the Rev. Ansell Bourne, described most eloquently by the U.S. psychologist William James. This clergyman wandered away from home for two months and acquired a new identity. On his eventual return, he was found to have no memory of the period of absence, though it was eventually restored under hypnosis. In not all cases, however, is the basis of the fugue so manifestly psychogenic. Indeed, close observation in some instances may reveal minor alterations in consciousness and behaviour that suggest an organic basis, probably epileptic. According to one view, pathological wandering with subsequent amnesia is due to a constellation of factors, among which are a tendency toward periodic depression, history of a broken home in childhood, and predisposition to states of altered consciousness, even in the absence of organic brain lesion. Psychoanalysts, on the other hand, see in the fugue a symbolic form of escape from severe emotional conflict.

#### PARAMNESIA AND CONFABULATION

The term paramnesia was introduced by a German psychiatrist, Emil Kraepelin, in 1886 to denote errors and illusions of memory. He distinguished three main varieties; one he called simple memory deceptions, as

Relief of amnesia through hypnosis

Possible basis in epilepsy

when one remembers as genuine those events imagined or hallucinated in fantasy or dream. This is not uncommon among confused and amnesic people and may also occur in paranoid states. Kraepelin also wrote of associative memory deceptions, as when a person meeting someone for the first time claims to have seen him on a variety of previous occasions. This has since been renamed reduplicative paramnesia or simply reduplication. Lastly there was identifying paramnesia, in which a novel situation is experienced as duplicating an earlier situation in every detail; this is now known as *déjà vu* or paramnesia *tout court*. The term confabulation denotes the production of false recollections generally.

*Déjà vu*. The *déjà vu* experience has aroused considerable interest, and is occasionally felt by most people, especially in youth or when they are fatigued. It has also found its way into literature, having been well described by, among other creative writers, Shelley, Dickens, Hawthorne, Tolstoy, and Proust. The curious sense of extreme familiarity may be limited to a single sensory system, such as the sense of hearing, but as a rule it is generalized, affecting all aspects of experience including the subject's own actions. As a rule, it passes off within a few seconds or minutes, though its repercussions may persist for some time. For some epileptics, however, *déjà vu* may continue for hours or even days and can provide a fertile subsoil for delusional elaboration.

In view of its occurrence among organically healthy individuals, *déjà vu* commonly has been regarded as psychogenic and as having its origin in some partly forgotten memory, fantasy, or dream. This explanation has appealed strongly to psychoanalysts; it also gains support from the finding that an experience very similar to *déjà vu* can be induced in normal people by hypnosis. If a picture is presented to a hypnotized person with the instruction to forget it and then is shown with other pictures when he is awake, the subject may report an intense feeling of familiarity that he is at a loss to justify. The *déjà vu* phenomenon also is attributable to minor neurophysiological abnormality; it is frequent in epilepsy. Indeed, *déjà vu* is accepted as a definite sign of epileptic activity originating in the temporal lobe of the brain and may occur as part of the seizure activity or frequently between convulsions. It seems to be more frequent in cases in which the disorder is in the right temporal lobe and has on occasion been evoked by electrical stimulation of the exposed brain during surgery. Some have been tempted to ascribe it to a dysrhythmic electrical discharge in some region of the temporal lobe that is closely associated with memory function.

*Reduplicative paramnesia*. Reduplication is observed mainly among acutely confused or severely amnesic people; for example, a patient may say that he has been in one or more hospitals that are very similar to his present location and that all bear the same name. The effect also can be induced by showing the person an object such as a picture and by testing him for recognition of the same picture a few minutes later. He is apt to say that he has seen a similar picture but definitely not the one now being shown. This effect appears to depend on loss of a sense of familiarity and on failure to treat a single object seen on a number of occasions as one and the same. It has been reported that reduplication of this kind is typically associated with confabulation, speech disorder (paraphasia), disorientation, and denial of illness.

*Confabulation*. Spurious memories or fabrications are very common in psychiatric disorders and may take on an expansive and grandiose character. They may also embody obvious elements from fantasy and dream. At a more realistic level, the production of false memories (confabulation) is best studied among sufferers of the Korsakoff syndrome, for whom consciousness and reasoning remain clear. When asked what he did on the previous day, such a person may give a detailed account of a typical day in his life several months or years earlier. Evidently his retrograde amnesia and his disorientation in time provide fertile soil for false reminiscence. When the confabulation embodies dramatic, fanciful elements, it is the exception rather than the rule.

Confabulation once was regarded as one's reaction to the social embarrassment produced by a memory defect; *i.e.*, as an attempt to fill memory gaps plausibly. Despite this possibility, many severely amnesic patients confabulate little, if at all; and there appears to be no relation between the severity of amnesia and frequency of confabulation. In consequence, individual differences in pre-amnesic personality have been stressed, particularly in regard to suggestibility. While many patients who confabulate are obviously highly suggestible, precise tests of suggestibility have not been used in most clinical evaluations. It also has been claimed that the superficially sociable, but basically secretive, individual is particularly prone to confabulate. The most critical factor appears to be the sufferer's degree of insight into his disorder; it has been observed that the amnesia sufferer who most strongly denies any lapse in memory is most prone to confabulate. By contrast, it also has been claimed that in chronic Korsakoff states the individual's insight into his condition is no guarantee of freedom from confabulation.

While confabulation is pathological by definition, all people include an inventive, imaginative (and therefore spurious) element in their remembering. Indeed, it seems valid to say that all remembering depends heavily on reconstruction rather than on mere reproduction alone. Among amnesiacs, reconstruction is especially drastic, inventive, and error prone, particularly in regard to chronological sequence. The difference, therefore, between normal and grossly amnesic confabulation may well be one of degree rather than kind.

#### HYPERMNESIA

Enhancement of memory function (hypermnnesia) under hypnosis and in some pathological states was frequently described by 19th-century medical writers; for example, cases were recorded of delirious people who would speak fluently in a language they had not had occasion to use for up to 50 or more years and apparently had forgotten. It was then categorically claimed that anyone under hypnosis would recollect events with invariably greater efficiency than in the waking state. It is true that experience inaccessible to ordinary recall sometimes can be recollected under hypnosis; some have attributed this effect to release from emotional inhibition. Nevertheless, evidence indicates that previously memorized material (*e.g.*, poetry) in many cases is reproduced no better under hypnosis than in the waking state.

*Memory prodigies*. Few individuals who exhibit exceptional gifts of memory have been studied extensively. The case of a Russian mnemonist (memory artist), "S," was studied over a period of 30 years, and his story has been delightfully written by a Soviet psychologist (see *Bibliography*). This man's exceptional mnemonic ability seemed largely to depend on an outstandingly vivid, detailed, and persistent visual memory, almost certainly eidetic ("photographic") in nature. "S" also reported an unusual degree of synesthesia, though whether this helped or hindered his feats of memory is not entirely clear. (A person shows signs of synesthesia when he reports that stimulation through one sense leads to experiences in another sense; for example, such a person may say that he sees vivid flashes of colour when he hears music or speech.) Although "S's" highly developed power of concrete visualization made possible feats of memory far beyond the ordinary, he exhibited genuine weakness in abstract thinking.

Exceptional memory capacity is occasionally observed among mathematicians and others with exceptional talent for lightning calculation. A mathematics professor at the University of Edinburgh, for example, was reported to be capable of remarkable feats of long-term memory for personal experiences, music, and verbal material in either English or Latin. This talented mathematician has been said to recall with complete accuracy a list of 25 unrelated words after only a brief effort to memorize, and to recite the value of pi (an endless number) to a thousand places or more. Likewise, some composers and musicians appear to possess exceptional auditory memory, though no systematic study of their attainments appears

Inventive  
memory

Photo-  
graphic  
memory

to have been made. The anatomical or physiological basis of hypermnnesia remains most incompletely understood.

## Memory: Retention and Forgetting

That experiences influence subsequent behaviour is evidence of an obvious but nevertheless remarkable activity called remembering. Learning could not occur without the function popularly named memory. Practice results in a cumulative effect on memory leading to skillful performance on the tuba, to recitation of a poem, and even to reading and understanding these words. So-called intelligent behaviour demands memory, remembering being prerequisite to reasoning. The ability to solve any problem or even to recognize that a problem exists depends on memory. Typically, the decision to cross a street is based on remembering many earlier experiences.

Practice (or review) tends to build and maintain memory for a task or for any learned material. Over a period of no practice what has been learned tends to be forgotten; and the adaptive consequences may not seem obvious. Yet, dramatic instances of sudden forgetting (as in amnesia) can be seen to be adaptive. In this sense, the ability to forget can be interpreted to have survived through a process of natural selection in animals. Indeed, when one's memory of an emotionally painful experience leads to severe anxiety, forgetting may produce relief. Nevertheless, an evolutionary interpretation might make it difficult to understand how the commonly gradual process of forgetting survived natural selection.

In speculating about the evolution of memory, it is helpful to consider what would happen if memories failed to fade. Forgetting clearly aids orientation in time; since old memories weaken and the new tend to be vivid, clues are provided for inferring duration. Without forgetting, adaptive ability would suffer; for example, learned behaviour that might have been correct a decade ago may no longer be. Cases are recorded of people who (by ordinary standards) forgot so little that their everyday activities were full of confusion. Thus, forgetting seems to serve the survival of the individual and the species.

Another line of speculation posits a memory storage system of limited capacity that provides adaptive flexibility specifically through forgetting. In this view, continual adjustments are made between learning or memory storage (input) and forgetting (output). Indeed, there is evidence that the rate at which individuals forget is directly related to how much they have learned. Such data offer gross support of contemporary models of memory that assume an input-output balance.

Whatever its origins, forgetting has attracted considerable investigative attention. Much of this research has been aimed at discovering those factors that change the rate of forgetting. Efforts are made to study how information may be stored; that is, to discover the ways in which it may be encoded. Remembered experiences may be said to consist of encoded collections of interacting information; and interaction seems to be a prime factor in forgetting.

### MEASURING RETENTION

Standard sentences, prose passages, and poems have been used to control input in studies of retention; but discrete

verbal units (such as words or sets of letters) are most frequently employed. The letters usually comprise lists of consonant syllables (three consonants; e.g., RQK) or so-called nonsense syllables (consonant-vowel consonant; e.g., ROK). The order in which verbal units are to be learned and to be recited may be left to the subject (free recall). A schoolboy who can recite the names of all African countries probably has learned such a free-recall task. Units also can be presented serially (in a constant order), the subject being asked to recite them in that order; reciting the alphabet in the usual way represents such serial learning.

Pairs of words may be offered; in such paired-associate tasks the subject eventually is asked to produce the missing member of each pair when only one word is shown. This is akin to learning English equivalents for words from another language.

For these and similar tasks investigators commonly permit subjects enough practice trials to reach some preselected criterion or level of performance. This level effectively defines an immediate retention score against which later forgetting may be measured. Subsequent tests of retention are then made to investigate the rate at which forgetting proceeds. This rate tends to vary with the methods used, basically those of recall, recognition, or relearning.

**Recall.** Subjects may be asked to reproduce (recall) previously learned data in any order or in the original order in which they were learned.

In a free-recall test the instructions might be: "Yesterday you learned a list of words; please write as many of those words as you possibly can as they occur to you." For the paired-associate task the subject may be told: "Yesterday you learned some pairs of words; I will show you one word from each pair and you try to give the other." He may be paced, being limited to a few seconds to produce each word; or he may be unpaced, being given no rigidly specified limits.

If retention of any kind is to be measured over different periods (e.g., an hour, a day, a week) a separate group of individuals should be used for each period. The reason is that the very act of remembering constitutes practice that keeps memory lively, tending to give misleading underestimates of the rate of forgetting if the same subjects are tested over successive intervals.

**Recognition.** The subject's task is simpler in tests of recognition, since reproduction or retrieval (as in recall) is not required. The subject simply is asked to remember previously presented information when it is offered to him again. For example, he may be given a list of words for study; on the subsequent test of retention these are mingled with additional words, the subject being asked to identify (recognize) the original words. Apparently the recognition test stresses ability to choose between "old" (studied) data and "new" words, although this need not mean that choices are based only on temporal discrimination (awareness of time distinctions).

In an alternative variety of recognition test, each word studied might be paired with a new one, the task being to choose the old member of each pair. Or, the test words might be presented one at a time for identification as old or new. Sometimes learning and testing are combined: a very long list of words may be presented one at a time, some being repeated; the task is to recognize the repeats.

Some recognition tests stress memory of the order of presentation. The subject learns a serial list (reciting in a prescribed order); the list then is scrambled, and he is tested on his ability to rearrange it appropriately. Order may be based on how units are arranged in space (e.g., printed on a page) or on their numerical position in a series or on associative information. Thus, if a paired-associate list has been learned, the test may consist of the unmatched presentation of all units with a request to pair them properly. This sort of recognition seems to emphasize associative attributes. If some elements on the test were not presented originally, the temporal attribute also may be involved.

**Relearning.** The number of successive trials a subject takes to reach a specified level of proficiency may be

Free recall,  
serial learning,  
paired-associate  
tasks

compared with the number of trials he later needs to attain the same level. This yields a measure of retention by what is called the relearning method. The fewer trials needed to reach the original level of mastery, the better the subject seems to remember. The relearning measure sometimes is expressed as a so-called savings score. If ten trials initially were required, and five relearning trials later produce the same level of proficiency, then five trials have been saved; the savings score is 50 percent (that is, 50 percent of the original ten trials). The more forgetting, the lower the savings score.

Although it may seem paradoxical, relearning methods can yield both sensitive and insensitive measures of forgetting. Tasks have been devised that produce wide differences in recall but for which no differences in relearning are observed. (Some theorists attribute this to a form of heavy interference among learned data that has only momentary influence on retention.) Six months or a year after initial learning, some tests may give zero recall scores but can show savings in relearning.

Short-term  
and  
long-term  
memory

When relatively long retention intervals (usually hours or days) are used, the methods are said to involve long-term memory. In a sense, methods for studying short-term memory are miniaturized versions of these. A list may be as short as one item, level of proficiency is very low, and retention intervals are in seconds (or minutes at most).

For example, the subject may be shown a single nonsense syllable for a few seconds' study. Next he is given a simple task (such as counting backward) to occupy him for a half minute so that he cannot rehearse, and then is asked to recall the syllable. Forgetting is observed to occur over such short intervals, tending to be greater when length of interval increases, as in long-term memory. The same procedure can be used with a single paired-associate item or with a short list of four or five pairs. In a short-term counterpart of serial learning, a string of about eight single-digit numbers or letters is presented very rapidly (say, two per second), and the subjects are asked to recall them in the order in which they were presented. Recognition tests also can be adapted for measuring short-term retention. When only one presentation is used for learning, however, relearning measures are obviously unfeasible.

#### TIME-DEPENDENT ASPECTS OF RETENTION; STORAGE AND RETRIEVAL

Some workers theorize a distinct short-term memory system of sharply limited capacity that can retain information perhaps only a few seconds and a long-term system of relatively unlimited capacity and retention.

Among typical people, short-term function seems limited to about seven separate units (*e.g.*, seven random letters or unrelated common words). Thus, one may consult a telephone directory and forget the number before dialing is completed. Information seems to enter long-term storage by such processing as rehearsal and encoding, as if short-term retention is a way station between incoming information and more enduring memory.

Other theorists do not distinguish short- and long-term systems as inferred from observed differences in capacity and retention. Positing only one storage system, they attribute short-term phenomena to very low levels of learning. Those who postulate distinct systems point to the results of injury to a specific brain region (the hippocampus): (1) information stored prior to hippocampal damage seems to be retained; (2) sufferers seem incapable of new long-term storage; (3) the short-term functions appear to be unimpaired and subjects perform as well as ever in tests of immediate memory (*e.g.*, for a set of random numbers). It is as if new information no longer can be transferred from some sort of short-term system to relatively enduring storage.

Other data that bear on the controversy among theorists come from studies of people without known brain injury. When one has just seen a new list of words one at a time, the initial words in the list tend to be recalled best (primacy effects), those at the end next best (recency effects), while items from the middle are least likely to be recalled.

This is quite consistently found as long as recall begins immediately following presentation of the last word. If, however, a short interval follows, during which the subject is otherwise occupied to prevent rehearsal, the recency effect may completely disappear; words at the end are no better recalled than those in the middle. Primacy effects are essentially undisturbed, while a delay as short as perhaps 15 seconds is enough to abolish the recency phenomenon. Although some suggest that recency effects depend on a separate short-term memory system and that primacy effects are mediated by a long-term system, a single memory function also may be invoked to accommodate the findings. Nevertheless, interest is growing in multisystem theories on the grounds that they enhance appreciation of the processes involved in establishing relatively enduring memory.

Investigators concerned with physiological bases for memory seek a kind of neurochemical code with enough stability physically to produce a structural change or memory trace (engram) in the nervous system; mechanisms for decoding and retrieval also are sought. Efforts at the strict behavioral level similarly are directed toward describing encoding, decoding, and retrieval mechanisms as well as the content of the stored information.

One way to characterize a memory (or memory trace) is to identify the information it encodes. A learner may encode far more information than is apparent in the task as presented. For example, if a subject is shown three words for a few seconds and (after 30 seconds of diversion from rehearsal) is asked to recall and then another triad of words is given under the same procedure, then another, and so on, then if all triads share some common element (*e.g.*, all are animal names), poorer and poorer recall is observed on successive trials. Such findings may be explained by assuming that the learner encodes this animal category as part of his memory for each word. Initially, the common code might be expected to aid recall by sharply delimiting the word population. Successive triads, however, should tend to be encoded in increasingly similar ways, blurring their unique characteristics for the subject. An additional step provides critical supporting evidence for such an interpretation. If a final triad of vegetable names is unexpectedly presented, recall recovers dramatically. The subject tends to reproduce the vegetable names much better than he does those of the last animal triad; recall is about as efficient as it was for the first three animal names. This particular shift clearly seems to provide escape from earlier confusion or blurring, and it may be inferred that a common conceptual characteristic was encoded for each animal name.

Any characteristic or attribute of a word may be investigated in this way to infer whether it is incorporated in memory. When recall does not recover it would seem that the manipulated characteristic has little or no representation in memory. For example, grammatical class typically does not appear to be encoded; decrement in recall produced after a series of triads consisting of verbs tends to continue when a shift is made to three adjectives. Such an experiment does not indicate what common encoding characteristic might be responsible for the decrement, suggesting only that it is not grammatical class.

Encoding mechanisms also may be inferred from tests of recognition. For example, subjects study a long list of words, being informed of a multiple-choice memory test to follow. Each word studied is made part of a test item that includes other carefully chosen new words (distractors). Distractors are selected to represent different types of encoding the investigator suspects may have occurred in learning. If the word presented for study is chosen by the subject, little can be inferred about the nature of the encoding. Any errors, however, can be most suggestive. Thus, if the word presented for study was TABLE, the multiple-choice item might be TABLE, CHAIR, ABLE, FURNITURE, PENCIL. If CHAIR is incorrectly selected, it may be suspected that this associatively related word occurred to the subject implicitly during learning and became so well encoded that the subject later could not determine whether it or TABLE had been presented. If the wrong choice is ABLE, acoustical resemblance to

Encoding  
mech-  
anisms

TABLE may have contributed to the confusion. If FURNITURE is erroneously chosen, perhaps conceptual category was prominent in the encoding.

Since it is not related in any obvious way to TABLE, the word PENCIL may be intended as a control, unlikely to be a part of the memory for TABLE. If this is the case, subjects should be more likely to select distractor words other than PENCIL (if indeed they have been encoded along with TABLE).

Although a subject may have encoded in ways suggested by particular distractors, he still may be able to choose the correct word. Or he may have encoded in ways not represented by the distractors.

Evidence has been accumulating to suggest that a long-term memory is a collection of information or of attributes that can serve in discriminating it from other memories and can function as retrieval cues. In addition to verbal attributes, visual images may be a part of the memory; emotional responses produced at the time the memory is established may be incorporated.

The common experience of having a name or word on the tip of the tongue seems related to specific perceptual attributes. In particular, people who report the "tip-of-the-tongue" feeling tend to identify the word's first letter and number of syllables with an accuracy that far exceeds mere guessing. There is evidence that memories may encode information about when they were established and about how often they have been experienced. Some seem to embrace spatial information; *e.g.*, one remembers a particular news item to be on the lower right-hand side of the front page of a newspaper. Research indicates that the rate of forgetting varies for different attributes. For example, memories in which auditory attributes seem dominant tend to be more rapidly forgotten than those with minimal acoustic characteristics.

If a designated (target) memory consists of a collection of attributes, its recall or retrieval should be enhanced by any cue that indicates one of the attributes. For example, on failing to recall the term horse (included in a list he has just seen), one may be told that there was an animal name among the words. Or he may be asked if an associate term (say, barn or zebra) helps him think of a word he missed. While some additional recall has been observed with this kind of help, failures are common even with ostensibly relevant cues. Though it is possible that the cues frequently are inappropriate, nevertheless, if words were not learned (encoded or stored) with accompanying attributes, cuing of any kind should be ineffective.

#### THEORIES OF FORGETTING

When memory of past experience is not activated for days or months, forgetting tends to occur; and any theory of forgetting must cope with this primitive observation. Such auxiliary phenomena as differences in the rates of forgetting for different kinds of information also must be accommodated.

It has been theorized that as time passes the physiological bases of memory tend to change. With disuse, it is held that the neural engram (the memory trace in the brain) gradually decays or loses its clarity. While such a theory seems reasonable, it would, if left at this point, do little more than restate behavioural evidence of forgetting at the nervous-system level. Decay or deterioration does not seem attributable merely to the passage of time; some underlying physical process needs to be demonstrated. Until a neurochemical basis for memory can be more explicitly described, any decay theory of forgetting must await detailed development.

Interference theory; retroactive and proactive inhibition

A pre-eminent theory of forgetting at the behavioral level is anchored in the phenomena of interference; in what are called retroactive and proactive inhibition. In retroactive inhibition, new learning interferes with retention of the old; in proactive inhibition, old memories interfere with the retention of new ones. Both phenomena have great generality in studies of any kind of learning, although most research among humans has considered verbal learning.

People may, for example, learn two successive verbal lists; the next day some are asked to recall the first list and

others to recall the second. Still a third (control) group learns only one list and is asked to recall it a day later. People who learn two lists almost unfailingly will recall much less than do the control group. The amount by which controls exceed those who recall the first list is a measure of retroactive inhibition; the degree to which they are better than those who recall the second list is a measure of proactive inhibition. While retroactive inhibition usually will be observed in relearning, it is unusual to detect proactive deficit under such circumstances.

Theorists attribute the loss produced by these procedures to interference between list-learning tasks. When lists are constructed to exhibit varying differences, the degree of interference seems to be related to the amount of similarity. Thus loss in recall will be reduced when two successive lists have no identical terms. Maximum loss generally will occur when there appears to be heavy (but not complete) overlap in the memory attributes for the two lists. One may recall parts of the first list in trying to remember the second and vice versa. (This breakdown in discrimination may reflect the presence of dominant attributes that are appropriate for items in both lists.) Discrimination tends to deteriorate as the number of lists increases, retroactive and proactive inhibition increasing correspondingly, suggesting interference at the time of recall.

In retroactive inhibition, however, all of the loss need not be attributed to competition at the moment of recall. Some of the first list may be lost to memory in learning the second; this is called unlearning. If one is asked to recall from both lists combined, first-list items are less likely to be remembered than if the second list had not been learned. Learning the second list seems to act backward in time (retroactively) to destroy some memory for the first. So much effort has been devoted to studying conditions that affect unlearning that it has become a major topic in interference theory.

Retroactive and proactive effects can be quite gross quantitatively. If one learns a list one day and tries to recall it the next, learns a second list and attempts recall for it the following day, learns a third and so on, recall for each successive list tends to decline. Roughly 80 percent recall may be anticipated for the first list; this declines steeply to about 20 percent for the tenth list. Learning the earlier lists seems to act forward in time (proactively) to inhibit retention of later lists. These proactive phenomena indicate that the more one learns the more rapidly one will forget. Similar effects can be demonstrated for retroactive inhibition within just one laboratory session.

Such powerful effects have led some to theorize that all forgetting is produced by interference. Any given memory is said to be subject to interference from others established earlier or subsequently. Interference, theoretically, may occur when memories conflict through any attributes. With a limited group of attributes and an enormous number of memories, it might seem that everyday attempts to recall would be chaotic. Yet even if all of the memories shared some information, other attributes not held in common could still serve to distinguish them. For example, every memory theoretically is encoded at a different time and temporal attributes might serve to discriminate otherwise conflicting memories. Indeed, when two apparently conflicting lists are learned several days apart, proactive inhibition is markedly reduced. Assuming memories to be multiple-encoded, interference theory need not predict utter confusion in remembering.

Sources of interference are most pervasive and should not be considered narrowly. For example, any memory seems to be established in specific surroundings or context, and subsequent efforts to remember tend to be less effective when the circumstances differ from the original. Alcoholics, when sober, tend to have trouble finding bottles they have hidden while intoxicated; when they drink again, the task is much easier. Some contexts also may be associated with other memories that interfere with whatever it is that one is trying to remember.

Each new memory tends to amalgamate information already in long-term storage. Encoding mechanisms invariably adapt or relate fresh data to information already present, to the point that what is coded may not be a direct

representation of incoming stimuli. This is particularly apparent when input is relatively meaningless; the newly encoded memory comes to resemble those previously established (*i.e.*, it accrues meaning). For example, a nonsense word such as LAJOR might be encoded as MAJOR.

To recall any nonsense word correctly requires that an appropriate decoding rule be a part of the memory; but coding rules are subject to forgetting (interference) in the same way that any attribute is. Qualitative changes in memory may result when the information presented does not allow precise decoding; thus, when one sees a drawing of a jagged figure that resembles a star he might encode it as a star, knowing full well that it is not perfect. Subsequent decoding in recall (or recognition) thus produces only an approximation of the original jagged figure; it may well be influenced by other equally imprecise decoding rules already stored. In like fashion, somewhat incoherent sentences may become more reasonable during encoding; they tend to be reproduced in memory tests more coherently. When the learner has trouble making sense of any new stimulus (when he cannot specify encoding and decoding rules with precision) the decoded memory tends to resemble previously established memories.

Although interference has attracted wide support as an account of forgetting, it must be placed in perspective. Interpretations that emphasize distinctions between short- and long-term memory and that posit control processes for handling information are potentially more comprehensive than is interference theory. Behavioral evidence for interference eventually may be explained within such systems.

In addition, a number of deductions from interference theory have not been well supported by experiment. The focus of difficulty lies in the hypothesis that interference from established memories is a major source of proactive inhibition. The laboratory subject is asked to learn tasks with attributes that have varying degrees of conflict with memories established in daily life. Theoretically, the more conflict, the greater the proactive interference to produce forgetting. Yet a number of experiments have failed to provide much support for this prediction.

Interference theory also fails to account for some pathological forms of forgetting. Repression as observed in psychiatric practice, for example, represents almost complete, highly selective forgetting; far beyond that anticipated by interference theorists. Attempts to study repression through laboratory procedures have failed to yield systematic data that could be used to test theoretical conclusions.

#### CORRELATES OF RATE OF FORGETTING

Reminiscence

Although forgetting normally is expected to begin as soon as practice ceases, at times an exception (known as reminiscence) has been reported. In reminiscence, memory seems to improve without practice; retention is even better if tested after a rest period than if tested immediately after learning trials stop. Observed only over periods of a few minutes, this elusive phenomenon produces very small improvements, and forgetting follows. Scores of studies designed to elicit reminiscence have failed to do so, yielding only evidence of forgetting. Reasons for the conflicting findings have not been identified.

**Degree of learning.** The degree of learning is found to be directly associated with the amount of practice. In a metaphorical sense, specific memory may be said to grow stronger and stronger as practice proceeds. Even after a task can be performed or recited perfectly, continued practice (sometimes called overlearning) increases the "strength" of the memory. The rate of forgetting is slower when the degree of learning is greater. If there were one universal prescription for resisting forgetting, it would be to learn to a very high level initially; results seem even better when learning trials are not bunched together. Practice trials may be given en masse in a single session or the same number of trials may be distributed in sessions held on different days. The interrupted schedule is far superior to massed practice in that the rate of forgetting that follows distributed practice is much slower. The

laboratory evidence also confirms the belief that cramming for an examination may produce acceptable performance shortly afterwards, but that such massed study results in poor long-term retention. Information learned in widely distributed practice appears less susceptible to interference; memories established under distributed schedules also are less likely to produce proactive inhibition than are those learned in massed trials.

**Mnemonic systems.** The principle that new information is encoded to previously stored data has been used in an effort to aid memory function. When encoding techniques are formally applied, they are called mnemonic systems or devices. (The popular rhyme that begins "Thirty days hath September . . ." is an example.) Verbal learning can be enhanced by providing an appropriate mnemonic system (even to a bright college student who may have devised efficient systems of his own). Thus, paired associates (*e.g.*, DOG-CHAIR) will be learned more rapidly if they are included in a simple sentence (*e.g.*, The dog jumped over the chair.) Imagery that can relate different words to be learned (even in a bizarre fashion) has been found beneficial. Some investigators hold that pure rote learning (in which no use is made of established memories except to directly perceive the stimuli) is rare or nonexistent. They suggest that all learning elaborates on memories already available. This could be taken to mean that the rate of forgetting would be the same whether or not a formal mnemonic system were used in learning.

Indeed, there seem to be no experimental results in which formal mnemonic instruction has resulted in forgetting more rapidly than when such special training is not given. Yet, while there often is no difference in the rate of forgetting, a number of studies indicate slower forgetting following instruction in a mnemonic system. These discrepancies may mean that some mnemonic systems are more subject to interference than are others. Perhaps the methods used fail to adequately distinguish between learning and forgetting.

Factors that influence rate of learning should be distinguished from those that affect rate of forgetting. For example, nonsense syllables are learned more slowly than are an equal number of common words; if both are studied for the same length of time, the better learned common words will be forgotten more slowly. But this does not mean that rate of forgetting *intrinsically* differs for the two tasks. Degree of learning must be held constant before it may be judged whether there are differences in rate of forgetting. Rates of forgetting can be compared only if tasks are learned to an equivalent degree. Indeed, when degree of learning is experimentally controlled, different kinds of information are forgotten at about the same rate. Nonsense syllables are *not* forgotten more rapidly than are ordinary words. In general, factors that seem to produce wide differences in rate of learning show little (if any) effect on rate of forgetting. (Despite discrepant evidence, mnemonic systems may prove an exception.)

**Individual differences.** Experimental findings seem to contradict the common intuition that people inherently differ in the rate at which they forget. This intuitive belief appears largely to derive from definite, wide individual differences in rate of learning; some people do learn faster than others. Thus, given the same number of trials or identical time in which to study, people will vary widely in the level of learning they achieve. Individual differences in forgetting then can be predicted efficiently, merely on the basis of how well each person has learned. This powerfully indicates that ordinary estimates of one's rate of forgetting are spurious, being obscured by uncontrolled differences in learning ability. One's talent for learning seems to swamp efforts to assess his inherent tendency to forget. Under less ordinary circumstances, however (*e.g.*, selective brain injury, stroke, neurotic amnesia), the degree of learning does seem to be almost completely irrelevant to the rate at which one forgets. An amnesia sufferer may forget his own name and still may be able to remember that Sofia is the capital of Bulgaria (see MEMORY, ABNORMALITIES OF).

**BIBLIOGRAPHY.** J.A. ADAMS, *Human Memory* (1967), provides a well-considered account of memory as viewed from laboratory findings. A somewhat more abbreviated account is J. JUNG, *Verbal Learning* (1968). Two versions of formal models of memory are given in K.W. and J.T. SPENCE (eds.), *The Psychology of Learning and Motivation*, 3 vol. (1967-69), one by G. BOWER, "A Multicomponent Theory of the Memory Trace," 1:229-325 (1967); the other by R.C. ATKINSON and R.M. SHIFFRIN, "Human Memory: A Proposed System and its Control Processes," 2:89-195 (1968). The most comprehensive account of interference in long-term memory is provided by G. KEPPEL, "Retroactive and Proactive Inhibition," in *Verbal Behavior and General Behavior Theory* ed. by T.R. DIXON and D.L. HORTON, pp. 172-183 (1968). A parallel analysis for short-term memory is given by L. POSTMAN, "Short-term Memory and Incidental Learning," in *Categories of Human Learning* ed. by A.W. MELTON, pp. 145-201 (1964). B.J. UNDERWOOD, "Attributes of Memory," *Psychol. Rev.*, 76:559-573 (1969), summarizes evidence that memory can be described as a collection of information.

(B.J.U.)

## Memphis (Egypt)

Memphis, the capital of ancient Egypt during the Old Kingdom (c. 2686-c. 2160 BC), was located south of the Nile Delta, on the west bank of the river. Closely associated with the city site are the cemeteries, or necropolises of Memphis, where the famous pyramids of Egypt and the Great Sphinx are located. From north to south, the main pyramid fields are: Abū Ruwaysh, Giza, Zawayet el-Aryan, Abū Šir, Šaqqārah, and Dahshūr.

**History.** *Foundation and Early Dynastic Period.* According to a commonly accepted tradition, Memphis was founded around 3100 BC by Menes, who supposedly united the two prehistoric kingdoms of Upper and Lower Egypt. The precise historical identity of this king is still in question, but there is little doubt as to his connection with Memphis or of the importance of the city from the earliest period. The site had obvious political advantages, being located at the junction of the boundaries of the two formerly separate kingdoms. The local god of Memphis was Ptah, patron of craftsmen and artisans and, in some contexts, a creator god as well. The Great Temple of Ptah was one of the city's most prominent structures. According to an Egyptian document known as the Memphite Theology, Ptah created mankind through the power of his heart and speech; the concept, having been shaped in the heart of the creator, was brought into existence through the divine utterance itself. In its freedom from the conventional physical analogies of the creative act and in its degree of abstraction, this text is virtually unique in Egypt, and it testifies to the philosophic sophistication of the priests of Memphis.

The original name of the city was the White Wall, and the term may have referred originally to the king's palace, whose walls would have been built of whitewashed brick. The colour also had significance politically; white was the colour of the Lower Egyptian crown.

No remains of the period of Menes have come to light in the city site itself, but the evidence of the Memphite necropolises confirms the traditional age of the city. The large, elaborately niched tombs of the 1st and 2nd dynasties (c. 3100-c. 2686 BC) found at Šaqqārah have been claimed as royal tombs, but some scholars doubt that Memphis was the sole, or even the primary, capital of Egypt under those dynasties. According to the 3rd-century-BC historian Manetho, the 1st and 2nd dynasties originated at Tjene, or Thinis, in Upper Egypt. Thinis is near Abydos, and excavations at Abydos uncovered rectangular cut-stone tombs (mastabas) of this period that were long believed to be the royal burials of the first dynasties. To complicate the matter still further, there are equally important tombs of the period at other sites, such as Tarkhan and Abū Ruwaysh. Scholars disagree as to which of these are actually royal tombs, which are simply memorials, and which are tombs of important courtiers.

*The Old Kingdom.* By the 3rd dynasty the pre-eminence of Memphis is unquestioned. Manetho calls the 3rd and 4th dynasties (c. 2686-2494) Memphite, and the huge royal pyramid tombs of this period, in the necropolises of Memphis, confirm this. Djoser, the second king

of the 3rd dynasty, was the builder of the Step Pyramid of Šaqqārah, the first large monument to be constructed entirely of stone. Imhotep, the King's architect and adviser, is credited with this architectural feat; his reputation as a wise man and physician led, in later times, to his deification and his identification with the Greek god Asclepius.

The remains of several unfinished or badly ruined pyramids near Memphis have been attributed to other 3rd-dynasty kings. The first king of the 4th dynasty, Snefru, built two pyramid tombs at Dahshūr. The three great pyramids of Giza belong to Khufu, Khafre, and Menkaure, later-4th-dynasty monarchs. The Great Sphinx at Giza dates from the time of Khafre. The last legitimate king of this dynasty, Shepseskaf, built his tomb at South Šaqqārah. It was not a pyramid but a distinctive oblong structure with sloping sides, now called the Maštabat Fir'awn.

The royal pyramids are surrounded by large cemeteries where the courtiers and officials who had served the king during his lifetime were buried. The beautiful reliefs in certain of these tombs include scenes of daily life and thus give some idea of the crafts, costumes, and occupations of the royal court of Memphis. Since little has survived of domestic architecture and household furnishings, these reliefs are a valuable source of information on such subjects. A notable exception to the general rule of loss and destruction is the hidden tomb of Queen Hetepheres, the mother of Khufu, which was discovered near the Great Pyramid of Giza. Though the Queen's body was unaccountably missing from her sarcophagus, her funerary equipment and furniture survived. The exquisite taste and craftsmanship of these objects testify, as do the splendid low reliefs of the tombs, to the high development of the arts and crafts of the period. Indeed, it is believed by some scholars that the Old Kingdom, influenced by the craftsmen of the Memphite court and the philosopher-theologians of Ptah, reached a peak of "classic" culture that was never surpassed in Egypt.

The kings of the 5th dynasty (c. 2494-c. 2345) moved south of Giza to build their funerary monuments; their pyramids, at Abū Šir, are much smaller than those of the 4th dynasty, but the pyramid temples and causeways were decorated with fine reliefs. This dynasty was probably marked by a decline of Memphite influence paralleling the rise of a sun cult centred at Heliopolis. The major monuments of the period are not the pyramids but the sun temples, which were, however, also part of the so-called Memphite pyramid area, not far from Abū Šir.

During the 6th dynasty (c. 2345-c. 2181), which Manetho also designates as Memphite, the funerary monuments, in the pyramid field of Šaqqārah, continue to decline in size and workmanship; a curious fact is that the modern name of Memphis is ultimately derived from Men-nefer, the name of the pyramid city of the 6th dynasty king Pepi I. This relatively small and obscure pyramid thus gave its name to the entire region. At this time the influence of the centralized government at Memphis began to wane, as is indicated by the increased prominence of provincial cities and the number of fine tombs located away from the Memphis area. This process of decentralization ended in the First Intermediate Period, a time of internal breakdown. Manetho's 7th and 8th dynasties are both called Memphite, but it is believed that both dynasties together comprised a very short period and that the old Memphite house lost its control over the provincial princes soon after the end of the 6th dynasty.

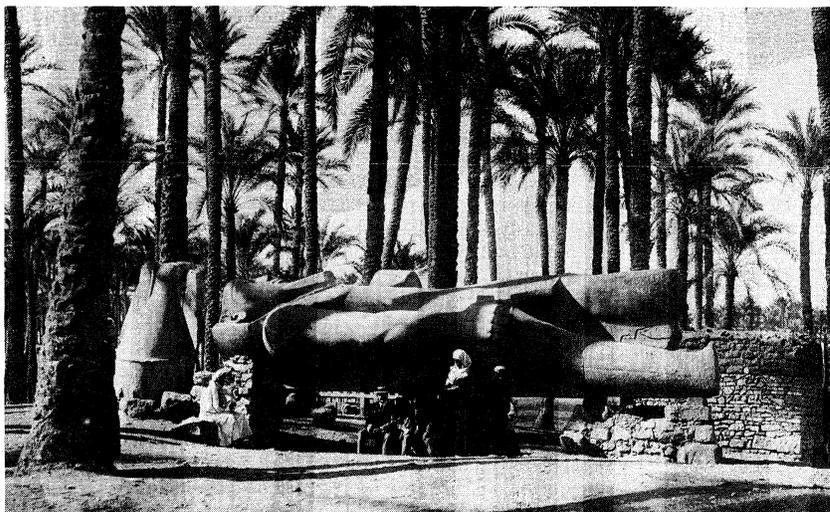

*Later history.* Memphite influence continued during the Middle Kingdom, (c. 2040-1786) when Egypt was once more reunited, but the official residence of the 12th dynasty (1991-1786) was at Lisht, near the entrance to al-Fayyum. Several 12th-dynasty monarchs erected pyramids at Dahshūr, the southernmost of the Memphite pyramid fields, but the majority of Middle Kingdom monuments were located nearer to Lisht. Yet the predominant artistic and administrative influences during this period seem to be Memphite, and virtually every 12th-dynasty ruler added to the Great Temple of Ptah.

Another period of political and social chaos followed

the 12th dynasty. This Second Intermediate Period (1786–1567) is characterized by the presence in Egypt of the Asian Hyksos peoples. According to the 1st-century-AD historian Josephus, the Hyksos king, whom he calls Salitis, made his capital at Memphis and from there ruled both Upper and Lower Egypt. Inscriptional and archaeological evidence, though scanty, tends to confirm the assumption that the invaders controlled northern Egypt, but their capital is generally supposed to have been located at Avaris, near Tanis, in the Delta. Records left by Kamose, the 17th-dynasty king who began the reconquest of Egypt from the Hyksos, describe his holdings as running from Elephantine to Hermopolis Magna but note that he “could not pass by (the invader) as far as Memphis.”

With the final expulsion of the Hyksos and the restoration of a united kingdom under the 18th dynasty, based at Thebes in Upper Egypt, Memphis entered on a new period of prosperity. Some scholars claim that Memphis never lost its political pre-eminence and that during the New Kingdom, as in earlier times, the city was the actual political capital of Egypt, with Thebes merely the religious centre. Such a hypothesis is impossible to prove, and it may well be that such distinctions, with their rigidity and exclusiveness, are meaningless in terms of Egyptian culture.

The importance of Memphis was based to a considerable extent upon its venerable religious role. Certain of the coronation ceremonies were traditionally enacted in Memphis, as was the Sed festival, a re-enactment of the coronation that restored and restated the supernatural powers of the kingship.

During the New Kingdom (1567–1085), Memphis probably functioned as the second, or northern, capital of Egypt. At one time it seems to have been the principal residence of the crown prince. Several 18th-dynasty (1567–1320) inscriptions mention royal hunting parties in the desert near the Sphinx. Amenhotep II (reigned 1450–1425) was born at Memphis and held the office of high priest there. Both he and his son, Thutmose IV (reigned 1425–1417), left inscriptions at Giza.

Despite the rise of the god Amon of Thebes, Ptah remained one of the principal gods of the pantheon. The Great Temple was added to or rebuilt by virtually every king of the 18th dynasty. Chapels were constructed by Thutmose I and Thutmose IV, and by Amenhotep III. The latter's son, Prince Thutmose, was high priest of Ptah. Amenhotep III's son, the religious reformer Akhenaton, built a temple to his god Aton in Memphis. A number of handsome private tombs dating from this period in the Memphite necropolis testify to the existence of a sizeable court.

During the New Kingdom the city shared the increasingly cosmopolitan character of the nation, as trade, for-

eign conquest, and travel developed. Though Memphis was not on the Nile, it was connected with it by a canal, and it was probably important as a commercial centre. Specific quarters of the city were named after the foreign colonies—slaves, prisoners of war, or merchants—who resided there. A section called the “Field of the Hittites” is known, as are, in later periods, sections inhabited by Carians and Phoenicians.

Under the 19th dynasty (1320–1200) a new royal residence was built farther north at Per-Ramessu in the Delta, but Memphis continued to be important. The Great Temple was rebuilt. The kings of that period pillaged the monuments of their predecessors for building materials, and some of the reused blocks come not only from structures in the city but also from temples and pyramid complexes in the Memphite necropolises. Ramses II (reigned 1304–1237) erected several colossi in the temple. The Sarapeum, dedicated to the cult of Apis, the bull-god, and built in the form of a labyrinth, was begun under the son of Ramses II, Khaemwese, high priest of Ptah.

By the end of the 20th dynasty the united kingdom had begun to break down once again. The official capitals were Tanis and Thebes, but the royal palace at Memphis continues to be mentioned. The growing popularity of the Apis cult led to further enlargement of the Sarapeum. In the 8th century BC, the Nubian king Piankhi conquered Egypt and restored its unity. Nubia (or Kush), to the south of Egypt, had been under Egyptian political and cultural influence for centuries. An inscription describing Piankhi's campaign has survived, and it mentions a siege of Memphis. The city had fortified walls and was surrounded by water, presumably from its encircling canals. Piankhi took the city, but it was left to his brother and successor, Shabaka, to claim the royal title. There are some indications that this king made Memphis his capital. But the Kushite dynasty was overthrown shortly thereafter, when the Assyrians invaded Egypt. Records left by the Assyrian king Esarhaddon (680–669 BC) refer to the siege and destruction of Memphis, the royal residence of one Tarku, king of Egypt, who is probably to be identified with Taharqa, who became pharaoh in 689 BC. After the death of Esarhaddon, Taharqa regained Memphis, but he was driven out of the city again by Ashurbanipal of Assyria, in 667 BC.

The collapse of Assyria (612 BC) led to brief Egyptian independence under the 26th dynasty, but it was not long before new invaders appeared. The Persian Cambyses took Memphis by siege in 525 BC. After years of Persian rule Egypt was ready to welcome Alexander the Great in 332 BC. The conqueror used Memphis as his headquarters while making plans for his new city of Alexandria. After his death at Babylon, his body was brought to Egypt and was laid to rest temporarily in Memphis before being buried at Alexandria.

Memphis  
in the New  
Kingdom

Kushite  
occupation

Under the Hellenistic Ptolemaic dynasty (305–30 BC), Memphis retained its cosmopolitan character and had a sizable Greek population. Some of the diversified racial types to be found in the city during Greco-Roman times are depicted in a series of striking terra-cotta heads dating from this period.

At the beginning of the Roman period (1st century BC) Memphis was still considered an important provincial capital. The serious decay of the ancient city began after the rise of Christianity, when zealots of that faith defaced and destroyed the remaining pagan temples. In the 5th century AD the Christian monastery of Apa Jeremias rose among the venerable tombs of Şaqqārah. The capital continued to deteriorate, receiving its death blow during the Muslim conquest of Egypt in AD 640. A garrison and fort called Babylon occupied the eastern end of the bridge that crossed the Nile from Memphis, and after a long siege the fortress was taken by the Arab general 'Amr ibn al-'Aṣ. Memphis was abandoned, and later the few remaining structures were dismantled so that the stone might be reused in the neighbouring villages and in Cairo, after that city's foundation in the 10th century.

**Archaeology.** The ancient city of Memphis lies near the modern village of Mit Ruhaynah. At the beginning of the 20th century some ruined walls were still to be seen, but these have now disappeared, and the only monument above ground is a colossal statue of Ramses II, which once adorned the Great Temple of Ptah. Few city sites in Egypt have been excavated, and, like so many other ancient Egyptian sites, Memphis is known primarily from the exploration of its necropolises, which tend to yield more dramatic finds than the city itself.

The first archaeologist to work at the city site for any prolonged period was Flinders Petrie, who excavated between 1908 and 1913, uncovering sections of the Great Temple of Ptah. These remains, left exposed, soon disappeared under the effects of weather and the depredations of the nearby villagers. In recent times expeditions have been led by Ahmad Badawi, in 1942, and by Labib Habachi, in 1950. A University of Pennsylvania expedition worked at the site in 1917, finding foundations of a palace of Merneptah (1236–1223 BC) east of the temple of that king. The University sponsored further digging in 1955 and 1956, excavating parts of the Great Temple and a small temple of Ramses II.

For the past century there has hardly been a season when archaeological activity was not proceeding at one or another of the pyramid sites. Almost all of the pyramids, and a majority of the large private tombs, were entered by treasure hunters before the beginning of scholarly excavation. One of the earliest scholars to work in the Memphite area was Auguste Mariette, who discovered the Sarapeum in 1851. Among the most important of Mariette's successors were G.A. Reisner and Hermann Junker, who excavated at Giza; Ludwig Borchardt, who excavated the sun temples and the 5th-dynasty pyramids at Abū Sir; Ahmad Fakhry, who worked in the pyramids of Snefru at Dahshūr; and Zakaria Goneim, who discovered a previously unknown pyramid, probably of the 3rd dynasty, to the southwest of the Step Pyramid at Şaqqārah. Also noteworthy are the excavations of J.P. Lauer in the Step Pyramid complex. In the 1930s, W.B. Emery began the excavations that uncovered the great 1st-dynasty tombs. His work in the archaic cemetery disclosed another huge labyrinth resembling that of the Sarapeum, the precise function of which is as yet undetermined. Extensive as the work has been in these necropolises, it is certain that new discoveries are waiting to be made. Yet of all these areas it is unlikely that any deserves painstaking excavation more than does the city site of Memphis itself.

## Mencius

The Chinese philosopher and follower of Confucius, Mencius has long been considered the second Sage by the Chinese (Confucius being the first). Although his surname is Meng and his personal name K'o, the philosopher is usually referred to by his honorific title, Meng-tzu (in Pin-yin romanization Meng-zu; "Master Meng"); Mencius is its Latinized form. Among all of the philosophers and teachers of China, only Confucius and Mencius have had their names Latinized.

Mencius, ink and colour on silk by an unknown artist. In the National Palace Museum, Taipei, Taiwan.

Of noble origin, the Meng family settled in the state of Tsou, a minor state about the size of a county in the present province of Shantung. Mencius was born there about 371 BC. In several respects his life was similar to that of Confucius. Tsou and Lu (the state of Confucius' origin) were adjacent states. Like Confucius, Mencius was only three when he lost his father. Mencius' mother paid special attention to the upbringing of her young son. A traditional story tells of her moving their home several times and finally settling near a school, so that the boy should have the right kind of environmental influence, and of her cutting up the cloth on her loom in order to teach her son an unforgettable lesson about perseverance and devotion in his studies. Among the Chinese, the mother of Mencius has been for ages upheld as the model Chinese mother.

As a young scholar Mencius had for his mentor a pupil of Tzu Ssu, the grandson of Confucius. Thus, the continuity of the Confucian orthodoxy in all its purity was assured. In due time Mencius became a teacher himself and for a brief period served as an official in the state of Ch'i. He spent much time travelling, offering his advice and counsel to the various princes on government by *jen* ("human heartedness"), or humane government. The effort was foredoomed because the times were chaotic, and the contending princes were interested not in humane government but in power.

The Chou dynasty (c. 1122–221 BC) was founded on the feudalistic principle of a sociopolitical hierarchy, with clearly defined prerogatives and obligations between those of high and low status. As time went on, however, ambition and intrigue resulted in usurpations and imposi-

Early life

tions, eroding the feudalistic system at the root and bringing on a condition of political and moral disorder. This trend, which caused alarm to Confucius, continued to worsen at an accelerating rate, and the age in which Mencius lived is known as the period of Warring States in Chinese history (481–221 BC). Under such conditions, Mencius' preachments to the princes on virtuous personal conduct and humane government fell on deaf ears; yet, he continued to speak his mind, even though he knew that he was championing an unpopular cause.

Philosopher for the people

According to Mencius, the ruler was to provide for the welfare of the people in two respects: material conditions for their livelihood and moral and educational guidance for their edification. Mencius had worked out a definite program to attain economic sufficiency for the common people, and it is recorded in the book of *Mencius* three times. He also advocated light taxes, free trade, conservation of natural resources, welfare measures for the old and disadvantaged, and more nearly equal sharing of wealth. It was his fundamental belief that "only when the people had a steady livelihood would they have a steady heart."

While Mencius patiently exhorted the princes to cultivate the way of moral power and to forsake the way of force and intrigue, he also reminded them emphatically of the responsibility that came to them with the mandate of Heaven to govern for the good of the people. With unusual courage, Mencius declared: "The people are the most important element in a nation; the spirits of the land and grain come next; the sovereign counts for the least." He also quoted for all to hear from the *Shu Ching* ("Classic of History"), one of the Five Classics of Confucianism, the saying "Heaven sees as the people see; Heaven hears as the people hear." The outspoken sympathies of Mencius made him a champion of the common people and an advocate of democratic principles in government.

Mencius' sojourn covered several states, but nowhere did he find a prince willing to put his lofty principles of government into practice. His sense of disappointment grew with the years and finally brought him back to his native state of Tsou, where he devoted the remaining years of his life to the instruction of his pupils. The work *Mencius* is a collection of the records of the doings and sayings of the master by his disciples, arranged in seven books with two parts to each book.

Doctrine of human nature

The philosophic ideas of Mencius might be regarded as an amplification of the teachings of Confucius. Confucius taught the concept of *jen*, love or magnanimity, as the basic virtue of manhood. Mencius made the original goodness of human nature the keynote to his system. That the "four beginnings," or "four principles" (*ssu tuan*)—the feeling of commiseration, the feeling of shame, the feeling of courtesy, and the feeling of right and wrong—are all inborn in man was a self-evident truth to Mencius; and the "four beginnings," when properly cultivated, will develop into the four cardinal virtues of *jen*, righteousness, decorum, and wisdom. This doctrine of the goodness of human nature on the part of Mencius has become an enduring topic for debate among the Chinese thinkers throughout the ages.

Mencius went further and taught that man possessed intuitive knowledge and intuitive ability and that personal cultivation consisted in developing one's mind. Mencius said: "He who has developed his mind to the utmost, knows his nature. Knowing his nature, he knows Heaven." Hence, all men could become like the great sages Yao and Shun, the legendary heroes of the archaic past, according to Mencius.

While Mencius has always been regarded as a major philosopher, special importance was attributed to him and his work by the Neo-Confucianists of the Sung dynasty (AD 960–1279). For the last 1,000 years, Mencius has been revered among the Chinese people as the co-founder of Confucianism, second only to Confucius.

Mencius died in about 289 BC.

**BIBLIOGRAPHY.** Among the several translations of the *Mencius* into the English language, the one by JAMES LEGGE, *The Chinese Classics*, vol. 2, *Mencius*, 2nd ed. (1893–95;

3rd ed., 1960), is the standard one. W.A.C.H. DOBSON's translation, *Mencius: A New Translation Arranged and Annotated for the General Reader* (1963), is also worth consulting. ALBERT F. VERWILGHEN, *Mencius: The Man and His Ideas* (1967), is the only general treatise on the subject in English. For the philosophy of Mencius, see FUNG YU-LAN, *A History of Chinese Philosophy*, 2nd ed., vol. 1 (Eng. trans. 1952).

## Mendel, Gregor Johann

Gregor Johann Mendel, the Austrian monk whose discoveries of the first laws of heredity laid the foundation of the science of genetics, was born Johann Mendel, in Heinzendorf, which was then in Austrian Silesia, on July 22, 1822. His interest in natural science developed early. After two years' study at the Philosophical Institute at Olmütz (now Olomouc, Czechoslovakia), he entered the Augustinian monastery at Brünn, Moravia (later Brno, Czechoslovakia), in 1843, taking the name Gregor. He was ordained a priest in 1847. During the period of his monastic training he taught himself a certain amount of science. From 1849 he acted for a short time as a substitute teacher of Greek and mathematics in the secondary school at Znaim (Znojmo), near Brünn. In 1850 he took the examination for certification as a regular teacher but failed, his lowest marks being given, ironically, in biology and geology. He was then sent by his abbot to the University of Vienna, where he studied physics, chemistry, mathematics, zoology, and botany (1851–53). In 1854 Mendel returned to Brünn and taught natural science in the technical high school there until 1868, although he never succeeded in passing the examination for a teacher's license. In that year he was elected abbot of his monastery.

Mendel, etching by August Potuczek (1917- ).

The experiments that led to his discovery of the basic principle of heredity and, subsequently, to the science of genetics were begun in the small monastery garden in 1856. He worked for himself but in an atmosphere conducive to scientific interests. Among his colleagues at the high school were several men engaged in science, some of whom founded in Brünn, in 1862, the Natural Science Society, in whose meetings Mendel took an active part. The libraries of both monastery and school contained essential scientific books, especially on agriculture, horticulture, and botany, subjects in which Mendel's interest had been aroused by experience in his father's orchard and farm. That Mendel himself bought new books in these fields as they appeared is shown by his marginal notes in the works of Charles Darwin that appeared in the 1860s and 1870s. But it is also certain that he had begun his experiments before Darwin's first book was published and before the essential role assigned to heredity as the basis of evolutionary change had been widely recognized. In fact, when he reported the results of his experiments to the Brünn Society for the Study of Natural Science on February 8 and March 8, 1865, he referred

First experiments

to his field of interest as "plant hybridization," and after indicating his familiarity with the work of his predecessors in this field, he boldly stated that

among all the numerous experiments made, not one has been carried out to such an extent and in such a way as to make it possible to determine the number of different forms under which the offspring of hybrids appear, or to arrange these forms with certainty according to their separate generations, or definitely to ascertain their statistical relations.

It was this formulation by Mendel of the essential requirements for the experimental study of heredity and his provision of experimental data satisfying these requirements—both original achievements—that led him to the solution of a problem that underlies not only the understanding of heredity and of evolution but of biological processes generally.

Mendel crossed varieties of the garden pea that had maintained, under his observation, constant differences in such single alternative characters as tallness and dwarfishness, presence or absence of colour in the blossoms and axils of the leaves, and similar alternative differences in seed colour, seed shape, position of the flowers on the stem, and form of the pods. He theorized that the occurrence of the visible alternative characters of the plants, in the constant varieties and in their descendants, is due to the occurrence of paired elementary units of heredity, now known as genes. (For the behaviour of these units in heredity, see HEREDITY.) The novel feature of Mendel's interpretation of his data, amply confirmed by subsequent observations on other organisms, including man, is that these units obey simple statistical laws. The principle of these laws is that in the reproductive cells of the hybrids, half transmit one parental unit and half transmit the other. This separation of alternative characters in the reproductive cells, now known as Mendel's first law, or the principle of segregation, adequately accounts for the results when single pairs of alternative characters are observed through several generations and serves reliably as a basis of prediction. Mendel showed, moreover, that when several pairs of alternative characters are observed, the several pairs of elements enter into all possible combinations in the progeny. In the pea varieties at his disposal he observed that the seven pairs of differentiating characters recombined at random, according to the law, or principle, of independent assortment, and he worked out the statistical consequences of this principle and confirmed them by experiment.

It is known now that Mendel's second principle (independent assortment) applies only to genes that are transmitted in different "linkage groups" or chromosomes in which genes are organized. Likewise the appearance (or dominance) in the hybrid of one of the alternative characters, which was true of all seven pairs observed by Mendel, proves, on wider experience, not to be true of all alternative characters. But neither of these limitations affects the fundamental truth of the system of particulate heredity by units or genes, which he was the first to prove. In the early years of the 20th century, while it was being tested and confirmed, this system was called Mendelism; it proved to be of general application and is one of the basic principles of biology.

This theory and the description of the experimental results from which it was deduced were presented in two papers that Mendel read at meetings of the Natural Science Society early in 1865 and published in detail in the transactions of the society in 1866. The article, entitled "Versuche über Pflanzenhybriden" ("Experiments with Plant Hybrids"), seemed to have had no effect whatever on the biological thinking of his time in Brünn or elsewhere, although his publication reached the major libraries in Europe and America. Perhaps typical of the reception given Mendel's monumental publication was that of the eminent botanist Karl Wilhelm von Nägeli, at the University of Munich; from his correspondence with Mendel it appears that Nägeli neither fully understood the spare, mathematical logic of Mendel's paper nor adequately appreciated the implications of the monk-scientist's revolutionary discoveries.

Nevertheless, Mendel continued his research, attempt-

ing to test his theory by experiments with other plants. He published one further paper in 1869, but the plant he chose to investigate—the hawkweed (*Hieracium*), which Nägeli encouraged Mendel to work with—was inherently unsuited to serve as test material and no corroboration of Mendel's principles was obtained because in this genus the embryo is formed from the ovum without fertilization (somatic parthenogenesis). Although Mendel's interest and work in botany, bee culture, and meteorology continued almost until his death, science ceased to occupy the central position in his life, for his election as abbot of his monastery in 1868 brought with it a host of administrative duties and a protracted struggle with the Austrian government over the taxation of the monastery.

Mendel died on January 6, 1884, respected and loved by his fellow monks and townsmen but unknown as the great biological scientist that he was.

Fame came to him only after his death. In 1900 three other European botanists, Carl Erich Correns, Erich Tschermak von Seysenegg, and Hugo de Vries, independently obtained results similar to Mendel's and in searching the literature found that both the experimental data and the general theory had been published 34 years previously. What followed is now a part of the history of genetics: confirmation and extension of his theory by biologists in many countries and its incorporation as the basis of a rapidly developing science with primary influence on the understanding of evolution, development, physiology, biochemistry, medicine, agriculture, and social science.

## Mendeleev, Dmitry Ivanovich

Dmitry Ivanovich Mendeleev made a basic contribution to the study of chemistry by proving that all chemical elements are related members of a single ordered system. Mendeleev arranged all the known elements according to their atomic weights on what he called a periodic table and by his periodic law proved that the chemical properties of the elements are periodic functions of their atomic weights. His work was the culmination of a search for a relation between the elements that had been foreshadowed in classical times, a search that had been resumed since the beginning of scientific chemistry in the early 18th century. Mendeleev, by establishing a periodic classification of the elements, merits a place with Antoine Lavoisier, who clarified the concept of an element as the ultimate chemical species resisting further analytical breakdown, and with John Dalton, who showed how each element can be considered as constituted of identical atoms characterized by a determinable atomic weight.

Mendeleev was born at Tobolsk, Siberia, on February 7 (January 27, old style), 1834, the 17th and last child of the director of the gymnasium there. In the same year his father became blind, and, in order to support the family, his mother leased and operated a glass factory in a town 20 miles (32 kilometres) away. At school Dmitry excelled in mathematics, physics, and geography but fared badly in the compulsory classical languages.

In 1847 his father died, and the next year fire destroyed the glass factory. Faced with these disasters, his mother made a brave decision: she turned her back on Tobolsk and, with her only two dependent children (Dmitry and his sister), set out for Moscow to place her son in the university.

Notwithstanding her good connections, she could not

Discovery  
of laws  
of heredity

prevail in the face of the inflexible regulations that restricted admission according to place of origin: Siberia was outside the academic pale. She pressed on to St. Petersburg, but the university there, too, was closed to her son. Dmitry was also refused admission to the medical school, but, ten weeks before her death, his mother finally secured him a place in the Pedagogic Institute.

In 1855 he qualified as a teacher, winning a gold medal for his academic achievements. On account of his health, he was posted, at his own request, to the Crimea, where he continued his chemical studies at Odessa; he returned to St. Petersburg in 1856 to obtain an advanced degree in chemistry. In 1857 he received his first university appointment.

In 1859 the government sent him for further study to the University of Heidelberg. Although Robert Bunsen, the chemist and inventor, and the physicist Gustav Kirchhoff were then the dominant figures in the natural sciences at Heidelberg, Mendeleev preferred to work independently. His study of molecular cohesion was begun at this time, and while at Heidelberg he attended the celebrated Karlsruhe conference (September 1860) and made valuable contacts with French chemists and with the Italian chemist Stanislao Cannizzaro, whose insistence on the distinction between molecular and atomic weights influenced Mendeleev considerably.

In 1861 Mendeleev returned to St. Petersburg. The lack of a permanent position led him to take up editing

its validity becoming apparent only with time. The table of elements had gaps, but Mendeleev predicted that they would be filled by elements not yet discovered; three were discovered within 20 years, and they possessed the properties he had predicted. Gradually the table became the framework for a great part of chemical theory and proved to be most useful in the interpretation of the processes of the natural transformation of one element into another, called radioactive decay, more than 20 years after the table's conception.

Although Mendeleev's textbooks ran to many editions in many languages, the periodic theory remained his chief monument. Mendeleev's mind however, was not, limited to theory and to classroom teaching. He was also by nature a practical man, aware of the necessity to use science in solving the problems of the world. In 1865, he farmed a small estate and improved the yield and quality of crops by the application of his scientific knowledge, a measure he knew was essential to the improvement of the general agricultural condition of Russia.

In 1867 he was sent to organize the Russian pavilion at the Paris Exposition of that same year. His study of the French chemical industry during his stay helped him improve the Russian soda industry, and, later, he spent much time working on the problems of the Russian petroleum industry. During a visit to the United States in 1876, he criticized the manner in which American oil interests concentrated on mere expansion of production without giving attention to scientific improvements of either the efficiency of the industry or the quality of its products. At home he was equally critical of the way Russian oil was exploited by foreign interests, and he constantly urged that Russia develop its own oil for its own profit. His interest in aeronautics led him to make balloon ascents for scientific observation and to encourage his colleagues to pursue the possibilities of heavier-than-air flight.

Politically, Mendeleev held progressive views and was much interested in social reform. The tsarist regime did not approve of his political views, and, although a man of his stature could not be suppressed, he was often snubbed—as, for example, in 1880, when he was ostentatiously refused advancement from corresponding to full membership of the Imperial Academy of Sciences. In 1890 Mendeleev's transmittal of a request from students at the university for alleviation of unjust conditions led to an open clash between him and the government. For this allegedly improper action he was retired from the university. He held no further major academic post.

He was too useful, however, to be left idle. In 1891 he was officially employed in setting up a new system of import duties on heavy chemicals, and in 1893 he headed the Bureau of Weights and Measures, a post he filled efficiently until his death.

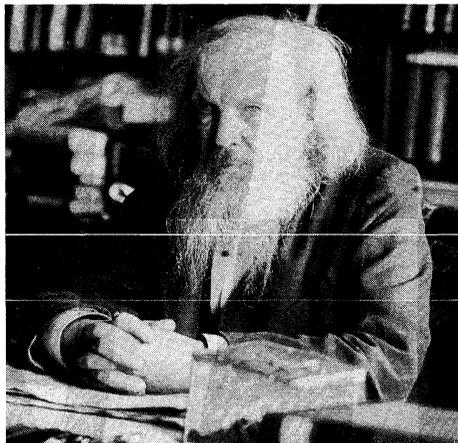

His last years were saddened not only by declining health but by the political events that preceded the uprising of 1905. He died on February 2 (January 20, O.S.), 1907. He had been greatly honoured by colleagues of many countries as a guest lecturer and as an honorary member of academies. He was recognized in his day as a leader of the movement to systematize and make cohesive the study of chemistry. He is recognized now as the discoverer of the interrelationship of chemical elements, which not only underlies most of chemistry but also unifies a great deal of modern physics.

**BIBLIOGRAPHY.** The definitive biography is that of N.A. FIGUROVSKY, *Дмитрий Иванович Менделеев, 1834–1907* (1961). The only substantial biography in English is D.Q. POSIN, *Mendeleev: The Story of a Great Scientist* (1948), a fanciful and romanticized version. An excellent brief bibliography may be found in a popular but well-presented account of his life by P. KOLODKINE, *Dmitri Mendeleiev et la loi périodique* (1963). Studies of Mendeleev's scientific work are included in J.R. PARTINGTON, *History of Chemistry*, vol. 4, ch. 21 (1964), which also gives biographical notes on and estimates of the work of his principal contemporaries, with many references. Mendeleev's works were collected in 25 volumes (1934–52). A 3rd English language edition of *Principles of Chemistry*, 2 vol., trans. from the 7th Russian edition was published in 1905.

Mendeleev.

and scientific writing. In 1864 he became professor of chemistry at the Technical Institute, and three years later he was made professor of general chemistry at the university there. Since he could not find a textbook that met his needs, he set about writing his own: the result was *The Principles of Chemistry* (1868–70), a classic textbook.

In the course of writing the book, Mendeleev probed deeply into the relationship between the properties of elements in an attempt to devise a system of classifying them. Other scientists had also tried to construct such a system of classification. After the English chemist and physicist John Dalton had developed the idea of atomic weights, chemists sought arithmetic connections between them, partly to see whether there was any likelihood of all elements being composed of a simple, common substance and partly to see whether occasional similarities in their properties pointed to similarities in structure. Johann Döbereiner and William Odling, both of whom had also done work with atomic weights, were the most prominent among the chemists who attempted to devise a logical order for the elements. It was Mendeleev, however, who formulated the periodic law, according to which, when all known elements are arranged in order of increasing atomic weight, the resulting table shows a periodicity of properties and allows one to observe the many types of chemical relation hitherto studied only in isolation. The new system did not win wide acceptance at first,

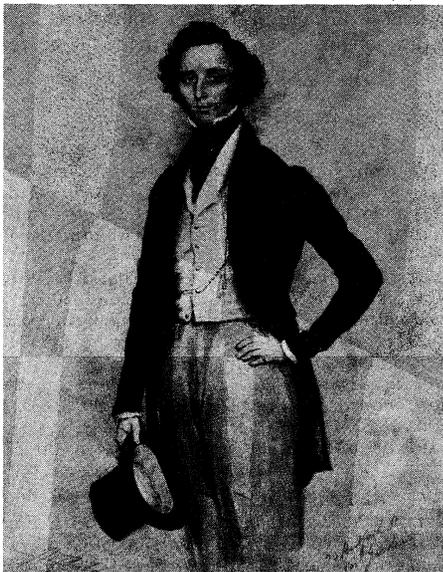

Formulation of the periodic law

Death

## Mendelssohn, Felix

The work of Felix Mendelssohn, composer, pianist, and conductor, was pivotal in the history of music by largely observing classical models and practices while initiating key aspects of Romanticism—the late 18th-century movement that exalted feelings and the imagination at the expense of rigid forms and traditions. Born at Hamburg on February 3, 1809, of Jewish parents, Jakob Ludwig Felix Mendelssohn-Bartholdy was the grandson of the philosopher Moses Mendelssohn and son of Abraham Mendelssohn. His mother was Lea Salomon, from whom he took his first piano lessons. Though the Mendelssohn family was proud of their ancestry, they considered it desirable, in accordance with 19th-century liberal ideas, to mark their emancipation from the ghetto by adopting the Christian faith. Accordingly Felix, together with his brother and two sisters, was baptized in his youth as a Lutheran Christian. The name Bartholdy, a family property on the river Spree, was held by a wealthy maternal uncle who had embraced Protestantism. When the fortune of this relative passed to the Mendelssohns his name was adopted by them.

Boyhood works

In 1811, during the French occupation of Hamburg, the family had moved to Berlin, where Mendelssohn studied the piano with Ludwig Berger and composition with K.F. Zelter, who, as a composer and teacher, exerted an enormous influence on his development. Other teachers gave the Mendelssohn children lessons in literature and landscape painting, with the result that at an early age Mendelssohn's mind was widely cultivated. His personality was nourished by a broad knowledge of the arts and was also stimulated by learning and scholarship. He travelled with his sister to Paris where he took further piano lessons and where he appears to have become acquainted with the music of Mozart. He wrote numerous compositions during this boyhood period, among them five operas, 11 symphonies for string orchestra, concerti, sonatas, and fugues, most of which, long preserved in manuscript in the Preussische Staatsbibliothek, Berlin, are believed to have been lost in World War II. He made his first public appearance in 1818—at the age of nine—in Berlin.

In 1821 Mendelssohn was taken to Weimar to meet Goethe, for whom he played works of Bach and Mozart and to whom he dedicated his *Quartet in B Minor*. A remarkable friendship developed between the aging poet and the 12-year-old musician. In Paris in 1825 Cherubini discerned his outstanding gifts. The next year he reached his full stature as a composer with the *Overture to A Midsummer Night's Dream*. The atmospheric effects and

the fresh lyrical melodies in this work revealed the mind of an original composer, while the animated orchestration looked forward to the orchestral manner of Rimsky-Korsakov. Mendelssohn also became active as a conductor. On March 11, 1829, at the Singakademie, Berlin, he conducted the first performance since Bach's death of the *St. Matthew Passion*, thus inaugurating the Bach revival of the 19th and 20th centuries. In the meantime he had visited Switzerland and had met Weber, whose opera *Der Freischütz*, given in Berlin in 1821, encouraged him to develop a national character in music. The greatest work of this period was the *Octet* (1825), displaying not only technical mastery and an almost unprecedented lightness of touch but great melodic and rhythmic originality. Mendelssohn developed in this work the genre of the swift-moving scherzo (a playful musical movement), also shown in the incidental music to *A Midsummer Night's Dream*.

In the spring of 1829 Mendelssohn made his first journey to England, conducting his *Symphony in C Minor* at the London Philharmonic Society. In the summer he went to Scotland, of which he gave many poetic accounts in his evocative letters. He went there "with a rake for folk-songs, an ear for the lovely, fragrant countryside and a heart for the bare legs of the natives." At Abbotsford he met Sir Walter Scott. The literary, pictorial, and musical elements of Mendelssohn's imagination are often merged. Describing, in a letter written from the Hebrides, the manner in which the waves break on the Scottish coast, he noted down, in the form of a musical symbol, the opening bars of the *Hebrides Overture*. Between 1830 and 1832 he travelled in Germany, Austria, Italy, and Switzerland and, in 1832, returned to London, where he conducted the *Hebrides Overture* and where he published the first book of his *Lieder ohne Worte* (*Songs Without Words*), completed in Venice in 1830. Gradually Mendelssohn, whose music in its day was held to be remarkable for its charm and elegance, was becoming the most popular of 19th-century composers in England. His main reputation was made in England, which, in the course of his short life, he visited no less than ten times. At the time of these visits the character of his music was held to be predominantly Victorian, and indeed he eventually became the favourite composer of Queen Victoria herself.

Mendelssohn's subtly ironic account of his meeting with the Queen and the Prince Consort at Buckingham Palace in 1843, to both of whom he was affectionately drawn, shows him also to have been alive to both the pomp and sham of the royal establishment. His *Scottish Symphony* was dedicated to Queen Victoria. And he became endeared to the English musical public in other ways. The fashion for playing the "Wedding March" from *A Midsummer Night's Dream* at bridal processions originates from a performance of this piece at the wedding of the Princess Royal after Mendelssohn's death, in 1858. In the meantime he had given the first performances in London of Beethoven's *Emperor* and *G Major* concerti. He was among the first to play a concerto from memory in public—Mendelssohn's memory was prodigious—and he also became known for his organ works. Later the popularity of his oratorio *Elijah*, produced at Birmingham in 1846, established Mendelssohn as a composer whose influence on English music equalled that of Handel. After his death this influence was sometimes held to have had a stifling effect. Later generations of English composers, enamoured of Wagner, Debussy, or Stravinsky, revolted against the domination of Mendelssohn and condemned the sentimentality of his lesser works. But there is no doubt that he had, nevertheless, succeeded in arousing the native musical genius, at first by his performances and later in the creative sphere, from a dormant state.

Many new experiences marked the grand tour that Mendelssohn had undertaken following his first London visit. Lively details of this tour are contained in his long series of letters. On Goethe's recommendation he had read Laurence Sterne's *Sentimental Journey*, and, inspired by this work, he recorded his impressions with great verve. In Venice he was enchanted by the paintings of Titian and Giorgione. The papal singers in Rome, how-

First journey to England

Impact on English music

ever, were "almost all unmusical," and Gregorian music he found unintelligible. In Rome he describes a "haggard" colony of German artists "with terrific beards." Later at Leipzig, where Berlioz and Mendelssohn exchanged batons, Berlioz offered an enormous cudgel of lime tree covered with bark, whereas Mendelssohn playfully presented his brazen contemporary with a delicate light stick of whalebone elegantly encased in leather. The contrast between these two batons precisely reflects the violently conflicting characters of the two composers.

In 1833 he was in London again to conduct his *Italian Symphony* and in the same year became music director of Düsseldorf, where he introduced into the church services the masses of Beethoven and Cherubini and the cantatas of Bach. At Düsseldorf, too, he began his first oratorio, *St. Paul*. In 1835 he became conductor of the celebrated Gewandhaus Orchestra at Leipzig, where he not only raised the standard of orchestral playing but made Leipzig the musical capital of Germany. Chopin and Schumann were among his friends at Leipzig, where, at his first concert with the Gewandhaus Orchestra, he conducted his overture *Meeresstille und glückliche Fahrt* (*Calm Sea and Prosperous Voyage*.)

In 1835 Mendelssohn was overcome by the death of his father, Abraham, whose dearest wish had been that his son should complete *St. Paul*. He accordingly plunged into this work with renewed determination and the following year conducted it at Düsseldorf. The same year at Frankfurt he met Cécile Jeanrenaud, the daughter of a French Protestant clergyman. Though she was ten years younger than himself, that is to say, no more than 16, they became engaged and were married on March 28, 1837. His sister Fanny, the member of his family who remained closest to him, wrote of her sister-in-law: "She is amiable, childlike, fresh, bright and even-tempered, and I consider Felix most fortunate for, though inexpressibly fond of him, she does not spoil him, but when he is capricious, treats him with an equanimity which will in course of time most probably cure his fits of irritability altogether." This was magnanimous praise on the part of Fanny, to whom Mendelssohn was drawn by musical as well as emotional ties. Fanny was not only a composer in her own right—she had herself written some of the *Songs Without Words* attributed to her brother—but she seems to have exercised, by her sisterly companionship, a powerful influence on the development of his inner musical nature.

Works written over the following years include the *Variations sérieuses*, for piano, the *Lobgesang* (*Hymn of Praise*), *Psalm CXIV*, the *Second Piano Concerto*, and chamber works. In 1838 Mendelssohn began the *Violin Concerto*. Though he normally worked rapidly, throwing off works with the same facility as one writes a letter, this final expression of his lyrical genius compelled his arduous attention over the next six years. Later, in the 20th century, the *Violin Concerto* was still admired for its warmth of melody and for its vivacity, and it was also the work of Mendelssohn's that, for nostalgic listeners, enshrined the elegant musical language of the 19th century. Nor was its popularity diminished by the later, more turgid, and often more dramatic, violin concerti of Brahms, Bartók, and Alban Berg. It is true that many of Mendelssohn's works are cameos, delightful portraits or descriptive pieces, held to lack the characteristic Romantic depth. But occasionally, as in the *Violin Concerto* and certain of the chamber works, these predominantly lyrical qualities, so charming, naïve, and fresh, themselves end by conveying a sense of the deeper Romantic wonder. In 1843 Mendelssohn founded at Leipzig the conservatory of music where, together with Schumann, he taught composition. Visits to London and Birmingham followed, entailing an increasing number of engagements. These would hardly have affected his normal health; he had always lived on this feverish level. But at Frankfurt in May 1847 he was greatly saddened by the death of Fanny. It is at any rate likely that for a person of Mendelssohn's sensibility, living at such intensity, the death of this close relative, to whom he was so completely bound, was calculated to undermine his whole being. In fact, after the death of his sister, his energies deserted him, and, following the

rupture of a blood vessel, he died at Leipzig on November 4, 1847.

Though the music of Mendelssohn, stylish and elegant, does not fill the entire musical scene, as it was inclined to do in Victorian times, it has elements that unite this versatile 19th-century composer to the principal artistic figures of his time. In the *Midsummer Night's Dream* music, with its hilarious grunting of an ass on the bassoon and the evocative effect of Oberon's horn, Mendelssohn becomes a partner in Shakespeare's fairyland kingdom. The blurred impressionist effects in *Fingal's Cave* foreshadow the later developments of the painter J.M.W. Turner. Wagner understood Mendelssohn's inventive powers as an orchestrator, as is shown in his own opera *The Flying Dutchman*, and, later, the French composers of the 20th century learned much from his grace and perfection of style.

In recent times the appeal of Mendelssohn's work has not dwindled. It is true that *Elijah* is not so frequently performed as it was and some of his fluent piano works are now overshadowed by the more enduring works of Beethoven and Schumann. But the great pictorial works of Mendelssohn, the *Scottish* and *Italian* symphonies, repeatedly yield new vistas. Mendelssohn was one of the first of the great 19th-century Nature composers, and in this sense he remains even today a figure to be rediscovered.

#### MAJOR WORKS

##### Orchestral works

SYMPHONIES: *No. 1 in C Minor*, op. 1 (1824), really *No. 13*, as twelve symphonies for strings were written earlier; *No. 2* (see ACCOMPANIED CHORAL MUSIC); *No. 3 in A Minor-Major* (*Scottish*), op. 56 (1830-42); *No. 4 in A Major-Minor* (*Italian*), op. 90 (1833); *No. 5 in D Major* (*Reformation*), op. 107 (1829-30).

OVERTURES: *A Midsummer Night's Dream*, op. 21 (1826); *The Hebrides*, also known as *Fingal's Cave*, op. 26 (1830-32); *Meeresstille und glückliche Fahrt* (*Calm Sea and Prosperous Voyage*), op. 27 (1828-32); *Die schöne Melusine* (1833), overture for opera, libretto by Grillparzer.

CONCERTI: *Piano Concerto No. 1 in G Minor*, op. 25 (1831); *Piano Concerto No. 2 in D Minor*, op. 40 (1837); *Violin Concerto in E Minor-Major*, op. 64 (1844).

INCIDENTAL MUSIC: *A Midsummer Night's Dream*, op. 61 (1842).

##### Chamber music

STRING QUARTETS: *E Flat Major* (1823); *No. 1 in E Flat Major*, op. 12 (1829); *No. 2 in A Major*, op. 13 (1827); *No. 3 in D Major*, op. 44, no. 1 (1838); *No. 4 in E Minor*, op. 44, no. 2 (1837); *No. 5 in E Flat Major*, op. 44, no. 3 (1838); *No. 6 in F Minor*, op. 80 (1847).

STRING QUINTETS: *No. 1 in A Major*, op. 18 (1826; second version 1832); *No. 2 in B Flat Major*, op. 87 (1845).

PIANO QUARTETS: *No. 1 in C Minor*, op. 1 (1822); *No. 2 in F Minor*, op. 2 (1823); *No. 3 in B Minor*, op. 3 (1825).

PIANO TRIOS: *No. 1 in D Minor*, op. 49 (1839); *No. 2 in C Minor*, op. 66 (1847).

OTHER CHAMBER MUSIC: *String Sextet in D Major*, op. 110 (1824); *String Octet in E Flat Major*, op. 20 (1825); *Sonata for Violin and Piano in F Minor*, op. 4 (1825); *Four Pieces for String Quartet*, op. 81 (1827-47).

##### Vocal music

OPERAS: *Die Hochzeit des Camacho*, op. 10 (1825); *Die Heimkehr aus der Fremde*, op. 89 (1829), operetta.

CHURCH MUSIC: *Three motets*, op. 39 (1830); eight psalms; six anthems for eight-part chorus, op. 79 (1843-46); hymn, *Hear My Prayer*, for soprano chorus and organ (1844).

ACCOMPANIED CHORAL MUSIC: (ORATORIO): *St. Paul*, op. 36 (1836); *Elijah*, op. 70 (1846). (CANTATA): *Lobgesang* (*Hymn of Praise*), op. 52 (1840; always counted as *Symphony No. 2*); *Lauda Sion*, op. 73 (1846).

##### Piano music

Five fantasies; eight books of *Lieder ohne Worte* (*Songs Without Words*); seven preludes and fugues; three sonatas; *Kinderstücke*, op. 72 (1842); five sets of variations including *Variations sérieuses*, op. 54 (1841).

##### Organ music

Three preludes and fugues, op. 37 (1833-37); six sonatas, op. 65 (1844-45).

## Menelik II of Ethiopia

Menelik II, creator of the modern Ethiopian state, was emperor of Ethiopia in the decades preceding World War I, a period during which Ethiopia, alone of the polities of Africa, maintained its independence in the face of European colonialism.

Menelik, or Sahle Mariam as he then was, was born on August 17, 1844, at Ankober, one of the capitals of the Ethiopian kingdom of Shewa. His father was Haile Malakot, later negus (or king) of Shewa. His mother was a court servant who actually married Haile Malakot shortly after Menelik was born. Menelik II's forefathers had been rulers of Menz, the heartland of Shewa, since the 17th century, and it has been claimed that further back they were related to the so-called Solomonic line of emperors who ruled Ethiopia between 1268 and 1854 (alternate dates 1270–1855). The name Menelik was significant: Menelik I was a legendary son of Solomon and the Queen of Sheba.

By courtesy of the Senat, Paris; photograph, J.E. Bulloz

Menelik II, oil painting by Paul Buffet, 1897. In the Senate Palace, Paris.

In 1855 the vigorous emperor of Ethiopia, Tewodros II, invaded the then semi-independent kingdom of Shewa. Early in the subsequent campaigns Menelik's father died, and Menelik was captured and taken to the Emperor's mountain stronghold, the Amba Magdela. Menelik, in nearly ten years of captivity, had opportunity to observe Tewodros' dedication to the unification and modernization of the empire and also the heavy-handed and often violent methods that ultimately led to the Emperor's failure and suicide.

Menelik contrived to escape from Magdela in 1865 and returned to Shewa, which had remained in a state of sporadic unrest and revolt against Tewodros. Although only 21 years of age, Menelik was able to displace Bezebeh, a ruler appointed by the Emperor in 1859, who had subsequently declared himself negus of the province.

King of  
Shewa

Menelik stood six feet tall and had a very dark complexion and fine white teeth, but smallpox had left its marks on his face. He usually wore traditional dress—a *shamma*. As a diplomat he was very courteous and made a great impression on the many foreign emissaries who visited his court. With their help he steadily imported firearms, the better to equip his armies and the garrisons and settlers that he planted in their wake.

On the death of Tewodros, Menelik, as negus of Shewa, aspired to the position of emperor. But he was not the only claimant and had to submit first to Tekle Giorgis (1868–72) and then Yohannes IV (1872–89). Before Yohannes died fighting the Sudanese in 1889, he obliged Menelik to direct his ambitions mainly to the south and east. Menelik subsequently incorporated Arusi, Harer (Harar), Jimma, Kaffa, and the several kingdoms and states of southern Ethiopia within his domains. By the time of Yohannes' death, Menelik had emerged as the strongest man in Ethiopia and was able to assume the imperial crown for which he had waited so long.

A circular letter sent to the heads of state of Britain, France, Germany, Italy, and Russia in 1891 provides a good illustration of Menelik's aims and attitudes as emperor:

... tracing today the actual boundaries of my Empire, I shall endeavour, if God give me life and strength, to re-establish the ancient frontiers (tributaries) of Ethiopia up to Khar-toum, and as far as Lake Nyanza with all the Gallas. Ethiopia has been for fourteen centuries a Christian land in a sea of pagans. If Powers at a distance come forward to partition Africa between them, I do not intend to be an indifferent spectator. As the Almighty has protected Ethiopia up to this day, I have confidence He will continue to protect her, and increase her borders in the future. I am certain He will not suffer her to be divided among other Powers.

During the period of his rivalry with Emperor Yohannes and the latter's son, Mengesha, Menelik appeared to befriend the Italians, but a quarrel soon developed. The Italians interpreted Article XVII of the Treaty of Wachile (Ucciali), concluded in 1889 by the Italians and Menelik, as giving Italy a protectorate over Ethiopia. It is quite inconceivable that Menelik would have agreed to his historic country becoming a protectorate. When he learned of the Italian interpretation, which was gaining some acceptance in Europe, he at once denied it and, in 1893, renounced the whole treaty.

The Italians had established themselves along the Red Sea coast, and the governor of the Italian colony of Eritrea, after much intrigue and several minor military skirmishes, risked a major confrontation. His army was crushingly defeated by the Ethiopians in one of the greatest battles in the history of Africa—the Battle of Adowa, on March 1, 1896.

A settlement cancelled the Treaty of Ucciali and acknowledged the full sovereignty and independence of Ethiopia, but the Italians were allowed to retain Eritrea. After Adowa, Menelik's Ethiopia was at once accepted by the European powers as a very real political force. The crushing defeat of a European army greatly enhanced Menelik's international reputation, causing a host of foreign advisers, ambassadors, emissaries, and pure adventurers to flow into the country.

Menelik's later activities as emperor included the creating of ministries, the initiating of modern education, and the constructing of telephone and telegraph systems and of a railway from Djibouti to the highlands of Shewa. But, beginning in 1906 or 1907, he suffered a series of paralytic strokes, and power passed to his wife, the empress Taitu; to Ras Tesemma, who became regent; and to Lij Iyasu, the grandson who was to succeed him. The stricken emperor finally died in 1913. (The exact date is disputed, but December 12 is usually given.)

**BIBLIOGRAPHY.** GUEBRE SELASSIE, *Chronique du Règne de Ménélik II*, 2 vol. (1930–32), was written by a court chronicler, traditionally uncritical of his monarch. This is thus a biased though standard work. See also KOFI DARKWAH, *Menelik of Ethiopia* (1971); and HAROLD MARCUS, *The Life and Times of Menelik II of Ethiopia, 1844–1913* (in press).

## Mennonites

The Mennonites, named after Menno Simons (1496–1561), are a Christian denomination of approximately 460,000 members located in many countries of the world, with heaviest concentrations in the United States and Canada. They are an offshoot of the 16th-century Anabaptists, a radical reform movement of Europe.

### NATURE AND SIGNIFICANCE

Anabaptist and Mennonite thought has been characterized by a separation between religion and the world. Under the impact of severe persecution in the 16th century, Anabaptism was driven to a strategy of withdrawal from society in its attempt to survive, a strategy that became central in Mennonite theology. Consequently, most Mennonites have possessed a strong cultural cohesion that they maintained externally by withdrawal and internally by rigorous group discipline. This isolation encouraged the sectarian virtues of frugality, hard work, piety, and mutual helpfulness but frequently also led to schism. By the mid-20th century, however, Mennonites were deeply involved in the social, educational, and economic world around them, an involvement that led to revolutionary changes in their life and thought. It also led to a new search for identity as a distinct group in the modern world, through a study of their denominational history, sociological analysis, and theological interaction with other groups.

Mennonites are trinitarian (believing in the doctrine of the Trinity—*i.e.*, Father, Son, and Holy Spirit), affirm the Scriptures (especially the New Testament and the teachings of Jesus) as their final authority for faith and life, and appeal to the pattern of the early church as their congregational model. They stress the importance of Baptism on confession of faith and a symbolic understanding of the Lord's Supper. Some practice foot washing, a practice based on an act of Jesus with his disciples. The doctrines of nonconformity to the world, nonswearing of oaths, nonresistance in lieu of military service, and church discipline are generally affirmed but not practiced universally.

### HISTORICAL DEVELOPMENT

**Reformation origins.** Mennonites trace their origins back to the 16th-century Anabaptists, particularly to those known as the Swiss Brethren, who formed their first congregation on January 21, 1525, in the face of imminent persecution for their nonconformity to the demands of the state church led by the Reformation theologian Huldrych Zwingli (1484–1531). Though these demands centred on infant baptism, which Anabaptist leaders Conrad Grebel, Felix Manz, and others questioned on the basis of biblical studies, the real issue was the nature of the church. Christ, according to their view, is Lord of the church. Only those who submit to that lordship can be true members of his body. Furthermore, the body of Christ receives its guidance from Christ himself through the Scriptures and the Holy Spirit, not from or through the civil magistracy. Persecution soon scattered the Swiss Brethren across Europe; their doctrinal views found quick response among many people, and for a time the movement grew.

**Menno Simons.** Though Mennonites are the direct descendants of the Anabaptists of the 16th century, the two movements are not identical. Menno Simons, a Dutch priest who joined the Anabaptist movement in 1536, gathered the scattered Anabaptists of northern Europe into vital congregations that were soon called by his name. These congregations led by Menno Simons were similar to another Anabaptist-related group organized in Strassburg under Melchior Hofmann in 1530. Initially, Menno Simons was not directly influenced by the Swiss Brethren; but with the death of the first Swiss and south German Anabaptist leaders soon after the defeat of the peasant forces led by some radical revolutionary Anabaptists—such as Thomas Müntzer (*c.* 1490–1525)—in the Peasants' War (1525), Simons began to consolidate and institutionalize the work that the moderate Anabaptist

leaders of Europe had begun. He represents a second generation of leaders in which the emerging tradition determined basic faith and doctrine.

**Hutterites.** Another Anabaptist movement flourished in central Germany under the leadership of Hans Hut (died 1527), Hans Denk (*c.* 1500–27), and especially Pilgram Marpeck (*c.* 1492–1556), a major early lay theologian. Still another movement came to be known as the Hutterian Brethren because of the coordinating leadership of Jakob Hutter (died 1536). The Hutterites were soon known for their communal living and for an intense missionary zeal that continued into the 17th century, after all other Anabaptist groups had found relative physical security by withdrawing geographically and socially from the mainstream of European life.

**Developments from the 17th century to the 19th.** Mennonites found political freedom first in The Netherlands, after their last martyr died there in 1574. Before that date, however, many had emigrated from there to the Vistula River area in what is now northern Poland, where their communities became large and flourishing. By 1700 there were 160,000 baptized members in the Mennonite churches of The Netherlands. Because many of the professions were legally closed to them, they turned to business and in the process became wealthy and urbanized. In matters of faith, they followed the Enlightenment, a 17th- and 18th-century intellectual movement that placed its hope for human betterment on the use of right reason. They became well known as artists, writers, and patrons of social programs; but membership declined to about 15,300 in 1837.

Persecutions that continued in Switzerland into the 18th century drove many Mennonites to south Germany, Alsace, The Netherlands, and the United States. A major schism occurred (1693–97) when the Swiss Mennonite bishop left the Mennonites to form the Amish Church in an attempt to preserve biblical discipline among the membership. From the 17th to the 20th centuries, most Mennonites in Switzerland, south Germany, and Alsace lived in semiclosed rural communities with a simple agrarian economy. Religiously, they were influenced by Pietism, a Lutheran-based movement that emphasized personal religious experience and reform.

In 1788 the first of a long stream of Mennonites left the Vistula Delta of northern Poland (Prussia) to settle in the Ukraine, where they acquired land and escaped military conscription. By 1835 about 1,600 families had settled in 72 villages with landholdings amounting to about 500,000 acres. By World War I, these settlements had grown to over 120,000 members living in autonomous communities where religious, educational, social, economic, and even political affairs were under their own control. All Mennonite communities in Russia were either destroyed during World War II or dissolved by the Soviets soon after 1945. Mennonites today live scattered among the Russian population.

Beginning in 1663, Mennonites emigrated to North America to preserve the faith of their fathers, to seek economic opportunity and adventure, and especially to escape European militarism. Until the late 19th century, most Mennonites in North America lived in rural communities and engaged successfully in farming. They retained their German language, partly as a religious symbol and partly as insulation against their environment. Their main concern was to be left alone to worship God according to their conscience and tradition. In 1775 they addressed a statement to the Pennsylvania Assembly that read:

It is our principle to feed the hungry and give the thirsty drink; we have dedicated ourselves to serve all men in everything that can be helpful to the preservation of men's lives, but we find no freedom in giving, or doing, or assisting in anything by which men's lives are destroyed or hurt.

In 1783 Mennonites in Lancaster County were accused of treason for feeding destitute British soldiers. During the U.S. Civil War, rather than fight, some hired substitutes or paid an exemption fee of \$300 in the North and \$500 in the South. Those who fought in the armed forces were usually excommunicated for doing so.

The Amish Church

Emigration to North America

Anabaptist view of the church

**20th-century developments.** Mennonite migrations continued during the 20th century, primarily from Russia to North and South America—to Brazil, Paraguay, Uruguay, Bolivia, Mexico, and British Honduras. By 1970 about 92 families from The Netherlands had located in Australia and New Zealand. Mennonite missionaries from North America and Europe planted still more churches in Latin America, Africa, India, and other parts of Asia. In 1970 there were approximately 60,000 members in eight nations of Africa, 70,000 in six nations of Asia, 100,000 in ten European nations, including the U.S.S.R., 200,000 in the United States and Canada, and 30,000 in 12 nations of Latin America, giving a worldwide total of 460,000 members of which nearly one-third were nonwhite. The fastest growing Mennonite Church in 1970 was in Indonesia.

In the 20th century, the Mennonites of North America gave new emphasis to higher education, especially by supporting their own colleges and seminaries, while continuing to maintain secondary and Bible schools. New interest in the faith of early Anabaptists was fostered by the scholarly work of both Mennonite and non-Mennonite historians. This activity not only offered new insights for the renewing of church life but accentuated the disparity between the 16th-century Anabaptist ideals and present Mennonite beliefs and practices. A rediscovery of their history also gave new meaning to urban social relationships; witness, service, discipleship, and evangelism became household words and shaped Mennonite identity. Instead of withdrawal, they found in witness and service a new way of relating to the world.

#### TEACHING, ORGANIZATION, AND PRACTICE

**Teaching.** In describing the Anabaptists, the historian Walther Köhler wrote: "The Anabaptists are the Bible Christians of Reformation history, distinguished from the Reformers through the extension of the Biblical norm beyond the purely religious into economic and social life" (*Religion in Geschichte und Gegenwart*; Tübingen, J.C.B. Mohr, 1931). This "extension" has often been described as discipleship that, together with brotherhood and love, is frequently considered to be the central theme of the movement.

The first "Brotherly Union," called the Schleithem Confession (1527), or common confession of faith, adopted seven articles of faith. Article I taught that baptism was only for those who asked for it and were willing to "walk in the resurrection" and participate in (not imitate) the life of Christ. Article II taught that church discipline was necessary for salvation and for being a witness of the church because members voluntarily joined the group and asked in baptism for help and admonition. Article III taught that the Lord's Supper celebrated the unity of the church and was intended only for true believers. Article IV taught separation from unbelievers in daily life, including separation from secular, social, and governmental organizations. Article V taught the need for support of pastors and outlined their place within the congregation. Article VI taught love and the way of the cross as the believer's only legitimate response to violence and evil. Article VII taught honesty in word and deed, thereby making the swearing of oaths unnecessary and sinful.

Such early Mennonites as the Anabaptists insisted that they were not teaching new doctrines but restoring biblical church practices. Baptism of believers implied a willing witness to others that made Mennonites the only missionaries of the Reformation movement. Voluntary church membership implied discipline and mutual helpfulness to one another. The way of the cross meant nonresistance and implied suffering; it meant the renunciation of power in all relationships. Separation of church and state implied differing views of man and the world. For Mennonites, the church was gathered around the confession that "Jesus Christ is Lord," while the state proclaimed that "Caesar is Lord." The place of the state was "outside of the perfection of Christ."

The uniqueness of Anabaptism, and some Mennonitism, centres in their understanding of the Bible and of the

work of Christ. Both Old and New Testaments are truly the word of God but follow a progressive order of promise and fulfillment. The New Testament, especially the words of Christ, are God's final revelation to man but can be rightly understood only when read and studied within the circle of believers under the guidance of the Holy Spirit. And Christ, it is believed, did not come simply to change man's condition in a mysterious way by dying for him but to reconcile him to God by redeeming him morally from slavery to sin. This redemption thus gives to man a new ethical possibility, thereby establishing communion again without destroying man's freedom or by making of God a pagan deity who needs a human sacrifice to be appeased.

**Organization and practices.** All Mennonites are congregational in polity: they call their own ministers, decide their own priorities, and even write their own statement of faith, if they so desire. These congregations are joined together into many conferences, seven of which are in North America. The Amish, Hutterian Brethren, and some conservative Mennonites do not form conferences. Since 1925 there has been a Mennonite World Conference that meets every five years for fellowship, study, and inspiration but does not make decisions binding on its member bodies.

The desire to express positively the ethic of love and nonresistance has historically given Mennonites a deep social concern. An emergency relief committee for national and international aid, founded by the Dutch Mennonites in 1725, is still active. In 1920 North America Mennonites founded the Mennonite Central Committee (MCC) for the same purpose, initially to relieve famine in Russia. By 1970 this work was carried on in 35 countries, through approximately 700 volunteer workers with an annual budget of just over \$4,000,000.00.

**Worship.** Mennonite worship services are sermon-centred. A simple, almost austere, liturgy surrounds the Gospel proclamation. By the 1970s, however, there were many signs of experiment in worship similar to those found in other denominations. Mennonites have traditionally practiced the lay ministry, but many congregations are served by fully trained and salaried pastors. Most congregations have one or more deacons or elders, sometimes selected for life, but the contemporary pattern of committee organization is dominant. Baptism was traditionally observed once each year but is increasingly administered as candidates ask for it. The Lord's Supper is normally observed from two to four times annually. In some congregations, the love-feast pattern, involving a meal from which some bread and wine is reserved for the Lord's Supper, is observed. Foot washing is practiced by some congregations.

**Social, political, and cultural attitudes.** Because of their historical experience of suffering and because of a basic church-world dualism in their theology, Mennonites have, for most of their history, been content to live as "the quiet of the land." Today, this pattern has been shattered by the revival of an earlier sense of mission and by growing urbanization. Except in certain parts of North and South America, Mennonites have become an integral part of their environment on various levels of accommodation or even assimilation. Many Mennonites are entering the helping professions in society, and some have been elected to political office. Earlier political conservatism is breaking down, especially in North America, under the impact of growing concern over the great social issues of race, war, and poverty.

**BIBLIOGRAPHY.** *The Mennonite Encyclopedia*, 4 vol. (1955-59), is the standard reference work in English. C.J. DYCK (ed.), *An Introduction to Mennonite History* (1967), is a popularly written general history of the Anabaptist-Mennonite movement. ANNI DYCK (ed.), *Mennonites Around the World* (1967), gives a short interpretive overview. Two comprehensive treatments of wider Anabaptist relationships to other movements, together with a thorough analysis of these movements are G.H. WILLIAMS, *The Radical Reformation* (1962); and D.F. DURNBACH, *The Believers' Church* (1968). LEONARD VERDUIN, *The Reformers and Their Stepchildren* (1964), compares Anabaptism to other movements in the history of the church. The theological and contemporary

significance of the movement is explored in G.F. HERSHBERGER (ed.), *The Recovery of the Anabaptist Vision* (1957); and J.H. YODER, *The Christian Witness to the State* (1964). Further detailed bibliographies may be found in H.J. HILLERBRAND (ed.), *A Bibliography of Anabaptism, 1520-1630* (1962), and continued in *A Mennonite Bibliography, 1631-1961*, 2 vol. (in prep.).

(C.J.D.)

## Menno Simons

Menno Simons, the 16th-century Dutch priest who became a member of the radical reform group known as the Anabaptists after some revolutionary Anabaptists had failed to establish the Kingdom of God by force at Münster in 1535, is known as the leader of those who formed the Mennonite Church. Through his writings and courageous leadership, the peaceful wing of Dutch Anabaptism became normative and grew rapidly. His influence has been significant in the life of the Mennonite Church and in the area of pacifism to the present time.

By courtesy of the Mennonite Library and Archives, North Newton, Kansas

Menno Simons, engraving by Christopher van Sichem, 1605-08.

meant, according to Menno's interpretation, that only persons of mature faith, who acknowledged Jesus as Lord and had counted the cost of following him, could be eligible for membership. Only such persons could be baptized as a seal (sign of guarantee) of the covenant and a witness to all the world. Little children were indeed sinners with all mankind, but, Menno claimed, the grace of Christ was sufficient for them until they reached the age of accountability and made a conscious choice either for or against him. The experience of conversion came to be central to all of Menno's life and theology.

Meanwhile, the revolutionary wing of early Dutch Anabaptism continued its agitation. On April 7, 1535, the Olde Klooster near Bolsward, which had been occupied by them as a staging area for aid to Münster, fell before the onslaught of the state militia. Among those killed were members of Menno's congregation and Peter Simons, who may have been his brother. This prompted him to preach openly against the errors of the revolutionaries. In doing so he articulated with increasing clarity what he believed to be the true nature of a believers' church: pure doctrine, scriptural use of sacraments, ethical obedience, love of neighbour, a clear and open witness to the faith, and a willingness to suffer. The fall of Münster on July 25, 1535, increased pressure within him to help those whom he considered to be misguided spirits. This bold and outspoken ministry soon jeopardized his safety, and in January 1536 he went into hiding after a spiritual struggle of 11 years.

In describing his decision he wrote,

Pondering these things my conscience tormented me so that I could no longer endure it. . . . If I through bodily fear do not lay bare the foundation of the truth, nor use all my powers to direct the wandering flock who would gladly do their duty if they knew it, to the true pastures of Christ—oh, how shall their shed blood, shed in the midst of transgression, rise against me at the judgment of the Almighty and pronounce sentence against my poor, miserable soul!

Menno spent a quiet year in hiding, finding a sense of direction for his future work. During this time he wrote "The Spiritual Resurrection," "The New Birth," and "Meditation on the Twenty-third Psalm." Late in 1536 or early 1537, he was rebaptized, called to leadership by the peaceful Anabaptist group founded in 1534 by Obbe Philips, and ordained by Obbe. He also married Gertrude. From this time on his life was in constant danger as a heretic. In 1542 the Holy Roman emperor Charles V (1500-58) himself issued an edict against him, promising 100 guilders reward for his arrest. One of the first Anabaptist believers to be executed for sheltering Menno was Tyaard Renicx of Leeuwarden, in 1539.

From 1543 to 1544 Menno worked in East Friesland, where in January 1544 he had a major interview or debate with the Polish reformer Johannes à Lasco (1499-1560). The following two years, 1544-46, were spent in the Rhineland, after which he travelled from his new home base in Holstein, near Oldesloe, northeast of Hamburg, until his death on Jan. 31, 1561. Here he found time for extensive writing and established a printing press to circulate Anabaptist writings. His travels not only took him back to The Netherlands but also to Danzig.

Menno was not the founder of the Mennonite Church nor the most articulate spokesman of early Anabaptist theology. His greatness lay rather in the leadership he gave to northern Anabaptism during its formative first generation, a leadership maintained through his calm, biblically oriented approach and through his writings, which consolidated the insights of the movement. Though these writings often seem tedious and excessively polemical, they delineated the Anabaptist faith he defended against both Catholic and Protestant attacks on the one hand and distortions by zealots from within the movement on the other. During the last years of his life he was troubled particularly by some of his own brethren who pressed for great rigour in the application of the ban (expulsion from the church) and other measures of discipline. His more than 40 extant writings are all prefaced with I Cor. 3:11 "No other foundation can any one lay than that which is laid, which is Jesus Christ."

Menno's concept of the believers' church

### Education and conversion

Little is known about his early life. He was born into a Dutch peasant family in Witmarsum, in the province of Friesland, in 1496. At an early age Menno was enrolled in a monastic school, possibly at the Franciscan monastery in Bolsward, to prepare for the priesthood. In March of 1524, at the age of 28, he was ordained at Utrecht and assigned to the parish at Pingjum near the place of his birth. Seven years later, in 1531, he became the village priest in his home parish at Witmarsum.

Though Menno was to become a major spokesman of ethical Christianity, his initial concern was doctrinal. During his first year as priest he began to question the real presence of Christ in the bread and wine of the Eucharist (Lord's Supper). This was probably due largely to the anti-sacramental tendencies prevalent in the Netherlands at that time, tendencies that grew in the fertile soil of Erasmian Humanism and the ethical concerns of the Brethren of the Common Life, leading ultimately to the *Epistola Christiana* of Cornelius Hoen. These doubts led Menno to read both the Bible and the writings of Martin Luther for the first time. At first he read the Bible with real fear, for he knew this step had driven Luther and the Swiss reformer Huldrych Zwingli (1484-1531) out of the Roman Church, but he soon confessed with them that biblical authority ought to be primary in the life of the believer and in the church. By 1528 he was known as an evangelical preacher, though he continued as parish priest.

From doubts about the Eucharist, Menno moved gradually to questions about infant Baptism and the meaning of church membership. His discovery of the New Testament led him to the firm conviction that the church was the body of Christ, called to holiness and purity. This

WENGER, 1956), the definitive English language edition; K. VOS, *Menno Simons, 1496-1561* (1914), the standard work (in Dutch).

(C.J.D.)

## Menopause

Description and causation

"Menopause" (female climacteric) is a term that implies the final cessation of menstruation and therefore the end of a woman's reproductive life. The popular term "change of life" is neither descriptive nor accurate for it tends to indicate a physical, mental, and sexual deterioration, whereas deterioration does not occur.

In about half of all women, menopause begins between the ages of 45 and 50 years. Although the average age for onset is about 48 years, menopause may begin as early as age 40 or be delayed to the early 50s. Although the age of onset is probably determined by the hereditary background of the individual, good nutrition and health habits tend to postpone onset.

A premature menopause—i.e., one that takes place spontaneously before the age of 40—occurs in about 8 percent of women. An artificial menopause may be induced by removing the ovaries by surgery or by destroying them with X-rays or radium.

The natural life of the ovaries is about 35 years. The menopause is brought on by a progressive decline in ovarian function. This decline is a normal result of aging and is accelerated as the menopause approaches. During the reproductive years follicles in the ovaries mature and release their ova periodically under hypothalamic-pituitary stimulation. In the years immediately preceding the menopause, however, first some follicles and later all follicles fail to rupture and release their ova. The failure to ovulate results in a disturbed menstrual pattern. A woman may miss a period or two and suspect pregnancy. A medical examination, however, will establish the proper diagnosis. The continued decline in ovarian activity may provoke prolonged intervals between periods or irregular bleeding episodes. The length of the periods may vary, and the flow may become either more scant or profuse. In a fortunate small minority the periods cease abruptly.

As the ovaries decline in function, they produce smaller and smaller amounts of the hormone estrogen; this decline in estrogen initiates subtle rearrangements in the hormonal activity of the glands that control the reproductive function. The decrease in output of estrogen disturbs the neurovascular mechanism of the hypothalamus and probably initiates the vasomotor changes that may provoke the characteristic "hot flashes" of the menopause. The metabolism of the pituitary gland is altered and increasing amounts of follicle stimulating hormone (FSH) appear in the blood and urine. Rearrangements in the hormonal activity of the adrenal and thyroid glands also take place, for the metabolic activities of all these glands are interrelated. These adjustments are usually made without physical or mental disturbances in most women.

Hot flashes are the only characteristic symptoms of the menopause. They often appear before its obvious onset and their duration is usually limited to two or three years. The young woman who has her ovaries removed for disease or other reasons will develop flashes within a week following the operation.

The hot flash usually begins as a sense of warmth over the upper chest. It then spreads to the neck and face and may extend over the entire body, sometimes giving rise to

a prickling sensation. The woman is acutely aware of blushing, which usually is disturbing to her, particularly in company. The flashes may recur frequently during the night and may interfere with sleep. She may awaken because of a chilly sensation and may perspire freely.

A variety of other symptoms can and do occur, although many are entirely unrelated to the changes incidental to the menopause. Nervousness, headaches, and dizziness are common complaints. The fear of aging, the altered pattern of life, and changing family relationships also may precipitate many disturbing symptoms.

Many women complain of weight gain during the menopause. Occasionally this is related to decreased thyroid function. In most cases, however, it is brought about by decreased physical activity and by increased food intake as a substitute for many emotional and social satisfactions. The menopause need not be associated with any unusual changes in physical appearance and fitness.

There are three principal aspects to the medical management of the menopause: (1) education, (2) periodic examination, and (3) the substitution of estrogenic hormone when this is desirable.

Medical management

Providing information to women concerning the physiologic function of their reproductive organs will make them aware of the limited duration of their reproductive years and prepare them for the important transitional years leading into the menopause. The menopause need not be a harbinger of old age. The woman in the climacteric, because of her makeup and the vicissitudes of her environment, enters middle life with an uneasy and uncertain tread. It is a time for introspection, of inventories, of soul searching. It is a period of boredom, of phobias, and fears. An intelligent understanding of the problems she may face and the proper medical guidance, if necessary, will prevent serious sequelae.

Every woman, including those of menopause age, should have a health examination at least once a year. At this time she should be screened for cancer by having a smear taken for uterine cancer and by receiving an examination for breast cancer. She also should be instructed on the proper method for self-examination for breast cancer.

Finally, the administration of estrogenic hormones may be indicated and desirable for the prompt relief of symptoms. Estrogen should be taken only under the direction of a physician but can be taken indefinitely without harmful side effects. It will stop flashes and will retard the shrinkage of the tissues of the external genitalia, which otherwise may become irritated and infected. Studies indicate that estrogen also may slow the development of atherosclerosis and osteoporosis, bone decalcification, and may influence the aging process favourably (see also HORMONE; REPRODUCTIVE SYSTEM, HUMAN).

## Menstruation

Menstruation is the periodic discharge from the vagina of blood, secretions, and disintegrating mucous membrane that had lined the uterus.

The biological significance of the process can best be explained by reference to the reproductive function in other mammals. In a number of species of wild sheep, for example, there is only one breeding season in the year; during this season a cycle of changes takes place in the reproductive organs, characterized by ripening and release of ova from the ovaries, increased blood sup-

ply to the genital tract, growth of the uterus, and proliferation of its lining. There is a discharge of blood and mucus from the uterus and vagina, and this is the time when coition may take place. Pregnancy normally follows, but if the ewe is not served by the ram the changes regress until the next breeding season. This cycle of changes is termed the estrous cycle (see REPRODUCTION; REPRODUCTIVE SYSTEMS, ANIMAL).

In many domesticated sheep there is more than one estrous cycle in the breeding season. If the ewe does not become pregnant in the first cycle there is a short resting phase; then ovulation is repeated and another cycle of activity of the reproductive system takes place. After each breeding period, with its succession of estrous cycles, there is a relatively long resting phase.

In most female primates, including women, there is no resting phase; an unbroken series of estrous cycles occurs throughout the year, and pregnancy can occur in any one of them.

In some animals a variety of external stimuli act through the central nervous system on the hypothalamic region of the brain. The hypothalamus controls the release from the pituitary gland of hormones that induce ripening of ovarian follicles—ova and the cellular structures that enclose them. These pituitary hormones, called gonadotropic hormones, are carried to the ovaries by way of the bloodstream. In primates the hypothalamic mechanism normally is independent of external stimuli, and regular discharge of ova into the tubes leading to the uterus occurs even in the absence of coitus. Under the influence of the pituitary gonadotropic hormones, the ovary produces other hormones, which cause growth and increased vascularity of the uterus and vagina. These hormones are estrogens—chiefly 17 beta-estradiol—and progesterone. It is as though the ovary prepares the uterus for the reception of the ovum that is released in the particular cycle.

**Menstrual cycle.** The normal human menstrual cycle is 28 days, but no woman is always precisely regular, and cycles as short as 21 days or as long as 35 days are not abnormal. It is customary to call the first day of the menstrual period the first day of the cycle, although menstruation is the end rather than the beginning of a process. On this basis the cycle is described as starting with about

five days of menstruation, followed by a proliferative phase that lasts to about the 14th day, and then a secretory phase that lasts until the next menstruation. The external manifestation of menstruation depends upon cyclical change in the lining of the body of the uterus. The lining, called endometrium, consists of tubular glands that open into the uterine cavity. The glands lie in a vascular framework, or stroma, and are separated by it.

At the end of menstruation, just at the beginning of the proliferative phase, the endometrium is thin, with short, straight glands, and the ovary is quiescent. Under the influence of the gonadotropic hormones from the pituitary gland an ovarian follicle (occasionally more than one) ripens in one of the ovaries. This ovarian follicle contains the ovum, which is a cell about 0.14 millimetre in diameter, surrounded by a group of smaller cells, called granulosa cells. The granulosa cells multiply, with the ovum situated in the wall of the rounded structure that they form, and secrete an estrogenic hormone, estradiol (see HORMONE). This hormone causes proliferative changes in the endometrium, so that the glands become taller and the whole endometrium becomes thicker and more vascular.

At about midcycle ovulation occurs: The ovum is discharged out of the follicle and from the surface of the ovary, to be received into the fallopian tube, down which it is carried to the uterus. After ovulation the granulosa cells lining the follicle from which the ovum has been extruded accumulate yellow lipid and are therefore called lutein cells, from the Latin word *luteus*, "saffron-yellow." The altered follicle is called corpus luteum. The corpus luteum continues to secrete estrogens but now also secretes progesterone; this additional hormone induces the secretory phase in the endometrium. The endometrial glands are distended with secretion and become very tortuous, while the stromal cells are swollen. The appearance of the endometrium at the end of the menstrual cycle is indistinguishable from that of early pregnancy, and this endometrial change is a preparation for the reception of the ovum. If it is fertilized, the ovum liberated at mid-cycle reaches the uterine cavity at a time when the endometrium is in the secretory phase, and the ovum embeds itself in the endometrium and starts its growth. If the ovum is not fertilized the endometrium breaks down and menstruation occurs. Menstruation has therefore been described as the outward evidence of the abortive close of one cycle and the hopeful commencement of the next.

When the ovum dies, the corpus luteum degenerates and ceases to produce hormones. On the withdrawal of estrogens and progesterone there is sudden spasm of the endometrial blood vessels, and all but the basal layer of the endometrium dies. The disintegrating endometrium is shed, together with some blood. The endometrium contains plasmin, an enzyme that dissolves blood clot, so that the menstrual discharge is normally fluid. The total blood loss does not ordinarily exceed 50 millilitres.

After menstruation the endometrium regenerates from the residual basal layer during the proliferative phase of the next cycle.

**Hormonal control of menstrual cycle.** The ovarian hormones circulate in the blood and are excreted in modified forms in the urine. Estimation of the urinary output by chemical methods gives an indication of the blood levels and of the total production of these substances. There are several natural estrogens, and numerous synthetic modifications of these and of progesterone have been devised; many are active when taken by mouth and are used for treatment of hormonal disorders and as oral contraceptives.

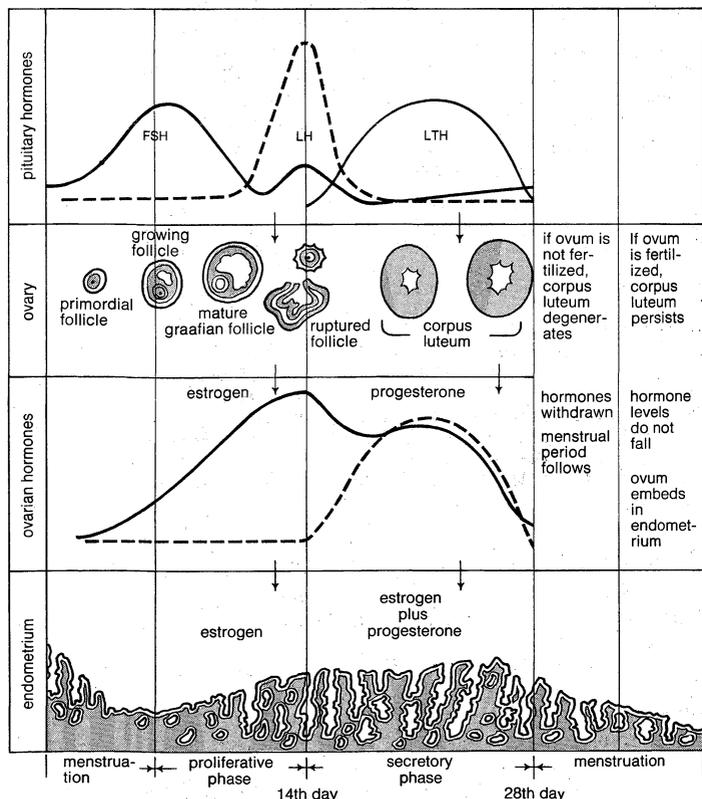

The cyclic events in the ovary that have already been mentioned depend on gonadotropic hormones secreted by the anterior lobe of the pituitary gland; this gland is situated in a small recess at the base of the skull. There are two, and possibly three, gonadotropic hormones: follicle-stimulating hormone (FSH), luteinizing hormone (LH), and, possibly, luteotropic hormone (LTH).

FSH is secreted in greatest amount in the first half of the menstrual cycle, and LH has its peak of secretion at mid-cycle. It is believed that the sequential action of FSH and

The proliferative phase

The secretory phase

Menstrual cycle.

LH causes ripening of the follicle and ovulation. In some animals LTH is necessary for maintenance of the corpus luteum, but in women under treatment for infertility ovulation has been successfully induced with FSH and LH alone. Multiple births, as the result of multiple ovulation, have occurred after excessive doses of FSH have been given.

Inhibitory effect of estrogens and progesterone

The pituitary gland stimulates the ovary to produce estrogens and progesterone, but there is a "negative feedback" by which the estrogens inhibit the output of FSH from the pituitary gland (and probably stimulate the output of LH). In addition, progesterone is believed to inhibit the further output of LH. In this process, in which the pituitary first stimulates the ovary, and the ovary then inhibits the pituitary, the basic rhythm is under the control of the hypothalamus; nevertheless, ovulation can be inhibited by oral contraceptives, which contain estrogens and progestogens—modifications of progesterone.

The anterior lobe of the pituitary gland is connected by its stalk to the hypothalamic region of the brain. The anterior lobe secretes many important hormones, including those that control the activity of the adrenal and thyroid glands, the growth hormone, and the gonadotropic hormones. From the hypothalamus substances are carried in the veins in the pituitary stalk that cause release of hormones from the pituitary, including FSH and LH, but also a factor that inhibits release of LTH. The higher brain centres no doubt affect the hypothalamic function; this explains the temporary disturbances of menstruation that may follow emotional stress.

**Ovulation and the fertile phase.** Ovulation occurs at about the midpoint of each normal cycle, and the ovum is probably capable of fertilization for only about two days after this. In the majority of women the time of ovulation is fairly constant. In women with cycles of irregular length the date of ovulation is uncertain; in these women the long menstrual cycles are usually due to prolongation of the proliferative phase; the secretory phase tends to remain normal in length. In some animals, ovulation only follows coitus; this mechanism has been used to explain cases in which human pregnancy has apparently followed coitus early or late in the menstrual cycle, but there is no definite evidence for such a mechanism in women.

The rhythm method of contraception is based on the fact that ovulation normally occurs at midcycle, but the date of ovulation may vary unexpectedly even in women whose menstrual cycle were previously regular.

**The menarche.** The first menstruation, or menarche, usually occurs between 11 and 13 years of age, but in a few otherwise normal children menstruation may begin sooner or may be delayed. If the menstrual periods have not started by the age of 16 gynecological investigation is indicated. The menarche is preceded by other signs of estrogenic activity, such as enlargement of the breasts and the uterus and growth of pubic hair. The ovarian response to gonadotropic hormones may be erratic at first, so that irregular or heavy bleeding sometimes occurs, but this irregularity nearly always disappears spontaneously.

**Normal menstruation.** Each menstrual period lasts for about five days, but the duration and amount of the flow vary considerably even in perfect health.

Discomfort in normal menstruation

In some women there may be premonitory symptoms such as pelvic discomfort, soreness of the breasts (because of the response of these organs to estrogens), and emotional tension. Ovarian hormones cause retention of sodium and water in the tissue fluids; premenstrual tension may be partly due to this and in some cases can be relieved by diuretics, drugs that increase the production of urine. When the menstrual flow starts the uterus contracts to expel the blood and disintegrating endometrium. These contractions may be painful, especially in young women who have never been pregnant.

Menstrual discomforts such as those that have been mentioned vary greatly in degree from woman to woman and from time to time but ordinarily do not interfere with normal activities.

**The menopause.** Just as puberty is a gradual process, so are the changes leading to the termination of the reproductive period. Before the final cessation of the menstrual

cycles—known as the menopause—there is a gradual decline in ovarian activity, and fertility declines because ovulation does not take place in every cycle. The menopause generally occurs between ages 47 and 52, but in a few otherwise normal women it may occur earlier or later. An early onset of menstruation is often followed by a late menopause, and this may be an inherited characteristic. In some women the periods cease abruptly; in others they gradually diminish or occasionally are missed. Irregular or heavy bleeding at this time is not normal and calls for investigation.

After the menopause atrophic changes occur in the breasts, uterus, vagina, and vulva, but many women continue to have normal intercourse. A common symptom at this time is flushing of the face and body with sweating, which may occur several times a day. The flushes are thought to be due to a temporary excess of pituitary gonadotropic hormone. In troublesome cases the flushes can be controlled by administration of estrogens, but the flushes usually cease spontaneously after a few months (see MENOPAUSE).

**Menstrual disorders.** Abnormalities of menstrual function include absence of menstruation, called amenorrhea; excessive blood loss at each period, known as menorrhagia; irregular cycles, or metrorrhagia; and painful menstruation, or dysmenorrhea. In addition, there may be premenstrual tension, and in a few women, pain at the time of ovulation. As a sexual and reproductive function, menstruation has deep emotional significance, but the popular belief that regular menstrual flow is necessary for health is unfounded. The belief arises in part from the fact that in any severe illness, and during emotional disturbances and psychiatric illness, the cycles may be disturbed. This is particularly true of diseases of the endocrine system, not only of the pituitary gland but of other glands, such as the thyroid and the adrenal, as well.

Menstrual abnormality may also be a symptom of local disease of the pelvic organs. Irregular bleeding, bleeding after intercourse, and bleeding at or after the menopause may be early signs of uterine malignant disease.

A few women have transient abdominal discomfort at the time of ovulation because of slight bleeding from the follicle into the peritoneal cavity. Oral administration of estrogens and progestogens will remedy the condition by suppression of ovulation, but the discomfort seldom recurs in every cycle or is severe enough to merit such treatment.

Premenstrual tension has already been mentioned. When it is due to fluid retention there is increase in weight before menstruation, and diuretics such as chlorothiazide give relief. In most instances emotional tension is the main complaint, and relief is attained by the use of mild sedatives or tranquilizers. Objective studies of women who do fine work show a reduction in accuracy and in concentration at this time, and outbursts of emotion may occur. The claim that relief is obtained by administration of progestogens is not generally accepted.

Painful menstruation in young women who have not borne children is a common complaint; the pain is sometimes so severe as to interfere with daily occupations. There is, as a rule, no endocrine or anatomical abnormality, and fertility is normal. The pain occurs during the active menstrual flow and is due to colicky contractions of the uterus. Minor degrees of pain are adequately controlled with analgesic drugs. In the past severe cases were often treated by surgical dilation of the cervix, and occasionally by severing the nerves that carry the pain impulses from the uterus, but now hormonal treatment is more usual. This type of dysmenorrhea usually does not persist after birth of a child.

Another type of dysmenorrhea results from pelvic disease such as inflammation of the tubes and ovaries, or from endometriosis. In endometriosis, deposits of endometrium, which undergo cyclic response to the ovarian hormones, are found in the ovaries and in other sites outside their normal location; these deposits form blood-filled cysts, and pain and excessive bleeding result. In painful menstruation secondary to pelvic disease there is, before menstruation, pain associated with a feeling of

Ovulatory pain, premenstrual tension, dysmenorrhea

congestion, and the menstrual bleeding is often excessive. Surgical treatment may be required, although the symptoms of endometriosis can be suppressed by use of progestogens.

Excessive or irregular menstrual bleeding, intermenstrual bleeding

Excessive or irregular menstrual bleeding may be due to an imbalance of the pituitary and ovarian hormones, but it may also be the result of local disease of the pelvic organs. This local disease may be inflammation due to infection; it may be a benign tumour such as a fibromyoma, or fibroid; it may be a polyp, or projecting mass of endometrium; or it may be a cancer, especially after age 35. Some types of local pelvic disease may require removal of the uterus or treatment by irradiation but polyps and some fibroids can be removed without loss of the uterus.

Irregular or excessive bleeding often results from emotional disturbance; this type of abnormality tends to disappear spontaneously.

As the menopause approaches, extremely heavy bleeding may occur, causing anemia, tiredness, and ill health. Menorrhagia in this instance is due to overdevelopment of the endometrium as a result of excessive or unbalanced action of estrogens. Younger or childless women can be treated with progestogens; for others removal of the uterus may be necessary.

Bleeding between periods or after intercourse is frequently due to some abnormality of the cervix; in women who have borne children the possibility of cancer must be borne in mind. Such bleeding may also come from a simple polyp on the cervix or a cervical erosion. The latter is a rather common condition in which the glandular lining of the canal of the cervix extends out onto its surface. Treatment is often unnecessary, but erosions are easily dealt with by cauterization. Polyps require removal.

Irregular bleeding also may occur during pregnancy when there is danger of abortion; if any menstrual periods have been missed this possibility must be considered.

Amenorrhea

Amenorrhea, or absence of menstruation, is normal during pregnancy and for a variable time after delivery. If the mother is breast-feeding her baby, as much as six months may pass before return of menstruation; earlier return of menstruation is not abnormal and is to be expected if the mother is not producing milk. Pregnancy is the commonest cause of amenorrhea during the reproductive years.

The term primary amenorrhea refers to the absence of menstruation in a woman who has never previously menstruated. In rare cases, primary amenorrhea is due to gonadal dysgenesis, the failure of the ovaries to develop normally, and may be associated with chromosomal abnormalities. Instead of the normal female complement of 46 chromosomes in each cell, including two X-chromosomes, a patient may have only one X-chromosome, or even a male pattern of an X- and a Y-chromosome (see BIRTH DEFECTS AND CONGENITAL DISORDERS). In such persons the uterus and tubes often are absent, although the general physique may be female.

Even with normal ovaries, absence of the uterus occasionally occurs. A less rare abnormality is vaginal atresia, or closure, an obstruction of the vagina by a membrane just above the level of the hymen; menstruation occurs, but the discharge cannot escape and distends the vagina. This condition, called false amenorrhea or cryptomenorrhea, is easily corrected by an incision in the membrane.

Cessation of periods after menstruation has been established, but before the normal time for the menopause, is usually the result of some general illness, some emotional disturbance, or a psychiatric illness. It may also be due to disease of the endocrine system, not only of the pituitary gland but of other endocrine glands as well. Secondary amenorrhea results if the ovaries are removed or are irradiated but is unlikely to be caused by ovarian disease, as both ovaries would have to be totally destroyed to stop all function. There is a functional disorder of the ovaries, described by I.F. Stein and M.L. Leventhal, in which production of estrogens is disturbed. Symptoms of this disorder include abnormal growth of facial hair because of abnormal androgenic—that is, masculinizing—activity. An ovarian tumour, arrhenoblastoma, that secretes an-

drogenic hormone, is another extremely rare cause of amenorrhea and abnormal growth of hair.

Most cases of secondary amenorrhea are temporary, and spontaneous improvement is to be expected, especially when the cause is some general illness or emotional disturbance. Treatment of amenorrhea serves no purpose unless pregnancy is ultimately desired and is possible. The feasibility of treatment with hormones is determined by a general medical examination and a complete pelvic examination, including various hormonal assays and inspection of a specimen of endometrium.

In some women who complain of infertility but apparently have normal periods, it has been found that the cycles are anovular. Estrogens are produced in each cycle in amounts sufficient to cause endometrial proliferation, but ovulation does not occur and the corpus luteum is not formed, so that there is no secretion of progesterone. The endometrium breaks down and bleeds in each cycle as the estrogens are withdrawn. Cycles of this type occur in women who are using oral contraceptives.

A simple way to determine whether ovulation is occurring is to record the woman's early morning temperature daily. In a normal cycle the temperature is about 0.5° C lower in the first than in the second half of the cycle, and the rise in temperature occurs at the time of ovulation. No rise occurs in anovular cycles. Another test is to remove and inspect a fragment of endometrium in the late part of the cycle; if microscopic examination shows that normal secretory changes are present ovulation must have taken place.

In persons with anovular cycles and in some with amenorrhea it is now possible to induce ovulation by injection of FSH or of a synthetic drug, clomiphene, followed by injection of a luteinizing hormone.

## Mental Health and Hygiene

Since the founding of the United Nations the concept of mental health has achieved international acceptance. As defined in the 1946 constitution of the World Health Organization, "health is a state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity." The term mental health represents a variety of human aspirations: rehabilitation of the mentally disturbed, prevention of mental disorder, reduction of tension in a conflict-laden world, and attainment of a state of well-being in which the individual functions at a level consistent with his mental and physical potentials. As noted by the World Federation for Mental Health, the concept of optimum mental health refers not to an absolute or ideal state but to the best possible state insofar as circumstances are alterable. Mental health is regarded as a condition of the individual, relative to his capacities and to his social-environmental context. Mental hygiene includes all measures taken to promote and to preserve mental health. Community mental health refers to the extent to which the organization and functioning of the community determines, or is conducive to, the mental health of its members.

### HISTORY OF TREATMENT

Throughout the ages the mentally disturbed have been viewed with a mixture of fear and revulsion. Their fate generally has been one of rejection, neglect, and ill treatment. Though, in medical and biblical writings there are ancient references to mental disturbance that display views very similar to modern humane attitudes; interspersed in the same literature are instances of socially sanctioned cruelty based upon the belief that mental disorders have supernatural origins such as demonic possession. Even reformers sometimes used harsh methods of

Menstruation without discharge of an ovum

treatment; for example, Benjamin Rush (see below) endorsed the practice of restraining mental sufferers with his once notorious "tranquilising chair."

**Early institutions.** The history of care for the mentally ill reflects man's cultural diversity. The earliest known hospitals in the Arab world were established in Baghdad (AD 918) and in Cairo with that special consideration traditionally given disturbed people, the "afflicted of Allāh." Some contemporary African tribes benignly regard hallucinations as communications from the realm of the spirits; among others, Hindu culture shows remarkable tolerance for what is considered to be bizarre behaviour in Western societies. Belief in demonic possession reached its height during a prolonged period of preoccupation with witchcraft (15th through 18th century) in Europe and in colonial North America.

So-called madhouses such as Bedlam (founded in London in 1247) and the Bicêtre (the Paris asylum for men) were typical of institutions in which sufferers were routinely shackled during the 18th century. Inmates of these places often were believed to be devoid of human feeling and their management was indifferent if not brutal; the primary consideration was to isolate the mentally disturbed from ordinary society. In British colonial America, mentally deranged persons frequently were auctioned off to be cared for (or exploited) by farmers; some were driven from towns by court order, and others were placed in almshouses. Only after more than a century of colonization was the first colonial asylum for the insane established in Williamsburg, Virginia, in 1773. In the 1790s, the French reformer Philippe Pinel scandalized his fellow physicians by "striking the chains" from 49 inmates of the Bicêtre. At about the same time, William Tuke, a Quaker tea and coffee merchant, founded the York (England) Retreat to provide humane treatment. Benjamin Rush, the physician-signer of the Declaration of Independence, also advocated protection of the rights of the insane. Despite this progress, more than half a century of independence passed in the U.S. before Dorothea Dix, a teacher from Maine, discovered that in Massachusetts the insane were being jailed along with common criminals. Her personal crusade in the 1840s led to a flurry of institutional expansion and reform in her own country, in Canada, and in Great Britain.

While these pioneering humanitarian efforts tended to improve conditions, one unplanned result was a gradual emphasis on centralized, state-supported facilities in which sufferers were sequestered, often far from family and friends. Largely kept from public scrutiny, the unfortunate inmates of what fashionably were being called mental hospitals increasingly became victims of the old forms of maltreatment and neglect.

**Modern approaches.** The modern mental-health movement received its first impetus from the energetic leadership of a former mental patient in Connecticut, Clifford Whittingham Beers. First published in 1908, his account of what he endured, *A Mind That Found Itself*, continues to be reprinted in many languages, inspiring successive generations of students, mental-health workers, and laymen to promote improved conditions of psychiatric care in local communities, in schools, and in hospitals. With the support of prominent persons, including distinguished professionals, Beers in 1908 organized the Connecticut Society for Mental Hygiene, the first association of its kind. In its charter, members were charged with responsibility for the same pursuits that continue to concern mental-health associations to this day: improvement of standards of care for the mentally disturbed, prevention of mental disorder and retardation, the conservation of mental health, and the dissemination of sound information. In New York City less than a year later, on February 19, 1909, Beers led in forming the National Committee for Mental Hygiene, which in turn was instrumental in organizing the National Association for Mental Health in 1950.

While philosophic and scientific bases for an international mental-health movement were richly available, Beers seems to have served as a catalytic spark. Charles Darwin and his contemporaries already had shattered traditional

beliefs in an immutable human species with fixed potentialities. By the time Beers began his public agitation, it was beginning to be understood that developing children need not suffer some of the crippling constraints imposed on their parents. A newly emerging scientific psychology had revealed some of the mechanisms by which the environment had its effects on individual adjustment, fostering hopes that parents and community could provide surroundings that would enhance the growth and welfare of children beyond levels once thought possible. In this spirit, the mental-health movement early inspired the establishment of child-guidance clinics and programs of education for parents and for the public in general.

Psychiatric and psychological developments during and after World War I provided fresh impetus to the movement. Over the same period, the European development of psychoanalysis, initiated by Sigmund Freud in Vienna, placed heavy emphasis on childhood experiences as major determinants of psychiatric symptoms and led worldwide to increasing public awareness of psychological and social-environmental elements as primary factors in the development of mental disorders.

**International.** Beers formed an International Committee for Mental Hygiene in 1919. By 1930, the time of the First International Congress of Mental Hygiene in Washington, D.C., there were mental-hygiene societies in 25 countries. In London at the third international congress in 1948, the World Federation for Mental Health was formed. By 1970 it had more than 160 member associations in more than 50 countries. It provides consultants and shares informal reciprocal functions with several United Nations agencies, including the World Health Organization (in which a mental-health unit was established in 1949). The federation has convened international study groups and expert committees, held regional and international meetings, and developed close contacts with mental-health workers in more than 100 countries. The 20th anniversary of the federation was celebrated at the Seventh International Congress of Mental Health in London in 1968. The public throughout the world is aware of mental health as a major social issue. In almost every country there is increasing recognition of the interrelationship between mental health, population pressures, and social unrest. With growing urgency, people almost everywhere seek to promote mental health and to educate the public to pursue conditions conducive to individual growth and peaceful development.

**National.** For more than a century before World War II, the mental hospitals of many countries had been the responsibility of local government. Under the British National Health Service Act of 1946, however, the task of providing hospital care fell almost completely on the national government through boards of hospital administration acting as regional agencies for the Ministry of Health. In the same year, existing privately supported mental-health organizations combined to form the (U.K.) National Association for Mental Health. This voluntary national group provides resident facilities for disturbed persons, offers follow-up services, and trains mental-health personnel, in addition to carrying on educational programs. The Mental Health Act of 1959 nullified earlier British laws governing policies toward psychiatric disturbance and retardation. The act provided that a person requiring treatment for a psychological disorder could obtain it in a hospital on the same basis as any medical complaint. Community mental-health services were placed under the jurisdiction of local health authorities working in close association with hospital and outpatient centres. British research into mental-health problems is mainly under the direction of the government-financed Medical Research Council.

Provisions for treating and caring for mentally disturbed persons and for encouraging mental hygiene are generally organized in this manner over most of the continent of Europe. In such countries as the Soviet Union, the state, either through the central or regional governments, has the task of providing and maintaining facilities for disturbed or retarded persons. In other European countries, including members of the Common Market, government

health laws

shares its mental-health function with religious groups or with other nongovernmental agencies. Many innovative mental-health services have been initiated in Europe, including the concept of integrated community services, the use of tranquilizing drugs, the sheltered workshop, and the employment of nonprofessional workers in positions of responsibility.

Imported European ideas combined with the traditional reliance on self-improvement and adjustment already present in Canadian and U.S. culture to give the mental-health movement in those countries additional momentum in the 1930s and early 1940s.

World War II and the postwar problems of returning veterans stimulated further public interest in mental health. The mental-health movement and the mass media discovered each other, and a flood of exposés swept Canada and the U.S., notably Albert Deutsch's *The Shame of the States* in 1948. Published in 1946, Mary Jane Ward's *The Snake Pit* became a Hollywood film success, followed by many more honestly realistic portrayals of mental problems on screen and television. A psychodynamic approach to the understanding and guidance of children infused North American popular culture. The introduction of pharmacotherapy (e.g., tranquilizing and mood-elevating drugs) stimulated further progress.

In 1946 the passage of the National Mental Health Act in the U.S. made possible the creation of the National Institute of Mental Health (NIMH) in 1949 within what became the Department of Health, Education, and Welfare. State hospital systems were reorganized with increased budgets, while significant federal funds were made available for research, training, and clinical facilities. NIMH is the major funding resource in the U.S. for basic and applied research in mental health and in the behavioral sciences, for demonstration projects, and for the training of mental-health professionals. It has developed special programs in a broad range of social problem areas, from drug addiction to suicide prevention. The National Clearinghouse for Mental Health Information, operated by NIMH, is a valuable resource, as is the periodical publication *Mental Health Digest*. Additional sources of support for mental health in the U.S. include the National Institute of Child Health and Human Development, the Veterans Administration, the Office of Education, the Social and Rehabilitation Service, the National Science Foundation, and the medical sections of the Department of Defense. Charitable foundations also have provided generous support over the years. Meanwhile, the National Association for Mental Health continues to grow; by 1970 more than 800 state and local associations were affiliated with the association, bringing to more than 1,000,000 the number of volunteers in the mental-health movement in the U.S.

The situation in Australia and New Zealand is similar to that of North America and Europe. Developments in Latin America, Africa, and Asia commonly have been hampered by a shortage of trained institutional staff members and of local sources of support. In many so-called developing countries, mental health and hygiene depend heavily on missionaries, intergovernmental aid programs, and the efforts of agencies of the United Nations.

#### PREVALENCE AND TYPES OF MENTAL DISTURBANCE; TREATMENT

Few countries provide reliable statistics on which to base valid judgments concerning the prevalence of mental disorder or of emotional instability. As a result, there are considerable difficulties in comparing the actual incidence of psychiatric problems in different geographic areas and at various levels of society throughout the world. Reports of the World Health Organization do suggest, however, that the per capita incidence of severe or major mental disturbance (psychosis) is much the same in most countries. While some varieties of mental distress may manifest symptoms related to specific cultures (e.g., Haitian voodoo bewitchment), the relative number of people likely to develop signs of schizophrenia, for example, does not seem to vary significantly from one population group to another (see PSYCHOSES).

Much has been written about an alleged increase in anxiety and in other neurotic symptoms (see PSYCHONEUROSES) both in the highly industrialized nations and in those developing lands where professional mental-health manpower is very scarce. It may be understandable that under the changing culture patterns of any country, psychotic conditions may seem to be occurring more frequently, but it has also been suggested that these are simply being recognized more often. Previously, persons suffering even major mental disturbance could remain in large family or tribal groups, thus escaping official attention.

One of the commonest factors invoked as a producer of pathological anxiety is fear of failure. Faster communication, new industries, and mechanized agriculture bring stresses with them that seem to lead to anxiety. In many regions of the world there is additional psychiatric strain as tribes or other groups shift from economies based on barter to those founded on money.

The quality of mental-health facilities is variable throughout the world. Contemporary improvements include the introduction of day hospitals, where patients still living at home can be treated during ordinary working hours in a pleasant and welcoming atmosphere; the provision of night hospitals for those working in the community; and growing experience with transient facilities such as "halfway" houses for partially treated drug addicts, as well as outpatient clinics and vocational rehabilitation. These developments have led in many countries to much greater demand for earlier treatment; typically the result has been the rapid return home of about 75 percent of people admitted to hospitals for the first time.

**Children and youth.** The mental-health movement long has fostered the establishment of better services for children. In the U.S., with the support of congressional funds, a Joint Commission on Mental Health of Children was organized in 1965. In its 1970 report, *Crisis in Child Mental Health: Challenge for the 1970's*, the commission noted a large number of emotionally disturbed children in the U.S. who need care. It viewed as a "national tragedy" the lack of any unified commitment to children and youth. The tendency "to rely on a proliferation of simple, one-factor, short-term and inexpensive remedies and services" was deplored. To alter this situation, the commission called for a "commitment to change" to bring about a truly "child-oriented society."

As part of its work, the commission surveyed worldwide practices in mental-health care. What emerged from the information gathered was that in most advanced countries of the world child mental-health services are an integral part of, or are closely affiliated with, formal health and welfare programs. These usually are perceived as being more of a public than a private or voluntary responsibility. The expenditure of government monies for children's services is widely accepted, generally in addition to any programs sponsored by private sick-benefit insurance funds. In the U.S. there exists a confusing array of overlapping and professionally competitive mental-health services. Most Scandinavian nations, Israel, Great Britain, The Netherlands, and the socialist countries of eastern Europe, present a different picture. Mental-health services are planned on a nationwide basis, with integration and coordination on the local level. By contrast, in the U.S. rarely is there a central organizing authority with power to coordinate the maze of local or regional programs or to cut through a complex network of eligibility requirements. County services compete with city services, and private agencies vie with state facilities; schools often are self-isolating, and county chapters of professional organizations seldom participate in planning integrated community services.

By comparison, in many other developed countries, a broader and better integrated range of services is more readily available to all socio-economic strata of the population. Greater responsibility and status are accorded to members of the child-care staff who have limited formal qualifications. There is less emphasis on formal evaluation or cost and more concern with finding practical solutions to immediate problems. Perhaps most noteworthy

Mental-health training and research

World-wide practices

is a considerable emphasis on the therapeutic meaning of work and on vocational training of adolescents. Industrial workshops are fully staffed and supervised, and institutional training and work assignments are made meaningful; there is no "make-do" work.

Responsibility for disturbed children in western and northern Europe varies by law and by custom. At one pole is Switzerland, which takes a position most similar to that of the U.S. in emphasizing individual responsibility in choosing and in paying for private services; the family is viewed as the primary social unit, and the state is relegated to a minor role in mental health and hygiene. At the opposite pole is Denmark, where the state assumes almost the complete burden of seeing to the economic and social well-being of its citizens. In Denmark the state can and does assume the functions of parents; local councils examine evidence of parental neglect and are empowered to prescribe a course of action after parents are given a hearing.

In sharp contrast with current U.S. practice are those welfare-oriented, sometimes collectivist societies that have established central planning, state-directed coordination of mental-health services, including some control over manpower training and placement, coupled with a strong tradition of comprehensive social security and sick-benefit insurance. These tendencies are increasingly displayed along a continuum that includes The Netherlands and the United Kingdom, through the Scandinavian countries and Israel, to the managed economies of the socialist countries of eastern Europe and Asia.

Particularly informative are reports prepared by the 1967 U.S. Mission on Mental Health to the Soviet Union. These describe an elaborate array of services that has been developed in the Soviet Union, including creches, nurseries, boarding schools, forest schools, sanitariums, and invalid houses. Children are accommodated days, evenings, or on a residential basis. After a mother delivers her child to the facility, the district children's "poli-clinic" is immediately notified by the hospital. These district polyclinics are the medical hub of all services for children; there is one in each Soviet district serving approximately 15,000 children. They also provide most of the medical and mental-health services for kindergarten and school children, including physical and psychological examinations. When he grows older, the Soviet child and his record are transferred to centres for adolescents or adults, including the aged. With this procedure, continuity of service is maintained; waiting lists are rare; and there is no need to initiate new records at every health agency consulted during the individual's life.

The U.S. mission to the Soviet Union noted a continuing Soviet effort to identify gaps in services and to fill them by swelling the ranks of existing medical and supporting personnel and by increasing the number and variety of facilities. Delivery of health care was observed to be a highly organized process, functioning through a coordinated network of prevention-oriented, readily available, and geographically accessible services, free of cost to all Soviet citizens. The mission reported a strong social commitment to the needs of children in the hierarchy of Soviet values.

**Juvenile delinquency.** Among the most baffling social maladies of the 20th century is that of juvenile delinquency. A worldwide phenomenon, it varies in quality and frequency from country to country. Again, the U.S. seems unique, showing at least one significant difference between its juvenile statistics and those of other countries. Nearly everywhere else, a youngster is taken into court only if charged with breaking a law that also would define a crime when violated by an adult. In the U.S., legal definitions of juvenile delinquency have become so all-encompassing that children enter official statistical records for such "offenses" as truancy from school, stubbornness, leaving home, and curfew violations.

Despite extensive surveys and reports, a precise estimate of the extent to which mental-health principles actually have been applied to work with delinquent youth does not seem feasible. Efforts in this direction vary considerably among countries and among types of institutions within

any given nation, and nearly all who are concerned with problems of delinquency reflect dissatisfaction with progress made so far. Workers in countries that have relatively high ratios of staff to inmates in institutions for treating delinquents and that boast a comparatively extensive complement of mental-health specialists are no more content than are their counterparts in countries still aspiring to such levels of effort.

Well-intentioned endeavours had limited effect on a rising worldwide rate of juvenile delinquency in the 1970s. The mere construction of housing developments and playgrounds, the organization of boys' clubs, reduction in the number of working mothers, the mending of broken homes, and the widespread use of child-guidance clinics failed to show far-reaching effects. Still unsatisfactory but more encouraging experiences reported from some countries suggest that some results can be obtained by providing meaningful jobs; by lowering the age at which some children can leave academically oriented schools to enter vocational training programs; and by improving and expanding the work of police, parole, and volunteer agencies with youngsters. Regardless of local legal definitions of delinquency, there appears to be an international consensus that correctional institutions should stress rehabilitation and therapy, rather than punishment. There is, nevertheless, considerable evidence of wide divergence between institutional aspirations and actual practices in terms of requests for staff and operating personnel and in the application of new concepts of treatment.

Often enough, promising methods for rehabilitating delinquents have been developed locally by highly motivated groups of workers, but they have failed to inspire imitative programs either in their own country or abroad. Though change may be advocated by administrators of facilities for youthful offenders, those involved in daily operations tend to be more concerned with problems of inmate control and restriction. Change is feared in itself and often is misunderstood. Neither a growing variety of available services nor an increasing sophistication in pioneering programs seemed to have a marked effect on the worldwide rise in delinquency.

**Group care.** A major issue facing mental-health specialists and others entrusted with caring for children is the so-called deprivation syndrome, a combination of intellectual retardation, personality defect, and social maladaptation. The syndrome generally is found among children who are deprived of nutritional and other environmental elements necessary for normal growth and development, usually in association with gross social disturbance in the community.

Worldwide evidence reflects the predictable results of economic deprivation and maternal ill health, of poor prenatal and infant care, and of malnutrition. Numerous studies have shown personality defects and delinquent behaviour patterns to be especially common among deprived youth. Such children tend to receive little intellectual stimulation at home; often barely motivated to attend school, they commonly are crowded into inadequate classrooms. They are likely to live in enclaves of decay, neighbourhoods rich only in opportunity for trouble and characterized by values and ethical standards often in conflict with those of dominant surrounding culture.

Many of these children contribute to the statistics on delinquency and disorder; they become premature and inadequate parents themselves and impose similar lives of deprivation on a succeeding generation. To stop this pernicious cycle, increasing consideration is being given in almost all modern societies to substitutes for parental care. The Western world, strongly influenced since the turn of the century by Freudian concepts and laissez-faire philosophy, has leaned toward parental substitution in the form of individual child care in foster homes. Manpower shortages, a scarcity of housing, and considerable employment of mothers in agriculture and industry have combined with ideological considerations to favour the practice of group care in the predominantly Roman Catholic lands of Europe and Latin America, in Israeli collective settlements (*kibbutzim*), and in socialist societies of Asia and eastern Europe.

Mental-health practices in the Soviet Union

Deprivation syndrome

Infant  
group care

Under some group-care programs, newborn infants are placed directly in residential institutions; e.g., in special facilities established for the babies of graduate students at Soviet universities. Children of working parents may spend five days a week in an institution and the weekend at home. Other youngsters go directly to the nursery from about three months of age onward and continue in day care throughout their preschool years. While the concept of infant group care remains a subject of controversy, its proponents hold that it might well open the way for breaking the vicious circle that perpetuates damage to mental health. Socio-economic and cultural deprivation are widespread even in some of the most industrially advanced countries; for example, nearly a quarter of all children in the United States are reported to suffer these conditions.

**Manpower problems.** A shortage of professional and nonprofessional mental-health and child-care workers is recognized almost everywhere. In some countries, it is particularly acute in residential facilities for emotionally disturbed, culturally deprived, or delinquent youngsters. The treatment model in most North American children's centres places primary emphasis on diagnosis and group and individual therapy conducted by professional workers.

Unfortunately, those professionals who have the least contact with the daily lives of children tend to accumulate the highest status and rewards and to exercise major control over therapy; those who deal most closely with the children and with their immediate behaviour frequently receive the least formal recognition for their work. While child-care workers as a group enjoy minimal prestige in the U.S., newer, more respected roles have emerged more rapidly in Europe.

Particular attention has focussed on professionals called *éducateurs* in France and on persons identified as *orthopedagogues* in The Netherlands. By 1970 the training of *éducateurs* had been well developed in France for more than two decades. The graduate *éducateur* is in considerable demand throughout Europe; he is recognized as a representative of an independent discipline that is not subordinate to medicine, psychology, social work, or education. His training does not stress diagnosis or therapy; neither is he a teacher who is expected to raise a maladjusted child to a particular academic level; nor is he a houseparent or attendant preoccupied with policing the behaviour of his wards. Rather, the *éducateur* is a highly trained professional youth worker who is assigned primary concern for the total life process of individual children with whom he works. He is expected to stimulate, during the child's leisure time, activities that will facilitate physical, moral, social, and intellectual development.

In many institutions for disturbed youngsters (in France and elsewhere on the Continent), *éducateurs* are the central adult figures in the lives of the children. Deeply involved in day-to-day re-education and resocialization, *éducateurs* work in and frequently manage institutions for such maladapted children as delinquents, the mentally retarded, the physically handicapped, the socially and emotionally disturbed, and the homeless and neglected.

They also are trained to function as street workers in slum areas. These functions are applied to integrate the traditional professional roles of psychiatrists, psychologists, social workers, and teachers who may operate within an institution under the daily management and leadership of an *éducateur-directeur* and his *éducateur* colleagues.

During the 20 years after 1950 there was more socio-economic and technological change in the Western world than there had been in the previous century and a half; and during those 150 years more change occurred than had occurred in the preceding 2,000. The rate of change seems likely to accelerate even more. In North America especially, statistics demonstrate starkly that existing systems for organizing and delivering mental-health care, typically demanding individual payment for services, are outmoded and that they fail to meet the health, education, and welfare requirements of millions of children. There are differing approaches and ideologies in diverse geo-

graphic regions; however, no one country, no one profession, and no one ideology has a monopoly on innovative programs.

For additional details on the mental-health problems of the aged see also HEALTH AND SAFETY LAWS; HEALTH AND DISEASE, ECONOMICS OF; and OLD AGE, SOCIAL ASPECTS OF: *The aged individual*.

**BIBLIOGRAPHY.** C.W. BEERS, *A Mind That Found Itself: An Autobiography* (1908); A. DEUTSCH, *The Mentally Ill in America: A History of Their Care and Treatment from Colonial Times* (1937); and N. RIDENOUR, *Mental Health in the United States: A Fifty Year History* (1961), are good historical references. The concept of mental health is well discussed in M. JAHODA, *Current Concepts of Positive Mental Health* (1958). The wide scope of mental health is delineated in A. DEUTSCH (ed.), *The Encyclopedia of Mental Health* (1963). Of special interest are the report of the JOINT COMMISSION ON MENTAL HEALTH OF CHILDREN, *Crisis in Child Mental Health: Challenge for the 1970s* (1970); and the chapter by R.N. SANFORD on the prevention of mental illness in B.B. WOLMAN (ed.), *Handbook of Clinical Psychology* (1965). For international trends in mental health, see H.P. DAVID, *International Resources in Clinical Psychology* (1964), *International Trends in Mental Health* (1966), and *Child Mental Health in International Perspective* (1971). The U.S. DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE issued a report on *The First U.S. Mission on Mental Health to the U.S.S.R.* (1969). Topical reference lists are available from the National Association for Mental Health, New York; and from the National Institute of Mental Health, Rockville, Maryland.

(H.P.D.)

**Mercator, Gerardus**

Gerardus Mercator, the greatest cartographer of the 16th century, produced maps and globes that exhibited the best scientific knowledge of his time, and were so well-designed that they remain a pleasure to the eye today. His achievement rested on a unique combination of qualities: a thorough knowledge of mathematics and land-surveying; competence in astronomy and instrument-making; the ability to seek out, digest, and apply reliable information; and a consummate talent for graphic design, engraving, and calligraphy. He developed the technique known today as "Mercator's projection" for drawing the map of the world, and invented the term "atlas" for a collection of maps.

Copyright Bibliothèque Royale Albert Ier, Bruxelles, Reserve Precieuse, (VH 14.348 C L.P.)

Mercator, portrait attributed to H. Goltzius, 1574. In the Bibliothèque Royale Albert Ier, Brussels.

Mercator was born on March 5, 1512, at Rupelmonde in Flanders, of a German family that had recently moved from that country. The family name was probably de Cremer, but Mercator invariably used the Latinized ver-

sion. His formal education began at a school of the Brothers of the Common Life at 's Hertogenbosch, where he received training in Christian doctrine, dialectics, and Latin. In 1530 he entered the University of Louvain (Belgium) to study the humanities and philosophy and graduated with a master's degree in 1532.

Religious doubts assailed him about this time, for he could not reconcile the biblical account of the origin of the universe with that of Aristotle. After two years of study which led him to Antwerp and Mechelen he emerged from his personal crisis, fortified in his faith, with less enthusiasm for philosophical speculation. Moreover, he brought back to Louvain a freshly acquired taste for geography, which may have been inspired by conversations with scholars in Mechelen, and he may have studied engraving at Antwerp, where good copper plates were manufactured.

A poor youth who had to make his way in life unaided, Mercator now immersed himself in study, often neglecting food and sleep. Under the guidance of Gemma Frisius, the leading theoretical mathematician in the Low Countries, who was also a physician and astronomer, Mercator mastered the essentials of mathematics, geography, and astronomy. Frisius and Mercator also frequented the workshop of Gaspar a Myrica, an engraver and goldsmith. The combined work of these three men soon made Louvain an important centre for the construction of globes, maps, and astronomical instruments. In 1534 Mercator married Barbara Schellekens, by whom he had six children.

By the time he was age 24, Mercator was a superb engraver, an outstanding calligrapher, and a highly skilled scientific-instrument maker. In 1535-36 he cooperated with Myrica and Frisius in constructing a terrestrial globe, and in 1537 its celestial counterpart. Here, for the first time, may be seen the free and graceful italic lettering with which Mercator was to change the face of 16th-century maps. He now began to build his reputation as the foremost geographer of the century with a series of printed cartographic works: in 1537 a map of Palestine, in 1538 a map of the world on a double heart-shaped projection, and about 1540 a map of Flanders. In 1540 he also published a concise manual on italic lettering, the *Literarum Latinarum quas Italicas cursoriasque vocant scribende ratio*, for which he engraved the wood blocks himself. He produced a terrestrial globe in 1541 and a celestial globe in 1551.

Mercator's career was interrupted suddenly in 1544 when he was arrested and imprisoned on a charge of heresy. His inclination to Protestantism, and frequent absences from Louvain to gather information for his maps, had aroused suspicions; he was one of 43 citizens trapped in this affair. But the university authorities stood behind him, and he was released after seven months. Mercator was able to resume his former way of life. He obtained a privilege to print and publish books, and was free to continue his scientific studies, such as his calculations concerning magnetic variation.

In 1552 Mercator moved permanently to Duisburg in the Duchy of Cleve (now in West Germany). One attraction was the more tolerant religious attitude in Germany. Another was a possible appointment as professor at a university Duke Wilhelm was planning. Soon he became a well-known figure, for he was frequently called upon to give professional opinions in land disputes, and he assisted the Duke in establishing a grammar school by helping to design its curriculum. After establishing a cartographic workshop and engaging his own engravers, he was able to return to his lifework.

In 1554 he published a map of Europe that he had begun at Louvain, and between 1559 and 1562 he further assisted the Duke by teaching mathematics in the grammar school. During these busy years he also undertook genealogical research for the Duke, drew up a Concordance of the Gospels, and composed a detailed commentary on the first part of the Letter of Paul to the Romans. In 1564 he completed a map of Lorraine (now lost) and another of the British Isles. Public recognition of his accomplishments came in 1564 with his appointment as court "cos-

mographer" to Duke Wilhelm of Cleve, to whom Mercator dedicated some of his works. During these years he perfected his cylindrical projection, which enabled mariners to steer a course over long distances by plotting straight lines without continual adjustment of compass readings. This technique immortalized his name in the "Mercator projection," which he used on his map of the world in 1569.

Mercator now embarked on a series of publications to realize his long-planned design of describing the creation of the world and its subsequent history. He called his new work his *Atlas (Atlas sive Cosmographicae meditationes de Fabrica Mundi et fabricati figura)*—the term still used today for a collection of maps—for he saw in the Greek demigod a symbol of the study of celestial and terrestrial events. He planned, however, something more ambitious than a useful collection of maps such as those published in 1570 by Abraham Ortelius, who had acted on his suggestion. But Mercator's ambitious scheme was never completed.

In 1569, as the first section, he published a chronology of the world from the Creation to 1568. He then published 27 of the maps originally prepared by the Greek geographer Ptolemy, with corrections and commentary in 1578, under the title *Tabulae Geographicae C. Ptolemei ad mentem auctoris restituae et emendatae*. The next part of the *Atlas*, consisting of a set of new maps covering France, Germany, and the Netherlands, came out in 1585, with maps of Italy, "Sclavonia" (now the Balkan countries) and Greece following in 1589. A last section, on the British Isles, was included in an edition with the previous sections, which was seen through the press after his death by his son in 1595. Another printing followed in 1602, and further maps were added in a subsequent edition of 1606, usually known as the "Mercator-Hondius Atlas."

A contemporary described Mercator as a highly respected citizen of Duisburg, a hardworking, modest, and frugal man, fond of serious conversation, yet congenial and witty when the occasion called for it and a good neighbour who always helped the poor. Mercator suffered a series of strokes beginning in 1590, which led to his death in 1594.

**BIBLIOGRAPHY.** GUALTERUS GHYMMIUS (WALTER GHIM), *Vita . . . Gerardi Mercatoris* (1595), the principal original source for Mercator's life; J. VAN RAEMDONCK, *Géard Mercator, sa vie et ses oeuvres* (1869), a biography now out of date but still worth consulting; H. AVERDUNK and J. MUELLER-REINHARD, *Gerhard Mercator* (1914), the standard full-length biography (in German); *Correspondance Mercatorienne*, ed. by M. VAN DURME (1959), the only complete collection of Mercator's letters—inaccurate in some details; *Duisburger Forschungen*, vol. 6 (1962), a collection of essays to mark the 450th anniversary of Mercator's birth that is essential reading, especially de Smet's contribution on Mercator's activity at Louvain; A.S. OSLEY, *Mercator* (1969), a work dealing with Mercator as calligrapher, containing facsimile and English translation of Mercator's writing-book, English translation of Ghim's *Vita*, and a general bibliography. De Smet's article in *Catalogus van de mercatorverzameling van de Oudheidkundige Kring van het Land van Waas te Sint-Niklaas* (1971, in Flemish), is also valuable.

## Mercury

Mercury, designated ☿ in astronomy, the planet closest to the Sun, revolves around it in a flood of sunlight. Its average distance from the Sun is 58,000,000 kilometres, compared with 150,000,000 kilometres for the Earth, and therefore it always appears close to the Sun. Its greatest elongation (angular distance from the Sun), 27° 45', occurs only near aphelion (when it is furthest from the Sun). The brightness of the daytime sky prevents Mercury from being seen with the naked eye except as a morning "star," just before sunrise, or as an evening "star," just after sunset. At these times Mercury is never far from the horizon, and the long optical path through mist and haze compounds the difficulties of observation. As the orbit of Mercury is interior to the Earth's, the planet exhibits phases, as do Venus and the Moon, during its 88

(Earth) day period of revolution about the Sun. Near inferior conjunction (when it is at its closest approach to the Earth, some 92,000,000 kilometres on the average) it may be seen through the telescope as a thin crescent, some 6" (seconds of arc) in angular extent. At greatest elongation the apparent disk of Mercury is half-illuminated. At superior conjunction (when the planet, the Sun, and the Earth are practically in line and the fully illuminated face of Mercury is most distant) it has its smallest angular diameter, 2" or 3", compared to 1,800" for the Moon. The planet is so difficult to observe as a naked-eye object that there is a story (probably apocryphal) that Nicolaus Copernicus, who devised a self-consistent heliocentric theory of planetary motions before the invention of the telescope, regretted on his deathbed only that he had never seen the planet Mercury. Probably no more than a few dozen people have ever seen the surface features of Mercury through a telescope, and photographs showing reliable surface detail on Mercury are still extremely rare.

Mercury was known as a planet in Sumerian times in the 3rd millennium BC. In classical Greece, as a morning star designated Apollo, it was distinguished from its apparition as an evening star designated Hermes, the Greek equivalent of the Roman Mercury. That these two apparitions were of the same body was known to classical astronomers; Heraclitus, a pre-Socratic Ionian philosopher, used the small angular elongations of Mercury and Venus from the Sun to argue that these two planets revolved about the Sun and not the Earth—an important forerunner of the Copernican theory.

Next to that of Pluto, Mercury's orbit among the planets departs most markedly from a circle, with an eccentricity of 0.2056. It is at 46,000,000 kilometres from the Sun at perihelion (closest approach to the Sun) and recedes to 70,000,000 kilometres from the Sun at aphelion. The average orbital speed is 48 kilometres per second, somewhat less near aphelion, somewhat more near perihelion. Mercury is named appropriately after the fleet messenger of the gods.

**Mass and radius.** The inclination of its orbit to the invariable plane of the solar system is 7°, the second largest for any planet, after Pluto. Mercury's diameter, measured optically, is around 4,840 kilometres, but more reliable radar measurements make it  $4,868 \pm 2$  kilometres. Mercury is the smallest planet in the solar system, with the possible exception of Pluto. The innermost and outermost planets thus share aberrant qualities. Mercury is only a little larger than the Moon and is comparable in size to the largest moons of Jupiter, Saturn, and Neptune. A planet's mass is usually calculated from the orbits and speeds of its satellites or its perturbing effects on the orbits of other planets. Mercury has no satellite, and its small mass hardly disturbs the orbits of other planets; the best determination of its mass has been made from the perturbations it has caused in the orbit of the minor planet (asteroid) Eros, which sometimes passes relatively near Mercury. Mercury's mass is  $3.2 \times 10^{26}$  grams, or 0.054 times the mass of the Earth.

The escape velocity—the speed that any object, molecule or space vehicle, must have to escape from a planet's gravitational field—at the surface of Mercury, calculated from the mass and radius, is 4.2 kilometres per second (compared with 11.2 kilometres per second for escape from the Earth). The low escape velocity on Mercury and the high temperature due to its proximity to the Sun imply that any atmosphere once held by Mercury has long since escaped to space. Only gases of very high molecular weight, such as carbon dioxide (one molecule of which is 44 times as heavy as a hydrogen atom) or argon (40 times as heavy) have any chance of being retained by Mercury—except for very small amounts of hydrogen retained between capture from the solar wind streaming out from the Sun past Mercury and rapid gravitational escape from Mercury into space. The results of observational searches for an atmosphere on Mercury are described below.

The mean density of Mercury, calculated from the mass and radius, is about 5.2 grams per cubic centimetre, near

that of the Earth, which is 5.5 grams per cubic centimetre. But the Earth, much more massive than Mercury, contains regions in its interior of high pressure and thus of high compression. In the smaller Mercury, the high mean density must imply a larger abundance of intrinsically high-density material—probably iron-nickel—in its interior. The high density makes understanding of the mean densities of Mercury, Venus, the Earth, the Moon, and Mars on a common basis very difficult, if identical interiors, with the differences in mean density attributed to differences in compression and to phase transitions, are assumed.

The question of separation of an iron or any other core from a silicate mantle on Mercury is also undecided. Mercury may have originally had amounts of silicate and iron-nickel quite similar to the primitive Earth, and the planet would have been more intensely bombarded by solar electromagnetic and corpuscular radiation in the earliest phases of the evolution of the Sun. This radiation may have been intense enough to vaporize and drive off much of the upper silicate mantle of Mercury. Johannes Kepler, in his *Astronomia Nova* (published in 1609), suggested that Mercury had the highest density of all the planets—although he proposed that the planet had the same density as the element Mercury, 13.6 grams per cubic centimetre, a curious conclusion of no more than alchemical significance.

Table 1 shows basic data for Mercury.

Table 1: Planetary Data for Mercury

Average distance from Sun	58,000,000 km (36,250,000 mi)
Eccentricity of orbit	0.2056
Inclination of orbit to invariable plane of solar system	7°
Sidereal period of revolution (year)	87.969 Earth days
Rotation period	59 ± 3 Earth days or 58.65 Earth days
Mean synodic period	116 Earth days
Mean orbital velocity	48 km/sec (30 mi/sec)
Inclination of equator to orbit	less than 10°
Mass (Earth = 1)	0.054
Diameter	4868 ± 2 km (about 3,050 mi)
Density (water = 1)	5.2 (5.2 gm/cm <sup>3</sup> )
Satellites	none known

**Mercury and theories of gravitation.** The proximity of Mercury to the Sun and the eccentricity of its orbit makes it useful for studying the Sun's gravity. The orbit of a planet is not fixed in space but responds to the net gravitational influence of bodies in its environment. Through combinations of many small effects, the long axis (the line of apsides) in Mercury's orbit is in slow movement around the Sun. The perihelion point moves eastward almost 10" per century. Most of this precession is due to the gravitational influence of the other planets; but a residual of 35" per century, not readily explained, was found in 1845 by Urbain-Jean-Joseph Le Verrier, the codiscoverer of Neptune. Subsequently this value was improved to about 40" per century. Le Verrier attributed this discrepancy to the effect of hypothetical planets between Mercury and the Sun. Marginal observations in the 19th century had suggested that such a planet might exist; it was even named Vulcan. Some such objects were reportedly observed in transit across the face of the Sun, but very complete and careful observations of the Sun and its neighbourhood at times of total eclipse during the last century have not confirmed their existence. Another idea, that the residual in the perihelion advance is due to small particles responsible for the zodiacal light in the vicinity of the Sun, has also been shown to be untenable.

In 1915 Albert Einstein showed that the general theory of relativity, a generalization of the Newtonian equations of motion, predicted a perihelion advance of Mercury of 43" per century that the classical Newtonian theory did not. Thus the motion of Mercury's orbit has been considered as an important observational verification of the general theory of relativity. A third gravi-

Loss of atmosphere

Advance of perihelion

tational theory, the Brans-Dicke scalar-tensor theory, predicts yet another value of the perihelion advance. Robert Dicke of Princeton University, one of the originators of this theory, proposes that the difference in the observed perihelion motion is due to the Sun's mass distribution rather than to the correctness of Einstein's theory. The matter is not yet settled.

There is, however, a further test of the general theory of relativity for which Mercury is important. A ray of electromagnetic radiation—for example, visible light or radio waves—will travel a longer path when it passes close to a massive body, according to general relativity. A radar signal from the Earth bounced off Mercury when Mercury is at inferior conjunction or at greatest elongation does not pass close to the Sun and is not a good experimental situation for this test of the general theory of relativity. But when Mercury is near superior conjunction, a radar ray reaching it and reflected back to the Earth must pass very close to the Sun. Radar observations made at the Lincoln Laboratory of the Massachusetts Institute of Technology in 1967, when Mercury was near superior conjunction, showed a time delay in approximate accord with the predictions of the general theory of relativity.

**Transits of Mercury.** Roughly 15 times per century, Mercury crosses, or transits, the Sun's disk as seen from the Earth. It then appears as about the same size as a modest sunspot, but much sharper in definition. Some of the evidence against Mercury having an extensive atmosphere is obtained on such occasions. As Mercury's orbit is inclined to the ecliptic plane by 7°, at most of the inferior conjunctions the planet passes north or south of the Sun. But inferior conjunction sometimes occurs near one of the nodes of Mercury's orbit—where its orbit crosses the ecliptic plane—and on these occasions transits are observed. Table 2 lists the dates of transits of Mercury be-

**Table 2: Transits of Mercury from 1677 to 2003**

(Times given are Greenwich Mean Time)

year	month and day	hour	year	month and day	hour
1677	Nov. 7	0	1845	May 8	8
1690	Nov. 9	18	1848	Nov. 9	2

\*Mercury grazes the Sun's limb.

tween 1677 (the first accurately observed transit) and 2003, giving Greenwich Mean Time for the middle of the transit; the hours are reckoned from noon. All 44 of the observed transits occur in the first half of May or the first half of November. The Earth passes near the line of nodes of Mercury's orbit only near May 7 and November 9, and consequently transits can occur only near these two dates.

**The rotation of Mercury.** *Early studies of surface features and rotation period.* In the late 1960s dramatic new developments in the study of Mercury occurred. In order to understand these developments it is first necessary to consider the earlier theories and observations of the surface of the planet.

Composite prints have been made with several photo-

graphs of Mercury at a variety of telescopes, in New Mexico, Texas, and France, in the 1960s. They were taken under conditions of excellent atmospheric steadiness or "seeing," as is indicated by the sharp definition of the edge of the planet. Nevertheless, detail is fuzzy (though better than on the original photographic plates from which the composites were made). Much more detail can on occasion be seen by a trained human eye at the focus of the telescope, because the human eye can recall fleeting moments of clarity and good "seeing" during exceptional atmospheric steadiness that the photographic plate cannot. But this superior definition is often offset by vexing questions of human judgment; and visual observers have differed among themselves as to just what features on Mercury—an object of very small angular size seen very close to the horizon and obscured by sunlight scattered from the sky—are real. By watching true surface details move across the disk of the planet it would be possible to determine the period of rotation (that is, the length of the day) of Mercury and the tilt of the axis of rotation to the orbital plane. But, in practice, great difficulties were encountered.

At the beginning of the 19th century Johann Hieronymus Schröter, a German astronomer, published drawings of Mercurian surface features from which the celebrated German astronomer Friedrich Wilhelm Bessel derived a period of rotation of 24 hours 0 minutes and 53 seconds, with an axis of rotation lying 20° out of the orbital plane—a very large axial tilt. As the Earth and Mars have rotation periods near 24 hours, and it had been erroneously deduced that Venus had a similar rotation period, this produced an agreeable but incorrect uniformity in the length of the day for all of the inner or terrestrial planets.

Bessel's result was accepted for some 75 years, until the Italian planetary astronomer, Giovanni Schiaparelli, demonstrated conclusively from visual observations that the rotation period must be much longer than 24 hours. Schiaparelli concluded that Mercury rotated once every 87.96 terrestrial days, a period exactly equal to the length of the Mercurian year. Schiaparelli's conclusion implied that Mercury was rotating synchronously, making one rotation for each revolution (except for a relatively small effect due to libration, which is an apparent oscillation of the planet as seen from the Sun, due chiefly to the eccentricity of its orbit). This implied that one hemisphere of Mercury was forever bathed in intense sunlight, the other hemisphere being forever averted from the Sun. Mercury was thus considered to be at the same time both the hottest and the coldest place in the solar system. It is now known that it is neither of these.

A synchronously rotating Mercury fitted well with the tidal-evolution theory of planets then being developed by the British physicist Sir George Howard Darwin. The Moon raises tides not only in the Earth's oceans but also very small ones in the solid body of the Earth. Darwin showed that tidal friction in the Earth and the Moon, acting in accord with the conservation of energy and angular momentum in the two bodies, leads to slow changes in the period of rotation of the Earth, as well as in the distance, period of revolution, and period of rotation of the Moon. He showed that a stable situation arises when the Moon has a period of rotation equal to its period of revolution about the Earth. The length of the lunar day equals the length of the month: our natural satellite is in synchronous rotation. It seemed plausible that the much greater solar tides raised in the solid body of Mercury had also brought that small planet into synchronous rotation about the Sun.

After Schiaparelli, several observers made systematic visual studies of the Mercurian surface features, all concluding that the rotation period was synchronous with the period of revolution to high accuracy. The Franco-Greek astronomer E.M. Antoniadi gave names rich in Latin and Greek classical allusions to the features that he observed, many of the names having some mythological association with the god Mercury. For example, Caduceata refers to the caduceus, the double helix of snakes

Attempts to determine rotation period from surface details

that was the staff of Mercury; and the large feature Solitudo Hermae Trismegisti is the Solitude of Thrice-Great Hermes.

**Difficulties with synchronous rotation.** The first hint that something was amiss in the view of a synchronously rotating Mercury came in 1962, when the first successful detection of radio emission from Mercury was made at the University of Michigan. Mercury cannot be resolved by a single ground-based radio telescope because of its small angular size, and the Michigan observations made near 3 centimetre wavelength were of the radio emission from the entire disk of Mercury. At the time of the observations Mercury showed only a thin crescent; the bulk of the radio-wave emission must have been from the presumably very cold dark side. Earlier infrared measurements at Mt. Wilson Observatory had shown the illuminated hemisphere of Mercury to be at a temperature near 620° K (347° C; Celsius temperatures are 273° lower than Kelvin temperatures). With only a thin sliver of crescent visible and a dark side temperature near absolute zero, the Michigan investigators should have observed much less microwave radiation than they did. Either the bright or the dark side of Mercury had to be hotter than had been assumed up to that time. If the culprit was the bright side, the temperature had to be about 1,100° K, in disaccord with the infrared measurements—and indeed much hotter than even a perfectly absorbing solid body at Mercury's distance from the Sun should be. The alternative was that the dark-side subsurface, at least at the level from which the radiowaves were coming, was at a temperature above 300° K, much too high a temperature to be maintained by starlight and heat conducted from the interior of a synchronously rotating Mercury. It was then proposed that winds in a thin Mercurian atmosphere might carry heat from the illuminated to the unilluminated hemisphere, but because Mercury could have at most only a very thin atmosphere, the velocities required were very large indeed, almost supersonic.

But there was a difficulty even with a thin Mercurian atmosphere, although some spectroscopic and polarimetric observations of Mercury had suggested the presence of an atmosphere of carbon dioxide or argon with total pressure of one to ten millibars (1 millibar = 1/1,000 atmosphere). The surface properties of Mercury appeared to be very similar to those of the Moon; Table 3 shows

Temperatures on bright and dark sides

Table 3: Comparison of Optical, Thermal, and Electrical Properties of Mercury and the Moon

property	Mercury	Moon

photometric and radar-reflecting properties of the two bodies. Similarly, the polarization phase curve of Mercury—which measures the polarization (asymmetry in the directions of lightwaves) produced in the previously unpolarized sunlight by reflection from the planetary surface, in terms of the angle between the Sun and the observer (the phase angle)—closely resembles that of the Moon. It is now known that the early polarimetric data had been erroneously interpreted in terms of a Mercurian atmosphere. (A range of recent attempts to measure the infrared spectrum of various carbon dioxide bands on Mercury has not met with success, one of the upper limits being 10<sup>-2</sup> millibar of carbon dioxide set in 1970.) With no atmosphere there would be no way of heating the dark side by winds. If this argument and the Michigan observations had both been taken seriously, it might

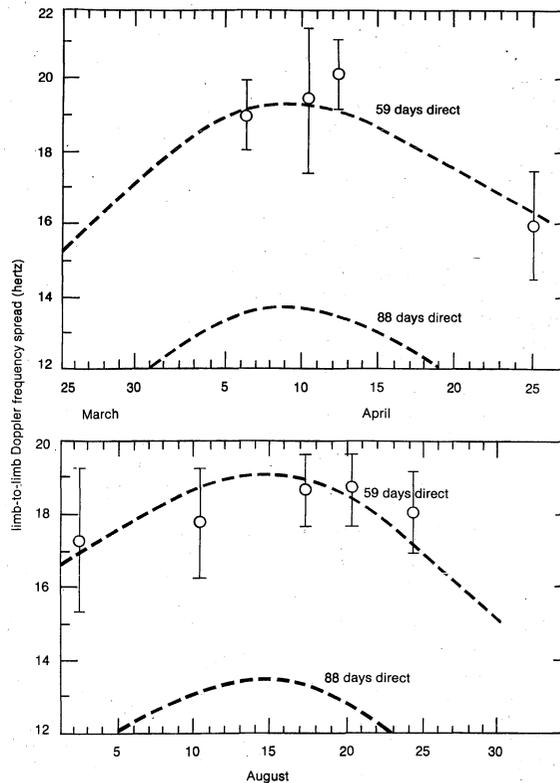

Figure 1: Radar observations (circles with vertical bars of Mercury made in 1965 at Arecibo Ionospheric Observatory, Puerto Rico. The limb-to-limb Doppler frequency spread is a function of the date. The theoretical curves (dashed lines) were computed for sidereal rotation periods of 59 and 88 days, assuming no inclination of the rotation axis.

have been possible to conclude that Mercury did not rotate synchronously. But no one was willing to take such a step at the time.

**The two-thirds spin-orbit coupling with the orbital period.** The decisive evidence was provided directly in 1965 when Rolf Dyce and Gordon Pettengill of Cornell University's Arecibo Observatory in Puerto Rico attempted to measure the rotation period of Mercury by radar techniques. The principle used was the Doppler effect, familiar through the change in pitch of an automobile horn moving towards or away from a listener, and in the red shift observed in the light from galaxies moving away from the Earth. The Arecibo radar telescope sent a pulse of radio waves out toward Mercury, a small portion of which was intercepted by the planetary surface and reflected back to Earth. The part of the pulse reflected from the edge of Mercury receding, because of planetary rotation, from Earth was shifted to longer wavelengths; the fraction of the pulse reflected from the approaching edge of the planet was shifted to shorter wavelengths. The Doppler spread of the returned signal is directly proportional to the speed of rotation of the planet. When many such pulse reflections were made, over a period of some months, to resolve possible ambiguities, the results shown in Figure 1 were obtained. The most recent radar data show that Mercury rotates in a direct sense (that is, in the same sense as it revolves around the Sun) with a sidereal period of 59 ± 3 days, and with an inclination of the rotation axis to a vertical through the planetary orbit of less than 10°.

Rotation period measured by radar

How could this radar finding be reconciled with the tidal theory and with optical observations that seemed to point unambiguously to 88 days? The idea of a stable synchronous rotation was based on the assumption of a circular orbit. But Mercury has an extremely eccentric orbit; the present rotational velocity could be the result of the average torque exerted by the Sun on the tidal bulge it rises on Mercury. The eccentricity of Mercury's orbit causes this torque to vary greatly between aphelion and perihelion.

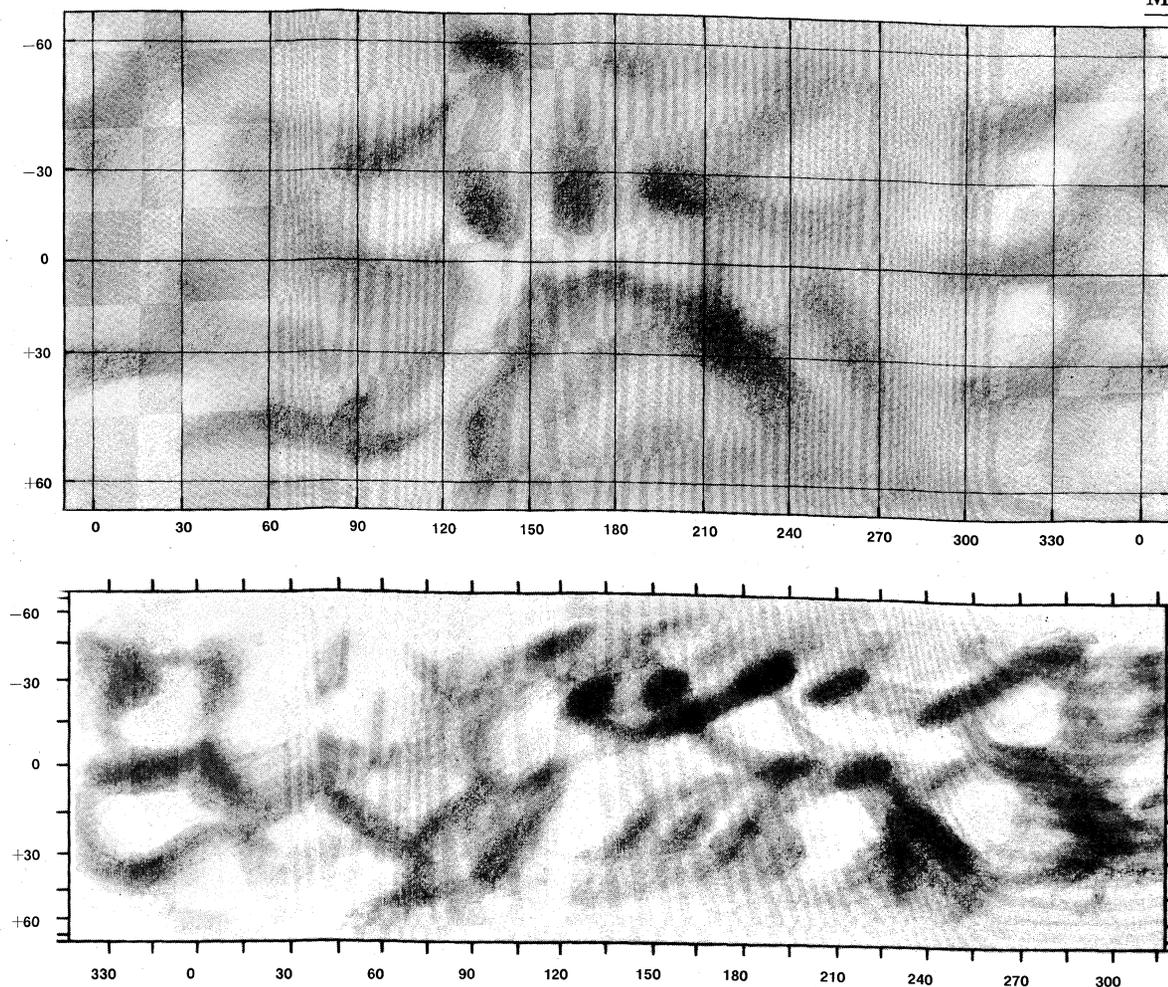

Figure 2: Modern maps of Mercury.

The maps are based on the assumption that the rotation period is exactly  $\frac{2}{3}$  of the orbital period and that the axis of rotation is perpendicular to the orbital plane. The coordinate scales of the maps are different. The feature resembling a script figure 5 at the extreme right of the upper map corresponds to the comparable figure at the extreme left of the lower map. (Top) Drawn by H. Camichel and A. Dollfus from photographic and visual data. (Bottom) Compiled by C. Chapman from 130 selected drawings and photographs by many observers.

An Italian astronomer, Giuseppe Colombo, of the University of Padua and the Smithsonian Astrophysical Observatory, quickly pointed out that two-thirds of Mercury's precisely determined orbital period of 87.969 days is 58.656 days, close to the period found with radar. Colombo and Shapiro then showed that, provided Mercury had a permanent asymmetry in its mass distribution, the two-thirds resonance lock—*i.e.*, the ratio of three rotations to two revolutions maintained by the tidal effects of the Sun—would be stable. The only puzzling aspect of the tidal theory for Mercury, for a two-thirds resonance lock between rotation and revolution, is that although the condition is stable the probability of ever getting into it from some other rotation period seems to be low.

There being little difficulty with the present version of the tidal theory, how can the optical period have been so wrong? If both hemispheres of Mercury see the Sun, why are there no early maps of the "other" hemisphere? The time between successive apparitions of the same phase of Mercury—for example, full phase—is 116 Earth days and is called the synodic period. The solar day on Mercury is the time between successive sunrises at a given spot on Mercury. If the rotation period is two-thirds the period of revolution, then the solar day on Mercury is 176 terrestrial days and exactly two Mercurian years. A day two years long is quite different from terrestrial experience. Moreover, the solar day is very close to  $1\frac{1}{2}$  synodic periods. Thus the same side of Mercury is seen at the same phase after every three synodic periods. But since three synodic periods is close to one terrestrial year, the most favourable times for observing Mercury also recur

every three synodic periods (see last section). At such times, the same surface markings are seen at the same phase, at least for a period of years. Thus every observer who draws pictures of surface markings on Mercury over a period of years will always see the same markings at the same phase and will be sorely tempted to conclude that the planet is in synchronous rotation. But astronomers observing at some different epoch should see different hemispheres of Mercury, because three synodic periods do not exactly equal one Earth year, and the stroboscopic effect gradually slips out of phase. Indeed, markings seen by the older observers appear to be not in perfect accord. The earlier observers were delinquent in not pointing out that other rotational periods besides 88 days were consistent with their observations. Indeed, the whole episode is a cautionary tale: observations that are consistent with a given hypothesis do not necessarily demonstrate its correctness.

Now that the period of rotation is established with some reliability, it is possible to combine the best earlier observations with excellent recent observations to produce Mercury cartography. Two recent attempts at such cartography are shown in Figure 2, which should be compared with the earlier drawings. Most recent visual observations give a period of  $58.650 \pm 0.006$  days, and it has been estimated that the rotation axis is within  $3^\circ$  of perpendicular to the orbital plane. Thus the most recent optical work is in excellent agreement both with the radar data and with the stable two-thirds resonance lock of tidal theory.

The two-thirds spin-orbit coupling of Mercury then re-

Length of  
"day" and  
"year" on  
Mercury

solves the problems posed by the earlier infrared and microwave temperature measurements. The illuminated hemisphere should be at 600° or 700° K because it spends a long time in the sunlight. The surface of the dark hemisphere should be very cold (but not as cold as if Mercury were in synchronous rotation). The subsurface temperature on the dark side, emitting measured radiowaves of a few centimetres wavelength, should be at some intermediate temperature, because the heat delivered to the subsurface by sunlight in daytime is only slowly conducted outward and lost at night. Violent winds carrying heat from the bright to the dark side are not needed—which is just as well, as there is no evidence whatever for an atmosphere on Mercury. Thus the surface photometric and polarimetric properties of Mercury could be understood on the same basis as the surface properties of the Moon, regardless of whether these properties are produced by solar wind bombardment, micrometeoritic infall, or by a coincidence of basaltic chemistry.

**Apparent solar motion in the sky of Mercury.** The thermal and electrical properties of the soil of the planet Mercury can in principle be understood by comparing microwave and infrared observations with theory. It is necessary also to understand the apparent solar motion on Mercury; that is, how a hypothetical observer standing on the surface of the planet would view the apparent motion of the Sun. This motion is unique in all the solar system as a result of two factors—the two-thirds spin-orbit coupling and the high eccentricity of the Mercury orbit. The solar day on Mercury is about 176 terrestrial days long, equal to two orbital revolutions and to three planetary rotations. The eccentricity of the orbit causes the apparent angular size of the Sun in the (black) sky of Mercury to range from 1.1° to 1.6°; the Sun is about 0.5° in angular size as seen from the Earth. The combination of these two effects leads to a complicated periodic solar heating of the planetary surface. More than twice the intensity of sunlight falls on Mercury at perihelion than at aphelion. As a result, at some longitudes on the planetary surface there is more solar heating when the Sun is only 30° above the horizon than when it is overhead. A diagram of the apparent motion of the Sun in the Mer-

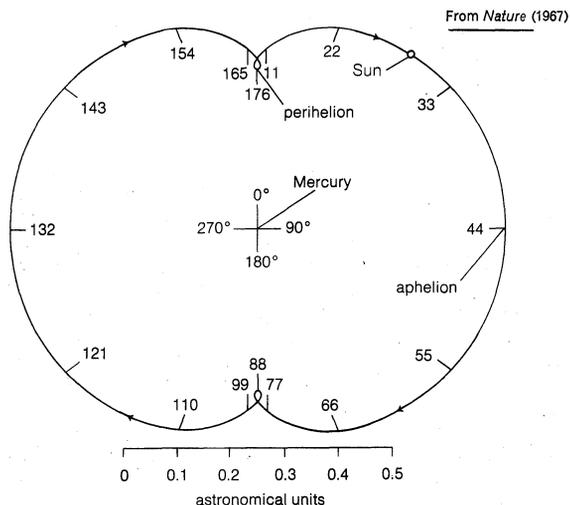

Figure 3: Apparent path of the Sun as seen from Mercury. Positions and distances are drawn to scale, with time marked in 11-day intervals. The two loops occur at perihelion, when the Sun briefly seems to move in a retrograde sense.

Strange behaviour of Sun as seen from Mercury

curian sky is shown in Figure 3. The two longitudes on the Mercurian surface marked 0° and 180° in the figure, where the Sun is overhead at perihelion, receive more than twice the energy received at the longitudes marked 90° and 270°. The intersections of these longitudes with the equator may be called the "hot poles" and the "warm poles" of Mercury, respectively. These temperature non-uniformities are permanently locked to specific locales on the surface, and it will be interesting to see, when better photographs of Mercury become available from space vehicle missions, whether there are any characteristic

topographic features associated with these "poles." In partial compensation for the complexity introduced by the apparent solar motion, the small inclination of the Mercury spin axis means that there are no seasons in the terrestrial sense on Mercury.

To a hypothetical Mercurian living at one of the hot poles, the Sun would rise with a small angular size, gradually swelling and moving more and more slowly as it approached the zenith about 44 terrestrial days after rising. About a degree past the zenith it would stop dead in its tracks. It then would reverse its apparent motion for about one degree, stopping and reversing again, and moving forward with increasing speed and decreasing apparent size toward the horizon, where it would set 88 terrestrial days, or one Mercurian year, after sunrise. The stars would be moving through the sky roughly three times as fast as the Sun, and stars that rise with the Sun would set and rise again before the Sun set.

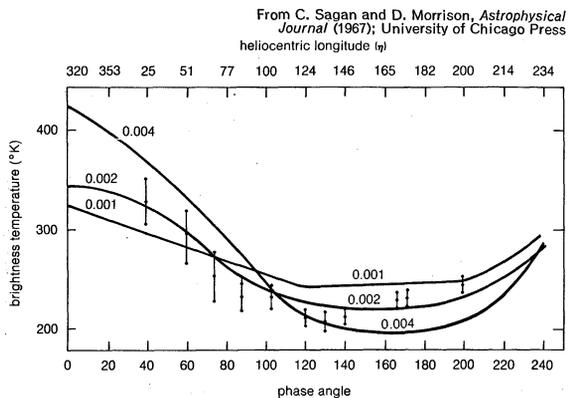

Figure 4: Measured radio brightness temperature shown with error bars for a given range of phase angle, heliocentric longitudes, and calculated temperature for three values of the thermal parameter. Theory and observation match best for the value 0.002 calorie per square centimetre per square root second.

An observer situated at one of the warm poles of Mercury would have quite a different story. He would see a large Sun rise slowly, stop at the horizon, and ponderously set again. It would then rise in earnest, shrinking in angular size and increasing in angular speed; a small Sun would speed through the zenith, swelling as it set, and very slowly sinking below the horizon. It would slowly rise again and finally set—not to rise again for an entire Mercurian year. At longitudes that are intermediate between the hot poles and the warm poles, a somewhat more complex but equally unearthly solar choreography would be observed.

**Mercury's surface material.** With various assumptions about the thermal and electrical properties of the Mercurian surface and subsurface material, the corresponding variations of subsurface temperature with time or phase angle (see above) can be calculated. Radio telescopes measure the temperature from the whole disk, not from a particular point, so that calculated surface temperatures must be appropriately averaged or integrated before being compared with observations. The combined effects of spin-orbit coupling and orbital eccentricity make the temperatures dependent on phase angle and also on heliocentric longitude (the actual position of Mercury in its orbit). Figure 4 shows radio temperatures for three different values of a thermal parameter. Putting this parameter equal to 0.002 calorie per square centimetre per square root second agrees best with the observations. The predicted temperature variation at the equator of Mercury at both a hot pole and a warm pole are shown in Figure 5 for two different thermal parameters, both close to the value mentioned above. The mean night equatorial surface temperature is a little more than 100° K. Infrared observations of the night side of Mercury show a disk-averaged temperature of about 110° K. This agreement in turn tends to confirm the choice of thermal parameter as well as the other assumptions in this theory.

Temperatures on the surface

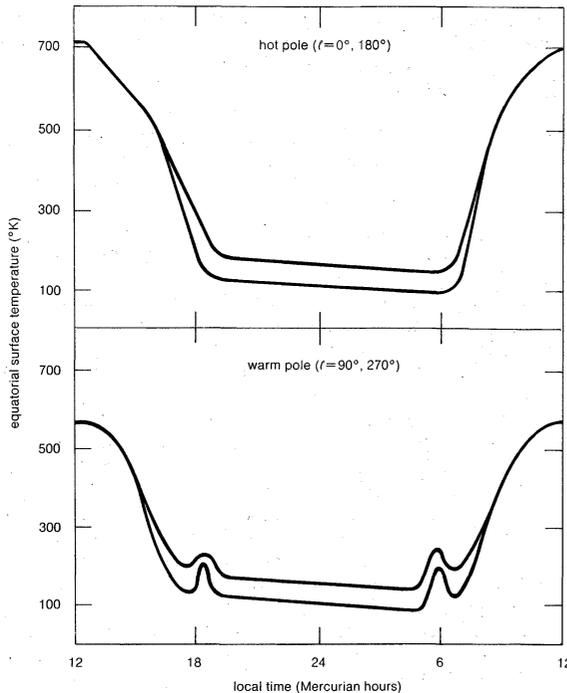

Figure 5: Computed temperature variations during a day on Mercury at a hot pole and a warm pole. One "hour" is  $\frac{1}{24}$  of Mercury's "day" and 176 times longer than on Earth. The two curves are shown for slightly different values of the thermal parameter.

From D. Morrison, *Space Science Reviews* (1970); D. Reidel Publishing Company

In theory, heat may be transferred through the surface in two ways—by contact conduction or by radiation conduction, in which adjacent particles that are not in contact in the soil of Mercury may nevertheless exchange heat by radiation. Radiation conduction is usually assumed proportional to something like the third power (the cube) of the temperature. This leads to a kind of solid-surface "greenhouse effect" analogous to the atmospheric greenhouse effect well known for planetary atmospheres. Radiation falling into a glass greenhouse, or an atmosphere, may be retained as heat if it is converted to infrared energy that cannot readily pass out again through the glass or air. In daytime on Mercury the surface and immediate subsurface temperatures are high, the radiative conductivity is high, and therefore the solar heat is rapidly transported to some depth. At night, however, the temperatures are lower, the conductivity is lower, and the heat of regions slightly below the surface does not escape to the surface so easily. As a result the temperatures of the radiation of longer wavelengths coming from greater depths within the surface (see next paragraph) tend to be higher; this does not hold for depths great enough to be unaffected by daytime heating. Observations seem on the whole to favour an important contribution from radiation conduction but are not yet good enough for this to be certain. All models so far have been homogeneous in depth, ignoring, for example, the possibility of looser packing of dust at the surface than at depth.

Table 3 also compares lunar and Mercurian surface properties deduced from such radio information and shows that Mercury is remarkably like the Moon at all wavelengths observed. The thermal skin depth of the Mercurian surface is about 10 centimetres; that is, the diurnal temperature variation produced by the rising and setting Sun on Mercury is damped to about 37 percent of its surface amplitude at a depth of about 10 centimetres. The electrical skin depth, a measure of the depth from which radiowave radiation is observed, is approximately 10 wavelengths. So radiation at 10-centimetre wavelength is coming from approximately one metre below the Mercurian surface. From the average 10-centimetre temperatures it appears that at about a metre below the surface of Mercury the temperatures must be quite Earth-like.

Temperatures just below the surface

But because of the absence of an atmosphere and the searing effect of the electromagnetic and charged-particle radiation from the Sun, the prospects for life on Mercury appear very bleak.

**Mercury's peculiar periods.** The synodic period of Mercury is the time required for swiftly moving Mercury to gain one lap on the Earth in their orbits around the Sun. If the orbital periods (in Earth days) of the two planets are designated  $P_M$  and  $P_E$ , Mercury will be seen on the average to move  $1/P_M$  of a revolution per day, while the Earth moves  $1/P_E$  of a revolution in pursuit. Mercury's daily gain on the Earth is  $(1/P_M - 1/P_E)$  of a revolution, so that the time for Mercury to gain one complete revolution on the Earth, the synodic period  $S$ , is given by:

$$\frac{1}{S} = \frac{1}{P_M} - \frac{1}{P_E}; \text{ or } S = \frac{P_M \times P_E}{P_E - P_M}$$

In units of terrestrial days, the synodic period is:

$$S = \frac{88 \times 365}{277} = 116 \text{ days.}$$

To find the length of the solar day on Mercury, it must be noted that the planet's rotation and revolution are both in a counterclockwise direction as viewed by a hypothetical observer from the direction of the North Star. Assuming the position of a Mercurian living in northern latitudes and facing south, one notes that the effect of Mercury's rotation, acting alone, is to cause the Sun to rise on the left and set on the right, as on Earth, while the effect of revolution acting alone is to move the Sun across the sky in the opposite direction, from right to left. In the special case of equal periods of rotation and revolution, the Sun would stand still in the sky. It is clear, then, that the apparent angular velocity of the Sun is the difference between the axial and orbital angular velocities of the planet:

$$\frac{1}{P_{sun}} = \frac{1}{P_{rot}} - \frac{1}{P_{rev}}; \text{ or } P_{sun} = \frac{P_{rot} \times P_{rev}}{P_{rev} - P_{rot}}$$

With the radar rotational period of 59 terrestrial days, the solar day on Mercury is:

$$P_{sun} = \frac{88 \times 59}{29} = 176 \text{ days.}$$

Thus, for  $P_{rot} = \frac{2}{3} P_{rev}$ ,  $P_{sun} = 3P_{rot} = 2P_{rev}$ , so that a day on Mercury is two years long. There is also the numerical coincidence that  $2P_{sun}$  and  $3S$  are each approximately one terrestrial year.

## Mercury Products and Production

Mercury, also known as quicksilver, and its principal ore mineral, cinnabar, have been known and used by man for

more than 2,300 years. In early times, mercury was used in religious ceremonies, in medicinal ointments and cosmetic preparations, and in the recovery of gold and silver by the process of amalgamation. Mercury readily forms alloys (amalgams) with gold, silver, and many other metals. Since the 17th century the importance of mercury has steadily increased with advancing science and industry.

Metallic mercury, symbol Hg, is a silvery-white liquid at ordinary temperatures. Its unique combination of physical properties includes high specific gravity, high surface tension (mercury does not wet glass), low electrical resistivity, constant volume expansion over the entire temperature range of its liquid state, and the ability to amalgamate with other metals.

Cinnabar

Of the more than 25 known minerals that contain mercury, the principal ore mineral is cinnabar—a soft red to reddish-brown mercury sulfide. Mercury is found in the elemental state in some deposits. Cinnabar has been found in all types and ages of rock, usually alone, but sometimes in association with antimony, gold, iron, and zinc.

Air samples taken in the vicinity of sulfide and precious metal ores have shown a mercury content several times greater than that found in samples taken over non-mineralized areas, and such air sampling for mercury content promises to become an important tool in exploration for mercury and associated minerals.

**Mining.** Mercury deposits are small and irregular, usually veinlets but sometimes small disseminated deposits, a situation that precludes large-scale, highly mechanized mining methods.

Most of the ore comes from underground mines in which the ore is broken by conventional drilling and blasting and is removed by scrapers or is mechanically loaded into cars. Surface mining is also carried on.

**Important sources.** Despite the widespread occurrence of mercury, only a few commercial-size deposits have been found. The largest of these so far known is at the Almadén Mine in Spain, which has produced more than one-third of the world's total output since production first began about 400 BC. The next largest producer is the Idria Mine in Yugoslavia, followed by the Monte Amiata district in Italy. The fourth largest producer, the Santa Barbara Mine, Huancavelica, Peru, was the world's major producer during the 17th century. The next largest producer, the New Almadén Mine in California, helped make the United States the world's largest producer for a few years following 1875, though today two-thirds of U.S. needs are supplied by imports from Canada, Spain, Italy, Mexico, Yugoslavia, and the Philippines. Mercury is also produced in China, Japan, Turkey, and the U.S.S.R.

Secondary mercury, that is, mercury that has been recovered after primary uses, is a significant source in most developed countries.

**Recovery and refining.** The recovery of the metal from the ore is one of the more simple of the metallurgical extraction processes. Mercury is separated by roasting the ore as mined or as a concentrate at temperatures near or above 580° C (1,080° F), the temperature near which mercury sulfide sublimates (changes from solid to vapour directly). The mercury sulfide vapours react with oxygen in the air to form mercury and sulfur dioxide and are then passed through a dust collector and into a series of condenser pipes.

Because concentrates and some ores contain relatively large amounts of sulfur, various substances are added to assist in oxidizing the sulfur and to prevent the formation of a synthetic cinnabar or free sulfur in the condenser pipes. Brine, iron filings, and scrap iron are some of the substances used.

Cinnabar is roasted in a variety of furnaces. The most common is a retort or tube, ranging in size from 10 to 20 inches (25 to 50 centimetres) in diameter and 6 to 12 feet (1.8 to 3.6 metres) in length, supported by some type of masonry construction with a firebox below or beside the retort. A number of other types of furnaces are used to provide greater capacity and continuous operation.

The upper end of the furnace is connected to a condenser system. The typical condenser system consists of a

series of vertical cast-iron pipes connected at the top with cast-iron or glass fibre return bends and at the bottom with cast-iron hoppers. The gaseous mercury condenses and collects in the hoppers under a water seal.

Mercury recovered in this manner, pure enough for most commercial uses, is of prime virgin grade averaging not less than 99.9 percent bright and clean mercury.

Mercury is packaged in cast-iron, wrought-iron, or spun steel bottles or flasks four to seven inches in diameter and about 12 inches high. The net weight of one flask of mercury is 34.5 kilograms, or 76 pounds, the commercial unit of world trade.

Most mercury is recovered by furnace treatment of ore that has come directly from the mine without processing other than crushing. Ore from some mines may be low grade or may contain impurities that create problems in roasting. In such cases the mercury content may be upgraded by the ore flotation process, which takes advantage of mercury's nonwetting characteristic to separate it from other substances. The concentrates are then treated by the roasting process described above.

Although it is not done in current mining operations, mercury can be recovered by leaching with a solution of sodium hydroxide and sodium sulfide. Metallic mercury is precipitated from solution by adding aluminum.

Generally neither flotation concentration prior to furnacing nor leaching of mercury can compete economically with direct furnacing of the ore.

Laboratory tests have shown that electrochemical oxidation in a brine slurry is a promising method of recovering mercury from low-grade ore.

**The metal and its alloys and amalgams.** Perhaps the best known use for mercury is the "mercury" thermometer, which is based on mercury's property of constant volume expansion over its entire range in the liquid state. Mercury is also used in many measurement and control instruments, including barometers, manometers, flow meters, and pressure gauges. These instruments utilize mercury's high surface tension, high density, and low vapour pressure.

But by far the greatest usage of mercury is in electrical applications. The largest single application is in the production of chlorine and caustic soda by the electrolysis of brine in a mercury cell. This process makes use of mercury's electrical conductivity, as well as its ability to amalgamate with other metals. As a moving cathode, mercury amalgamates with the liberated sodium, which immediately reacts with water to form metallic mercury and sodium hydroxide. Chlorine is recovered at the anode. Investigations have shown the feasibility of using mercury cathode cells in the recovery of uranium and vanadium by electrolysis. Mercury is used in an electrolytic process to remove impurities from metals.

The next largest use is the mercury dry cell battery. These batteries operate under conditional high temperature and humidity, have long life, deliver the same ampere-hours of service at the rated current range whether operated continuously or intermittently, and have large power output per unit size. The mercury battery is used in hearing aids, guided missiles, communications equipment, and other applications in which a constant output of electric current is required.

Mercury-vapour arc lamps are compact and have high wattage and high lumens-per-watt output. They are used particularly for industrial floodlighting and street lighting. Other uses for mercury lamps are in motion-picture projection, photography, dental examination, and heat therapy. Electrical applications also include rectifier bulbs, oscillators, power-control switches, and home-type wall switches.

In precision casting, patterns have been made of frozen mercury, a technique used particularly for the casting of complex parts. A possible space-age use of mercury is as the propellant in a low-thrust ionic engine for long journeys in deep space. Another possible space application is a mercury-filled flywheel for spacecraft stabilization.

Mercury amalgamates readily with many metals. Gold and silver are recovered by amalgamation. Amalgams of sodium and potassium are used as reducing agents. A

Electrical applications

Amalgams

mercury-thallium amalgam with a melting point of  $-60^{\circ}\text{C}$  ( $-76^{\circ}\text{F}$ ) is used as a low-temperature thermometer. Mercury-silver amalgams are used in dentistry for repairing cavities.

Although prime virgin grade mercury is satisfactory for most uses, it may have to be purified to meet the special requirements of dental and medical instrument and battery applications. Mercury is purified by redistilling or treatment with nitric acid.

Mercury vapour boilers have been tried for power generation but were found uneconomical.

**Chemical compounds.** Mercury compounds are used in the chemical industry, in pharmacology, in the paint industry, and in agriculture. Mercury sulfate is used as a catalyst in the production of glacial acetic acid, methyl styrene, and vinyl chloride. Bichloride of mercury, mercurochrome and ointments of metallic mercury, yellow mercuric oxide, and ammoniated mercuric chloride are used as skin antiseptics. Mercurous chloride (calomel) has been used as a diuretic and a cathartic.

Phenylmercury compounds, predominately the acetate, are used for treating and storing seeds, for spraying fruit trees, for weed control, and as textile preservatives. Though mercury compounds were once widely used for slime control in the production of pulp and paper, this use has declined considerably in recent years because of the potential health hazard in paper used for food products.

A growing use for mercury is in mildew-proofing paints. The use of mercury for antifouling paints—*i.e.*, paints resistant to marine growth—has declined in recent years. Mercury as a solid solution of mercury sulfide and cadmium sulfide is used in producing heat- and light-fast red pigments.

Mercury fulminate, resulting from a reaction of alcohol and mercuric nitrate, explodes on impact and is used in percussion caps as a detonator for other explosives.

**Health hazards.** Exposure to metallic mercury or mercury compounds, even in small amounts, over a period of time can result in mercury poisoning. Mercury can enter the body by inhalation of fumes or dust, by ingestion, or by absorption through the skin. Early symptoms of chronic mercury poisoning are weakness, fatigue, inflammation of the mouth, loosening of teeth, excessive salivation, body tremours, and emotional instability. Acute poisoning causes nausea, abdominal pain, vomiting, headaches, diarrhea, and occasionally cardiac weakness.

Working areas in mines, furnaces, and industrial plants can be made relatively safe by taking such preventive measures as providing proper ventilation, personal hygiene, and plant cleanliness. Large exhaust fans to draw clean air over workers and the maintenance of negative pressures in furnaces or heating equipment reduce the pollution of the air by fumes and dust. Smooth, impervious plant floors and work benches slope to a point where spillage can be collected and removed. All surfaces require frequent washing, and personnel are trained to wash hands and rinse mouth before eating and to take hot showers at the end of the workday. Clothes must fit snugly at neck, wrists, and ankles, and are changed at the end of work, and washed frequently. Because leather absorbs liquids containing mercury, rubber boots, or at least rubber-soled shoes, are worn. Mercury-vapour detectors are used to indicate the level of contamination, and periodic physical and dental examinations monitor the occurrence of poisoning.

**Economic importance.** There are few satisfactory substitutes for the applications of mercury that depend on mercury's high specific gravity, fluidity at room temperatures, or electrical conductivity. In the pharmaceutical field, sulfa drugs, iodine, and various antiseptics and disinfectants can be substituted for mercury. Plastics, porcelain, and other metals may replace mercury-silver amalgams for some dental uses. Other types of dry-cell batteries may replace mercury batteries for other than specialized uses.

During the 1960s, mercury was in short supply in much of the world due to large increases in demand, in the U.S., Europe, the U.S.S.R., and China, and declining production in many countries. As a result, the price rose from a previously stable rate of about \$190 for a 76-pound flask

to \$710 per flask in 1965. Since 1967 the price has ranged from \$450 to \$500 per flask.

Since it is indispensable for many military and other essential uses during defense emergencies, some governments stockpile mercury.

#### World Production and Reserves of Mercury (flasks)

## Meredith, George

Unlike most of his fellow novelists in the England of the last half of the 19th century, George Meredith considered himself primarily a poet and was impatient of the mechanics and skills of constructing a conventional novel; he achieved his often magnificent effects mainly by the brilliance of his dialogue and by building up grand scenes with all the wit, intellect, and poetry at his command. His novels are also distinguished by psychological studies of character and a highly subjective view of life that, far ahead of his time, regarded women as fully independent individuals, as truly the equals of men.

**Origins and early years.** George Meredith, the son and grandson of tailors, was born above the family tailor shop in Portsmouth, Southampton, on February 12, 1828. The name Meredith is Welsh in origin, and family tradition held that its bearers were descendants of Welsh kings and chieftains. In keeping with this tradition, the young Meredith was proud and patrician in his bearing. A small inheritance from his mother, who died when he was five, enabled him to attend a superior local seminary and thus early to assume the role of a young "gentleman." Yet the sensitive boy must gradually have become conscious of the contrast between this role and his actual social status. And the reality was to become even harsher with the bankruptcy of the tailoring shop when he was about 11 and his father's subsequent marriage to the girl who had been their housekeeper.

A second legacy, this time from an aunt in 1840, enabled him to go first to a boarding school and then, in 1842, to the Moravian School at Neuwied on the Rhine River, which was to leave its stamp upon the remainder of his life. The picturesque Rhineland, with its cliffs, its ruined castles, and its legends, stimulated the fancy of the already romantic youth. Tolerant religious in-

Industrial safety measures

Meredith, oil painting by G.F. Watts, 1893. In the National Portrait Gallery, London.

struction was combined with humanism: the boys were taught to think for themselves, to respect truth and scorn falsehood, to admire courage and abhor cowardice, to love nature, and to live in peace and amity with their fellows. The monotony of study was broken by daily sports, storytelling, playacting, and in vacations by week-long expeditions or boating trips down the Rhine. All of these influences except the religious remained with Meredith throughout life. After "a spasm of religion which lasted about six weeks," he later said, he never "swallowed the Christian fable" and thereafter called himself a freethinker.

Meredith's return to England in 1844, at the age of 16, ended his formal education. Like all of the other great Victorian novelists, he was to be largely self-educated. After several false starts, he was apprenticed at 18 to a London solicitor named Richard Charnock and was ostensibly launched upon a career in law. There is no evidence, however, that he ever pursued it. Probably like the writer and politician Benjamin Disraeli, the novelist William Makepeace Thackeray, and others before him, he found it intolerably dull and abandoned it at the start. But if not the law, what profession offered hope to a young man who was brilliant but untrained, ambitious but without means? If to be a poet seems an unlikely choice, it nevertheless accorded with his romantic nature and was the one he made. He was steeped in *The Arabian Nights* and German legends and literature; he had already written verse, and he soon found that Charnock's interests were more literary than legal and that he had gathered around him a coterie of young friends whose interests were also literary. Perhaps all of these were influences. At any rate, among the Charnock circle was Edward "Ned" Peacock, son of Thomas Love Peacock, the eccentric author; and through Edward he met Edward's sister, Mary Ellen Nicolls, then a widow with a small daughter. She was brilliant, witty, handsome, and about eight years older than he. Not unnaturally, in the course of editing and writing for a manuscript literary magazine conducted by the Charnock circle, he fell in love with her. Shortly after he reached his majority and came into the remainder of his little inheritance, they were married and spent their honeymoon on the Continent.

**Beginnings as poet and novelist.** On their return, the Merediths took lodgings at Weybridge, Surrey, near Peacock's house at Lower Halliford, Middlesex, and George busied himself writing poems and articles and making translations. Unfortunately, they brought in little money. Somehow, nevertheless, he managed to pay the publication costs of a little collection of verse, entitled *Poems*, in 1851. Though the writer and critic William Michael Rossetti praised it, Charles Kingsley, the novelist, found "very

high promise" in it, and the poet Alfred Tennyson said kindly that he wished he might have written the beautiful "Love in the Valley," praise added nothing to the family coffers.

Beset by creditors, the Merediths had to take refuge in Peacock's house, where their only child, Arthur, was born in 1853. Understandably, Peacock soon preferred to rent a cottage for them across the village green from him. As poetry did not pay, Meredith now in desperation turned his hand to prose, writing a fantasy entitled *The Shaving of Shagpat: An Arabian Entertainment*, published in 1855. Original in conception but imitative of *The Arabian Nights* in manner, it baffled most readers, who did not know whether to regard it as allegory or fairy tale. But the most perceptive of the critics, the novelist George Eliot, praised it as "a work of genius, and of poetical genius."

Poverty, disappointment, and the growing antagonism between two highly strung, critical natures placed an unbearable strain upon the marriage of the Merediths. Little more is known of this period in their lives, except that Mrs. Meredith was in Wales, in the company of an artist friend of the couple, Henry Wallis, during the summer of 1857. In April 1858 she gave birth to a son, whose father was registered as "George Meredith, author," but whose paternity Meredith always denied. Subsequently, Mrs. Meredith and Wallis went off to Capri together. She died in 1861, leaving Meredith with his eight-year-old son Arthur.

Work was Meredith's only solace, and he was feverishly working upon a novel, *The Ordeal of Richard Feverel* (published in 1859), with which he hoped to win fame and fortune. It was characteristic of his best work in many respects: in form it is a romantic comedy (but with a tragic ending, as is frequent in Meredith); it deals with the relationship between a baronet and his son; the son falls in love with a lower class girl and is subjected to an ordeal—a recurring motif in Meredith—by his father; the novel is rich in allusion, image, and metaphor; the dialogue is sparkling, witty, and elliptical as in life; there are frequent intrusions by the author; three of the chapters are written in highly lyric prose; and the psychology of motive and rationalization is explored in depth. Father and son suffer from excessive pride and self-delusion (regarded by Meredith as forms of egoism), which it is the purpose of comedy, as he later said in his "Essay on Comedy," to purge and replace with sanity. Though not without faults, the novel nevertheless remains Meredith's most moving and most widely read novel. But delicate readers found it prurient and had it banned by the influential lending libraries, scattering Meredith's hopes of affluence. He was forced to accept employment as a reader of manuscripts for a publisher and as a writer of editorials and news items for a provincial newspaper. His own writing had to be done in what spare time remained.

*Feverel* was followed by *Evan Harrington* (1860), an amusing comedy in which Meredith used the family tailoring establishment and his own relatives for subject matter. The hero is the son of a tailor who has been brought up abroad as a "gentleman" and has fallen in love with the daughter of a baronet. His ordeal comes when he returns home to find his father dead and himself heir to the tailor shop and a considerable debt. Taking up poetry again, Meredith next published a volume of poems, *Modern Love, and Poems of the English Roadside, with Poems and Ballads*, in 1862. If *Evan Harrington* had exorcised the tailor demon that haunted him, "Modern Love" doubtless served a similar purpose for his own disastrous marriage. Semi-autobiographical, it is concerned with the tragedy of marital infidelity and its nemesis, though his own wound was now sufficiently healed for him to write compassionately. The poem deserves a place among his permanent contributions to English poetry.

After a walking tour on the Continent, he once more turned to prose. The theme of his next novel, *Emilia in England* (later renamed *Sandra Belloni*), was the contrast between a simple but passionate girl and some sentimental English social climbers—an excellent theme for

Literary influences

First novels

Second  
marriage

Meredithian comedy. Its publication in 1864 was made the occasion of the first general consideration of all his works up to this point in an article in the *Westminster Review* by the Irish journalist and writer Justin M'Carthy. A second event of importance in 1864 was his remarriage. Arthur had been placed in boarding school, and Meredith's own loneliness was intensified. Luckily, he met an attractive, well-bred young woman of Anglo-French descent, Marie Vulliamy, fell in love with her, and, after undergoing his own ordeal in persuading her father of his respectability, married her in September 1864. Thus ended a period in his life: he was no longer unknown and no longer lonely.

A son was born to the couple in 1865 and a daughter in 1871. With a family to support and popularity still elusive, Meredith had to keep hard at work for the next 15 years, with only occasional walking expeditions on the Continent. In 1866, however, he was sent out by *The Morning Post* to report the Italian campaign in the Austro-Prussian War, which lasted only seven weeks but enabled him to spend three months in his beloved Italy. After his return he was able to purchase a comfortable cottage near the bottom of Box Hill, Surrey, where he was to live quietly until his death. It stands today much as when he lived in it.

**Mature works.** During the next 20 years, from 1865 to 1885, Meredith continued the drudgery of reading manuscripts but substituted weekly readings to an elderly rich widow for the newspaper work. It was, however, a period marked by the birth of the children, the publication of seven novels and a volume of poems, and, in the 1880s, by growing public recognition. The next two novels, *Rhoda Fleming* (1865) and a sequel to *Emilia*, entitled *Vittoria*, added nothing to his reputation. With *The Adventures of Harry Richmond* (1871), however, Meredith returned to what was his forte—romantic comedy. Once more he wrote a close study of a father-son relationship, only this time the father is an impostor who out-Micawbers Dickens' Mr. Micawber in his belief that something will "turn up" to make his fortune. The son's ordeal is that he must perceive and reject the world of fantasy in which his father lives and achieve maturity through painful experience. After an interval of about four years came *Beauchamp's Career*. Its hero is a self-deluded idealist who is converted to radicalism and whose ordeal is both political and personal. It is one of Meredith's better novels and confirmed what was clear by now, that one of his greatest strengths was the creation of spirited, flesh and blood women who think for themselves.

The next two novels of consequence, *The Egoist* (1879) and *Diana of the Crossways* (1885), marked the beginning of Meredith's acceptance by a wider reading public and a more favourable reception by critics. Both are comedies, full of Meredithian wit and brilliant dialogue and notable for women characters who prove their right to be accepted as individuals, equal with men, rather than puppets. In *The Egoist* the enemy is egoism, and the egoist is tested by a succession of ordeals before joining the ranks of humanity. While that novel is concerned with the dangers of wrong choice before marriage, *Diana* is the first of a series of studies of mismatching in marriage. Diana herself is a memorable character of spirit and brains, although Meredith is less successful in persuading readers that she could naïvely be guilty of a grave breach of confidence. In both novels, however, the men that Meredith approves of and hands the heroines over to are rather flat and uninteresting.

A new period now began in Meredith's life. Fame, if not popularity, and financial independence had come at last. Yet his enjoyment of them was to be tempered by the death of his wife in 1885 and of Arthur in 1890, by the beginning of deafness, and by the onset of ataxia that was first to limit his ability to walk and finally to render him immobile. Honours and testimonials came in plenty: an honorary LL.D. degree from the University of St. Andrews, Fife, Scotland; election to the prestigious office of President of the Society of Authors; and in 1905 the Order of Merit, strictly limited to 24 members, was conferred upon him by order of the King. Meredith had

become a public institution, his home at Box Hill almost a literary shrine.

After 1885 his work was done except for three novels and five volumes of poems that were increasingly more philosophic than poetic. *One of Our Conquerors* (1891) is probably the most difficult of his novels because of the indirect and cryptic style, metaphor, and long passages of interior monologue. *Lord Ormont and His Aminta* (1894), unlike its predecessor, was praised for the brilliancy and clarity of its style. The final novel, *The Amazing Marriage* (1895), repeats the theme of *Lord Ormont*—that a wife is free to leave a husband who does not recognize her as an equal.

In person Meredith was slightly built but athletic, remarkably handsome, and aristocratic in manner. Because of his concern with upper class life in his novels, he has sometimes been accused of being ashamed of his lowly birth and of being at heart a snob. The charge hardly bears inspection: he chose the fashionable world as a subject because it was fittest for his brand of comic treatment. His own tastes and manner of living were almost spartanly simple, his greatest pleasures being long walks and communion with nature. His friends, for the most part, were not aristocrats; they were chiefly writers and artists, along with a few professional men. It is true that in the years of his fame he was taken up by various fashionable ladies—usually young ones whom he had fascinated—and that journalists began to beat a path to his door. If he was not the oracle with all the answers, he was willing to play the role. A brilliant talker, he delighted in expressing radical and startling ideas to journalists—that the Boers should have been given their freedom; that Britain should join the United States; that marriage should be for a ten-year trial period, renewable by mutual consent; that there was no future life; and that Britain should arm itself against impending German aggression. On his 80th birthday he was presented with another testimonial, with 250 signatures of the great ones of the world, and both King Edward VII and President Theodore Roosevelt sent congratulations. After a short illness he died on May 18, 1909.

**Reputation and influence.** On his 80th birthday the newspapers of the world saluted Meredith as "the Dean of English Writers," the "last Great Victorian," the "Grand Old Man of Letters," and the "Sage of Box Hill." Shortly after his death, *The Times Literary Supplement* said that his mind was "so rich, so full, that one wonders where there is another mind so rich, outside Shakespeare, in English literature." As not infrequently happens, however, his great reputation went into eclipse, and other gods—Henry James, James Joyce, Joseph Conrad, and D.H. Lawrence—replaced him. Ardent Meredithians remained, but the pendulum of popular taste has not swung back. *The Ordeal of Richard Feverel* and *The Egoist* will continue to have a share in college and university curricula, *The Adventures of Harry Richmond* and *Beauchamp's Career* may have limited appeal, and for the rest, Meredith will be left to scholars and the intellectual elite.

The influence of Meredith on the novel has been indirect rather than direct. Although his highly personal style was incapable of imitation, his extensive use of interior monologue anticipated the stream-of-consciousness technique of James Joyce and others. Moreover, with George Eliot he was creating the psychological novel and thus was an important link between his 18th-century precursors and 19th- and 20th-century followers. Among later novelists influenced by him the Marxist critic Jack Lindsay cites George Robert Gissing, Thomas Hardy, Henry James, and Robert Louis Stevenson; and the writer and critic J.B. Priestley points to Virginia Woolf, D.H. Lawrence, and E.M. Forster.

#### MAJOR WORKS

**POETRY:** *Poems* (1851), including the first version of "Love in the Valley"; *Modern Love, and Poems of the English Roadside, with Poems and Ballads* (1862); *Poems and Lyrics of the Joy of Earth* (1883), including "The Woods of Westminster," "A Ballad of Past Meridian," "The Day of the Daughter of Hades," "The Lark Ascending," "Phoebus with Admetus," final version of "Love in the Valley," "Earth and Man," "Lucifer in Starlight," and "The Spirit of Shakespeare"; *Bal-*

Final  
years

lads and Poems of Tragic Life (1887), including "The Nuptials of Attila" and "Phaëthón"; *A Reading of Earth* (1888), including "The Thrush in February," "Hymn to Colour," and "Meditation Under Stars"; *Poems. The Empty Purse. **BIBLIOGRAPHY.** M. BUXTON FORMAN, *A Bibliography of the Writings in Prose and Verse of George Meredith* (1922, suppl. 1924) and C.L. CLINE, "George Meredith," in LIONEL STEVENSON (ed.), *Victorian Fiction: A Guide to Research* (1964), provide a fairly complete listing of works by and about Meredith. The Altschul Collection at Yale University and the Morgan Library in New York hold most of his manuscripts and papers. The University of Texas at Austin holds several hundred Meredith letters. The Memorial Edition of the *Works of George Meredith*, 27 vol. (1909–11), is the standard edition. Vol. 2, *The Ordeal of Richard Feverel*, however, reprints the revised edition of 1896, to which reprints of the original edition of 1859 are preferable. Good reprints of the 1859 edition are available in the Modern Library editions (ed. by LIONEL STEVENSON) and the Houghton Mifflin Riverside editions (ed. and annot. by C.L. CLINE). *The Letters of George Meredith*, 2 vol., ed. by his son, W.M. MEREDITH, was published in 1912. C.L. CLINE, *The Letters of George Meredith*, 3 vol. (1970), is now the standard edition. LIONEL STEVENSON, *The Ordeal of George Meredith* (1953), is the standard biography; see also J.B. PRIESTLEY, *George Meredith* (1926) a biographical and critical study.

## Merovingian and Carolingian Age

The period of the Merovingian and Carolingian Frankish dynasties (476–887) marked the transition from antiquity to what can properly be called the Middle Ages. In the 4th and 5th centuries, Germanic peoples penetrated within the Roman Empire and brought the existence of that Mediterranean state to an end. The Franks played a key role in Gaul, reunifying it under their rule. Merovingian and, later, Carolingian monarchs created a kingdom centred in an area between the Loire and Rhine but extending beyond the Rhine into large areas of Germany.

### ORIGINS

**Early history of the Franks.** In the second half of the 4th century the Salian Franks, who lived along the lower bank of the Rhine, occupied the Toxandria—an area west of the Meuse, along and on both sides of the modern Belgium–Netherlands border, that had formerly been Roman and had become depopulated—with the permission of the imperial authorities. Later, in the second quarter of the 5th century, all of the Franks moved southward toward the middle Rhine area (Cologne), the lower branches of the Moselle and Meuse, and the coastal region. In the latter area they took possession of Tournai and Cambrai and reached the Somme. These Franks along the coast were divided into many small kingdoms. One of the most important of the kingdoms was Tournai, the earliest known king of which was Childeric (died c. 481/482). Traditionally regarded as the son of Merovich (Merové or Merowe), eponymous ancestor of the Merovingian dynasty, Childeric placed himself in the service of the Roman Empire. Clovis was his son.

**Gaul and Germany at the end of the 5th century.** Other Germans had already entered Gaul. The area south of the Loire was divided between two tribes. One, the

Visigoths, occupied Aquitaine, Provence, and most of Spain. Their king, Euric (ruled 466–484), seems to have been the principal monarch in the West. The other tribe, the Burgundians, were masters of most of the Rhône Valley. In northern Gaul, the Alemanni occupied Alsace and moved westward into the area between the Franks and Burgundians, while the first British immigrants established themselves on the Armorican Peninsula (now Brittany). A territory that continued to call itself Roman remained within these areas of Gaul. An imperial functionary, Syagrius, was installed in Soissons and shared power with the local bishops.

In spite of the German influx, Gaul, which had been part of the Roman Empire for 500 years, remained basically romanized. While most of its administrative institutions could not withstand the crisis of the 5th century, Gaul's traditional Roman civilization survived, especially among the aristocratic classes. In addition, the Germans themselves were, to varying degrees, affected by this civilization. This influence was stronger among the Burgundians and the Visigoths, who had lived within the empire for a longer time and had intermingled with other Germanic peoples to a great extent, than it was among the Franks and Alemanni, who had only recently entered the empire. The Burgundians and Visigoths adopted a heretical form of Christianity—Arianism. The Franks and Alemanni remained pagan and preserved limited contacts with free Germany.

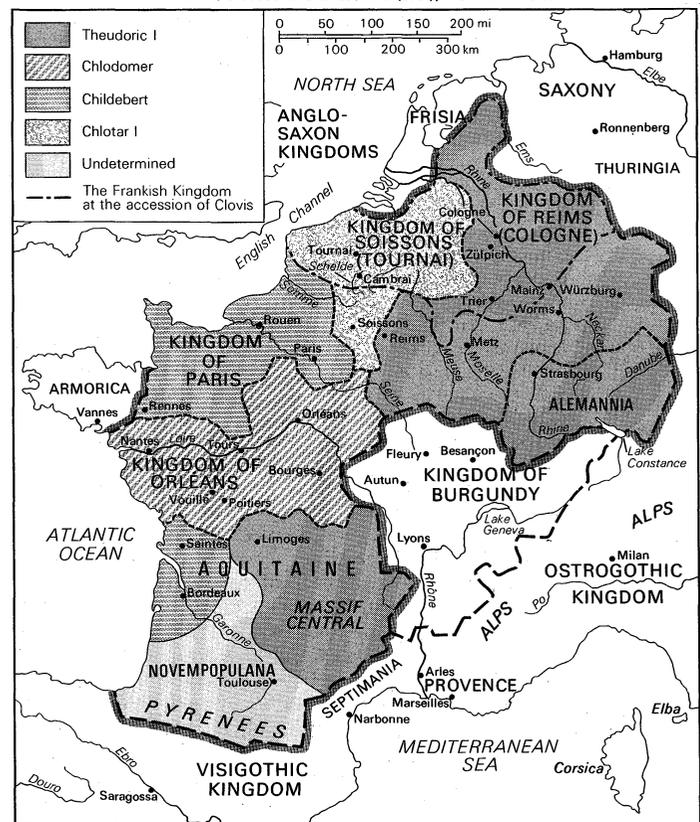

In effect, the Germanic peoples who penetrated into Roman Gaul were only the advance guard of the Germanic world. The northern Germans (Angles, Jutes, Saxons, Frisians) still occupied the coastal regions of the North Sea east of the Rhine; the Thuringians and Bavarians divided the territory between the Elbe and Danube; the Slavic world began on the opposite bank of the Elbe.

### THE MEROVINGIANS

**Clovis.** Clovis (ruled 481/482–511) unified Gaul with the exception of areas in the southeast.

**Frankish expansion and the unification of Gaul.** During the years following his accession Clovis consolidated

The division of the Frankish kingdom among the sons of Clovis at his death in 511.

Ancestor of the Merovingian dynasty

the position of the Franks in northern Gaul. In 486 he defeated Syagrius and occupied an area situated between the Frankish kingdom of Tournai, the Visigothic and Burgundian kingdoms, and the lands occupied by the Rhenish (Ripuarian) Franks and the Alemanni, removing it from Roman control once more. It was probably during this same period that he eliminated the other Salian kings. In a second phase, he attacked the other Germanic peoples living in Gaul, with varying degrees of success. An Alemannian westward push was blocked, probably as a result of two campaigns—one conducted by the Franks of the kingdom of Cologne in about 495–496 at the Battle of Tolbiac (Zülpich), the second by Clovis in about 506, after the annexation of Cologne. Clovis thus extended his authority over most of the territory of the Alemanni. Some of the former inhabitants sought refuge in Theodoric's Ostrogothic kingdom. Despite his marriage to a niece of Gundobad, one of the Burgundian kings, Clovis plotted (c. 500–501) with Godigisel, another Burgundian king. Gundobad, however, succeeded in foiling the plot and reuniting the kingdom. Clovis then turned against the Visigothic kingdom and, reconciled with Gundobad, defeated Alaric II at Vouillé (507). He annexed Aquitaine, between the Loire, Rhône, and Garonne, as well as Novempopulana, between the Garonne and the Pyrenees. Opposed to a Frankish hegemony in the West, Theodoric intervened on behalf of the Visigothic king and prevented Clovis from annexing Septimania, on the Mediterranean between the Rhône and the Pyrenees, which the Visigoths retained, while Theodoric occupied Provence. In the west, the eastern section of Amorica (the bishoprics of Nantes, Rennes, and Vannes) appeared to have submitted to Clovis. In addition, in the east Clovis eliminated the kingdom of Cologne and united the Frankish people under his own leadership.

Clovis established Paris as the capital of his new kingdom, and in about 507–508 he received from the Emperor an honorary consulship and the right to use the imperial insignia. These privileges gave the new king legitimacy of sorts and were useful in gaining the support of his Gallo-Roman subjects.

*The conversion of Clovis.* According to tradition, substantiated by Gregory of Tours, Clovis converted, under the influence of his wife Clotilda and Remigius, bishop of Reims, because of a vow taken during the campaign against the Alemanni. Avitus, bishop of Vienne, and Nicetus, bishop of Trier, also mention the conversion in their correspondence; historians disagree, however, as to the location of the Baptism (Reims or Tours) and the date (496 or 506). Because the other Germans in Gaul were Arians (anti-Trinitarian Christians), Clovis' conversion assured the Frankish king of the support of the Catholic hierarchy and, generally, of Catholic opinion. It also ensured the triumph in Gaul of Catholicism over paganism and Arianism and spared Gaul lengthy conflicts that punctuated the history of other Germanic kingdoms.

*The sons of Clovis.* Following the death of Clovis (511) the kingdom was divided among his four sons. This partition was not made according to ethnic, geographic, or administrative divisions. The only factor taken into account was that the portions be of equal value. Boundaries were poorly defined. The territory was divided into two general areas: one was the territory north of the Loire (that part of Gaul that was conquered earliest); the other, to the south in Aquitaine, was a region not yet assimilated. Theuderic I received lands around the Rhine, Moselle, and upper Meuse, as well as the Massif Central; Chlodomer, the Loire country on either side of the Rhine (this kingdom was the only one not composed of separated territories); Childebert I, the country of the English Channel and the lower Seine and, probably, the region of Bordeaux and Saintes; Chlotar I, the old Frankish country north of the Somme and an ill-defined area in Aquitaine. Their capitals were centred in the Paris Basin, which was divided among the four brothers; Theuderic I used Reims; Chlodomer, Orléans; Childebert I, Paris; Chlotar I, Soissons. As each brother died, the survivors

partitioned the newly available lands among themselves. This system resulted in bloody competition until 558, when Chlotar I succeeded in reuniting the kingdom under his own rule.

*The conquest of Burgundy and southern Germany.* In spite of these partitions, the Frankish kings continued their conquests. One of their primary concerns was to extend their dominion over the whole of Gaul. It took two campaigns to overcome the Burgundian kingdom. In 523 Chlodomer, Childebert I, and Chlotar I, as allies of Theodoric, moved into Burgundy, whose king, Sigismund, Theodoric's son-in-law, had assassinated his own son. Sigismund was captured and killed. Godomer, the new Burgundian king, defeated the Franks at Vézeronce and forced them to retreat; Chlodomer was killed in the battle. Childebert I, Chlotar I, and Theudebert, the son of Theuderic I, regained the offensive in 532–534. The Burgundian kingdom was annexed and divided between the Frankish kings. Following Theodoric's death (526), the Franks were able to gain a foothold in Provence by taking advantage of the weakened Ostrogothic kingdom. The Franks were thus masters of all southeastern Gaul and had reached the Mediterranean. But in spite of two expeditions (531 and 542: the Siege of Saragossa), they were unable to gain possession of Visigothic Septimania. Also, at least a portion of Amorica in the northwest remained outside the Frankish sphere of influence. During this period, British colonization of the western half of the Armorican Peninsula was at its height.

To the east, the Franks extended their domain in southern Germany, bringing Thuringia (in c. 531 Chlotar I carried off Radegunda, a niece of the Thuringian king), the part of Alemannia between the Neckar and the upper Danube (after 536), and Bavaria under subjection. The latter was created as a dependent duchy in about 555. The Franks were less successful in northern Germany; in 536 they imposed a tribute on the Saxons (who occupied the area between the Elbe, the North Sea, and the Ems), but the latter revolted successfully in 555.

Theudebert and his son, Theudebald, sent expeditions into Italy during a struggle between the Ostrogoths and Byzantines (535–554), but they achieved no lasting results.

*The grandsons of Clovis.* The Frankish kingdom was partitioned once more in 561 and again in 567. At the death of Chlotar I (561) the Frankish kingdom, which had become the most powerful state in the west, was once again divided, this time between his four sons. The partition agreement, based on that of 511, dealt with more extensive territories. Guntram received the eastern part of the former kingdom of Orléans, enlarged by the addition of Burgundy. Charibert's share was fashioned from the old kingdom of Paris (Seine and English Channel districts), augmented in the south by the western section of the old kingdom of Orléans (lower Loire Valley) and the Aquitaine Basin. Sigebert received the kingdom of Reims, extended to include the new German conquests; a portion of the Massif Central (Auvergne) and the Provençal territory (Marseilles) were added to his share. Chilperic's portion was reduced to the kingdom of Soissons.

The death of Charibert (567) resulted in a new partition. Chilperic was the principal beneficiary; he received the lower Seine district, which gave him a large tract of the English Channel coast. The remainder, most notably the Aquitaine Basin, was divided in a complex manner; and Paris was subject to joint possession. These two partitions, which served to reaffirm the division of Gaul, were the sources of innumerable intrigues and family struggles, especially between, on the one hand, Chilperic I, his wife Fredegund, and their children, who controlled northwestern Gaul, and, on the other hand, Sigebert I, his wife Brunhilda, and their descendants, the masters of northeastern Gaul.

*The shrinking of the frontiers and peripheral areas.* These events undermined the Frankish hegemony. In Amorica the Franks maintained control of the eastern region, but had to cope with raids by the Bretons, who had established heavily populated settlements in the western part of the peninsula. To the southwest the Gas-

struggles

cons, a highland people from the Pyrenees, had been driven northward by the Visigoths in 578 and settled in Novempopulana; in spite of several Frankish expeditions, this area was not subdued. In the south the Franks were unable to gain control of Septimania; they tried to accomplish this by means of diplomatic agreements, which were buttressed by dynastic intermarriage, and by military campaigns occasioned by religious differences (the Visigothic kings were Arians). In the southeast the Lombards, who had recently arrived in Italy, made several raids on Gaul (569, 571, 574); Frankish expeditions into Italy (584, 585, 588, 590), led by Childebert II, were without result. Meanwhile the Avars, an Asian people who settled along the Danube in the second half of the 6th century, threatened the eastern frontier; in 568 they took Sigebert prisoner, and in 596 they attacked Thuringia, forcing Brunhilda to purchase their departure.

*The parcelling up of the kingdom.* Internal struggles unleashed centrifugal forces. At the time of the partitions of 561 and 567, new political geographical units began to appear within Gaul. Austrasia was created from the Rhine, Moselle, and Meuse districts, which had formerly been the kingdom of Reims; Sigebert I (died 575) transferred its capital to Metz. Neustria was born out of the partition of the kingdom of Soissons; a portion of the kingdom of Paris was added to it, thus endowing the area with a broad coastal section and making the lower Seine Valley its centre. Its first capital, Soissons, was returned to Austrasia following the death of Chilperic; its capital was later moved to Paris, which had been controlled by Chilperic. The kingdom of Orléans, less its western territory but with part of the old Burgundian lands added to it, eventually became Burgundy; Guntram fixed its capital at Chalon-sur-Saône. Aquitaine submitted to the Frankish kingdoms centred farther north in Gaul; it was the object of numerous partitions made by sovereigns who regarded it as an area for exploitation. Aquitaine did not enjoy political autonomy during this period.

**The failure of reunification (613–714).** Territorial crisis was partially and provisionally averted during the first third of the 7th century.

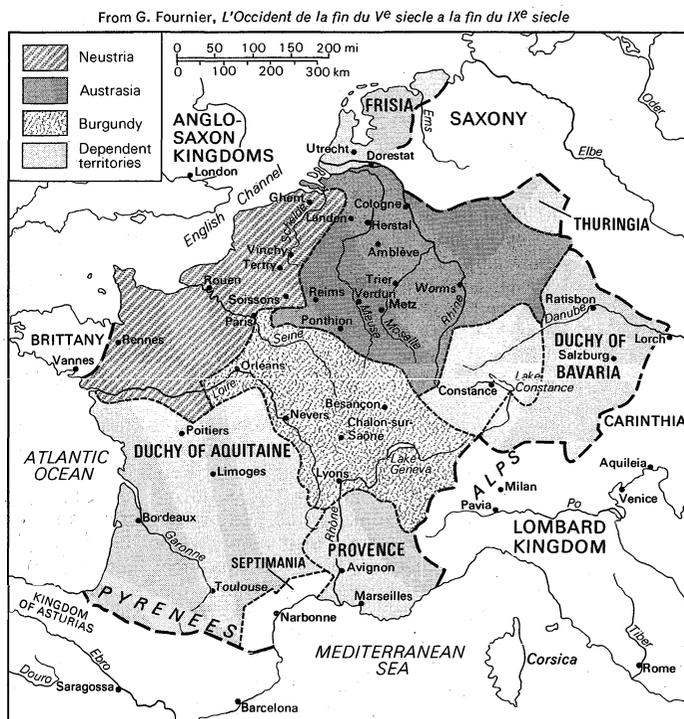

*Chlotar II and Dagobert.* Chlotar II, king of Neustria since 584, inherited Burgundy and Austrasia in 613 upon the death of Brunhilda, and thus the kingdom was reunited. He fixed his capital at Paris and, in 614, convoked a council there that, by increasing the powers of the church and the nobility, proved to be the most important meeting of the Merovingian epoch. His son Dagobert (ruled 629–639) was able to preserve this unity; and he journeyed to Burgundy, where the office of mayor of the palace was maintained, to Austrasia, and to Aquitaine, which was given the status of a duchy.

Dagobert had only limited success along the frontier. In 638 he placed the Bretons and the Gascons under nominal subjection, but ties with these peripheral regions were tenuous. He intervened in dynastic quarrels of Spain, entering the country and going as far as Saragossa before receiving tribute and quitting the country. Septimania remained Visigothic. On the eastern frontier there were incidents involving Frankish merchants and Moravian and Czech Slavs; after the failure of a campaign conducted by Dagobert, with the assistance of the Lombards and Bavarians (633), the Slavs attacked Thuringia. The King reached an agreement with the Saxons, who would protect the eastern frontier in return for remission of a tribute they had paid since 536.

*The hegemony of Neustria.* The territorial struggles began anew after 639. In both Neustria and Austrasia power was in the hands of aristocratic leaders, called the mayors of the palace. Ebroin, mayor of the palace in Neustria, attempted to unify the kingdom under his leadership but met with violent opposition. Resistance in Burgundy was led by St. Leodegar, who was assassinated in either 677 or 679. In Austrasia Ebroin was opposed to the Pepinid mayors of the palace; Pepin I of Landen was succeeded by Grimoald, who tried unsuccessfully to have his son, Childebert the Adopted, crowned king, and by Pepin II of Herstal (or Heristal), whom Ebroin was briefly able to keep from power (c. 680).

Frankish hegemony was once more threatened in the peripheral areas, especially to the east where Austrasia was endangered. The Thuringians (640–641) and Alemanni regained their independence. The Frisians reached the mouth of the Schelde and controlled the towns of Utrecht and Dorestat; the attempted conversion of Frisia by Wilfrid of Northumbria had to be abandoned (c. 680). In southern Gaul, Duke Lupus changed the status of Aquitaine from that of a duchy to an independent principality.

*Austrasian hegemony and the rise of the Pepinids.* The murder of Ebroin (681 or 683) reversed the situation in favour of Austrasia and the Pepinids. Pepin II, who defeated Neustria at Tertry (687), reunified northern Gaul under his own control. Austrasia and Neustria were reunited, theoretically under the Merovingian dynasty, but actually under Pepin II, who governed through his position as mayor of the palace. At the same time, Pepin II partially restabilized the frontiers by driving the Frisians north of the Rhine and by restoring Frankish suzerainty over the Alemanni. But control of southern Gaul continued to elude the Franks. In the early 8th century, Provence became an autonomous duchy, while power in Burgundy was divided.

The Frankish domains in the time of Charles Martel (boundaries approximate).

#### THE CAROLINGIANS

Representatives of the Merovingian dynasty continued to reign, at least in title, during most of the first half of the 8th century. They were slothful monarchs, according to a contemporary biographer of Charlemagne. In actual fact, power was in the hands of the Pepinids, who, thanks to their valuable land and loyal retainers, maintained a monopoly on the office of mayor of the palace. Because of their familial predisposition for the name Charles, and because of the significance of Charlemagne in the family's history, modern historians have called them Carolingian.

**Charles Martel and Pepin III the Short.** Pepin II's death in 714 jeopardized the Austrasian hegemony. His heir was a child of six. There was a revolution in Neustria, and Eudes, duke of Aquitaine, used the occasion to increase his holdings and make an alliance with the Neustrians. The Saxons crossed the Rhine and the Arabs crossed the Pyrenees.

*Charles Martel.* The situation was rectified by another of Pepin's sons, Charles Martel. Defeating the Neustrians

at Amblève (716), Vinchy (717), and Soissons (719), he made himself master of northern Gaul. He then re-established Frankish authority in southern Gaul, where the local authorities could not cope with the Islāmic threat; he stopped the Muslims at Poitiers (732) and used this opportunity to subdue Aquitaine (735–736); the Muslims then turned toward Provence, and Charles Martel sent several expeditions against them. At the same time, he succeeded in re-establishing authority over the dissident provinces in the southeast (737–738). Finally, he re-established Frankish influence in Germany. In his numerous military campaigns he succeeded in driving the Saxons across the Rhine, returned the Bavarians to Frankish suzerainty, and annexed southern Frisia and Alemannia. He also encouraged missionary activity, seeing it as a means to consolidate the Frankish empire; this undertaking was supported by the papacy, which was beginning to seek support in the West. Missionaries, most of whom were Anglo-Saxon (e.g., Willibrord and Winfrid, also known as Boniface), made definite progress in their task.

Charles Martel had supported a figurehead Merovingian king, Theuderic IV (ruled 721–737), but upon the latter's death he felt his own position secure enough to leave the throne vacant. His chief source of power was a strong circle of followers, who furnished the main body of his troops at a time when cavalry was becoming the most important element in the army. He attached them to himself by concessions of land, which he obtained by drawing on the considerable holdings of the church. This gave him large tracts of land at his disposal, which he granted for life (*precaria*). He was thus able to recruit a larger and more powerful circle of followers than that surrounding any of the other influential magnates.

*Pepin III the Short.* At the death of Charles Martel (741), as was the custom, the kingdom was divided between his two sons, Carloman and Pepin III the Short. This partition was followed by insurrections in the peripheral countries—Aquitaine, Alemannia, and Bavaria.

Carloman's abdication in 747 reunited the country. Pepin the Short was crowned king of the Franks with the complicity of the papacy, which, threatened by the Lombards and having problems with Byzantium, sought a protector in the West. The usurpation was accomplished in two stages: in 750, after obtaining the support of Pope Zacharias, Pepin deposed Childeric III; he then had himself elected king by an assembly of magnates and consecrated by a bishop, thus ending the nominal authority of the last Merovingian king, Childeric III, who had been placed on the throne in 743. The new pope, Stephen II, sought aid from Gaul; in 754 at Ponthion he gave Pepin the title patrician of the Romans, renewed the King's consecration, and consecrated Pepin's sons, thus securely establishing the line.

As king, Pepin limited himself to consolidating Frankish influence in Gaul, thus paving the way for later Carolingian expansion. Despite Pepin's efforts, the situation at the German frontier was unstable. The duchy of Bavaria, which the Franks had given to Tassilo III as a benefice, gained its independence in 763; several expeditions were unable to subdue the Saxons. On the other hand, Pepin achieved a decisive victory in southern Gaul by capturing Septimania from the Muslims (752–759). He broke down Aquitaine's resistance, and it was reincorporated into the kingdom (760–768). Pepin intervened in Italy twice (754–755; 756) on the appeal of the Pope and laid the foundations for the Papal States. He exchanged ambassadors with the great powers of the eastern Mediterranean—the Byzantine Empire and the caliphate of Baghdad.

**Charlemagne.** Pepin III, faithful to ancient customs, divided his kingdom between his two sons, Charles (Charlemagne) and Carloman. On Carloman's death in 771 the kingdom was reunited. Charlemagne established the base of his kingdom in northeastern Gaul (his preferred residence was Aachen [Aix-la-Chapelle]).

*The conquests.* He extended the territory controlled by the Franks considerably and unified a large part of the Christian West; he followed no devious policy of

expansion, taking advantage, instead, of situations as they arose.

Charlemagne consolidated Frankish authority up to the geographic limits of Gaul. Though he put down a new insurrection in Aquitaine (769), he was unable to bring the Gascons and the Bretons under submission. Charlemagne pursued an active policy toward the Mediterranean countries. In Spain he attempted to take advantage of the emir of Córdoba's difficulties; he was unsuccessful in western Spain, but in the eastern area he was able to establish a march south of the Pyrenees. Pursuing Pepin's Italian policy, he intervened in Italy, for at the request of Pope Adrian I, who was threatened by the Lombards, he took possession of Pavia and had himself crowned king of the Lombards; in 774 he fulfilled Pepin's promise and created a pontifical state; the situation on the peninsula remained confused, and many expeditions were necessary (in Friuli, in Istria, against the Lombards in Spoleto and Benevento). This enlargement of his Mediterranean holdings led Charlemagne to establish a protectorate over the Balearic Islands in the western Mediterranean to hold Muslim pirates in check (798–799).

Charlemagne conquered more German territory and secured the eastern frontier. By means of military campaigns and missionary activities he brought Saxony and northern Frisia under control; the Saxons, led by Widukind, offered a protracted resistance (772–804), and Charlemagne deported part of the population. To the south, Bavaria was brought under Frankish authority and annexed. Frankish conquests in the east brought them into contact with new peoples—Charles was able to defeat the Avars in three campaigns (791, 795, 796), from which he obtained considerable booty; he was also able to establish a march on the middle Danube, and the Franks undertook the conversion and colonization of that area. Charles held fast against the Slavs along the Elbe frontier; he constructed a march at the border of Jutland, facing the Danes, who in turn constructed a great fortification, the Danewirk, across the peninsula on their own shore. He also founded Hamburg on the banks of the Elbe. These actions gave the Franks a broad face on the North Sea.

The Frankish state now appeared to be the principal power in the West. Charlemagne claimed to be defender of Roman Christianity and, acting on this title, intervened in the religious affairs of Spain. Problems arose over doctrinal matters that, along with questions concerning the Italian border and the use of the imperial title, brought him into conflict with the Byzantine Empire; a peace treaty was signed in 810–812. Charles continued his peace policy toward the Muslim East: ambassadors were exchanged with the caliph of Baghdad and Charles received a kind of eminent right in Jerusalem.

*The restoration of the empire.* When, by the end of the 9th century, Charles was master of a great part of the West, he re-established the empire in his own name. He was crowned emperor in Rome (Christmas Day, 800), in the presence of Pope Leo III, but under uncertain circumstances. His new title replaced the ambiguous patrician of the Romans. Charles's powers in Rome and in relation to the pontifical state, which was incorporated, with some degree of autonomy, into the Frankish empire, were clarified. Above all, his new title, which did not replace King of the Franks or King of the Lombards but took precedence over them, was well suited to Charles's preponderant position in the old Roman West. The restoration of the empire discloses a will to unify the West; nevertheless, Charlemagne had to make concessions to certain national bodies—he preserved the kingdom of Italy, giving the crown to one of his sons, Pepin, and made Aquitaine a kingdom for his other son, Louis.

**Louis the Pious.** Only chance ensured that the empire remained united under Louis the Pious, the last surviving son of Charlemagne (the latter had anticipated the partitioning of his empire among his three sons). The era of great conquests had ended and, on the face of it, Louis's principal preoccupation was his relations with the countries to the north. In the hope of averting the threat posed by the Normans, who had begun to raid the coasts of the

North Sea and the Atlantic, Louis proposed to evangelize the Scandinavian world. This mission was given to St. Ansgar but was a failure.

During Louis's reign, the imperial offices were systematized. He saw the empire, above all, as a religious ideal, and in 816 the imperial coronation, originally a secular ceremony, was complemented by a religious ceremony, the anointment, at which the pope presided. At the same time, Louis the Pious took steps (*Ordinatio Imperii*, 817) to regulate the succession so as to maintain the unity of the empire. His oldest son, Lothair, was to be sole heir to the empire, but within it three small dependent kingdoms were maintained: Louis's younger sons, Pepin and Louis, received Aquitaine and Bavaria, respectively; his nephew Bernard was given Italy.

The remarriage of Louis the Pious and the birth of a fourth son, Charles the Bald, upset this project. In spite of opposition from Lothair, who had the support of a unitarian faction drawn from the ranks of the clergy, the emperor's principal concern was to create a kingdom for Charles the Bald. These divergent interests led to conflicts that weakened imperial prestige (in 833, abandoned by his followers at the Field of Lies, Louis the Pious was forced to make public penance at Saint-Médard in Soissons). The question of Aquitaine arose at the death of Pepin I, ruler there since 814; the emperor gave this subordinate kingdom to Charles, but the magnates rose up and proclaimed Pepin II, the son of the dead king.

**The partitioning of the Carolingian Empire.** After the death of Louis the Pious (840), his sons continued their plotting to alter the succession. Louis the German and Charles the Bald united against Lothair (Oath of Strasbourg, 842).

*The Treaty of Verdun.* Later the three brothers came to an agreement in the Treaty of Verdun (843). The empire was divided into three kingdoms arranged along a north-south axis: Francia Orientalis was given to Louis, Francia Media to Lothair, and Francia Occidentalis to Charles the Bald. The three kings were equal among themselves. Lothair kept the title of emperor, but this title had completely lost its universal character and had meaning only in a portion of the old empire.

*The kingdoms created at Verdun.* Until 861 the clerical ranks imposed a government of fraternity on the three brothers, manifested in the numerous conferences they held; but centrifugal forces destroyed it.

Francia Media proved to be the least stable of the kingdoms, and the imperial institutions bound to it suffered as a result. In 855 the death of Lothair I was followed by a partition of his kingdom among his three sons: the territory to the north and west of the Alps went to Lothair II (Lotharingia) and to Charles (kingdom of Provence); Louis II received Italy and the imperial title. At the death of Charles of Provence (863), his kingdom was divided between Lothair II (Rhône region) and Louis II (Provence). When Lothair II died in 869 Lo-

Norman  
invasions

tharingia was divided between his two uncles, Louis the German and Charles the Bald; the latter was made master of the Rhône regions of the ancient kingdom of Provence. Louis II (died 875) devoted most of his attention to fighting the Muslims who threatened the peninsula and the papal territories.

In Francia Occidentalis Charles the Bald was occupied with the struggle against the Normans, who ravaged the countryside along the Schelde, Seine, and Loire rivers. More often than not, the King was forced to pay for their departure with silver. Aquitaine remained a centre of dissension. For some time (until 864) Pepin II continued to have supporters there, and Charles the Bald attempted to pacify them by installing his sons—first Charles the Young (ruled 855–867) and then Charles the Stammerer (ruled 867–877)—on the throne of Aquitaine. The problems in Aquitaine were closely connected to general unrest among the magnates, who wished to keep the king under their own tutelage. By accumulating countships and creating dynasties, the magnates succeeded in carving out vast principalities at the still unstable borders: Robert the Strong and Hugh the Abbot in the west; Eudes, son of Robert the Strong, in this same region and in the area around Paris; Humfred, Vulgrin, Bernard Plantevelne, count of Auvergne, and Bernard of Gothia in Aquitaine and the border regions; Boso in the southeast; and Baldwin II in Flanders. Nevertheless, Charles the Bald appeared to be the most powerful sovereign in the West, and in 875 Pope John VIII bestowed upon him the imperial crown. But an expedition that he organized in Italy on the appeal of the pope failed, and the magnates of Francia Occidentalis rose up. Charles the Bald died on the return trip (877). Charles's son, Louis II, the Stammerer, reigned for only two years. At his death in 879 the kingdom was divided between his sons Louis III and Carloman. In the southeast, Boso, the count of Vienne, appropriated the royal title to the kingdom of Provence. The imperial throne remained vacant. The death of Louis III (882) permitted the reunification of Francia Occidentalis (except for the kingdom of Provence) under Carloman.

In Francia Orientalis, royal control over the aristocracy was maintained. But decentralizing forces, closely bound to the existence of strong ethnic communities, made themselves felt in the form of revolutions led by the sons of Louis the German. The latter partitioned his kingdom in 864, Bavaria going to Carloman, Saxony to Louis the Younger, Alemannia (Swabia) to Charles the Fat. Although Louis the German managed to gain a portion of Lotharingia in 870, he was unable to prevent Charles the Bald's coronation as emperor (875).

When Louis the German died in 876, the partition of his kingdom was confirmed. At the death of Charles the Bald, Louis the German's son Carloman seized Italy and intended to take the imperial title, but ill health forced him to abandon his plans. His youngest brother, Charles the Fat, benefitted from the circumstances and restored the territorial unity of the empire. The deaths of his brothers Carloman (880) and Louis the Younger (882) without heirs allowed him to acquire successively the crown of Italy (880) and the imperial title (881), and to unite Francia Orientalis (882) under his own rule. Finally, at the death of Carloman, son of Louis the Stammerer, Charles the Fat was elected king of Francia Occidentalis (885); the magnates had bypassed the last heir of Louis the Stammerer, Charles the Simple, in his favour.

Charles the Fat avoided involving himself in Italy, in spite of appeals from the pope, and concentrated his attention on coordinating resistance to the Normans, who had resumed the offensive in the valleys of the Schelde, Meuse, Rhine, and Seine. He was unsuccessful, however, and in 886 had to purchase the Normans' departure: they had besieged Paris, which was defended by Count Eudes. The magnates of Francia Orientalis rose up and deposed Charles the Fat (887).

#### THE FRANKISH WORLD

**Society.** *Germans and Gallo-Romans.* The settlement of Germanic peoples in Roman Gaul brought people

from two entirely different worlds into contact. Linguistic barriers were quickly overcome, for the Germans adopted Latin. At the same time, German names were preponderant. Although there were religious difficulties in those regions settled by peoples converted to Arianism (Visigoths, Burgundians), Clovis' conversion simplified matters. In keeping with the Roman principle of hospitality, the Germans who settled in Gaul were able to preserve their own judicial institutions. The first sovereigns committed the customs of the people to writing (Code of Euric, c. 470–480; Salic Law of Clovis, c. 507–511; Law of Gundobad, c. 501–515) and occasionally had summaries of Roman rights drawn up for the Gallo-Roman population (Papian Code of Gundobad; *Reviary of Alaric*); this system of individual law, certain aspects of which survived until the 9th century, did not prevent the eventual triumph of German judicial concepts. Multiple contacts in daily life produced an original civilization composed of a variety of elements, some of which were inherited from antiquity, some brought by the Germans, and all strongly influenced by Christianity.

*Social classes.* The collapse of the Roman Empire and the influx of Germans did not destroy the old Roman senatorial and landed aristocracy; the 6th-century kings called on its members to serve in their administrative bodies. A sort of military aristocracy had existed among the Germans: at the time of their settlement within the empire, its members were given lands confiscated from the Gallo-Roman aristocracy or awarded the *fisc* (royal treasury). The two groups fused rapidly. They shared a common life, discharging public and religious duties and frequenting the court. By the beginning of the 7th century there arose an aristocracy of office, whose signs of prestige were the possession of land and service to the king and church. This aristocracy increased in importance during the conflicts between the Merovingian sovereigns. The ascendancy of the Pepinids, Carolingian rule, and the power struggles in the 9th century furnished these magnates, on whom those in power were dependent, with a means of enriching themselves and augmenting their political and social influence.

Parallel to this class of lay magnates was an ecclesiastical aristocracy, which was one both of office and of land. The church found itself in possession of a vast landed fortune. At the beginning of the 7th century, at least, the church frequently benefitted from immunity, and regalian rights were conferred on abbots or bishops.

A class of small and middle-sized landholders apparently existed, about which little is known. It appears that both the power of the magnates and the practices born of the ancient patronage system had the effect of diminishing the size of this class. In fact, many free peasants appear to have been *coloni* who worked tenures.

During the Merovingian epoch, slavery, inherited from antiquity, was still a viable institution. Slaves continued to be obtained in war and through trade. But the number of slaves decreased under the influence of the church, which encouraged manumission and sought to prohibit the enslavement of Christians. Under the Carolingians, the slaves in Gaul formed only a residual class, although the slave trade was still active. Taken increasingly from the Slavic territories (the term *slavus* replaced the traditional *servus*), slaves were a commodity for trade with the Muslim lands of the Mediterranean.

*The origins of feudalism.* During the period of insecurity and turbulence that marked the end of the Merovingian epoch, bonds of personal dependence, which originated in earlier Roman and Germanic institutions, were formed with increasing frequency. In the 7th century this bond took one of two forms: recommendation (a free man placed himself under the protection of a more powerful lord for the duration of his life); precarious contract (a powerful lord received certain services in return for the use of his land for a limited time under advantageous conditions). In the 8th century, the Pepinids had to form a circle of followers, and cavalry began to assume a preponderant role in armies, increasing the expense of military service. This situation encouraged feudal practices, which then began to take their definitive

The  
mixing  
of  
cultures

form. Charlemagne attempted to encompass the entire population of his empire within the feudo-vassal relationship. He encouraged the development of feudal institutions and gave them administrative functions. During the 9th-century power struggles, however, these institutions were distorted. Enfeoffment became hereditary, though it was not originally meant to be so. In addition, before the end of the century a man could place himself in vassalage to several lords. Finally, the feudal bond allowed for the usurpation of regalian powers; and this led to the formation of territorial principalities, resulting in the disintegration of royal authority.

**Institutions.** The institutions of government underwent great changes under the Frankish monarchs.

**Kingship.** Kingship was the basic institution in the Merovingian kingdom. Since Clovis' reign, the power of the king had extended not only over a tribe or tribes but also over a territory inhabited by Germans of divergent backgrounds and by Gallo-Romans as well. The king exercised absolute power without legal limitations; the only possible curbs on him were civil war, assassination, and a belief in God and the saints. So constituted, royal power was dynastic and patrimonial. The Frankish kings successfully eliminated the common Germanic practice of the magnates electing the king (the Frankish king was content to present himself to the magnates who acclaimed him) and accepted the hereditary principle as a personal right. The kings had to concede, however, to the partition of the kingdom at each succession. Royal power, as was the case in all German monarchies, also had a sacred aspect; under the Merovingians the external sign of this was long hair.

The nature of the Frankish monarchy was profoundly changed during the Carolingian epoch. When Pepin III the Short restored the office of king in his own name, he had himself consecrated first by a bishop and then by the pope. This rite, of biblical origin, had already been adopted by the Visigoths; it gave a new foundation to royal authority because it reinforced the religious character of the monarchy and signified the king's receipt of special grace from God. The king was permitted to reign and was given stature above the common level because of this grace. Acclamation by the magnates became a pledge of obedience to a king whom God had invested with power.

To this new royal status Charlemagne added the title of emperor, which had not been used in the West since 476. He adopted this title as a concession to the situation at the time. It was conferred in the course of a ceremony that, in spite of the presence of the pope, was of secular character. Perhaps Charlemagne felt that it was only a provisional dignity, which would not survive him. But among the clerical ranks that formed the entourage of the new emperor, the revival of the empire was regarded as a magistracy conferred by God in the interests of Western Christianity and the church; imperial authority was considered a kind of priesthood, and its bearer was obligated to lead and protect the faithful. This idea reached fruition under Louis the Pious, who introduced the ceremony of anointment as part of the investiture; this ritual furnished the pope with the means for gaining a dominant role in the designation of the emperor. His role increased because, in spite of all the efforts of the clergy to maintain the integrity of the empire, the imperial title was returned to Italy. Later Carolingian emperors were designated on the basis of the interests and actions of the papacy.

**The central government.** By the time of Clovis, the ancient Germanic assembly of free men no longer participated in the conduct of affairs and was consigned to a military role. Within each kingdom, the king was surrounded by a court. This court had been a Roman imperial institution, which the Frankish sovereigns had adopted, modifying it to suit their own needs. The court encompassed domestic services (treasury, provisioning, stables, clergy), a bureau of accounts, and a military guard (antrustion). It was presided over by three men—the seneschal, the count of the palace, and the mayor of the palace—who travelled with the king who, while having various privileged places of residence, did not live at a fixed capital.

**Local institutions.** Except in the north, which was divided into regions called *pagi*, the Merovingians continued to use the city (the Roman *civitas*) as the principal administrative division. A count was installed in each *pagus* and town and given financial, military, and judicial authority. Groups of counts were placed under the authority of a duke, whose responsibilities were primarily military.

**The development of institutions in the Carolingian age.** The Carolingians contented themselves with refining their administrative system in order to strengthen royal control and to solve the problems posed by a large empire. The kingdom's cohesion was augmented by an oath of fidelity, which Charlemagne exacted from every free man (789, 793, 802), and by the publication of legislation—the capitularies—which regulated the administration and exploitation of the kingdom. While he did not forgo the itinerant life, Charlemagne did wish to make Aachen, where he constructed a vast palace, the centre of his state.

At the local level, a broad government—the march—was formed in the most exposed areas. In order to counterbalance the absolute power of the counts, the episcopate was given a central role in the administration. Charlemagne extended the use of the *missi dominici*—i.e., envoys who served as liaisons between the central government and local agents, and who were responsible for keeping the latter in line. In order to strengthen his control over the population, Charlemagne attempted to develop intermediary bodies; he tried to use both vassalage and immunity as means of government—in the first instance by creating royal vassals and feudalizing public offices, in the second, controlling protected institutions (monasteries, etc.) through the person assigned to defend them (the *advocatus*).

**Economic life.** Agriculture was the principal economic activity, and during the entire Frankish age the great estate, inherited from antiquity, remained the predominant characteristic of rural life. These estates were the residence and principal source of income of the aristocracy. The estates appear to have long been placed under direct cultivation by servile labour, which was abundant at the time. The heavy work was done with the assistance of day labourers; a portion, however, was given to the tenants—the *coloni*—who were compelled to pay annual charges. With the decline in slavery at the end of the Merovingian era, the number of tenancies was increased and tenants were compelled to render significant amounts of forced labour to cultivate land held directly by the lord. This system was not adopted throughout the Frankish empire (it was most widespread between the Seine and the Rhine), and it soon fell into disuse.

**Trade.** Most scholars formerly believed that the Germanic invasions had destroyed the ancient economy, the foundation of which was Mediterranean trade. Others, notably the great French historian Henri Pirenne, have maintained that the ancient economic system lasted until the Muslim invasions of the 7th–8th centuries. While the matter is not yet settled, the following facts are definite. Commerce did not decline abruptly—in Gaul, such goods as papyrus, oil, and spices were imported from the East, and there were numerous colonies of Syrians; currency continued to be based on the gold standard, and imperial units were still used; and all signs point to the existence of manufacturing for trade (marble from Aquitaine, Rhenish glass, ceramics).

During the Carolingian age the Mediterranean, although not completely closed (Italy was the single Western port of trade with the East), no longer occupied its long-standing place in the economy. The adoption of a new monetary system based on silver and a reduction in the number of Oriental goods and merchants are signs of the change. After the 7th century, trade among the countries bordering the English Channel and the North Sea and in the Meuse Valley increased steadily. In the north, trade continued among the Scandinavians, expanding until in the 9th century it brought them to Russia. The Vikings, with their great commercial centres at Birka in Sweden and Hedeby in Denmark, were both pirates and

Changes  
in the

nance  
of the  
estate

traders; they established new contacts between East and West.

In addition to this large-scale commerce there was agriculturally based local trade. The number of markets increased, and market towns (as opposed to the former Gallo-Roman cities, which survived mainly as fortresses and religious centres) began to appear.

*Frankish fiscal law.* The Frankish fiscal system reflected the evolution of the economy. Frankish kings were unable to continue the Roman system of direct taxation. Their principal sources of income were the exploitation of the domains of the fisc (royal treasury), war (booty, tribute), the exercise of power (monetary and judicial rights), and the imposition of *telonea* (taxes collected on the circulation and sale of goods), the number of which was increased by the kings.

**The church.** The episcopate and the diocese were practically the only institutions to survive the collapse of the Roman Empire. During the German conquest many bishops played important roles in defending the population. During the Frankish era bishops and abbots occupied a socially prominent position because of both their great prestige among the people and their landed wealth.

*Institutions.* The organization of the secular church took its final form under the Merovingian and Carolingian kings. The administrative bodies and hierarchy of the early Christian church were derived from institutions existing during the late Roman Empire. In principle, a bishop was responsible for the clergy and faithful in each town (*civitas*). The bishop whose seat was in the metropolitan city had pre-eminence and was archbishop over the other bishops in his district. During the Merovingian era, the episcopate became more discernibly national in character. By the 7th century, the practice of the king appointing bishops had become common. This was to have many consequences—in the first place, kings most often appointed bishops from among their followers without regard for religious qualifications; in the second, the metropolitan see was often fragmented in the course of territorial partitions and tended to lose its importance; and finally, the church in Gaul tended to withdraw more and more from papal control, despite papal attempts to re-establish ties.

The first Carolingians re-established the ecclesiastical hierarchy. They restored the authority of the archbishops and generalized the institution of cathedral chapters in order to have the clergy living around a bishop submit to a communal life. They did not renounce their right to nominate bishops, however, whom they considered more than ever to be agents of the monarchy.

During the 4th and 5th centuries, success at converting the countryside made it necessary for the bishops to divide the dioceses and create branches of the episcopal churches in the most important places. The first generation of these great parish churches was limited to between 15 and 40 per diocese. They were further divided in the Carolingian era and replaced by small parish churches better suited to the conditions of rural life.

*Monasticism.* Monasticism originated in the East. It was introduced in the West during the 4th century and was developed in Gaul, mainly in the west (St. Martin) and southeast (St. Honoratus and St. John Cassian). The earliest monasteries were not organized according to any definite system. In spite of efforts to impose a communal form of discipline, eremitism was the most widespread practice. Beginning in the 6th century, the number of monasteries throughout Gaul increased and efforts were made to regularize this kind of religious life. The Irish monasticism introduced by St. Columban (543–615) was very influential in the 7th century, but it was later superseded by the Benedictine rule, introduced from Italy. The monasteries suffered from the upheavals affecting the church in the 8th century. The Carolingians attempted to reform the monasteries. Louis the Pious, acting on the advice of St. Benedict of Aniane, imposed the Benedictine rule; its usage became general, and from that point on the Benedictine rule was a characteristic feature of western monasticism. On the other hand, the Carolingians continued the practice of having lay abbots.

*Education.* In the 6th century, especially in southern Gaul, the aristocracy and, consequently, the bishops drawn from it preserved an interest in traditional classical culture. Beginning in the 7th century, however, a new culture issued forth from the Columbanian monasteries based not on a study of the authors of antiquity but on the study of the Bible and the celebration of the liturgy. These new principles were triumphant in the Carolingian era.

*Religious discipline and piety.* One characteristic of the church in the 6th century was the frequent convening of councils to settle questions of doctrine and discipline. The conciliar institution declined, however, resulting in a struggle that was aggravated by intervention on the part of the secular powers, leading to liturgical anarchy and a moral and intellectual crisis among the clergy. At the same time that they were re-establishing discipline in the clergy, Charlemagne and Louis the Pious attempted to impose a uniform liturgy, inspired by the one used at Rome. They also took measures to raise the standard of education of both clerics and the faithful.

One of the most original aspects of faith during the Frankish epoch was the development of the cults of saints and relics. The desire to possess the greatest possible number of relics of distinguished saints became a permanent concern of clerics and the faithful. Beginning in the Carolingian era a veritable commerce in relics developed, with Rome as one of the key centres. The number of pilgrimages thus increased. The desire on the part of the faithful to be buried near relics upset funeral practices. Ancient cemeteries, peripherally located, were abandoned and burials in or near churches (burials *ad sanctos*) increased.

In spite of progress in conversions, the continuing influence of German paganism provoked a pagan reaction. During the 6th and 7th centuries, religious authorities were constantly denouncing pagan practices.

*The influence of the church on society and legislation.* The progressive Christianization of society influenced Frankish institutions significantly. The introduction of royal consecration and the creation of the empire afforded the clergy an opportunity to elaborate a new conception of power based on religious principles. The church was involved in trying to discourage slavery and in ameliorating the legal condition of those enslaved. It was during the Carolingian period that, in reaction to the polygamy practiced in German society, Christian doctrines of marriage were formulated.

**Merovingian literature and arts.** During the entire 6th century many writers, inspired by classical tradition, produced works patterned on antique models; such writers included Sidonius Apollinaris (died c. 488), Gregory of Tours (died 594), and Fortunatus (died 599). The writing of saints' lives—hagiography—became the most widespread literary genre of the period. Nevertheless, the standard of literature continued to decline, becoming more and more conventional and artificial. The use of popular Latin became common among writers.

Religious architecture remained faithful to the early Christian model (churches of basilican type, baptisteries and vaulted mausoleums with central plans). Because of the development of the cult of saints and the practice of burying *ad sanctos*, mausoleums became common in churches. As had been the case in antiquity, marble was the principal sculptural material. In the Pyrenees, sculptors produced capitals and sarcophagi in antique style, which they exported throughout Gaul; these workshops reached their zenith in the 7th century. The development of the art of metal work (fibulae, buckles) was another characteristic of the Merovingian age. As a result of Germanic influences, new techniques came to the fore (e.g., *cloisonné* and damascene work). A new aesthetic standard, characterized by the play of colour and the use of stylized motifs, eventually predominated.

**Carolingian literature and arts.** A renaissance movement occurred during the general work of renovation undertaken by the Carolingian monarchs; they supported the movement as an aid to religious reform and as a means to enhance their own prestige. The origins of the

secular  
church

The  
cults of  
saints  
and  
relics

The  
Carolin-  
gian  
renaissance

movement lie deep in the 7th and 8th centuries. It received great stimulus, however, when the growth of the empire brought the Franks into contact with lands where a higher cultural standard had been maintained and the antique tradition was still viable (Ireland, Italy, and Anglo-Saxon England). The Carolingian sovereigns attracted foreigners (e.g., the Anglo-Saxon Alcuin, the Italian Paul the Deacon) who played a decisive role in this renewal.

After raising the standard of the clergy, Charlemagne founded a new group of scholars. Even if, contrary to legend, there was no school established in the imperial palace, there were numerous schools opened in the vicinity of churches and monasteries. An attempt was also made to reform handwriting. Research was carried on simultaneously under the auspices of several monastic centres (most notably Tours) for the purpose of standardizing writing; this effort resulted in the adoption of a regular and uniform script (Carolingian minuscule). Improved teaching and a desire to imitate classical antiquity helped to revivify the Latin used by writers and scribes.

The imperial court was a hub of intellectual life, and from it came works dedicated to the glory of the emperors. Based on the examples of ancient authors, they were a characteristic product of this literary group; important works include Einhard's *Vita Karoli imperatoris* ("Life of Charlemagne"), the Astronomer's *Vita Hludowici imperatoris* ("Life of Louis the Pious"), Nithard's *Historiarum libri IV* ("History of the Sons of Louis the Pious"), and Hincmar's *De ordine palatii*.

Beginning in the mid-9th century, however, the kingdoms formed from the partitions of the empire saw a renaissance of national cultures. The fact that the Oath of Strasbourg was drawn up in Romance and German is an early indication of this development. There is a striking contrast between the *Annales Bertiniani* ("Annals of St. Bertin"), written at the court of Charles the Bald, and the *Annales Fuldenses* ("Annals of Fulda"), written at the principal intellectual centre in Francia Orientalis. They are, respectively, the French and German narratives of the same events.

Some of the great imperial monuments erected during the Carolingian age (palace of Ingelheim, place of Aachen) reveal the permanence of ancient tradition in their regular plans and conception. The churches were the subjects of numerous architectural experiments; while some were constructed on a central plan (Germigny-des-Prés, Aachen), most remained faithful to the traditional basilican type. Liturgical considerations and the demands of the faith, however, made certain modifications necessary: crypts on the east, a westwork or second apse on the west. These church buildings afforded architects an opportunity to make definitive experiments in balancing the arches. The extension of the vaults over the entire church, and the more rational integration of the annexes and church proper, gave rise to Romanesque architecture.

The buildings of the period were richly decorated with paintings, painted stucco, and mosaics in which figural representation increasingly replaced strictly ornamental decoration. North Italian ateliers were popularizing the use of interlace in chancel decoration. Sumptuary arts became more common, especially illumination, ivory work, and metalwork for liturgical use (reliquaries).

**BIBLIOGRAPHY.** The works listed on the general history of the period in this bibliography are rather general in nature. More detailed studies will be found in the bibliographies of these works.

*General works:* A chronological framework and an introductory approach to the subject may be found in *The Cambridge Medieval History*, 2nd ed., vol. 1-2 (1966); F. LOT, C. PFISTER, and F.L. GANSHOF, *Les Destinées de l'Empire en Occident de 395 à 888*, 2nd ed. (1940-41); and MARGARET DEANESLY, *A History of Early Medieval Europe, 476 to 911* (1956).

*The invasions:* The two works by LUCIEN MUSSET, *Les Invasions: les vagues germaniques* and *Les Invasions: le second assaut contre l'Europe chrétienne (VII<sup>e</sup>-IX<sup>e</sup> siècles)* (both 1965), constitute the best and most recent restatement of this subject.

*The Merovingians:* The works of EUGEN EWIG, *Die fränkischen Teilungen und Teilreiche (511-613)* (1953) and *Die fränkischen Teilreiche im 7. Jahrhundert, 613-714* (1954), have significantly revised the political history of Merovingian Gaul.

*The Carolingians:* LUCIEN HALPHEN, *Charlemagne et l'Empire carolingien*, new ed. (1949, reprinted 1968), remains the classic work. DONALD BULLOUGH, *The Age of Charlemagne* (1965), reflects the latest scholarship.

*The civilization:* CHRISTOPHER DAWSON, *The Making of Europe: An Introduction to the History of European Unity* (1932), remains a good essay on the development of medieval civilization. See also J.M. WALLACE-HADRILL, *The Barbarian West, 400-1000*, 3rd rev. ed. (1967), and *Early Germanic Kingship in England and on the Continent* (1971).

(G.Fo.)

## Meso-American Civilization, History of

The term Meso-America means that part of Mexico and Central America that was civilized in pre-Spanish times. In many respects, the American Indians who inhabited Meso-America were the most advanced native peoples in the Western Hemisphere. The northern border of Meso-America runs west from a point on the Gulf Coast of Mexico just above the modern port of Tampico, then dips south to exclude much of the central desert of highland Mexico, meeting the Pacific coast opposite the tip of Lower California. On the southeast, the boundary extends from the mouth of the Motagua River on the Caribbean across to the Pacific shore just south of Costa Rica's Nicoya Peninsula. Thus, about half of Mexico; all of Guatemala, British Honduras, and El Salvador; and parts of Honduras and Costa Rica are included in Meso-America.

Geographically and culturally, Meso-America consists of two strongly contrasted regions: highland and lowland. The Mexican highlands are formed mainly by the two Sierra Madre ranges that sweep down on the east and west. Lying athwart them is a volcanic cordillera stretching from the Atlantic to the Pacific. The high valleys and landlocked basins of Mexico were important centres of pre-Spanish civilization. In the southeast part of Meso-America lie the partly volcanic Chiapas-Guatemala highlands. The lowlands are primarily coastal. Particularly important was the littoral plain extending south along the Gulf of Mexico, expanding to include the Petén-Yucatan Peninsula, homeland of the Mayan peoples.

Agriculture in Meso-America was advanced and complex. A great many crops were planted, of which maize (corn), beans, and various squashes were the most important. In the highlands, hoe cultivation of more or less permanent fields was the rule, with such intensive forms of agriculture as irrigation and *chinampas* (the so-called "floating gardens" reclaimed from lakes or ponds) known in some regions. In contrast, lowland agriculture was usually of the slash-and-burn type; e.g., a patch of jungle is selected, felled and burned toward the end of the dry season, and planted with a digging stick in time for the first rains. After a few years, the field is abandoned to the forest, as weed competition and declining fertility result in diminishing yields. Demographic potential was very different in the two regions, and true cities were fairly well confined to the highlands.

The extreme diversity of the Meso-American environment produced what has been called symbiosis among its subregions. Interregional exchange of agricultural, luxury, and other products led to the development of large and well-regulated markets in which chocolate beans were used for money. It may have also led to large-scale political unity and even to states and empires. High agricultural productivity resulted in a nonfarming class of artisans who were responsible for an advanced stone architecture featuring the construction of stepped pyramids, and for highly evolved styles of sculpture, pottery, and painting.

The Meso-American system of thought, recorded in folding-screen books of deerskin or bark paper, was perhaps of even greater importance in setting them off from other New World peoples. This system was ultimately

The two major regions

Principal sites of Meso-American civilization.  
 Adapted from *Grosser Historischer Weltatlas*, vol. II, *Mittelalter* (1970); Bayerischer Schulbuch-Verlag, Munich

based upon a calendar in which a cycle of 260 (13 × 20) days intermeshed with a "vague year" of 365 days (intercalculations or leap years were not used), producing a 52-year Calendar Round (see CALENDAR). The entire religious life was geared to this cycle, which is unique to them. The Meso-American pantheon was closely associated with the calendar and featured an old, dual creator-god; a god of royal descent and warfare; a sun god and moon goddess; a rain god; a culture hero called Feathered Serpent; and many other deities. Also characteristic was the notion of a layered system of 13 heavens and 9 underworlds, each with its presiding god. Much of the system was under the control of the priesthood that also maintained an advanced knowledge of astronomy.

Language groups

As many as 14 language families were found in Meso-America, but these can be grouped into six large "phyla": Utoaztecan, Macromayan, Otomanguean, Tarascan, Huavean, and Xinca-Lencan. A dominant role was played by Utoaztecan, particularly by speakers of the Nahuatl groups of languages of which Náhuatl, official tongue of the Aztec Empire, was the most important. While Macromayan includes Zoquean and Totonacan, its largest member is Mayan, with 10 mutually unintelligible languages, at least some of which were spoken by the inhabitants of the great Maya ceremonial centres. The Mexican state of Oaxaca is the centre of the extremely heterogeneous Otomanguean phylum, but the only linguistic groups that played any great part in Meso-American civilization were the Mixtec and Zapotec, both of which had large, powerful kingdoms at the time of the Spanish Conquest. Still a linguistic puzzle is Tarascan, mother tongue of an "empire" in western Mexico that successfully resisted Aztec encroachments; it has no sure relatives. Huavean and Xinca-Lencan are little-known language groups of southeastern Meso-America.

The story of what happened in pre-Spanish Meso-America is part of the larger picture of New World culture history, although the Meso-Americans reached stages of development unknown away from those areas.

This article is divided into the following sections:

- Pre-Classical and Classical periods
- Early hunters (to 6500 bc)
- Incipient agriculture (6500–1500 bc)
- Early Formative period (1500–900 bc)
  - Early village life
  - The rise of Olmec civilization

- Middle Formative period (900–300 bc)
  - Horizon markers

Pre-Classical and Classical periods

EARLY HUNTERS (TO 6500 BC)

The time of the first peopling of Meso-America remains a puzzle, as it does for that of the New World in general. It

is widely accepted that groups of Mongoloid peoples had entered this hemisphere from northeastern Siberia, perhaps by a land bridge that then existed, at some time in the late Pleistocene, or Ice Age. There is abundant evidence that, by 11,000 bc, hunting peoples had occupied most of the New World south of the glacial ice cap covering northern North America. These men hunted such large grazing mammals as mammoths, mastodon, horse, and camel, armed with spears to which were attached finely made, bifacially chipped points of stone. Recent finds in Meso-America, however, confirm the existence of a "prebifacial-point horizon" and suggest that it is of very great age. In 1967, archaeologists working at the site of Tlapacoya, southeast of Mexico City, uncovered a well-made blade of obsidian associated with a radiocarbon date of about 21,000 bc. Near Puebla, Mexico, excavations in the Valsequillo region have revealed cultural remains of human groups that were hunting mammoth and other extinct animals, along with unifacially worked points, scrapers, perforators, burins, and knives. A date of about 21,800 bc has been suggested for the Valsequillo finds.

Tepepan  
finds

More substantial information on late Pleistocene occupations of Meso-America comes from excavations near Tepepan, northeast of Mexico City. The skeletons of two mammoths were excavated that showed that these beasts had been killed with spears fitted with lance-like stone points and butchered on the spot. A possible date of about 8000 bc has been suggested for the two mammoth kills. In the same geologic layer as the slaughtered mammoths was found a human skeleton; this Tepepan "man" has been shown to be female and rather a typical American Indian of modern form. While the association with the mammoths was first questioned, fluorine tests have proved them to be contemporary.

The environment of these earliest Meso-Americans was quite different from that of today's, for volcanoes were then extremely active, covering thousands of square miles with ashes. Temperatures were substantially lower, and local glaciers formed on the highest peaks. Conditions were ideal for the large herds of grazing mammals that roamed Meso-America, especially in the highland valleys much of which consisted of cool, wet grasslands not unlike the plains of the northern United States. All of this changed around 7000 bc, when worldwide temperatures rose and the great ice sheets of northern latitudes began their final retreat, bringing to an end the successful hunting way of life that had been followed by Meso-Americans, although man probably also played his role in bringing about the extinction of the large game animals.

#### INCIPIENT AGRICULTURE (6500-1500 BC)

The three  
major food  
plants

The most crucial event in the prehistory of Meso-America was man's capture of the food energy contained in plants. This process centred on three plants: maize (Indian corn), beans, and squashes. Since about 90 percent of all food calories in the diet of Meso-Americans eventually came from maize, archaeologists for a long time sought the origins of this plant, which has no wild forms existing today, in order to throw light on the agricultural basis of Meso-American civilization. This search has successfully ended in the dry Tehuacán Valley, in the state of Puebla, Mexico, where a number of caves and rock shelters on the edge of the valley produced a long sequence of occupations from the Early Hunters stage through the Conquest. Preservation of plant remains is remarkably good, and from these it is evident that shortly after 6500 bc the inhabitants of the valley were selecting and planting seeds of chili peppers, cotton, and one kind of squash.

Most importantly, between 5000 and 3500 bc they were beginning to plant mutant forms of maize that already were showing signs of the husks characteristic of domestic corn. Stands of truly wild maize, however, were also exploited. In terms of food energy available, there is little difference between the wild and early domesticated forms, but it has been estimated that there is more energy present in a single kernel of some modern races than in an ear of this ancient Tehuacán maize. Possibly some of this was popped, but a new element in food preparation is

seen in the *metates* (querns) and *manos* (handstones) that were used to grind the corn into meal or dough.

Beans appear after 3500 bc, along with a much improved race of maize. This enormous increase in the amount of plant food available was accompanied by a remarkable shift in settlement pattern. In place of the temporary hunting camps and rock shelters, which were only seasonally occupied by small bands, semipermanent villages of pit houses were constructed on the valley floor. Increasing sedentism is also to be seen in the remarkable bowls and globular jars painstakingly pecked from stone, for pottery was as yet unknown in Meso-America.

Pottery, which is a good index to the degree of permanence of a settlement (because of its fragility it is difficult to transport), was made in the Tehuacán Valley by 2300 bc. Fired clay vessels were made as early as 3000 bc in Ecuador and Colombia, and it is probable that the idea of their manufacture gradually diffused north to the increasingly sedentary peoples of Meso-America.

The picture, then, is one of man's growing control over his environment through the domestication of plants; animals played a very minor role in this process, with only the dog being surely domesticated before 1500 bc. At any rate, by 1500 bc the stage was set for the adoption of a fully settled life, with many of the sedentary arts already present. The final step was taken only when native agriculture in certain especially favoured subregions became sufficiently effective to allow year-round settlement of villages.

#### EARLY FORMATIVE PERIOD (1500-900 BC)

**Early village life.** It is fairly clear that the Mexican highlands were far too dry during the much warmer interval that prevailed from 5000 to 1500 bc for agriculture to supply more than half of a given population's energy needs. This was not the case along the alluvial lowlands of southern Meso-America, and it is no accident that the best evidence for the earliest permanent villages in Meso-America comes from the Pacific littoral of Chiapas (Mexico) and Guatemala, although comparable settlements probably existed along the Gulf Coast.

The Ocos (c. 1500-1200 bc) and Cuadros (1100-900 bc) phases on the Pacific coast of Guatemala are good examples of these early village cultures. From the rich lagoons and estuaries in this area, the villagers obtained oysters, mussels, clams, crabs, many kinds of fish, and turtles. They were productive corn farmers as well, raising a small-eared race of maize called Nal-Tel, which their wives and daughters ground on *metates* and *manos* and cooked in globular jars. Their villages were small, with perhaps 10 to 12 thatched-roof houses arranged haphazardly.

Ocos and  
Cuadros  
phases

Ocos pottery is highly developed technically and artistically. Something of the mental life of the times may be seen in the tiny, handmade clay figurines produced by the Ocos villagers. These, as in Formative cultures generally throughout Meso-America, represent nude females and may have something to do with a fertility cult. The idea of the temple-pyramid may well have taken root by this time, for one Ocos site has produced an earthen mound about 26 feet (8 metres) high that must have supported a perishable building. The implication of the site is that with increasing prosperity, some differentiation of a ruling class had taken place, for among the later Meso-Americans the ultimate function of a pyramid was as a final resting place for a great leader.

Eventually, the highlands also saw the appearance of effective village farming with nucleated settlements occupied throughout the year. But perhaps from the very beginning of Formative life there were different cultural responses directed toward both kinds of environment. In the highlands, divided into a number of mutually contrasting environments no one of which could have provided sufficient resources for the subsistence of a single settlement, villages were presumably linked to each other symbiotically. In the lowlands, particularly in the littoral, one especially favourable environment, such as the lagoon-estuary system, may have been so rich in resources that villages within it would have been entirely self-suffi-

cient. In effect, the former would have resulted in a cultural integration based upon trade, while the latter would have been integrated, if at all, by a unity of likeness. The two kinds of civilization that eventually arose in each region, urban and non-urban, reflect the same contrast.

**The rise of Olmec civilization.** Until recent years, it was assumed that the Formative stage was characterized only by simple farming villages. It is now realized, however, that coexisting with these peasant-like cultures was a great civilization, the Olmec, that had arisen in the humid lowlands of southern Veracruz and Tabasco, in Mexico.

The Olmec were perhaps the greatest sculptors of ancient Meso-America. Whether carving tiny jade figures or gigantic basalt monuments, the great artistry of their work has led a number of archaeologists to doubt their considerable antiquity, although a number of radiocarbon dates from the type site of La Venta showed that Olmec civilization was indeed Formative, its beginning dating to at least 1,000 years before the advent of Maya civilization.

The  
San  
Lorenzo  
site

San Lorenzo is now established as the oldest known Olmec centre. In fact, excavation has shown it to have taken on the appearance of an Olmec site by 1150 BC and to have been destroyed, perhaps by invaders, around 900 BC. Thus, the Olmec here had already achieved considerable cultural heights within the Early Formative, at a time when the rest of Meso-America was at best on a Neolithic level. The reasons for its precocious rise must have had something to do with its abundant rainfall and the rich alluvial soil deposited along the broad, natural levees that flank the waterways of the southern Gulf Coast. Thus, the ecological potential for corn farmers in this counterpart of Mesopotamia's Fertile Crescent was exceptionally high. The levee lands, however, were not limitless, and increasingly dense populations must inevitably have led to competition for their control. Out of such conflicts would have crystallized a dominant land-owning class, perhaps a group of well-armed lineages. It was this elite that created the Olmec civilization of San Lorenzo.

In appearance, the San Lorenzo site is a compact plateau rising about 160 feet (50 metres) above the surrounding plains. Cutting into it are deep ravines that were once thought to be natural but that are now known to be man-made, formed by the construction of long ridges that jut out from the plateau on the northwest, west, and south sides. Excavations have proved that at least the top 26 to 33 feet (8 to 10 metres) of the site was built by the labour of men. There are about 200 small mounds on the surface of the site, each of which once supported a dwelling house of pole and thatch, which indicates that it was both a ceremonial centre, with political and religious functions, and a minuscule town.

San Lorenzo is most noted for its extraordinary stone monuments. Many of these, perhaps most, were deliberately smashed or otherwise mutilated c. 900 BC and buried in long lines within the ridges and elsewhere at the site. They weighed as much as 44 tons and were carved from basalt from the Cerro Cintepec, a volcanic flow in the Tuxtla Mountains about 50 air miles to the northwest. It is believed that the stones were somehow dragged down to the nearest navigable stream and from there transported on rafts up the Coatzacoalcos River to the San Lorenzo area. The amount of labour involved must have been enormous and so would have the social controls necessary to see the job through to its completion.

The  
"Colossal  
Heads"

Most striking are the "Colossal Heads," human portraits on a stupendous scale. Seven of these are now known for San Lorenzo, the largest of which is nine feet high. The visages are flat-faced, with thickened lips and staring eyes. Each has a headgear resembling a football helmet, and it is entirely possible that these "helmets" were in fact protective coverings in a rubber-ball game that is known from Olmec figurines to have been played at San Lorenzo.

The central theme of the Olmec religion is a pantheon of deities each of which usually is a hybrid between jaguar and human infant, often crying or snarling with open mouth. This "were-jaguar" is the hallmark of Olmec art,

and it was the unity of objects in this style that first suggested to scholars that they were dealing with a new and heretofore unknown civilization. There is actually a whole spectrum of such were-jaguar forms in Olmec art, ranging from the almost purely feline to the human in which only a trace of jaguar can be seen.

These Olmec monuments were generally carved in the round with great technical prowess, even though the only methods available were pounding and pecking with stone tools. Considerable artistry can also be seen in the pottery figurines of San Lorenzo, which depict nude and sexless individuals with were-jaguar traits.

Exotic raw materials brought into San Lorenzo from distant regions suggest that the early Olmec controlled a large trading network over much of Meso-America. Obsidian, used for blades, flakes, and dart points, was imported from highland Mexico and Guatemala. Most items were obviously for the luxury trade, such as iron ore for mirrors and various fine stones like serpentine employed in their lapidary industry. One material that is conspicuously absent, however, is jade, which does not appear in Olmec sites until after 900 BC and the fall of San Lorenzo.

Olmec  
trade

There is growing evidence that the Olmec themselves had sent groups from their Gulf Coast "heartland" into the Meso-American highlands toward the end of the Early Formative, in all likelihood to guarantee that prestige goods needed by the elite of San Lorenzo would reach their destination. San Lorenzo-type Olmec ceramics and figurines have been found in burials at several sites in the Valley of Mexico, such as Tlapacoya, and in the state of Morelos. The Olmec involvement with the rest of Meso-America continued into the Middle Formative and probably reached its peak at that time.

San Lorenzo is not the only Olmec centre known for the Early Formative. Laguna de los Cerros, just south of the Cerro Cintepec in Veracruz, appears to have been a large Olmec site with outstanding sculptures. La Venta, just east of the Tabasco border, was another contemporary site, but it reached its height after San Lorenzo had gone into decline.

#### MIDDLE FORMATIVE PERIOD (900-300 BC)

**Horizon markers.** Once ceramics had been adopted in Meso-America, techniques of manufacture and styles of shape and decoration tended to spread rapidly and widely across many cultural frontiers. These rapid diffusions are called horizons, which enable archaeologists to link different cultures on the same time level. For the Early Formative, complex methods of rocker stamping (a mode of impressing the wet clay with the edge of a shell); the *tecomate* or globular, neckless jar; and Olmec excised pottery are good horizon markers. The beginning of the Middle Formative over much of Meso-America is marked by the diffusion of a very hard, white pottery, decorated with incised lines, and by solid pottery figurines with large, staring eyes formed by a punch. The people who replaced and probably overthrew the Olmec of San Lorenzo at about 900 BC had such pottery and figurines, the ultimate origins of which are still a puzzle.

During the Middle Formative, cultural regionalism increased, although the Olmec presence can be widely detected. The transition to fully settled life had taken place everywhere, and burgeoning populations occupied hamlets, villages, and perhaps even small towns throughout Meso-America, both highland and lowland.

**Olmec civilization at La Venta.** La Venta was located on an almost inaccessible island, surrounded at that time by the Tonalá River, which divides the states of Veracruz and Tabasco. As San Lorenzo's fortunes fell, La Venta's rose, and between 800 and 400 BC it was the most important site in Meso-America.

At the centre of La Venta is a 100-foot-high mound of earth and clay that may well house the tomb of a great Olmec ruler. Immediately north of the Great Mound is a narrow north-south plaza flanked by a pair of long mounds. Beyond the plaza is a ceremonial enclosure surrounded by a "fence" made entirely of upright shafts of columnar basalt.

A low, round mound on the north side of the ceremonial enclosure contained several tombs, one of which was surrounded and covered by basalt columns. In this tomb were found the bundled remains of two children, accompanied by magnificent ornaments of jade. Offerings were made not only to be placed with the dead but were also deposited as caches in the site, especially along the north-south axis of the ceremonial centre.

Olmec  
iron  
mirrors

Among the most beautiful objects manufactured by the Olmec were the concave mirrors of iron ore, which were pierced to be worn around the neck. These can throw pictures on a flat surface and can probably start fires on hot tinder. Olmec leaders at La Venta, whether kings or priests, undoubtedly used them to impress the populace with their supernatural powers. Olmec sculptors continued to produce basalt monuments, including Colossal Heads and "altars," at La Venta. Significantly, an increasing number of monuments were carved in relief, and some of these were stelae with rather elaborate scenes obviously based upon historical or contemporary events.

**Olmec colonization in the Middle Formative.** In the Middle Formative there are important Olmec sites located along what seems to have been a highland route to the west to obtain the luxury items that seemed to have been so desperately needed by the Olmec elite; e.g., jade, serpentine, iron ore for mirrors, cinnabar, and so forth. Olmec sites in Puebla, the Valley of Mexico, and Morelos are generally located at the ends of valleys near or on major passes; they were perhaps trading stations garrisoned by Olmec troops. The most impressive of these sites is Chalcatzingo, Morelos, a cult centre located among three denuded volcanic peaks rising from a plain. On a talus slope at the foot of the middle peak are huge boulders on which have been carved Olmec reliefs in La Venta style. The principal relief shows an Olmec woman, richly garbed, seated within the mouth of a cave; above her, cumulus clouds pour down rain.

Similar Olmec reliefs, usually narrative and often depicting warriors brandishing clubs, have been located on the Pacific plain of Chiapas (Mexico) and Guatemala. Within the last decade, spectacular Olmec cave paintings have been found in Guerrero, offering some idea of what the Olmec artists could do when they worked with a large spectrum of pigments and on flat surfaces.

There is a conspicuous absence of Olmec remains in the lowland Maya area. In fact, there is no sure evidence of any kind of human occupation there until after 800 BC, and the nonexistence of Olmec sites or carvings may simply reflect that the San Lorenzo and La Venta elite were uninterested in the region, perhaps because of even poorer agricultural potential than exists today.

It used to be thought that the Olmec worshipped only one god, a rain deity depicted as a were-jaguar, but a recent study has shown that there were at least 10 distinct gods represented in Olmec art. Surely present were several important deities of the later, established Meso-American pantheon, such as the Fire God, Rain God, Maize God, and Feathered Serpent. Other aspects of mental culture are less well-known; some Olmec jades and a monument from La Venta have noncalendrical hieroglyphs, but none of this writing can as yet be deciphered. To sum up the Olmec achievement, not only was this the first high culture in Meso-America—one that had certainly achieved political statehood—but either it or cultures influenced by it lie at the base of every other Meso-American civilization.

**Early Monte Albán.** Monte Albán is a prominent series of interconnected hills lying near Oaxaca, Mexico. One of these was completely levelled off in Middle Formative times to serve as the base for a site that was to become the Zapotec people's most important capital. A peculiar group of reliefs carved on sandstone slabs is believed to date from this earliest epoch, Monte Albán I. These slabs were affixed to the front of a rubble-faced platform mound and around a contiguous court.

The  
"Danzantes"  
figurines

The reliefs are usually called "Danzantes," a name derived from the notion that they represent human figures in dance postures. Actually, almost all of the "Danzante" sculptures show Olmecoid men in strange, rubbery pos-

tures as though they were swimming in honey. From their open mouths and closed eyes, it can be assumed with great certainty that they are meant to represent dead persons. On many "Danzantes" one or more unreadable hieroglyphs appear near the heads of the figures, most likely standing for the names of the sacrificed lords of groups beaten in combat by the Zapotec. Several slabs also bear calendrical notations, and it can be firmly stated that the Middle Formative elite of Monte Albán were the first in Meso-America to develop writing and the calendar (at least in written form).

**Village cultures of the Middle Formative.** When Europe had not yet emerged from Neolithic barbarism, the Near East had already entered Bronze Age civilization. A similar culture lag is to be found in those parts of Meso-America not strongly touched by the Olmec spark. On the western shores of the great lake filling the Valley of Mexico, for instance, remains of several simple villages have been uncovered that must have been not unlike small settlements that can be found in the Mexican hinterland today. The people who lived at El Arbolillo and Zacatenco had simply terraced off village refuse to make platforms on which their pole-and-thatch houses were built. *Metates* and *manos* are plentiful; pottery is relatively plain with the abundant hard, white-slipped ware of the Middle Formative, and amusing little female figurines are present by the thousands. Subsistence was based upon corn farming and upon hunting. In contrast to the nearby site of Tlatilco, which flourished under an Olmec-influenced elite in the Early and Middle Formative, there is virtually no evidence of ceremonial life for these two villages, which probably followed popular fertility cults.

In the Maya highlands, the key archaeological region has always been the broad, fertile Valley of Guatemala around present-day Guatemala City. The earliest substantial occupation of the valley is called Las Charcas, a Middle Formative culture known largely from the contents of bottle-shaped pits found dug into the subsoil on the western edge of the capital. In them have been excavated extremely fine ceramics, including red-on-white bowls with animal figures, effigy vessels, three-footed cups, and peculiar three-pronged incense burners. Solid female figurines are also present, but there are no detectable gods to be seen among them.

Las  
Charcas

It has been mentioned that the Maya lowlands, in spite of extremely intensive archaeological survey, have no sure occupation at all before 800 BC. At about this time, the early Middle Formative culture known as Réal-Xe appears at certain sites in the western part of the Maya area, such as Seibal and Altar de Sacrificios. The problem of the origin of the Mayan-speaking people has not been solved, but one possibility is that the *ur*-Mayans were the Olmec of the Gulf Coast "heartland." With the collapse of San Lorenzo about 900 BC, some Olmec groups may have begun colonizing the empty lowlands to their east. Another group could have moved north along the Gulf Coast to become the Huastec, who were also Mayan speakers. Thus, Olmec and Maya would have been the same people.

The succeeding Middle Formative culture, Mamom, has been found all over the Maya lowlands, from the central Petén Peninsula to northern Yucatan. It is known only from deeply buried refuse layers underneath the plazas of Maya ceremonial centres and is not very different from Las Charcas in its main features. Pottery is almost entirely monochrome—red, orange, black, and white—and figurines are female with the usual punched and appliqué embellishments. Little or nothing is known of Mamom architecture, perhaps because whatever might have existed is covered with towering masses of Late Formative and Classic Maya temple and palace structures. But from what is known, Maya culture of the Middle Formative was on the peasant level and in the cultural shadow of the Olmec civilization to the west.

#### LATE FORMATIVE PERIOD (300 BC-AD 100)

Probably the most significant features of the Late Formative are (1) the transformation of Olmec civilization in southeastern Meso-America into something approaching

Horizon  
traits

the earliest lowland Maya civilization and (2) the abrupt appearance, toward the end of the Late Formative, of fully urban culture at Teotihuacán in the Valley of Mexico. Most of the distinctive cultures that were to become the great Classic civilizations began to take shape at this time. There was no unifying force in the Late Formative comparable to the earlier Olmec; rather, regionalism and local cultural integration were the rule. There were, however, horizon traits, particularly in pottery, that were almost universal. Ceramics became highly involved in shape, often with composite or recurved outlines, hollow, bulbous feet, and flange-like protrusions encircling the vessel. The use of slips of several different colours as pottery decoration at times approached the elaborate polychromes of Classic times.

The idea of constructing temple-pyramids was probably also a general trait. It was a Meso-American custom to bury a dead person beneath the floor of his own house, which was often then abandoned by the bereaved. As an elite class of noble lineages became distinguished from the mass of the people, the simple house platforms serving as sepulchres might have become transformed into more imposing structures, ending in the huge pyramids of the Late Formative and Classic, which surely have funerary functions. The deceased leader or the gods from which he claimed descent, or both, would then have been worshipped in a "house of god" on the temple summit. These pyramids became the focal point of Meso-American ceremonial life, as well as the centres of their settlements.

**Valley of Mexico.** The Cuicuilco-Ticomán culture succeeded the Middle Formative villages of the valley but retained many of their traits, such as the manufacture of solid, handmade figurines. Of considerable interest is the type site of Cuicuilco, located on the southwestern edge of the valley. Lava from a nearby volcano covers all of Cuicuilco, including the lower part of the round "pyramid" for which it is best known. Ceramic analysis and radiocarbon dating, however, have proven the flow to have occurred at about the time of Christ. Rising up in four tiers, the Cuicuilco pyramid has a clay-and-rubble core faced with broken lava blocks. The summit was reached by ramps on both sides. Circular temples were traditionally dedicated in Meso-America to Quetzalcóatl, the Feathered Serpent, and he may have been the presiding deity of Cuicuilco.

In the Valley of Teotihuacán, a kind of side pocket on the northeastern margin of the Valley of Mexico, Cuicuilco-Ticomán culture eventually took on a remarkable outline, for there is evidence that by the beginning of the Christian Era a great city had been planned. There is little doubt that by the Proto-Classic stage (AD 100-300) it had become the New World's first urban civilization (see below).

**Valley of Oaxaca.** Occupation of the Monte Albán site continued uninterrupted, but ceramic evidence for Monte Albán II culture indicates that cultural influences from southeastern Mexico were reaching the Zapotec people. On the southern end of the site's main plaza is a remarkable stone structure called Building J; this is shaped like an arrow pointing southwest and is honeycombed with galleries. Some believe it to have been an astronomical observatory. Incised slabs are fixed to its exterior; these include some older "Danzantes" as well as depictions of Zapotec place glyphs from which are suspended the inverted heads of dead chiefs—surely again the vanquished enemies of Monte Albán. Dates are given in the 52-year Calendar Round, with coefficients for days and months expressed by bar-and-dot numerals, a system that is first known for Monte Albán I and that became characteristic of the Classic Maya. Throughout its long Formative and Classic occupation, the dominant ware of Monte Albán is a fine gray pottery, elaborated in Monte Albán II into the usual Late Formative shapes.

**Veracruz and Chiapas.** La Venta suffered the fate of San Lorenzo, having been destroyed by violence around 400 BC. Olmec civilization subsequently disappeared or was transformed into one or more of the cultures of the southeastern lowlands.

One centre that retained a strong Olmec tradition, however, was Tres Zapotes, near the Tuxtla Mountains in the old Olmec "heartland." Its most famous monument, the fragmentary Stela C, is clearly epi-Olmec on the basis of a jaguar-monster mask carved in relief on its obverse. On the reverse is a column of numerals in the bar-and-dot system, which was read by its discoverer, Matthew W. Stirling, as a date in the Maya calendar corresponding to 31 BC; this is over three centuries earlier than any known dated inscription from the Maya area itself. Thus, it is highly probable that this calendrical system, formerly thought to be a Maya invention, was developed in the Late Formative by epi-Olmec peoples living outside the Maya area proper.

**Izapan civilization.** Izapa, type site of the Izapan civilization, is a huge temple centre near Tapachula, Chiapas, on the hot Pacific coast plain. Its approximately 80 pyramidal mounds were built from earth and clay faced with river boulders. A large number of carved stone stelae have been found at Izapa, almost all of which date to the Late Formative and Proto-Classic. Typically, in front of each stela is a round altar, often crudely shaped like a toad.

These stelae are of extraordinary interest, for they contain a wealth of information on Late Formative religious concepts prevalent on the border of the Maya area. Izapan stelae are carved in relief with narrative scenes derived from mythology and legend; among the depictions are warfare and decapitation, ceremonies connected with the sacred world tree, and meetings of what seem to be tribal elders. Many deities are shown, each of which seems derived from an Olmec prototype.

Sites with Izapan-style sculpture are distributed in a broad arc extending from Tres Zapotes in the former Olmec region, across the Isthmus of Tehuantepec into coastal Chiapas and Guatemala, and up into the Guatemalan highlands. Izapan civilization is definitely the intermediary between Olmec and Classic Maya in time and in cultural content, for the following early Maya traits are foreshadowed by it: (1) the stela-altar complex, (2) long-lipped deities, (3) hieroglyphic writing and Long Count dates on some monuments, (4) such iconographic elements as a U-shaped motif, and (5) a cluttered, baroque, and painterly relief style that emphasizes narrative.

Perhaps it was not Izapa itself but the great site of Kaminaljuyú, on the western edge of Guatemala City, that transmitted the torch of Izapan civilization to the lowland Maya. This centre once consisted of more than 200 earth and clay mounds, most of which have been destroyed in recent years. The major occupation is ascribed to the Miraflores phase, the Late Formative culture of the Valley of Guatemala. Some of these huge Miraflores mounds contained log tombs of incredible richness. In one, the deceased lord was accompanied by sacrificed followers or captives. As many as 340 objects were placed with him, including jade mosaic masks, jade ear spools and necklaces, bowls of chlorite schist, and pottery vessels of great beauty. Also present in the tombs are peculiar "mushroom stones," which may actually have been used in rites connected with hallucinogenic mushrooms.

**The earliest Maya civilization.** By the Late Formative, the lowland Maya had begun to shape a civilization that was to become the greatest in the New World. The Petén-Yucatan Peninsula lacks many raw materials and has a relatively low agricultural potential. But what it does have in limitless quantities is readily quarried limestone for building purposes and flint for stoneworking. Cement and plaster could easily be produced by burning limestone or shells.

The heart of the Maya civilization was always the northern Petén, in Guatemala, where the oldest dated Maya stelae are found. The Late Formative culture of the Petén is called Chicanel, evidence of which has been found at many Maya centres. Chicanel pottery includes dishes with wide-everted and grooved rims, bowls with composite silhouette, and ice-bucket-like vessels. Figurines are curiously absent.

Tres  
ZapotesKaminal-  
juyú

Early  
architec-  
ture

Architecture was already quite advanced and had taken a form peculiar to the Maya. Temple-platforms were built by facing a cemented-rubble core with thick layers of plaster. At the site of Uaxactún, Structure E-VII-sub affords a good idea of a Chicanel temple-platform. It is a four-sided, stucco-covered, stepped pyramid with pairs of stylized godmasks flanking stairways on each side. On its summit was a thatched-roof temple. At Tikal, the giant among Maya ceremonial centres, the so-called Acropolis was begun in Chicanel times, and there was a great use of white-stuccoed platforms and stairways, with flanking polychromed masks as at Uaxactún. Most importantly, there is evidence from Tikal that the Maya architects were already building masonry superstructures with the corbel vault principle; *i.e.*, with archlike structures the sides of which extend progressively inward until they meet at the top.

Chicanel-like civilization is also known in Yucatán, where some temple-pyramids of enormous size are datable to the Late Formative. An outstanding site is the cave of Loltún in Yucatán, where a relief figure of a standing leader in pure Izapan style is accompanied by a number of unreadable hieroglyphs as well as a notation in the 260-day count. This inscription raises the question of writing and the calendar among the lowland Maya in the Late Formative. On the whole, the evidence is negative and suggests that several important intellectual innovations considered to be typically Maya were developed beyond the Maya area proper and only appeared there at the close of the Formative. Izapan civilization played the crucial role in this evolutionary process.

#### EARLY CLASSIC PERIOD (AD 100-600)

**Definition of the Classic.** In the study of the Classic stage, there has been a strong bias in favour of the Maya; this is not surprising in view of the fact that the Maya have been studied far longer than any other people in Meso-America. But the concept of a "Classic" period is a case of the Maya tail wagging the Meso-American dog, since the usual span given to that stage—AD 300–900—is the period during which the Maya were erecting dated stone monuments. This brackets the Maya apogee, but for most areas of non-Maya Meso-America only the first half of the period may be accurately called a "golden age." While the famous and yet mysterious Maya collapse took place at about AD 900, in many other regions this downfall occurred almost three centuries earlier.

From a qualitative point of view, there is little to differentiate the Classic from the Late Formative that preceded it. One can only say that various tendencies that were crystallizing in the last centuries before Christ reached fulfillment in the Classic. Two cultures stand out beyond all others. One is that of Teotihuacán, which during the Early Classic played a role in Meso-America similar to that which Olmec had performed in the Early Formative. The second is the lowland Maya civilization, which during its six centuries of almost unbroken evolution in the humid forests reached cultural heights never achieved before or since by New World natives. The curious contrast between the two—one urban and expansionist, the other non-urban and non-expansionist—exemplifies well the cultural results of the ecological possibilities offered by highland and lowland Meso-America.

**Teotihuacán.** Teotihuacán, which was located in the Valley of Teotihuacán, a pocket-like extension of the Valley of Mexico on its northeastern side, was probably the largest city of the New World before the arrival of the Spaniards. At its height, toward the close of the 6th century AD, it covered about eight square miles (20 square kilometres) and may have contained more than 150,000 people. The city was divided into quarters by two great avenues that crosscut each other at right angles, and the entire city was laid out on a grid plan oriented to these avenues. The Avenue of the Dead, the main north-south artery of the city, is aligned to a point 16° east of true north, which must have had astrological meaning.

Because irrigation plays some part in the present-day agricultural economy of the Valley of Teotihuacán, it has been suggested that the Early Classic city also was based

upon this subsistence system. It is almost inconceivable, however, that a city of such proportions could have relied upon the food production of its own valley or even upon the Valley of Mexico, whether irrigated or not.

Planning and construction of Teotihuacán began, according to radiocarbon dates, about the beginning of the Christian Era, in the Tzacualli phase. At this time, the major avenues were laid out and construction begun of the major ceremonial structures along the Avenue of the Dead. Figurines and potsherds extracted from fill inside the 200-foot (60-metre) high Pyramid of the Sun, the most prominent feature of Teotihuacán, prove that this was erected by the end of the Tzacualli phase. The pyramid rises in four great stages, but there is a fifth and much smaller stage between the third and fourth. An impressive stairway dramatically rises on its west side, facing the Avenue of the Dead. A recent re-examination suggests that there is a huge tomb at its base, but this has never been excavated.

On the northern end of the Avenue of the Dead is the Pyramid of the Moon, very similar to that of the Sun, but with an additional platform-temple jutting out on the south. This exhibits the *talud-tablero* architectural motif that is typical of Teotihuacán culture; on each body or tier of a stepped pyramid is a rectangular frontal panel (*tablero*) supported by a sloping batter (*talud*). The *tablero* is surrounded by a kind of projecting frame, and the recessed portion of the panel usually bears a polychrome mural applied to the stuccoed surface.

Near the exact centre of the city and just east of the Avenue of the Dead is the Ciudadela (Citadel), a kind of sunken court surrounded on all four sides by platforms supporting temples. In the middle of the sunken plaza is the so-called Temple of Quetzalcóatl, which is dated to the second phase of Teotihuacán, Miccaotli. Along the balustrades of its frontal stairway and undulating along the *talud-tablero* bodies of each stage of this stepped pyramid are sculptured representations of Quetzalcóatl, the Feathered Serpent. Alternating with the Feathered Serpents on the *tableros* are heads of another monster that can be identified with the Fire Serpent—bearer of the Sun on its diurnal journey across the sky.

On either side of the Avenue of the Dead are residential palace compounds (probably occupied by noble families), which also conform to the Teotihuacán master plan. Each is a square, 60 metres on a side, and is surrounded by a wall. The pedestrian would have seen only the high walls facing the streets, pierced by inconspicuous doors. Within the compounds, however, luxury was the rule. Roofs were flat, constructed of large cedar beams overlaid by brush and mortar. Interior walls were plastered and magnificently painted with ritual processions of gods and various mythological narratives. Interconnected apartments were arranged around a large central court that was open to the sky.

These dwellings were the residences of Teotihuacán's elite. Toward the periphery of Teotihuacán, however, the social situation may have been quite different. One excavation on the eastern side of the city disclosed a maze-like complex of much tinier and shoddier apartments that recall the poorer sections of Near Eastern cities. It may be guessed that here lay the crowded dwellings of the artisans and other labourers who made the city what it was. There is also evidence that certain peripheral sections were reserved for foreigners.

Teotihuacán must have been the major manufacturing centre of the Early Classic, for the products of its craftsmen were spread over much of Meso-America. The pottery, particularly during the Xolalpan phase, which represents the culmination of Teotihuacán as a city and empire, is highly distinctive. The hallmark of the city is the cylindrical vessel with three slab legs and cover, often stuccoed and then painted with scenes almost identical to those on the walls of buildings. There are also vessels shaped like modern flower vases and cream pitchers. Thin Orange ware is a special ceramic type produced to Teotihuacán specifications, perhaps in southern Veracruz, and exported by its own traders. Figurines were produced by the tens of thousands in pottery molds.

trade

Among its many commercial specializations, obsidian was probably pre-eminent, for the Teotihuacanos had gained control of the mines of green obsidian above the present-day city of Pachuca, in Hidalgo. They also had a local but poorer quality source. Millions of obsidian blades, as well as knives, dart points, and scrapers, were turned out by Teotihuacán workshops for export.

The name Teotihuacán meant Place of the Gods in Aztec times, and although the city had been largely deserted since its decline, the Aztec royal house made annual pilgrimages to the site. Teotihuacán culture exerted a profound influence on all contemporary and later Meso-American cultures. Many Aztec gods, such as Tlaloc, his consort Chalchiuhtlicue, and Quetzalcóatl, were worshipped by the Teotihuacanos. Like the Aztec, the Teotihuacanos generally cremated their dead. In fact, there are so many congruences between Teotihuacán practices and those of the later Toltec and Aztec that some authorities believe them to have been speakers of Nahuatl language and the precursors of those people. It is not known whether the people of the city were literate like the Maya.

Not only was Teotihuacán the greatest American Indian city in this hemisphere, it was probably the capital of the largest empire ever seen in Meso-America. Whatever the economic impetus that started it on the road to urbanism, the evidence both of its immense size and of its strong cultural presence in far-flung regions make it likely that Teotihuacán must have embarked upon imperial expansion after AD 400. At its absolute height it may well have controlled all of Meso-America, an achievement the Aztec never could have claimed. The Aztec never managed to subdue the Maya, or never tried. Apparently the Teotihuacanos did, and their interference in Maya affairs is a characteristic feature of Early Classic Maya culture. This universal spread of Teotihuacán traits truly constitutes an Early Classic horizon.

**Cholula.** The broad, fertile plains surrounding the colonial city of Puebla, to the southeast of the snowcapped volcanoes that border the Valley of Mexico, were from very ancient times an important centre of pre-Hispanic population. As the modern traveller approaches the city, he sees to its west, in the distance, what looks like a sizable hill rising from the plain. In actuality this is the pyramid of Cholula, the largest single structure in Mexico before the conquest.

Size and decoration of the Cholula pyramid

Archaeological exploration of the Cholula pyramid has shown that it was built from adobe in four great construction stages. In its final form, the pyramid covers 28 acres (11 hectares) and has a height of 180 feet (55 metres). By Late Post-Classic times the pyramid had been abandoned for so long that the Spaniards who subdued (and massacred) the residents of Cholula considered it a natural prominence. All four superimposed structures within the pyramid were carried out according to strict Teotihuacán architectural ideas. The earliest structure, for instance, has the usual *talud-tablero* motif, with stylized insect-like figures painted in black, yellow, and red appearing in the *tableros*. Similar decoration, also in Teotihuacán style, is to be found in the later structures.

Great quantities of ceramics and pottery figurines have been recovered from the excavations, and these demonstrate a near archaeological identity between Early Classic Teotihuacán and Cholula. Because of the staggering size and importance of its pyramid, it has been suggested that Cholula was some kind of sister city to Teotihuacán. Cholula was surely part of the Teotihuacán culture sphere and may well have participated in the administration of its empire.

Recent excavations at the base of the pyramid have produced a previously unsuspected cultural element. Several enormous slabs were uncovered, two of which were a kind of altar, while the third was set upright as a stela. All are rectangular, but with borders carved in low relief in the complex interlace motif that is the hallmark of the Classic Central Veracruz style.

**Classic Central Veracruz.** The Meso-American ball game has been mentioned several times above. It was played all over the area and still survives in attenuated

form in northwestern Mexico. On the eve of the conquest, games took place in a rectangular court bordered on the long sides by walls with both sloping and vertical rebound surfaces. There were two teams, each comprised of a small handful of players. The ball was of solid rubber, of substantial size, and travelled with considerable speed around the court. It could not be hit or touched with the open hands or with the feet; most times the player tried to strike it with the hip. Consequently, fairly heavy protective padding was necessary to avoid injuries, which in some cases were fatal. Leather padding was worn over the hips, and pads were placed on the elbows and knees. A heavy belt was tied around the waist built up from wood and leather, while in some parts of the Maya region and in Late Formative Oaxaca, gloves and something resembling jousting helmets were worn.

The Meso-American ball game

The Classic Central Veracruz style is almost purely devoted to the paraphernalia of the ball game and to the ball courts themselves. At the site of El Tajín, which persists through the end of the Late Classic, elaborate reliefs on the walls of the courts furnish details on how this equipment was used. *Yugos* (or "yokes") were the stone counterparts of the heavy protective belts. During the post-game ceremonies, which may have featured the sacrifice of the captain and other players on the losing side, these U-shaped objects were worn about the waists of the participants. On the front of the *yugo* was placed an upright stone object that may originally have functioned as a ball-court marker and that took two forms: *hachas* ("axes") or thin stone heads, and *palmas* ("palms"). All are carved in an extremely elaborate low-relief style in which life forms are enmeshed in undulating and interlaced scroll designs with raised borders. All of these items, and the style itself, may have evolved out of very late Olmec art on the Gulf Coast.

Very often the *yugos* represent the marine toad, a huge amphibian with swollen poison glands on the head; in its jaws is a human head. The earliest *hachas*, which are characteristically notched to fit on the *yugos*, are quite thick human heads and may well date to the Late Formative or Proto-Classic. In time, these become very thin and represent human heads wearing animal headgear. *Palmas* are paddle-shaped stone objects with trilobate bases and exhibit a much richer subject matter than either *hachas* or *yugos*, quite often illustrating brutal scenes of sacrifice and death, two concepts that were closely associated with the ball game on the Gulf Coast.

Despite the definite presence of the style at Teotihuacán and Cholula, Classic Central Veracruz is focussed upon north central Veracruz, where the type site of El Tajín is located, and contiguous parts of Puebla. Today, this region is dominated by speakers of Totonac, a distant relative of Mayan, and the Totonac themselves claim that they built El Tajín. Whether or not Classic Central Veracruz culture was a Totonac achievement, the style persisted through the Classic period and strongly influenced developments in distant regions.

**Southern Veracruz.** On the southern Gulf Coast plain, Olmec traditions seemed to have lasted into the Early Classic and merged with Teotihuacán artistic canons to produce new kinds of art. Cerro de las Mesas, lying in the plains of the Papaloápan River not far from the coast, is one of these hybrid sites. Dozens of earthen mounds are scattered over the surface in a seemingly haphazard manner, and the archaeological sequence is long and complex. The site reached its apogee in the Early Classic, when the stone monuments for which it is best known were carved. Most important are 15 stelae, some of which are carved in a low-relief style recalling Late Formative Tres Zapotes, early lowland Maya, and Cotzumalhuapa (on the Pacific Coast of Guatemala).

Cerro de las Mesas pottery, deposited in rich burial offerings of the Early Classic, is highly Teotihuacano, with slab-legged tripods predominating. At this and other sites in southern Veracruz, potters also fashioned large, hollow, handmade figures of the gods. An especially fine representation of the Old Fire God was found at Cerro de las Mesas. The most spectacular discovery, however, was a cache of 782 jade objects. Many of the specimens in this

Cerro de las Mesas pottery

treasure trove are of Olmec workmanship, obviously heirlooms from the much earlier Olmec civilization, while some are clearly Early Classic Maya.

The entire coastal plain from Cerro de las Mesas north to the borders of Classic Central Veracruz culture is famed for Remojadas-style pottery figurines, which must have been turned out in incredible quantity for use as burial goods. The Remojadas tradition goes back to the Late Formative and lasts until the Early Post-Classic. Figurines are hollow and largely mold-made in the Late Classic, while they were fashioned by hand in the Early Classic. The best known Classic representations are the "smiling figures" of grinning boys and girls wearing loincloths, skirts, or nothing at all. All kinds of genre scenes are represented, including even lovers in swings, as well as more grim activities such as the heart sacrifice of victims tied down in what look like beds.

**Classic Monte Albán.** Monte Albán III-A and III-B mark the Classic occupation of this major site in the Valley of Oaxaca. There can be little doubt that the people of Monte Albán were Zapotec speakers, who during Classic times had unequalled opportunity to develop their civilization unaffected by the major troubles that disturbed Teotihuacán and the Maya at the close of the Early Classic. Instead of the 18 or 19 sites known for the valley during the Late Formative, there now were more than 200, a testimony to Zapotec prosperity.

Zapotec  
prosperity

There is, however, a chronological problem. Monte Albán III-A is very closely linked with Teotihuacán, which may have exercised hegemony over the Zapotec between AD 300 and 600. But there is almost no difference between the products of III-A and those of III-B, suggesting that the latter cannot be substantially later than AD 600. Furthermore, radiocarbon dates on Monte Albán IV, supposedly belonging to the Early Post-Classic, fall within the Late Classic. Thus, "Classic" Monte Albán may be purely a product of the earlier period.

The Classic site of Monte Albán is quite impressive. Stone-faced platforms are fronted by stairways with flanking balustrades and exhibit a close counterpart of the *talud-tablero* motif of Teotihuacán. The temple superstructures had colonnaded doorways and flat beam-and-mortar roofs. One of the best preserved ball courts of Meso-America can be seen at Monte Albán, with a ground plan fashioned in the form of a capital "I." Spectators watched the game from stone grandstands above the sloping playing surfaces.

Subsurface tombs were dug in many parts of the site as the last resting places of Monte Albán's elite. The finest are actually miniature replicas of the larger temples on the surface, complete with facade and miniature painted rooms. The style of the funerary wall paintings is quite close to Teotihuacán, in which areas of flat colour are contained within very finely painted lines in red or black. Teotihuacán presence can also be seen in the finer pottery of Classic Monte Albán, but the manufacture is local as can be proved from the predominance of the fine gray ware that has always typified Monte Albán.

The tradition of literacy goes back to Monte Albán I. By Classic times, inscriptions are abundant, appearing on stelae, lintels, slabs used as doors, and wall paintings. The 52-year Calendar Round was the only form of writing dates. The subject matter of these inscriptions can be related to the scenes that they accompany: quite often it is a bound captive standing on a place-glyph, presumably an enemy leader taken in war—an old Monte Albán preoccupation.

The Zapotec of Monte Albán, like the Maya, never exerted much cultural or other pressure on peoples beyond their lands. They did, however, control lands from the Tehuacán Valley in Puebla as far south as the Pacific shore of Oaxaca. Whether they themselves were also controlled by Teotihuacán cannot yet be demonstrated, but it is likely.

**The Maya highlands and Pacific Coast.** Little is known about the Guatemalan highlands between the demise of the Late Formative Miraflores culture and the onset of the Early Classic. But at the ancient site of Kaminaljuyú, on the western side of Guatemala City, a group of in-

vaders from Teotihuacán built a miniature replica of their capital city. This happened about AD 400, when Teotihuacán was at the height of its power.

This implanted Teotihuacán culture is called Esperanza. Mexican architects must have accompanied the elite, for Kaminaljuyú structures copy the older prototypes down to the last detail, including the support of the lower moldings around *tableros* with slate slabs. The abundant volcanic building stone, however, so freely used at Teotihuacán, was not present, so that Esperanza temple-platforms are built from clay instead.

Each temple-platform was rebuilt several times, the later structures being raised over the earlier. Within the stairways fronting each successive platform a great leader was buried. The rich burial furniture in the tombs is quite informative, for it included three classes of goods: (1) items such as Thin Orange pottery manufactured in Teotihuacán or in one of its satellite areas, (2) hybrid Teotihuacán-Maya pottery and other objects, probably made in Kaminaljuyú, and (3) pottery imported from the Petén and of Early Classic Maya manufacture. Also discovered in one tomb was a slate mirror carved in Classic Central Veracruz style. Jade objects occur in abundance in the Esperanza tombs, and in one structure an enormous boulder was recovered; it had been imported from the Maya source along the Motagua River in the southeastern lowlands. The Esperanza elite were enormously wealthy.

What were they doing in the Maya highlands in the first place? Among the Aztec of the Late Post-Classic, there was an institution called the *pochteca*, a hereditary guild of armed merchants who travelled into distant lands looking for luxury goods to bring back to the royal house. Quite often the *pochteca* would seize lands of hostile peoples through which they passed, or they would provoke an incident that led inevitably to the intervention of the regular Aztec army.

The  
*pochteca*

It has been suggested that the Teotihuacanos in Kaminaljuyú were also *pochteca*. They had clear access to the Petén-Yucatán Peninsula and probably exercised political control over it. Kaminaljuyú may have been one of their principal bases of operations in the inclusion of the Maya, both highland and lowland, within the Teotihuacán state.

Within a restricted zone only 75 miles (120 kilometres) long and 30 miles (50 kilometres) wide, on the Pacific coast plain of Guatemala, is a cluster of nine compactly built ceremonial centres that together form the Cotzumalhuapa civilization. It forms a real puzzle, for there are strong affiliations with most other contemporary civilizations in Meso-America. Stylistic influence from the lowland Maya, Classic Central Veracruz, and Teotihuacán can be detected among others. While Cotzumalhuapa takes form by the Early Classic, it continues into the Late Classic, but there are great problems in dating individual sculptures.

The Cotzumalhuapa problem has been linked with that of the Pipil, a shadowy people living in the same region on the eve of the conquest, who spoke Nahua rather than Maya. It is possible that these Classic sites were actually Pipil capitals, but the case cannot be proved. There is some hieroglyphic writing on Cotzumalhuapa sculptures, mainly dates within what seems to be a 52-year Calendar Round, the glyphs for days being Mexican rather than Maya. There are no real texts, then, to help with the problem.

**Classic civilization in the Maya lowlands: Tzakol Phase.** Archaeologists have divided the entire area occupied by speakers of Mayan languages into three subregions: (1) the Southern Subregion, essentially the highlands and Pacific Coast of Guatemala, (2) the Central Subregion, which includes the department of Petén in northern Guatemala and the immediately adjacent lowlands to the east and west, and (3) the Northern Subregion, consisting of the Yucatán Peninsula north of the Petén proper. Between AD 300 and 900 the most brilliant civilization ever seen in the New World flourished in the forested lowlands of the Central and Northern subregions.

Lowland Maya civilization falls into two chronological

phases or cultures: Tzakol culture, which is Early Classic and began shortly before AD 300, and the Late Classic Tepeu culture, which saw the full florescence of Maya achievements. Tepeu culture began about AD 600 and ended with the final downfall and abandonment of the Central Subregion about AD 900. (These dates, based on the correlation of the Long Count system of the Maya calendar with the Christian calendar, are the most generally accepted; but there is a very slight chance that a rival correlation espoused by Herbert J. Spinden, which would make these dates 260 years earlier, may be correct.)

One of the earliest objects inscribed with the fully developed Maya calendar is the Leiden Plate, a jade plaque, now housed in the Leiden Museum, depicting a richly arrayed Maya lord trampling a captive underfoot. On its reverse side is a Long Count date corresponding to AD 320. Although it was found in a very late site on the Caribbean coast, stylistic evidence suggests that the Leiden Plate was made at Tikal, in the heart of the northern Petén. More recently, the University of Pennsylvania's ambitious field program at the Tikal site has produced Stela 29, erected 28 years before, in AD 292. Both objects and, in fact, almost all early Tzakol monuments draw heavily upon a heritage from the older Izapan civilization of the Late Formative, with its highly baroque, narrative stylistic content.

Ceremonial  
centres

Because of the Maya penchant for covering older structures with later ones, Tzakol remains in the Central Subregion have to be laboriously dug out from their towering Late Classic overburdens. Nevertheless, it is clear that at sites like Tikal, Uaxactún, and Holmul, Maya civilization had reached something close to its final form. Enormous ceremonial centres were crowded with masonry temples and "palaces" facing onto spacious plazas covered with white stucco. The use of the corbel vault for spanning rooms—a trait unique to the lowland Maya—was by this time universal. Stelae and altars (a legacy from Izapa) are carved with dates and embellished with the figures of men and perhaps gods. Polychrome pottery, the finest examples of which were sealed in the tombs of honoured personages, emphasizes stylized designs of cranes, flying parrots, gods, and men. These often occur on bowls with a kind of apron or basal flange encircling the lower vessel. Along with these purely Maya ceramics are vessels that show the imprint of distant Teotihuacán: the cylindrical vase supported by three slab legs, the "cream pitcher," and the *florero* ("flower vase").

Wall painting had already reached a high degree of perfection in the Central Subregion, as attested by an extremely fine mural at Uaxactún depicting a palace scene in which two important lords confer with each other. This mural art is quite different from that of Teotihuacán, being very naturalistic instead of formal, and including a definite interest in portraiture. Nonetheless, recent excavations in Petén sites have shown that Teotihuacán influence was quite pervasive. At Tikal, for example, a stela has been found depicting a richly garbed Maya lord, festooned with jade ornaments, standing between two warriors from Teotihuacán. These foreigners carry shields that bear the visage of the Teotihuacán rain god, Tlaloc. It is certain that there was a three-way trading relationship between Tikal, Kaminaljuyú, and Teotihuacán in Early Classic times.

Thus, the Teotihuacán involvement with Tikal and the Central Subregion may have taken, as at Kaminaljuyú, the form of *pochteca* trading colonies that more or less exerted military control over the lowland Maya. The lord on Stela 31 may have been a puppet ruler manipulated by tough merchant-warriors. It will be remembered that Teotihuacán as a city and capital of an empire began to weaken toward the close of the 6th century AD. It could therefore be expected that the disruptions that effectively ended the life of the great Mexican capital would be reflected in the Maya area. This is exactly the case. In the Guatemalan Highlands, Kaminaljuyú declined rapidly after AD 600, and the entire Southern Subregion was to play little part in Maya culture until the Late Post-Classic. The lowland Maya suffered even greater reverses; no stelae whatsoever were erected be-

tween 534 and 692 AD, and there is evidence of international mutilation of already existing monuments at that time. The great Teotihuacán crisis brought down most of the Early Classic cultures, most of which were never to recover. The Maya were the only important exception.

#### LATE CLASSIC NON-MAYA MESO-AMERICA (600-900)

The cultural situation in Late Classic Meso-America is the reverse of that prevailing in the Early Classic: Central Mexico now plays only a minor role, while the lowland Maya reach intellectual and artistic heights unattained by any other native peoples of the New World. In contrast to the old Teotihuacanos, however, the Maya were not expansionistic, surely a reflection of their lack of mercantile interests. It is true that Maya cultural influence can be detected along the Gulf Coast and in distant Morelos, but this surely was not the result of military takeover. The outcome of this state of affairs, with no one people powerful enough or sufficiently interested in dominating others, was a political and cultural fragmentation of Meso-America after AD 600. It was not until the great Toltec invasions of the Early Post-Classic that anything approaching an empire was to be seen again.

The decline in fortunes of the Valley of Mexico, and especially of Teotihuacán, cannot now be explained. Climatic deterioration, resulting in drier conditions and thus a diminished subsistence potential, may have been a factor.

Decline of  
Teoti-  
huacán

Nevertheless, Teotihuacán was never completely abandoned, even though its great palaces had been burned to the ground and its major temples abandoned. People continued to live in some sections, but their houses were mere hovels compared to the dwellings of the Early Classic. In general, the Valley of Mexico was a cultural and political vacuum in Late Classic times.

One of the very few centres of the Late Classic in Central Mexico to amount to much was Xochicalco, Morelos. Strategically located on top of a hill that was completely reworked with artificial terraces and ramparts, Xochicalco was obviously highly defensible, an indication of the unsettled times then prevailing in Central Mexico. The site shows a bewildering variety of cultural influences, particularly Maya. The principal structure of Xochicalco is a temple substructure of masonry that has been completely carved in relief with undulating Feathered Serpents, indicating that it was dedicated to the cult of Quetzalcóatl. All indications are that Xochicalco was a cosmopolitan and very powerful centre, perhaps the most influential west of Veracruz and northwest of the Maya area. It was literate and civilized at a time when most other parts of Central Mexico were in cultural eclipse.

The nature of the Late Classic occupation of Oaxaca, especially of the Valley of Oaxaca, is still a matter of debate. Monte Albán III-B is supposed to fall within the AD 600-900 range, but radiocarbon dates on the Monte Albán IV culture, said to be Early Post-Classic, also fall within this span. Until these contradictions are resolved, little can be said about Zapotec civilization on the eve of the Mixtec invasions, which probably began in earnest around AD 900. The Mixtec occupied the hilly, northern part of Oaxaca. Their own records extend back to the 7th century AD and show them to have been organized into a series of petty states headed by aggressive, warlike kings. By the Post-Classic, they became the dominant force throughout Oaxaca and in part of Puebla.

The tendencies in Central Veracruz art and architecture that began in the Late Formative culminated in the Late Classic at the great centre of El Tajín, placed among jungle-covered hills in a region occupied by the Totonac Indians, whose capital this may well have been. Its most imposing structure is the Pyramid of the Niches, named for the approximately 365 recesses on its four sides. In this and other buildings at El Tajín, the dominant architectural motif is the step-and-fret. There are a number of other temple-pyramids at the site, as well as palace-like buildings with flat, concrete roofs, a tour de force of Meso-American engineering knowledge. El Tajín's three

The  
Pyramid of  
the Niches

major ball courts are remarkably important for the reliefs carved on their vertical playing surfaces, for these give valuable information on the religious connotations of the sacred game. Like Xochicalco, El Tajín was in some way linked to the destiny of the lowland Maya, and the collapse of Maya civilization around AD 900 may have been reflected in the demise of the Veracruz centre.

Further down the Gulf Coast plain, the Remojadas tradition of hollow pottery figurines continued to be active in the Late Classic, with a particularly large production of the mysterious smiling figures of dancing boys and girls, which were intended as funerary offerings. But in addition, there was a great deal of pottery and figurines that were fashioned under very strong Maya influence. In fact, much of southern Veracruz at this time was a cultural extension of the lowland Maya. There is no indication, however, that these peoples had any acquaintance with Maya literacy or with Maya building techniques.

#### LATE CLASSIC LOWLAND MAYA (600-900)

**Settlement pattern.** There is still controversy over whether the Late Classic sites built by the lowland Maya were actually cities or whether they were relatively empty ceremonial centres staffed only by rulers and their entourages.

The common people built their simple pole-and-thatch dwellings on low earthen mounds to keep them dry and comfortable during the summer rains. Thus, total mapping of a particular site should always include not only masonry structures but also house mounds as well. So far, only a few Maya sites have been so mapped. The mightiest Maya centre of all, Tikal in the northern Petén, has a total of about 3,000 structures ranging from the tiny mounds up to gigantic temple-pyramids; these are contained, however, within an area of six square miles (16 square kilometres). The Tikal population has been estimated from this survey to be 10,000–11,000 persons, but perhaps as many as 50,000 souls within an even wider area could have belonged to Tikal.

This sounds very much like a city, but the evidence actually can be differently interpreted. First, at the time of the conquest the Maya generally buried their dead beneath the floors of houses, which were then abandoned. Thus, an increase in number of house mounds could just as easily indicate a declining population in which the death rate exceeded the birth rate. Second, the appearance of even such a tremendous centre as Tikal is quite different from that of such true cities as Teotihuacán. An ordinary Maya family typically occupied two or three houses arranged around a rectangular open space. These were grouped into unplanned hamlets near good water and rich, well-drained soils. A survey of the Petén has shown that for every 50 to 100 dwellings there is a minor ceremonial centre; this unit has been called a zone. Several zones formed a district for which a major centre like Tikal acted as the ceremonial and political nucleus. Neither Tikal nor any other such centre shows signs of town planning or neatly laid-out streets.

There are also ecological factors that set stringent limits upon the potential for urban life in the Maya lowlands. There is little or no possibility of intensive forms of agriculture, such as irrigation farming, or *chinampas*, in the tropical forest of the Petén-Yucatán Peninsula. While it is true that in good soils, shifting cultivation could support fairly large populations, these would have had to be relatively dispersed as weed competition and declining fertility forced farmers to seek new fields farther and farther from the settlement. In addition, the monotonous uniformity of the lowland environment made interregional exchange of subsistence products of little use; thus, there was little development of the intense trade that entered into the early rise of cities in central Mexico. The Maya cities, therefore, were actually organizational centres mainly occupied by the rulers and nobility, along with their followers, servants, and slaves. Nonetheless, these centres were the foci of a civilization that had no rivals elsewhere in the New World.

**Major sites.** While there are some important differences between the architecture of the Central and North-

ern subregions during the Late Classic, there are many features shared between them. A major Maya site generally includes several types of masonry buildings, usually constructed by facing a cement-and-rubble core with blocks or thin slabs of limestone. Temple-pyramids are the most impressive, rising in a series of great platforms to the temple superstructure above the forests. The rooms, coated with white stucco, are often little more than narrow slots because of the confining nature of the corbelled vaults, but this was probably intentional, to keep esoteric ceremonies from the public.

The so-called palaces of Maya sites differ only from the temple-pyramids in that they are lower and contain a great many rooms. Their purpose still eludes discovery; many scholars doubt that they really served as palaces, for the rooms are damp and uncomfortable, and there is little or no evidence of permanent occupation. The temples and palaces are generally arranged around courts, and often have inscribed stelae and altars arranged in rows before them. Leading from the central plazas are great stone causeways, the function of which was probably strictly ceremonial. Other features of lowland sites (but not universal) are sweat-houses, ball courts, and possibly even marketplaces.

There are more than 50 known sites that deserve to be called major. Most are in the Central Subregion, with probably the greatest concentration in the northern Petén, where Maya civilization had its deepest roots. Tikal is the largest and best known site of the Central Subregion, and may well have been the capital for much of the Maya lowlands. It is dominated by six lofty temple-pyramids, one of which is 229 feet (70 metres) high, the tallest structure ever raised by the Meso-American Indians. Lintels of sapodilla wood still span the doorways of the temple superstructures and are carved with reliefs of Maya lords enthroned amid scenes of great splendour. Some extraordinary Late Classic tombs have been discovered at Tikal, the most important of which produced a collection of bone tubes and strips delicately incised with scenes of gods and men. Causeways connect outlying temple-pyramids with the centre of the site. Ten large reservoirs, partly or entirely artificial, supplied the scarce drinking water for the residents of Tikal.

Other important sites of the northern Petén include Uaxactún, Naranjo, Nakum, and Holmul, of which only the first has been adequately excavated. To the southeast of the Petén are two Maya centres—Copán and Quiriguá—that show interesting differences with the Petén sites. Copán is located above a tributary of the Motagua River in western Honduras in a region now rich in tobacco. Its architects and sculptors had a ready supply of a greenish volcanic tuff far superior to the Petén limestone. Thus, Copán architecture is embellished with gloriously baroque figures of gods, and its stelae and other monuments are carved with an extraordinary virtuosity. Copán also has one of the most perfectly preserved ball courts in Meso-America. Quiriguá is a much smaller site 30 miles (48 kilometres) north of Copán. While its architectural remains are on a minor scale, it is noted for its gigantic stelae and altars carved from sandstone.

The principal watercourse on the western side of the Central Subregion is the Usumacinta River, originating in the Guatemalan highlands and emptying into the Gulf of Mexico. For much of its course the Usumacinta is lined with such great Maya ceremonial centres as Piedras Negras and Yaxchilán. Even more renowned is Bonampak, a satellite of Yaxchilán located on a tributary of the Usumacinta. The discovery in 1948 of the magnificent murals embellishing the rooms of an otherwise modest structure astounded the archaeological world. From floors to vault capstones, its stuccoed walls were covered with highly realistic polychrome scenes of a jungle battle, the arraignment of prisoners, and victory ceremonies. These shed an entirely new light on the nature of Maya society, which up till then had been considered peaceful.

In the hills just above the floodplain of the Usumacinta lies Palenque, the most beautiful of Maya sites. The architects of Palenque designed graceful temple-pyramids and “palaces” with mansard-type roofs, embellished with

Tikal

Ecological factors

The Bonampak murals

delicate stucco reliefs of rulers, gods, and ceremonies. The principal structure is the Palace, a veritable labyrinth of galleries and with interior courts; over it looms a four-story square tower that may have served as both lookout and observatory. A small stream flowing through the site was carried underneath the Palace by a long, corbel-vaulted tunnel. The Temples of the Cross, Foliated Cross, and Sun were all built on the same plan, the backroom of each temple having a kind of sanctuary designed like the temples of which they were a part. It can be supposed that all three temples served the same cult. The most extraordinary feature of Palenque, however, was the great funerary crypt discovered in 1952 deep within the Temple of the Inscriptions. Within a sarcophagus in the crypt were the remains of an unusually tall ruler, accompanied by the richest offering of jade ever seen in a Maya tomb. Over his face had been fitted a mask of jade mosaic, while a treasure trove of jade adorned his body.

As one moves north from the Central Subregion into the drier and flatter environment of the Yucatán Peninsula, the character of lowland Maya civilization changes. Just north of the Petén is the Río Bec zone, as yet little explored but noted for temple-pyramids and palaces with flanking false towers fronted by unclimbable "stairways" reaching dummy "rooms" with blank entrances. Río Bec structures are carved with fantastic serpents in deep relief, a feature that becomes even more pronounced in the Chenes country to the northwest, in the state of Campeche. At Chenes sites, Maya architects constructed frontal portals surrounded by the jaws of sky serpents and faced entire buildings with a riot of baroquely carved grotesques and spirals.

This elaborate ornamentation of buildings is far more restrained and orderly in the style called Puuc, so named from a string of low hills extending up from western Campeche into the state of Yucatan. The Puuc sites were for the Northern Subregion what the Petén sites were for the Central, for they are very numerous and clearly were the focal point for Maya artistic and intellectual culture. Uxmal is the most important Puuc ceremonial centre and an architectural masterpiece. It has all of the characteristics of the Puuc style: facings of thin squares of limestone veneer over a cement-and-rubble core; boot-shaped vault stones; decorated cornices around columns in doorways; engaged or half-columns repeated in long rows; and lavish use of stone mosaics in upper facades, emphasizing sky-serpent faces with long, hook-shaped noses, as well as frets and latticelike designs of criss-crossed elements.

The nearby centre of Kabah, connected to Uxmal by a ceremonial causeway, has an extraordinary palace completely faced with masks of the sky serpent. Other major Puuc sites are Sayil, with a multistoried palace, and Labná. The Puuc style reaches east across the Yucatán Peninsula, for at Chichén Itzá, a great site that was to occupy centre stage during the Toltec occupation of the Northern Subregion, there are several buildings strongly Puuc in character.

It was formerly believed that the Puuc sites represented a "New Empire" formed by survivors of the great collapse that took place in the Central Subregion at the close of the 9th century. Archaeological research, however, has shown that the ceramics associated with Puuc architecture are not only pre-Toltec but partake of many features typical of Late Classic Maya pottery elsewhere. Nevertheless, it is also clear, both on stratigraphic grounds and upon certain dates painted on Puuc capstones, that these centres were built in their present form in the final decades of the 9th century and probably were occupied until the latter half of the 10th, when the Toltec invaders ended the Late Classic in the Northern Subregion. As well as being late in the Classic sequence, the Puuc sites were under several influences from non-Maya Mexico, particularly from central Veracruz.

**Maya art of the Late Classic.** Maya art, at the height of its development, was fundamentally unlike any other in Meso-America, for it was highly narrative, baroque, and often extremely cluttered, unlike the more austere

styles found elsewhere. It is essentially a painterly rather than sculptural tradition, and it is quite likely that even stone reliefs were first designed by painters. Much of this art has disappeared for all time because of the ravages of the wet, tropical environment on such perishable materials as wood, painted gourds, feathers, bark, and other substances. There must have been thousands of bark-paper codices, not one of which has survived from Classic times.

Following the downfall of Teotihuacán, Maya artists were free to go their own way. Magnificently carved stelae and accompanying altars are found at most major sites, the greatest achievement in this line being found at Copán, where something approaching three-dimensional carving was the rule. Palenque and Yaxchilán specialized in graceful bas-reliefs placed as tablets or lintels in temple-pyramids and palaces. In the Northern Subregion, however, the sculptor's art was definitely inferior in scope and quality and shows strong influence from alien, non-Maya cultures.

A few wooden objects have miraculously survived. Particularly noteworthy are the massive wooden lintels of Tikal, with scenes of lords and their guardian deities, accompanied by lengthy hieroglyphic texts. In ancient times, wood carvings must have been vastly more common than sculptures. The wet climate has also destroyed innumerable examples of mural art.

Maya pottery can be divided into two groups: (1) the pots and pans of everyday life, usually undecorated but sometimes with geometric designs, and (2) grave offerings. Vessels meant to accompany the honoured dead were usually painted or carved with naturalistic and often macabre scenes. To achieve polychrome effects of great brilliance, the Maya potters painted in semi-translucent slips over a light background, then fired the vessels at a very low temperature. Relief carving was carried out when the vessels were leather-hard, just before firing.

The most precious substance of all to the Maya was jade, to which their craftsmen devoted great artistry. Jade was mainly fashioned into thin plaques carved in relief, or into beads. In the absence of metal tools, jade was worked by applying abrasives and water with cane or perhaps other pieces of jade.

**The Maya calendar and writing system.** It is their mental life that established the cultural superiority of the Maya over all other American Indians. Much of this was based upon a calendrical system that was partly shared with other Meso-American groups but that they perfected into a tool capable of recording important historical and astronomical information. (For an extended discussion of the Mayan calendar, see CALENDAR; CHRONOLOGY.) Most Maya inscriptions that have been interpreted are calendrical inscriptions. Since the late 1950s, it has been learned that the content of Classic Maya inscriptions was far more secular than had been supposed. For many years specialists believed that the inscriptions recorded little more than the passage of time and that, in fact, the Mayans were time worshippers. Since 1958 it has been shown that certain inscriptions recorded the birth, accession, marriage, and military victories of ruling dynasties. Yet it would be misleading to contend that the hurly-burly of Maya court affairs and conquests was all that mattered, for some texts must have been sacred and god-oriented. At Palenque, in the similar Temples of the Cross, Foliated Cross, and Sun, the dates inscribed on the tablets in the sanctuaries fall into three groups. The very latest seem to refer to events in the lives of reigning monarchs. An earlier group must deal with distant but real ancestors of those-kings, while the very earliest fall in the 4th millennium BC and apparently describe the birth of important gods to whom the respective temples were dedicated and who may have been regarded as the progenitors of Palenque's royal house.

The meaning of many noncalendrical signs and even of complete clauses is not known, but there is a difference between this and assigning an actual Maya word to an ancient glyph or a sentence to a glyphic clause. While it is certain that the language of the Classic inscriptions was Mayan, it is also certain that it was more archaic than any

Wood  
carvings

Uxmal

The Maya  
codices

of the Mayan languages spoken at the time of the conquest, six centuries after the Classic downfall. The three extant Maya codices, none dating earlier than AD 1100, contain a strong phonetic component, in fact a kind of syllabary, which can be successfully read as Yucatec-Maya, but the Classic peoples of the Central Subregion more likely spoke an ancestor of the Cholan branch of Maya. Furthermore, Maya hieroglyphic writing covers the entire span from c. AD 300 to the conquest, during which time both the language or languages and the writing system itself must have undergone extensive evolution.

In writing systems in general, there is usually a development from pictographic signs, in which a picture stands for a word or concept, through logographic systems in which words are still the basic unit but phoneticism is employed to reduce ambiguities (as in Chinese), to phonetic syllabaries, and finally to alphabets. Probably most Classic Maya hieroglyphs are logograms with a mainly ideographic orientation, and it seems that there was a considerable degree of flexibility in how the words and sentences could be written. By the Post-Classic, this had been codified into a much more rigid system closely resembling that of Japanese, in which a well-defined syllabary can supplement or even replace logograms. There are approximately 300 to 500 logograms in Classic Maya (the number varies according to how one separates affixes from so-called main signs), but it will probably be several years before the majority of these are satisfactorily deciphered. One can, however, expect great progress in unravelling their meaning in specific contexts.

**Classic Maya religion.** Most of what is known about ancient Maya religion is inferred from the descriptions that the Spanish friars have left of Maya life and thought on the eve of the conquest. All modern scholars have stressed the deep religious conservatism and resistance to change of the Maya, and it is highly likely that the 16th-century picture was not appreciably different from that prevailing in the Late Classic, in spite of centuries of Mexican contact.

Their view of the universe was essentially that of all Meso-Americans; there were four world directions, each associated with a colour and with a tree on the summit of which sat a particular bird. The heavens were 13-layered, and the underworld was stratified into nine layers. Classic Maya art indicates that the Earth was thought of as the back of a great saurian, floating in a pond with water lilies and fish.

The world directions were reached by four roads emanating from the "green tree of abundance," a gigantic silk-cotton tree at the Earth's centre. The counterparts of these divine roads are probably the great limestone causeways at such sites as Tikal. In the 16th century, important ceremonies were held for the impending New Year, at which time there were processions to shrines at the four entrances to a settlement. Perhaps the temple-pyramids found at the ends of causeways in Classic cities were the prototypes for such shrines.

It has been denied that there was any such thing as a pantheon of deities in Classic times, the idea being that the worship of images was introduced by the Toltec or Itzá invaders, or both, in the Post-Classic. Several gods who play significant roles in the Post-Classic codices, however, can be identified on Maya monuments. The most important of these is Itzamná, the supreme Maya deity, who functioned as the original creator-god, as well as lord of the fire and therefore of the hearth. In his serpent form, he appears on the ceremonial bar held in the arms of Maya rulers on Classic stelae. Another ophidian deity recognizable in Classic reliefs is the Feathered Serpent, known to the Maya as Kukulcán. Probably the most ubiquitous of all is the being known only as God K, a deity with a baroque branching nose who may have functioned as a god of royal descent; he is often held as a kind of sceptre in rulers' hands.

The Classic Maya lavished great attention on their royal dead, who almost surely were thought of as descended from the gods and partaking of their divine essence. Many reliefs and all of the pictorial pottery found in tombs deal with the underworld and the dangerous voy-

age of the soul through that land. Classic Maya funerary ceramics show that this dark land was ruled by a number of gods, including several sinister old men often embellished with jaguar emblems, the jaguar being associated with the night and the nether regions.

Contrary to what has often been claimed, the Classic Maya practiced human sacrifice on an extensive scale. Torture followed by decapitation was probably most common, on the evidence of pictorial ceramics, but heart sacrifice has also been depicted on the monuments. The victims were probably captives, as in non-Maya Mexico. Remains found in the passage leading to the tomb of the Temple of the Inscriptions at Palenque show that this practice was sometimes carried out to ensure companions for the deceased king in the other world. Self-sacrifice or mutilation was also a common practice; blood drawn by jabbing spines through the ear or penis, or by drawing a thorn-studded cord through the tongue, was spattered on paper as an offering to the gods.

**Society and political life.** There is a vast gap between the lavishly stocked tombs of the Maya elite who ran the ceremonial centres and the simple graves of the peasantry. Careful measurements of the skeletons found in tombs and graves have also demonstrated that the Maya ruling class was much taller than the tillers of the soil who provided them tribute. It is likely that this gulf was unspannable, for throughout Meso-America the rulers and nobility were believed to have been created separately from commoners.

The most astonishing testimony to this royal cult is the temple-pyramid itself, for in almost every one explored there is a great tomb hidden in its base. On death, each ruler might have been the object of ancestor worship by members of his lineage, the departed leader having become one with the god from whom he claimed descent. Ancestor worship, in fact, seems to be at the heart of ancient and modern society and religion among the Maya.

The ordinary folk may have participated in the ceremonies of even the greatest Maya centres. The modern highland Maya have a complex ceremonial life in which a man advances through a series of increasingly prestigious *cargos*, or "burdens," each one of which costs him a great deal of money and requires that he reside in the otherwise nearly empty centre for a year at a time carrying out his religious duties. The same may have prevailed in Classic times, but it should be remembered that all activities were then under the direction of a hereditary and divine elite class, long since destroyed throughout Maya land by the Spaniards.

Apparently, warfare was a continuing preoccupation of the Maya lords, but it was carried out not so much for territorial aggrandizement as to gain captives for slavery and sacrifice. It is not yet known whether any one centre dominated the others, but the inscriptions will some day throw light on Maya territorial organization during the Late Classic.

It has often been said that the Maya realm was a theocracy, with all power in the hands of the priests. That this is a misconception is apparent from the monuments themselves, which show kings, queens, heirs, and war prisoners, but no figures surely identifiable as priests. In 16th-century Yucatán, the priesthood was hereditary, and it is reported that younger sons of lords often took on that vocation. Quite probably such a class was also to be found among the Late Classic Maya, but neither for the Maya nor for any other Classic civilization of Meso-America can the term theocracy be justified.

**The collapse of Classic Maya civilization.** In the last century of the Classic, Maya civilization went into a decline from which it never recovered. Beginning about AD 790 in the western edge of the Central Subregion, such ceremonial activity as the erection of stelae virtually came to a standstill. During the next 40 years this cultural paralysis spread gradually eastward, by which time the great Classic civilization of the Maya had all but atrophied. A date in the Maya calendar corresponding to AD 889 is inscribed on the last dated monuments in the Central Subregion; soon after the close of the 9th century it is clear that almost all of this region was abandoned.

Human  
sacrifice

Warfare

For this event, which must have been one of the greatest human tragedies of all time, there are few convincing explanations. It now seems that the Classic Maya civilization in the region of its greatest development went out "not with a bang but a whimper." Massive foreign invasions can be discounted as a factor, but non-Maya elements did appear in the west at the same time as ceremonial activity terminated. These became the inheritors of whatever was left of the old civilization of the Central Subregion after AD 900, having established trading colonies and even a few minor ceremonial centres on its peripheries.

Whatever incursions did take place from the west were piecemeal and probably the result of the general decline, rather than its cause. Similarly, there is little reason to believe that there were peasant revolts on a general scale. The only real fact is that most of the inhabitants of the Central Subregion went elsewhere. Probably some were absorbed by such still flourishing ceremonial centres of the Northern Subregion as Uxmal and Kabah, while others might have migrated up into the congenial highlands of Chiapas. Although a population explosion and severe ecological abuse must have played their role in the tragedy, the full story of the decline and fall of this brilliant aboriginal civilization will only be told when the last Maya inscriptions can be read. (M.D.C.)

### Post-Classic Period (900–1519)

#### DEFINITION OF THE POST-CLASSIC

The final period of Meso-American history is referred to as the Post-Classic. Its beginning is usually placed at 900, and it terminates with the arrival of the Spanish conquistador Hernán Cortés in 1519 or his conquest of the Aztecs in 1521. The 900 date is based on two considerations: first, the 10th century witnessed the catastrophic collapse of the Lowland Maya civilization and the cessation of the custom of erecting monuments dated by the Long Count; second, it was also the approximate date of the founding of the city of Tula in central Mexico and the rise of a people called the Toltecs, who, according to the historical annals, built the first great empire in Meso-America. At one time it was thought that the date marked the collapse of all of the regional Classic civilizations of the area as the result of massive population dislocation. But it now appears that some Classic civilizations declined as early as 750, whereas others persisted until as late as 1200. The period is usually divided into two phases: Early Post-Classic (900–1200) and Late Post-Classic (1200–1519), the former equivalent with the period of the Toltecs, the latter with that of the Aztecs.

The Post-Classic period as a whole has also been distinguished from the Classic on the basis of assumed major changes in Meso-American political, economic, and social institutions. It has been asserted, for example, that the Classic period was one of relatively peaceful contact between polities, of the absence of large imperialistic states and empires (and of the militaristic élan and organization that accompanies such states). The Classic has been further characterized by the absence of true cities, by theocratic rather than secular government, and by an overall superiority of arts and crafts, with the exception of metallurgy, which appears for the first time in the Post-Classic period. In contrast, the Post-Classic was characterized as a period of intense warfare and highly organized military organization, of empires and cities, of secular government, and of overall artistic decline.

Recent research, however, has cast considerable doubt on these conclusions. Many of the contrasts were drawn from events in the Lowland Maya area and applied to the entire culture area; others were concluded essentially by a comparison of the Classic Maya of the lowland tropical forest of northern Guatemala and the Yucatán Peninsula with the Post-Classic Aztec living in Central Mexico in a dry mountain basin 7,000 feet above sea level. The differences, in part, are the product of separate culture evolution, conditioned by ecological factors. Cities and large states comparable to those built by the Toltecs and Aztecs were present in Early Classic times at Teotihuacán in Central Mexico and probably at Monte Albán in Oaxaca.

Militarism was at least significant enough to be a major artistic theme throughout the Classic period, even among the Lowland Maya. One could also question the criterion of artistic decline, since a number of Post-Classic crafts were highly developed, such as Aztec sculpture, Mixtec ceramics and metallurgy, and Zapotec architecture.

The separation between Post-Classic and Classic is therefore little more than a convenient way of splitting up the long chronicle of Meso-American cultural development into manageable units for discussion and analysis. It is a period also in which historical traditions combine with archaeological data, whereas the Classic essentially lacks a written history. Perhaps this is the best rationale for definition of the period.

At the time of the Spanish conquest, Meso-America was occupied by a number of peoples speaking languages as distinct from each other as English is from Chinese. On the Central Gulf Coast and adjacent escarpment were the Totonac; in Oaxaca and adjacent portions of Puebla and Guerrero, two major ethnic groups, the Mixtec and the Zapotec, shared the western and eastern portions of the area, respectively; and in Michoacán lived the Tarascans. Various peoples of the Maya linguistic family occupied most of Guatemala, the Yucatán Peninsula, eastern Tabasco, highland Chiapas; a detached group, the Huastec, occupied the North Gulf Coast. An equally widespread family, the Nahua (to which the Aztec belonged) occupied most of the Central Plateau, a huge area in the northwest frontier, portions of Guerrero, the Pacific Coast of Chiapas and Guatemala (where they were known as the Pipil), and the South Gulf Coast. Some detached groups had spread beyond the frontier of Meso-America into Nicaragua and Panama. The linguistic family to which the Nahua belong (the Uto-Aztecan) is the only Meso-American family with affinities to languages north of the Rio Grande, including those of such western United States Indians as the Hopi, Paiute, and Shoshoni.

One of the Nahua-speaking nations, the Méxica or Tenochcas (or the Aztecs, as they are commonly called), were the dominant people in Meso-America in 1519, having conquered an empire estimated as covering 80,000 square miles and having a population of 5,000,000 to 6,000,000 people.

All of these diverse ethnic groups shared a common cultural tradition, but separate historical origins and environmental factors had also produced a substantial degree of regional differentiation. Most of the cultural characteristics of the area go back at least to the beginning of the Post-Classic, and many appeared in Classic times. The various regional cultures and languages have great time depths and were undoubtedly present during the Classic period. Common institutional characteristics included organization into centralized polities, including populations minimally in the tens of thousands, with a formal government, supported by a highly organized taxation system; stratification into social classes (including slave and serf classes); occupational specialization—in some areas full time with a guildlike organization; highly organized local and interregional trade involving professional merchants and regularly meeting markets; and a professional priesthood.

The technological base of this elaborate institutional structure seems weak by western European standards, since the primary technology (*i.e.*, the tools used to manufacture other technology) was based on chipped and ground stone (metal being reserved primarily for ornaments). Since draft animals were absent, all power was based on human energy. The economic base of the civilization was a highly productive agriculture, but the basic tool kit was primitive—stone axes for clearing vegetation and a number of wooden digging tools for working the soil. The crop complex was a rich one, with maize serving as the staple food and beans an important source of protein. But the list of secondary crops is impressive: chili peppers, tomatoes, squashes, sweet potatoes, manioc, cotton, tobacco, cacao, pineapples, papayas, maguey, nopales, zapotes, peanuts, avocados, paper figs, and many others.

The Nahua peoples

Post-Classic technology

Many crops were limited to particular environmental zones, thus acting as a major stimulus to trade. In many areas, particularly the tropical lowlands, the system of farming was swidden; *i.e.*, a system in which forests are cleared, planted for up to three years, and rested for longer periods to restore fertility and eliminate the more difficult weeds. This regular rotation of fields resulted in high production per capita but had low demographic potential because in any given year most of the land lay fallow. In some lowland areas permanent grain and orchard cropping were practiced. In the drier highlands, a number of specialized techniques were used, and agriculture was more intensive. Particularly important were terracing, irrigation, and swamp reclamation. The per capita productivity of highland agriculture was probably less (because of the higher labour input), but the demographic capacity was considerably greater than in the lowlands. As a result of these highly effective approaches to farming, the population was dense when compared to western Europe in the 16th century. Population estimates for the conquest period have varied from 3,000,000 to 30,000,000; a reasonable estimate is between 12,000,000 and 15,000,000.

The diet of the average Meso-American was one of those cultural aspects that was relatively uniform throughout the area. Dried maize was boiled in lime-impregnated water to soften the hull, ground into a dough on milling stones (*manos* and *metates*), and then either made into pancakes (*tortillas*) or mixed with water and drunk as a gruel (*pozol*). The tortillas were eaten with sauces prepared from chili peppers and tomatoes, along with boiled beans. This was essentially the diet of the peasant, with the addition of pulque, the fermented sap of the maguey, at higher altitudes. To this were added the other crops in minor quantities and combinations depending on the specific local environment. Luxury foods included chocolate drinks, meats (from game or from the only two domestic animals of significance, the hairless dog and the turkey), and fish. The diet of the peasant, as is the case even today, was low in animal protein; but apparently the quantity of vegetable protein ingested made up for this deficiency.

Post-Classic arts and crafts

Major Post-Classic Meso-American crafts were cotton and maguey fibre weaving; ceramics for pottery vessels, figurines, and musical instruments; stone sculpture; featherwork used for personal and architectural ornament; lapidary work (jadeite, jade, serpentine, and turquoise); metalwork (using gold, copper, and, more rarely, silver) for ornaments and a few tools; woodworking, the products including large dugout canoes, sculpture, magnificently made drums, stools, and a great variety of household items; baskets for containers and mats; painting; and, most particularly, stone and lime concrete masonry architecture.

On the intellectual, ideological, and religious levels, although some diversity and certain elaborations occurred in some regions, there was a fundamental unity to the Meso-American area, the product of centuries of political and economic ties. The religion was pantheistic, with numerous gods specialized along the lines of human activities. There were gods for basic activities such as war, reproduction, and agriculture; cosmogenic gods who created the universe and invented man's culture; gods of craft groups, social classes, political systems and their subdivisions. Gods were all-powerful and had to be constantly propitiated with offerings and sacrifices, a concept reaching its peak in personal bloodletting and human sacrifice. Certain gods, such as the god of rain (called Tlaloc in Central Mexico), were found throughout the area. A fundamental concept was that of a quadripartite multilevel universe that, by 1519, had gone through five creations and four destructions. Meso-American religion heavily emphasized the astral bodies, particularly the Sun, the Moon, and Venus, and the observations of the movement of these bodies by the astronomer-priests were extraordinarily detailed and accurate. The major purpose of these observations was astrological, and the Meso-American priests had developed a number of time counts, or calendrical rounds, based in part on these observations. Two

basic calendars, a 260-day divinatory calendar and one based on the solar year of 365 days, were found all over the area (see CALENDAR: *Pre-Columbian*).

One of the great intellectual achievements of Meso-American civilization was writing; in Post-Classic times books were made from the inner bark of the paper-fig tree and used to record calendars, astronomical tables, dynastic history, taxes, and court records.

Religion was a pervasive force in Meso-American life, as the art demonstrates; and considerable surplus energy was devoted to it (*e.g.*, temple construction, support of a numerous professional priesthood). Many writers have stated that the major focus of Meso-American culture was in this sphere. In fact, the contrast between Post-Classic and Classic was in part based on the presumed even greater emphasis on religion in the art and architecture of the latter period.

#### THE HISTORICAL ANNALS

**The rise of the Aztecs.** A major characteristic of the Post-Classic in contrast to the Classic is the abundant historical documentation available for the former. The Aztec record is particularly rich, and much of it is undoubtedly genuine, although there is always the possibility that records were rewritten or doctored for political reasons. One of the functions of Meso-American writing was to record the succession and achievements of dynastic lines, and consequently it served as a validation of power. Virtually all of the dynasties of the local states recorded their history. A problem in the utilization of these documents, other than the low number of survivals, is the fact that many of them have strong mythological overtones. The Aztecs themselves, for example, as creators of a great empire, explained their rise in part to the fact that they were the chosen people of the sun god Huitzilopochtli, or Tonatiuh. They started their history as a poor, nomadic tribe from the north, who entered the Basin of Mexico, led by a magician priest, and ultimately settled on the lake islands because of a series of astrological predictions and signs. They lived for a while as a subject people and then embarked on their destined role as conquerors and priests of the sun god. Virtually all historic traditions of local groups begin with a migration, a period of trials, and ultimate success—and some records even claim that the people were hunters and gatherers during the early part of their history.

On the northern frontier of Meso-America, in the arid north Mexican plateau, true hunters and gatherers, referred to as the "chichimeca" by the civilized peoples, did actually reside in 1519. The name chichimeca was frequently applied to the migrant groups. It is difficult to see how hunting and gathering bands could successfully invade areas of dense civilized populations; but agricultural barbarians, during periods of dynastic weakness, undoubtedly could. In fact, the term chichimeca was also applied to agricultural but less civilized peoples (such as the Otomí in Central Mexico) and thus connoted a lack of polish or a rustic life-style. Since the northwest portion of Meso-America was occupied by such people and since they were Nahuatl in speech, the legends of periodic north to south migrations of invaders may have a factual basis but probably refer to movements of agricultural rather than hunting and gathering peoples.

The histories of these invading groups take on a more convincing historical character after the legends of migration. In the Aztec case they record the founding of Tenochtitlán in 1325. By 1376 the Aztecs had increased in numbers and prestige sufficiently to obtain a member of the ruling family of Culhuacan, a neighbouring state, to rule as their tlatoani, or king. His name was Acamapichtli. The Aztecs at this time were paying tribute to another state, Azcapotzalco, on the lake shore; and they remained under this obligation through the reigns of his two successors, Huitzilhuítl (1391–1415) and Chimalpopoca (1415–26). During the reign of Chimalpopoca, Maxtla, the ruler of Azcapotzalco, attempted to secure tighter control over subject states by replacing their tlatoanis with his own men. He succeeded in arranging the assassination of Chimalpopoca and the exile of Neza-

The chichimeca peoples

hualcōyotl, ruler of Texcoco, a state on the east shore of Lake Texcoco. In response to these acts, a coalition was formed between Nezahualcōyotl, Itzcōatl (Chimalpopoca's successor), and another small state (Tlacopan), and the power of Azcapotzalco was broken.

The triple alliance

A triple alliance was then formed between Tenochtitlán, Texcoco, and Tlacopan, which by 1519 resulted in the dominance of Aztec Tenochtitlán. Under the Aztec rulers Itzcoatl (1428–40), Montezuma I (1440–69), Axayacatl (1469–81), Tizoc (1481–86), Ahuizotl (1486–1503), and Montezuma II (1502–20), and the two Texcocan rulers—Nezahualcōyotl (1431–72) and Nezahualpilli (1472–1516)—the triple alliance succeeded in conquering the vast domain previously described. Tlacopan seems to have been relegated to an inferior political role early in the history.

The records of the Aztecs and neighbouring states in the Basin of Mexico between 1300–1519 are relatively free from mythological tales and have sufficient cross-referencing to present a reasonably clear picture of military events, dynastic succession, institutional changes, and economic development. The period from 1200 to 1300 is essentially one of migration legends of the dynasties of the various states, the historical traditions of which are discussed below.

**The question of the Toltecs.** The historical traditions also state that these migrations were responsible, along with a series of natural disasters, for the collapse of a great empire ruled by a people called the Toltecs from their capital of Tollan, or Tula. Many of the conquest period dynasties, not only in Central Mexico but even as far afield as highland Guatemala and Yucatán Peninsula, claimed descent from the Toltecs, apparently as a result of their dispersion after the fall of Tula.

The traditions describe the Toltecs as the first civilizers, the first city builders, and the originators of craft skills and astrological knowledge. The major questions are: Did the Toltecs really exist as a people? Where was Tollan? Did these people actually play the extraordinary political and cultural role ascribed to them?

To begin with, the annals themselves are in fundamental disagreement with respect to dates and the lists of Toltec kings. There are at least three major chronologies of the Toltec Empire (see the chart).

Ixtlilxóchitl	Anales de Cuauhtitlan	Codex Ramirez
Chalchiuhtlanetzin	510–562	Huetzín 869–?
Ixtlilcuechahauac	562–614	Totepeuh 7–887
Huetzín	614–666	Ihuitimal 887–923
Totepeuh	666–718	Topiltzín 923–947
Nacoxoc	718–770	Matlaxochitl 947–983
Mitl-tlacomihua	770–829	Nauhyotzín 983–997
Xihuiquenitzán	829–833	Matlaccoatzín 997–1025
Iztaccaltzín	833–885	Tilicoatzín 1025–46
Topiltzín	885–959	Huemac 1047–1122

Ixtlilxóchitl's dates place the Toltecs well within the Classic period of Meso-American archaeology, but the others would correlate them with the early portion of the Post-Classic. Most writers favour the later dates, but this would mean that the Toltecs were not the first civilized peoples in Meso-America, or at least in Central Mexico, as they claim.

Mythic evidence

Adding further doubt to the veracity of the Toltec history is the admixture of myth and magic in the annals, not only at the beginning (which, like the histories of later dynasties, begins with a migration under a magician priest) but throughout the narrative. The ruler Topiltzín, for example, is also called Quetzalcóatl (the name of a god); another ruler, Ce Acatl, is opposed by Tezcatlipoca (also a god) and is driven out of Tula. He flees with his followers to the Gulf of Mexico and embarks on a raft of serpents. The story sounds like a duplicate of the cosmic myth or conflict between the two gods. Interestingly, the Maya in Yucatán had a tradition of a landing on the west coast made by foreigners, under a leader named Kukulcán (which in Maya means Feathered Serpent, the meaning also of the Nahuatl Quetzalcóatl), who founded a city at Chichén Itzá and ruled over the Maya.

In spite of all the objections, the traditions of a great

empire and of the city of Tula are so persistent that they must refer to some historical event and, indeed, have some archaeological support.

#### ARCHAEOLOGICAL REMAINS OF POST-CLASSIC CIVILIZATION

The early Post-Classic period (900–1200) in Central Mexico is associated with three major sites, all of which probably began in Classic times: Cholula in Puebla, Xochicalco in Morelos, and Tula in Hidalgo. Cholula was a major centre as far back as Early Classic times, probably as a political dependency of Teotihuacán. It reached its maximum growth in Late Classic times, following the collapse of Teotihuacán, when the largest structure ever built by Meso-Americans was erected—a pyramid platform nearly 200 feet (60 metres) high and with a base measuring 1,000 feet (300 metres) to a side. In Post-Classic times Cholula continued as a major religious and cultural centre. Xochicalco probably was of minor significance in Early Classic times; but it went through a phase of explosive growth in the Late Classic and was probably abandoned by 1200, possibly earlier. Tula, on the other hand, a small centre in the Late Classic, went through a rapid growth during the period 900–1200 and then declined to a provincial centre in the Late Post-Classic. There is a strong suggestion that the demise of Classic Teotihuacán was in part related to the emergence of one or all of these major centres.

**Tula.** The location of the Toltec capital of Tollan, or Tula, is not certain. The archaeological site located on a low ridge near the contemporary town of Tula has been the persistent choice of all historians since the conquest, in part because of the coincidence of place-names. There is further support for this identification in that the annals provide a great number of place-names that have persisted since the conquest. There is also support for the identification in that the glyph Ce Acatl, the birthday and birth name of the great Toltec leader Quetzalcóatl Topiltzín has been found carved on a hill near Tula. Moreover, the sculpture from the site is heavily loaded with symbolism that relates to the Quetzalcóatl cosmology and cosmogony. It clearly was the city of the god Quetzalcóatl. The confusion between the god and the ruler can be ascribed to the fact that the name Quetzalcóatl may have served as a title of office carried by all Toltec rulers. The archaeological dates are in agreement with the *Anales de Cuauhtitlan* and the Codex Ramirez (see below *The nature of the sources*).

The major factors that have made some researchers reluctant to accept this identification lies in the claim that Tula was the capital of a great Pan-Meso-American empire and that the Toltecs were the first civilizers in Central Mexico. Archaeologically, it is quite clear that Tula was preceded by the great Classic centre of Teotihuacán. Tula as a site does not really approach the earlier Teotihuacán or the later Tenochtitlán in size, in the number of public buildings, or in estimated population. Furthermore, although some generic stylistic elements of the art and architecture of Tula are widespread, the style, in an integrated specific sense, is limited (with one notable exception) to a small area in Central Mexico. These facts make it difficult to accept Tula as the capital of a great empire. But archaeological evidence of even the Aztec Empire is skimpy. In both cases, this may mean that the expansion was a rapid, explosive one that failed to last long enough to register these effects. But at least in the case of Tenochtitlán it did result in the rapid growth of a truly gigantic urban centre.

Because of these objections and because Teotihuacán fits better the description of the Toltecs as the builders of the first truly civilized society in Central Mexico, that site must still be considered a possible candidate.

The art and architecture of Tula shows a striking similarity to the later art and architecture of Tenochtitlán, and the themes represented in the art indicate a close approximation in religious ideology and behaviour. The symbols of sun sacrifice and the marching predators represented in sculpture both suggest that the Aztecs' concept of themselves as the warrior priests of the sun god was directly borrowed from the people of Tula.

The question of Tula's existence

On the basis of the symbolism represented in the carvings at Structure B it has been concluded that it was dedicated to the god Quetzalcóatl, lending further support to the identification of the site as the Toltec capital.

**Chichén Itzá.** Also in support of the identification of Tula as the Toltec capital are the architectural characteristics and stylistic features of the sculpture of a large site in northern Yucatan called Chichén Itzá. The resemblance between the two sites is extraordinarily close. At Chichén are found flat beam and masonry roofs (contrasting sharply with the typical Maya corbelled vault), serpent columns, colonnaded halls attached to the bases of temples, altars with Atlantean figures, sculptured representations of skulls and crossbones, marching felines, canines and raptorial birds devouring human hearts, and depictions of warriors with typical Toltec accoutrements. Furthermore, there are even scenes showing Toltec and Maya warriors in combat. The Temple of the Warriors at Chichén Itzá looks like an attempt to duplicate a temple pyramid at Tula.

Tula and  
Chichén  
Itzá  
compared

One of the puzzling aspects of the relationship between the two sites is that the public architecture of Chichén Itzá is actually more monumental than that at Tula, leading at least one Meso-American specialist to believe that Tula's style was derived from Chichén. Many of the stylistic features themselves, however, have prototypes in Classic Teotihuacán, whereas there is little in Classic Maya culture that could be considered as the source. What is more probable, and this agrees with the Toltec version of the relationship, is that the Toltec state in Yucatan was politically independent from Tula. The presence of rival states in central Mexico such as Xochicalco and Cholula may have kept the core of the Toltec polity relatively restricted in space. The much larger area and population controlled by the Toltec state at Chichén would explain the differences in the scale of architecture. The superior military organization and equipment of the Toltecs might explain their apparent success in Yucatán.

**Archaeological unity of the Post-Classic.** The Post-Classic period of Meso-American archaeology generally is a period characterized by considerable regionalism combined with a certain degree of uniformity. To a great extent, the latter was the product of the large states and extensive trade networks centred in the central plateau region. The Early Post-Classic in some areas may be described as a continuation of the Late Classic; on the Gulf Coast, for example, sites like Tajin continued to be occupied, while in the Valley of Oaxaca (although Monte Albán was abandoned) the Zapotec tradition continued with the new centre at Mitla. In other areas, new styles either begin or reach their climactic development, such as the Mixteca-Puebla style in painting, ceramics, and metallurgy, which either evolved in western Oaxaca or more probably at Cholula in Puebla. On the Guatemalan Pacific piedmont and in Tabasco, two specialized ceramic traditions (both of which begin in Late Classic times) evolved and were widely traded: (1) plumbate (so called because of its slip, which has an unusually high iron content in the natural clay that fires to a lead colour glaze); and (2) Fine Orange (so called because of its fine-grained temperless paste).

Ceramic  
traditions

The unity of the Post-Classic consists primarily of the diffusion of religious ideology, particularly the sun god-warfare-sacrificial complex and of the related institutional development such as the military orders (the latter probably originated at Classic Teotihuacán). This ideology clearly originated in Central Mexico, either at Cholula or Tula or both. The specific artistic style of representation of the themes in painting and sculpture spread as well. Along with this was diffused a specific style of representation of the social calendar and writing generally and much greater emphasis on the 52-year cycle. The specific style most probably originated at Cholula.

In the highland areas of Meso-America the Late Post-Classic was a period of maximum population growth. The Early Post-Classic was, however, the period of maximum expansion of sedentary peoples on the northern frontier, probably the product of minor changes in climate as a result of increased rainfall. This frontier re-

tracted substantially in Late Post-Classic times, possibly because the rainfall decreased. This was perhaps the major factor in the precipitation of barbarous tribes into the plateau, as the annals state.

The Post-Classic, over large areas of the lowlands, on the other hand, was strikingly different. One of the most intriguing problems of Meso-American archaeology is the peculiar sequence of events in the Lowland Maya area. At the time of European contact much of the northern portion of the Yucatán was well settled. A narrow band of densely settled country also extended along the east coast south to Belize City and along the entire length of the west coast (where it joined another area of substantial settlement in the south Gulf Coast). Most of the heart of the peninsula, the department of Petén in Guatemala, and large portions of Campeche and Quintana Roo in Mexico (the most densely settled portion of the Classic Maya territory) were virtually abandoned.

One of the major problems of Meso-American archaeology is the explanation of this massive population decline. The immediate causes are clear: it must have been the product of migrations out of the area or a set of internal factors that caused an in situ decline or both. Various hypotheses as to processes and causes have been suggested. These may be grouped in the following categories: natural disasters (earthquakes, famines, epidemics, and hurricanes have all been suggested); ecological processes (primarily the deterioration of the natural environment by overintensification of land use in response to population pressure); and sociopolitical processes (internal warfare, invasion from outside, peasant revolts, breakdown of critical trade networks). Some of these are clearly derivations from others or are not explanations but descriptions of events that were produced by other processes. It seems certain that the causes were multiple and in some way interrelated.

Of great interest is the fact that at least one other lowland area, the Pacific Coastal plain of Guatemala, experienced a comparable Post-Classic decline.

#### AZTEC CULTURE TO THE TIME OF THE SPANISH CONQUEST

**The nature of the sources.** At the time of the Spanish conquest the dominant people of Meso-America was the Aztec. This description is based primarily on written documents from the 16th century but also includes some archaeological data. The literature, both published and unpublished, of the 16th century is enormous and takes in all aspects of Aztec culture. Much of it covers the period within a few decades after the conquest; and it is uncertain how much change had occurred because of the introduction of Spanish culture. Some Aztec institutions, such as the military orders, were immediately abolished by the Spaniards; and the sources, therefore, give only the barest outline of their organization. The sources can be classified by content and purpose into five categories:

First, there are the eyewitness accounts of Aztec culture on the eve of the conquest. These, of course, are the most directly pertinent sources because they describe Aztec culture before it became transformed by the Spanish conquest, but they are the least detailed of the sources.

Second, there are the post-conquest histories of the Aztec written in Spanish. Within a few decades of the conquest, a series of histories had been written in the Spanish language, based in part on Aztec books and in part on upper class informants.

Third, there are post-conquest ethnographic accounts written in Spanish and Nahuatl. They are comparable in methodology and subject matter to the kinds of studies of native peoples conducted by present-day anthropologists. One of them, Bernardino de Sahagún's monumental *Historia general de las cosas de Nueva España*, covers virtually all aspects of Aztec culture. It is particularly detailed in religion, ethnobotany, folk medicine, and economics. As a source, it has the added value of being written in the Aztec language.

Fourth, there are the native books, or codices. Because of their religious content only a small fraction of these escaped destruction by the Spaniards. What few have survived usually come accompanied by Spanish nota-

Reasons  
for the  
decline in  
population

The  
codices

tions. These sources are limited in scope and subject matter but nevertheless are valuable documents, particularly with respect to history and calendrics. Among those that were prepared in Central Mexico are the Codex Chimalpopoca (also called the *Anales de Cuauhtitlan*), the Codex Ramirez (also called the *Historia de los mexicanos por sus pinturas*), both historical texts. Other native books include the Codex Borbonicus, a calendar; the Codex Badianus, a herbal with magnificent drawings of medicinal plants; the Codex Mendoza and the *Matrícula de tributos*, both tax documents of the Aztec Empire.

A fifth source is comprised of official ecclesiastic and government records. Much of this literature is unpublished. Its purpose was administrative rather than intellectual, but it has provided an extraordinarily rich source of information for all 16th-century ethnic groups. The documents vary from tax lists, censuses, and marriage and baptismal records to broad geographic-economic surveys. One of the most valuable of the last type are the *Relaciones geográficas* of 1579–80, a survey ordered by Philip II of all of his overseas possessions. A formal questionnaire was drawn up that demanded information from each town in the empire on virtually all aspects of Meso-American life: questions on the natural environment and resources, crops, population history, settlement patterns, taxes paid, markets and trade, the language, native history and customs, and progress of the missionization program.

This information, combined with archaeological data, gives a fairly detailed picture of Aztec culture at the time of the Spanish conquest.

Factors  
limiting  
cultivation

**Agriculture.** The homeland of the Aztecs, from which they ruled their vast domain, was a large (about 3,000 square miles, or 8,000 square kilometres), mountain-rimmed, basin with a floor at approximately 7,000 feet (2,200 metres) above sea level. The surrounding ranges reached a maximum elevation of 18,000 feet (5,500 metres) with the volcano of Popocatepetl. The annual rainfall varied from 20 to 35 inches (500 to 900 millimetres) in the valley floor to a maximum of 50 inches (1,300 millimetres) on the southern escarpment. Approximately 80 percent of the rain fell between May 1 and October 1. Because of the high elevation, the area suffered from severe winter frosts that normally began in mid-October and lasted until the end of March. Normally, the rainfall was adequate for maize, even in the drier portions of the basin; but a major problem was the timing of the rains and the frosts. A delay of the rainfall to mid- or late June, accompanied by early autumn frosts, could produce crop disasters.

Another major problem for the pre-Hispanic cultivator was the paucity of level land. Much of the land surface is sloping, and the problem of soil erosion was acute. Furthermore, of the 1,600 square miles (4,150 square kilometres) of relatively level land, 400 square miles were occupied by a chain of lakes; and much of the immediate lakeshore plain was waterlogged.

Because of the effect of elevation on the growing season, the areas above 8,300 feet (2,800 metres) were also unsuitable for cultivation, removing an additional 400 square miles from the agricultural resource. Even within zones of cultivation, the presence of steep slopes and thin soil reduced even further the area of cultivation. It is doubtful that more than 50 percent of the basin was suitable for labour-extensive methods of cultivation. Yet in 1519 it supported a population of 1,000,000 to 1,500,000; *i.e.*, a density of 500 people per square mile (200 per square kilometre), the densest population in Meso-American history. This was achieved by an extraordinarily intensive system of farming that involved a number of specialized techniques. Soil fertility was maintained by plant and animal fertilizers, by short-cycle fallowing, and by irrigation. In gently sloping terrain, erosion was controlled by earth and maguey terraces, in steeper areas by stone terracing. The problem of humidity was solved by canal irrigation of both the floodwater and permanent type. Much of the irrigation was done just before planting in April and May in order to give the crop a head start and hence avoid the autumn frosts. Terracing functioned

also as a method of conserving humidity. There is also evidence that dry-farming techniques were applied to store moisture in the soil. The most impressive achievement of Aztec agriculture, however, was that of swamp reclamation, even including colonization of the lakes. This system of farming, called chinampa, was first applied to Lake Chalco. The lake covered approximately 60 square miles and apparently varied in its character from swamps to ponds of fairly deep, open water. By a process varying from digging drainage ditches to artificial construction of land from lake mud and vegetation, most of the lake was converted to highly productive agricultural land. A series of masonry causeway dikes were constructed across the lake to control flooding. By a system of dikes and sluice gates the Aztecs even managed to convert a portion of saline Lake Texcoco, the largest and lowest lake in the basin to a freshwater bay for further chinampa colonization.

The total area colonized was probably in the neighbourhood of 30,000 acres (12,000 hectares); and much of the food base for Tenochtitlán, the Aztec capital, depended on these lands. By a comparable method, much of the waterlogged lakeshore plain was also converted into agricultural land. Particularly impressive is the fact that all of these techniques of food production were achieved by human power and simple hand tools.

Aside from agriculture, the basin had a number of major resources, some of which were exploited not only for local consumption but also to supply other areas of Meso-America. Obsidian, a kind of natural glass, was a superb material for a great variety of stone tools; and the north-eastern ranges of the basin contained one of Meso-America's major deposits. Basalt for *manos* and *metates* (milling stones) was also abundant. Lake Texcoco was a major source of salt, and the lakes generally provided waterfowl, fish, and other aquatic foodstuffs. The great pine forests above the limits of agriculture were a major source of lumber. On the other hand, the basin, because of its high elevation, was unsuitable for a great variety of tropical products including cotton, paper, tropical roots and fruits, tobacco, copal incense, rubber, cacao, honey, precious feathers and skins, and such prized goods as metal, jade, and turquoise. The major motivation of Aztec conquest was to obtain control of these resources.

**Social and political organization.** Technologically, the Aztecs differed little from other Meso-American groups. One of the distinctive aspects of Aztec technology was its differentiation by status levels. The use of most of the extra-local resources noted above was limited to a small upper and middle class; and there were striking differences in dress, housing, and diet by social class. Commoners, for example, wore clothing woven from maguey fibre, while the upper classes wore cotton garments. The use of imported foods, at least on a regular basis, was limited to the upper and middle classes. Commoners lived in small adobe or stone and mud huts, the upper and middle class in large multi-roomed palatial houses of cut stone, lime plaster, and concrete.

Aztec social and political organization can be divided into a number of levels of increasing size and complexity of organization. The nuclear family—that is, a pair of cohabiting adults and their unmarried children—formed the lowest level of organization. The nuclear family functioned in procreation, education of children, and as a unit of food preparation and consumption with a well-defined division of labour between husband and wife. Among the Aztecs, however, a number of nuclear families usually resided together in a single cooperating household, or extended family. Such a family usually consisted of a man, his married sons or brothers, and their families. The average peasant household of this type was small. Up to three nuclear families occupied a small multi-room house divided into apartments for each family. The houses were usually placed within a courtyard fenced with organ cactus or adobe walls, forming a compound. The extended family household probably functioned as a unit of land use and food production. In the towns, however, some households could be considerably larger; and the household of Montezuma included several thousand people.

Other  
resources  
of the basin  
area

The  
nuclear  
family

*The calpulli.* A number of households, varying from a few score to several hundred, were organized into an internally complex corporate group referred to as a calpulli by the Aztecs and translated as a barrio ("ward") by the Spaniards. Questions about the structure and function of this level of Aztec organization have caused a great deal of debate among Meso-American specialists. It is clear, however, that it was a physical and territorial unit as well as a socially organized one. It was a unit of land tenure. Calpulli lands were owned communally but were distributed among various households. The household retained the right of usufruct, but only the calpulli as a whole could sell or rent lands. The calpulli rural communities varied considerably in physical appearance. Some were isolated, tightly nucleated physical settlements surrounded by their agricultural land, whereas in others houses were dispersed through the land holdings. In a few cases, they were physically attached as wards to one or more other calpulli. These differences correspond to ecological, economic, and political factors. Rural, dispersed settlements were found on terraced hillsides in which houses were tightly integrated with the terrace; in the chinampa area, each house was placed on its chinampa holding. On the other hand, nucleated, isolated calpulli were found in areas of level land, and the ward type was usually found in the towns and cities. In the latter case, many lost their agricultural character and became units of craft specialization.

The calpulli was a unit of political administration within the larger unit that will be referred to here as the state. It was ruled by a council of household heads presided over by a chief selected by the council from within a particular lineage. The calpulli functioned as a unit of taxation to the central government, as a unit of corvée labour, and as a military regiment.

The structure of the calpulli is open to question. Some sources call it a kin group, "a lineage" with a common ancestor; and as a result some anthropologists have referred to it as a clan, or sib. There is no evidence, however, of either exogamy or unilineal descent; in fact, marriage records from the post-conquest period show a strong tendency toward endogamy. There is some evidence of internal ranking and significant status differentiation, another non-clanlike feature. The sources also mention smaller territorial subdivisions, referred to as *barrios pequeños*, or "little wards." If these are descent lines, then the calpulli resembles quite closely a type of kin group called by anthropologists a ramage, or a conical clan. This is a group with a myth of common descent, divided up into ranked senior and junior lineages based on the seniority of older versus younger brother in the group genealogy. In support of this reconstruction is the statement that the calpulli god was a deified ancestor.

The calpulli also functioned as a unit of education as each possessed a school for young men—the *telpochcalli*—primarily for military and moral instruction.

*The Aztec state.* Above the level of the calpulli was the state. With the exception of those historical periods when larger polities, such as the Aztec Empire, emerged, such states in Meso-America, including the Basin of Mexico, were small. Just prior to the Aztec expansion there were 50 or 60 such states in the basin with an average size of about 50 to 60 square miles. In 1519 these once independent domains had an average population of 25,000 to 30,000 people. In less densely settled areas, the territories were larger and populations smaller. The range of size was from a few thousand up to 100,000.

The average small state included a central town with a population of several thousand, the balance of the population consisting of the rural calpulli. The central town was divided up into wards that corresponded in size and to a certain degree in structure to the rural calpulli but were clearly different in function; they in turn were divided into *barrios pequeños*. At the head of the state was an official called the *tlatoni*, or *tlatoque*, to whom all household heads owed allegiance, respect, and tax obligations. The *tlatoni*'s position was fixed within a particular lineage, the particular choice varying from state to state. In some areas, succession passed from

father to son; in others, the succession went through a series of brothers and then passed to the eldest son of the eldest brother. In still other states, the office was elective; but the choice was limited to sons or brothers of the deceased ruler. The office was accompanied by all of the trappings and sumptuary behaviour typical of despotic states. The ruler resided in a large, multi-room masonry palace inhabited by a great number of wives, servants, and professional craftsmen. He was carried in a sedan chair in public and treated with exaggerated respect by his subordinates. The *tlatoni* held considerable power: he appointed all lesser bureaucrats, promoted men to higher military status, organized military campaigns, and was the distributor of booty and tribute; he collected taxes in labour, military service, and goods from his supporters; he owned private estates manned by serfs; he was the final court of appeal in judicial cases; and he was titular head of the religious cult and head of the town market.

Many of these functions were delegated to a large staff of professional administrators: priests, market supervisors, military leaders, judges, tax collectors, and accountants. The tax collectors, or *calpixque*, were especially important administrators because they acted as the rulers' agents in collecting goods and services from the calpulli chiefs.

*Class structure.* Most of these positions were appointed and selected from two classes—the *pilli* and the professional warriors. Society was divided into three well-defined castes. At the top were the *pilli*, nobles by birth and members of the royal lineage. Below them was the macehual class, the commoners who made up the bulk of the population. At the base of the social structure were the *mayerques*, or serfs, attached to private or state-owned rural estates. Within these three castes, a great number of social classes could be differentiated, according to wealth, occupation, and political office. The Aztec system made a distinction between ascribed and achieved status. By a system of promotions, usually as a reward for military deeds, commoners were appointed to such political offices as *calpixque* and judges. Many *pilli* held no political office and, unless they had inherited private estates, were forced to live off the largess of the ruler. Commoners who had captured four enemy warriors in combat were promoted to the rank of *tecuhitli*, entered one of the military orders, were assigned a private estate with serfs for their maintenance, and acted as an elite professional army. The children of both *pilli* and *tecuhitli* could enroll in the religious college, or *calmecac*, where they could be trained as priests or political administrators. The *calmecac* apparently was also open to certain other commoners, such as wealthy and influential merchants and craftsmen.

Aside from the commoner-warriors, the macehual class was further differentiated into class levels. Certain occupations were accorded higher prestige than others (merchants, lapidarians, goldsmiths, and featherworkers are mentioned, and the list probably included stone sculptors); and all urban occupations were assigned higher status as compared with rural farming. Since occupations were restricted to calpulli membership and since the calpulli were kin groups, it follows that crafts tended to be hereditary. In small towns the craft specializing group would have to be the small *barrios*. In the cities it was definitely the larger unit, but in either case crafts would be found within hereditary corporate groups.

The system of social stratification emphasized ascribed status but also permitted considerable vertical mobility. The land-tenure system was an important aspect in maintaining both processes, as could be expected in a basically agrarian society. Although most of the land was held in common by the calpulli, private estates with serfs helped to maintain the prestige of the *pilli* class and similar estates assigned to political office; and the *tecuhitli* positions freed able commoners from the necessity of subsistence procurement.

The taxation system also helped to maintain the social system. All heads of households owed military service to the *tlatoni*. For the *pilli* and *tecuhitli*, this was the only

The three social castes

Structure of the calpulli

Functions of the *tlatoni*

tribute demanded. Urban craftsmen also paid tribute in their craft products but were exempt from *corvée* labour. That obligation, plus taxes in agricultural products, were the burdens of the rural peasants, and the *mayeques* owed their labour and agricultural produce to their overlord.

Pawns  
and slaves

Two other elements in the Aztec social system were pawns and slaves. The former were poor men who could sell themselves or members of their household for a specified period of time. Their rights were carefully defended by Aztec law, and they were not slaves but more like indentured servants. True slaves did exist and in some parts of Meso-America were used as workers or servants. Among the Aztec, the *mayeques* were their counterpart. Slaves were bought in lowland markets and used primarily for human sacrifice.

The high development of craft specialization—much of it full-time—in Aztec towns has already been noted. But many rural communities also had part-time specialties, a feature due in part to the heterogeneity of the highland environment, with its highly local distribution of resources. Foreign goods were brought into the Aztec homeland by great caravans of professional merchants called *pochteca*, who frequently undertook journeys exceeding a year in length. As a group the merchants enjoyed very high prestige and even had their own tribunals. Various merchant wards of a great number of towns and cities in central Mexico were organized into one great trading guild that had its centre at Tenochtitlán. They also organized and administered the town markets, another highly evolved aspect of Aztec institutions. These markets were held in great open plazas—in smaller towns every fifth day, in larger towns and cities daily, although in the latter case the market population reached a peak every fifth day.

*Organization of the empire.* The centres and the political organization of large states such as the Aztec Empire were fundamentally similar in character to small ones; but the vast differences in size (Tenochtitlán, the Aztec capital, may have had 140,000 to 200,000 inhabitants in 1519) demanded some changes. Generally, when one central Mexican state conquered another, the ruler of the conquering town extorted an annual tribute; but there was little attempt at political integration. In the case of the Aztecs, this policy was generally maintained, but many conquered states were replaced with Aztec governors. Furthermore, conquest was usually accompanied by an exchange of women from the two ruling lineages (conqueror and conquered), and successors to the throne of the conquered states were through these women, from the royal lineage of Tenochtitlán. As a result, the ruling class gradually tended toward a single kin group. Because of the great number of states conquered by the Aztecs (400 to 500), some form of intermediate level territorial and administrative organization became imperative. The land conquered by the Aztecs was grouped into 38 provinces. One of the towns served as capital for each province; and an Aztec tax collector-governor was placed there to supervise the collection, storage, and disposition of the tribute. In many provinces, the Aztecs established garrisons. These consisted of warriors and their families culled from all of the towns of the Basin of Mexico, and they were assigned lands in the conquered province. Since they supported themselves, they were colonists as well as troops. The planting of colonists, combined with such factors as the merchant guild and royal family intermarriage, suggests that the Aztec elite were attempting to integrate more closely the population of the Basin of Mexico as a kind of core nationality for the empire. Other indications that the Aztecs were in the process of achieving further political integration are statements in several *relaciones* that the tax collectors served as courts of appeals in serious judicial cases and also that the Aztecs introduced the cult of their national god Huitzilopochtli to conquered provinces.

Organiza-  
tion of the  
provinces

**Tenochtitlán.** Tenochtitlán itself was a huge metropolis covering more than five square miles (13 square kilometres). It was originally located on two small islands in Lake Texcoco; but it gradually spread into the

surrounding lake by a process, first of chinampa construction, then of consolidation. It was connected to the mainland by several causeway dikes that terminated in smaller lakeside urban communities. The lake around the city was also partly covered with chinampas with numerous rural settlements. Together, the complex of settlements—the city, the chinampa villages, and the settlements along the lakeshore plain—must have appeared from the air as one gigantic settlement. The population in 1519 was in the neighbourhood of 400,000 people, the largest and densest concentration in Meso-American history.

The majority of the people in the city were non-food-producing specialists; *i.e.*, craftsmen, merchants, priests, warriors, and administrators. In Tenochtitlán, as in other larger towns, the larger *calpulli* formed craft guilds. Guild organization was internally complex, an economic development related to the higher level of political integration and the greatly expanded trade and tax base that accrued from it. The great market in the barrio of Tlatelolco is reported by the Spaniards as having 60,000 buyers and sellers on the main market day. The Spaniards also describe the enormous canoe traffic on the lake moving goods to the market. There is even evidence that many chinampa cultivators, in response to the expanded market, were shifting to truck gardening rather than toward the production of staple crops.

The Aztec capital was originally two separate cities, Tlatelolco and Tenochtitlán, merged into one through the conquest of Tlatelolco. The division was maintained for administrative purposes, however, and with further growth it became necessary to divide Tenochtitlán into four great wards (confusingly referred to as *calpulli* also). Each ward contained 12 to 15 *calpulli*, 50 to 60 in all. Tlatelolco must have had 10 to 20 *calpulli* as well, bringing the total up to perhaps 80.

With this enormously expanded tax base, the central government became internally complex. The Spaniards describe Montezuma's palace as containing 300 rooms grouped around three courts. Land titles dating from after the conquest give it an area of 10 acres. Aside from the private apartments of the king, the palace included libraries, storehouses, workshops for royal craftsmen, great halls for justice and other councils, and offices for an army of accountants. The sources even describe a royal zoo and aviary and a number of country retreats. The internal organization of the taxation, military, and judicial departments must have been far more complex than in small states; but precise data is lacking.

Montezu-  
ma's palace

Within the city there were literally hundreds of temples and related religious structures. There were at least two large complexes, religious centres of the dual cities of Tenochtitlán and Tlatelolco. Each of the four great wards of Tenochtitlán, as well as each *calpulli*, had smaller temple complexes, so that the total number must have run into the hundreds. The great temple complex of Tenochtitlán consisted of three large pyramid-temples (the principal temple platform, dedicated to Huitzilopochtli and Tlaloc, was 100 feet high and measured 300 feet on a side at its base). There were also six small pyramid-temples, three *calmecac* buildings (dormitories and colleges for priests), a ball court, a great wooden rack for the skulls of sacrificed victims, a sacred pool, a sacred grove, and several large open courts. All of these structures were placed within a vast walled enclosure, 400 yards on a side. The temple complex at Tlatelolco was at least half as large.

**Aztec religion.** Perhaps the most highly elaborated aspect of Aztec culture was the religious system. The Aztecs derived much of their religious ideology from the earlier cultures of Meso-America or from their contemporaries. This was particularly true during the final phase of their history, when their foreign contacts broadened. Indeed, much confusion about Aztec religious ideology stems, in part, from the fact that Aztec civilization was still in a process of assimilation and reorganization of these multi-stranded religious traditions. Moreover, as the empire expanded and Tenochtitlán evolved into a heterogeneous community, the religious needs correspondingly changed

from those of a simple agrarian society. The ruling class, particularly, demanded a more intellectual and philosophical ideology. (For a detailed discussion of the Aztecs' religion, cosmology, and calendar see AZTEC RELIGION; CALENDAR.)

The great ceremonial rites

The Aztec approach to contact with the supernatural was through a complex calendar of great ceremonies held at the temples and performed by a professional priesthood that acted as the intermediary between the gods and man. Many of these were public in the sense that the populace played the role of spectators. Elements in all the ceremonies were very similar and included ritual ablutions to prepare the priests for the contact; offerings and sacrifices to gain the gods' favour; and theatrical dramas of myths by masked performers in the form of dances, songs, and processions. Each god had his special ceremony that, considering the richness of the pantheon, must have filled the calendar. These ceremonies must have played a significant recreative function, as do ceremonies held in honour of patron saints in present-day Mexico.

Aztec religion heavily emphasized sacrifice and ascetic behaviour as the necessary preconditions for approaching the supernatural. Priests were celibate and were required to live a simple, spartan life. They performed constant self-sacrifice in the form of bloodletting as penitence (by passing barbed cords through the tongue and ears). This pattern of worship reached its climax in the practice of human sacrifice; it was in this aspect of Aztec culture that religion, war, and politics became closely interrelated.

The Aztecs believed that, as a people, they had a divine mission to prevent the fifth destruction of the Earth. They believed that the previous destructions were caused by the death of the Sun and that therefore the way to prevent his death was by sustaining him with human hearts and blood. Ideologically at least, Aztec warfare was waged for the purpose of obtaining sacrificial victims. The tribute lists, of course, demonstrate that there was a more mundane purpose as well; and it would be a serious mistake to think of Aztec warfare as functioning primarily in the religious sphere.

The priesthood

The cult of the gods required a large professional priesthood. Spanish documents indicate that the priesthood was one of the most elaborate of Aztec institutions. Each temple and god had its attendant priestly order. At Tenochtitlán the high priests of Tlaloc and Huitzilopochtli served as heads of the entire priestly organization. Within the orders were priests in charge of ceremonies, of the education of novices, of astrology, and of the temple lands. (These consisted of specific rural communities assigned by the state to particular temples.) Furthermore, there were several grades of priests. As noted above, the priests maintained a number of schools, or *calmecacs*, where sons of the nobility and certain commoners were given instruction. Most of these novices ultimately left the priesthood and occupied economic and political statuses; others remained, joined the priesthood on a permanent basis, and lived at the *calmecac*.

Probably much of Aztec religion was practiced at home at special household altars. Common archaeological artifacts are small baked-clay idols or figurines, representing specific gods apparently used in these household ceremonies, along with incense burners.

The Post-Classical civilizations of Meso-America came to an abrupt end with the coming of the Spanish in the early 16th century. (For the history of the Spanish Conquest, see LATIN AMERICA AND THE CARIBBEAN, COLONIAL.)

*Pre-Classical and Classical periods:* MIGUEL COVARRUBIAS, *Indian Art of Mexico and Central America* (1957); WILLIAM T. SANDERS and BARBARA J. PRICE, *Mesoamerica: The Evolution of a Civilization* (1968); and ERIC R. WOLF, *Sons of the Shaking Earth* (1959), are good general introductions to Meso-America and its prehistory. Two books dealing with the Olmec civilization are MICHAEL D. COE, *America's First Civilization* (1968); and IGNACIO BERNAL, *The Olmec World* (1969). JOHN PADDOCK (ed.), *Ancient Oaxaca* (1966), deals with the Monte Albán civilization, among other matters.

Two up-to-date books on the Maya are J. ERIC S. THOMPSON, *The Rise and Fall of Maya Civilization*, 2nd ed. (1966); and MICHAEL D. COE, *The Maya* (1966). J. ERIC S. THOMPSON, *Maya Hieroglyphic Writing: An Introduction*, 2nd ed. (1960), is a monumental survey of Maya calendrics and writing. For a contrasting view of the nature of Maya script, see YURI V. KNOROV, *Selected Chapters from the Writing of the Maya Indians* (1967; orig. pub. in Russian, 1963).

*Post-Classical Period, 900-1519:* MICHAEL D. COE, *Mexico* (1962) and *The Maya* (1966), are the most recent syntheses on Meso-American archaeology as a whole and provide much descriptive information with a minimum of theoretical interpretation. WILLIAM T. SANDERS and BARBARA J. PRICE (*op. cit.*), has little descriptive detail and is essentially a theoretical interpretation of Meso-American archaeology from an evolutionary and ecological point of view. BERNARDINO DE SAHAGUN, *Florentine Codex*, trans. by CHARLES E. DIBBLE and ARTHUR J.O. ANDERSON, 9 vol. (1950-63), is the first full translation of this 16th-century Spanish writer of Aztec culture and is particularly full on Aztec religion. J. ERIC S. THOMPSON, *Mexico Before Cortez* (1940), and *The Rise and Fall of Maya Civilization*, 2nd ed. (1966), remain the best detailed descriptions of Aztec culture. GEORGE C. VAILLANT, *The Aztecs of Mexico*, rev. ed. (1966), now somewhat out of date, still is the best archaeological and ethnohistoric syntheses of the culture history of the Basin of Mexico.

(M.D.C./W.T.Sa.)

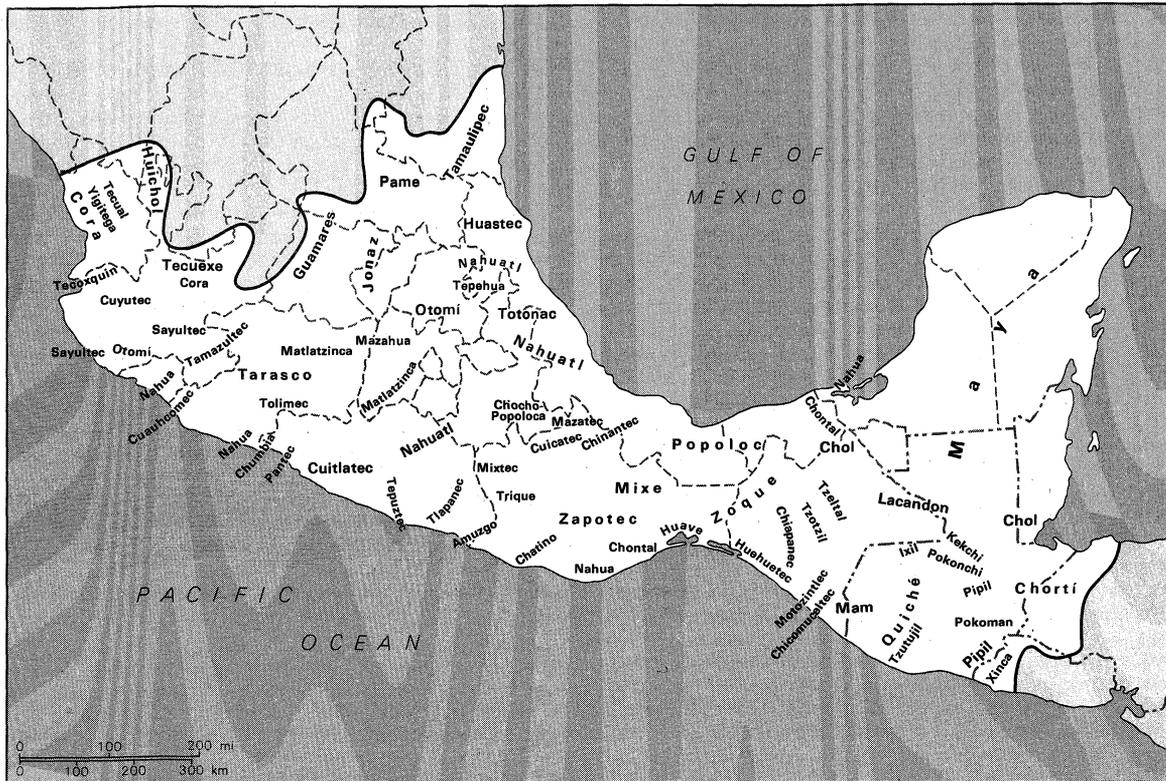

### Meso-American Indian Cultures

Indigenous to Mexico and Central America (roughly between latitudes 14° N and 22° N), Meso-American Indian cultures had a common origin in the pre-Hispanic civilizations of the area (see MESO-AMERICAN CIVILIZATION, HISTORY OF). Most Meso-American peoples belong to one of three linguistic groups: the Macro-Mayan, the Oto-Manguean, or the Uto-Aztec. Macro-Mayan peoples, with the exception of a northeastern enclave, the Huastecs, live at the southeastern extremity of Meso-America. Oto-Mangueans are to be found in a wide area of Meso-America between Uto-Aztec peoples to the north and east and Mayan and other peoples to the south. Oto-Manguean languages (now extinct) were spoken south of the Mayan area along the Pacific coasts of El Salvador, Honduras, and Nicaragua; and one Oto-Manguean language, North Pame, spoken in the central desert of highland Mexico, is outside Meso-America to the north. The main branches of the Oto-Manguean family are Oto-Pamean, Amuzgoan, Popolocan, Chinantecan, Mixtecan, Zapotecan, Manguean, and perhaps Huave and Tlapanec. The Tlapanec and Chontal languages of Oaxaca, spoken on the Pacific coast of Mexico, are held by some scholars to be related to the Hokan Coahuiltecan (sometimes termed the Hokaltecán) languages farther north. As a result of the expansion of the Aztec Empire centred in the valley of Mexico, Uto-Aztec enclaves are found throughout the area. Tarascan, a language the filiation of which is still in doubt, is spoken in the highlands of Michoacán, Mexico.

Main linguistic groups

**Settlement patterns.** The territorial unit that has prime importance for most Meso-American peoples is the *municipio*, a unit roughly corresponding to a county in Great Britain or the United States. Each *municipio* has a municipal centre where most civic, religious, and marketing activities take place. In the modern pattern, this centre is the largest settlement in the area. The usual elements, which vary according to the size and importance of the community, are laid out according to the standard pattern imposed by early Spanish administrators throughout New Spain: a plaza surrounded by public edifices (church or chapel, curacy, jail, perhaps a school, and a meeting place for civil authorities). Houses nearest the plaza are those of the principal persons. Larger communities are often divided into sociopolitical enclaves called *barrios*.

An older pattern, still found in some areas (as among some Mayan peoples of the south and among the Huichol of the north), is for the *municipio* centre to be an empty town, occupied continuously only by civil and religious authorities and perhaps a few merchants. The bulk of the population resides in hamlets or on individual farms most of the year, moving to town residences only for

Distribution of Meso-American Indians.

From H. Driver *et al*, *Indiana University Publications in Anthropology and Linguistics* (1953)

short periods either to transact business or to participate in a religious festival.

**Social, political, and religious institutions.** The basic social and economic unit of Meso-America is the extended family of from two to four generations. There is a strong tendency for the extended family to fragment into individual nuclear families, each consisting of one couple and their children. Kinship is reckoned bilaterally, no distinction being made between kinsmen related through males and those related through females. Such distinctions are made in a few Mayan and Zoque communities, and they are common immediately north of Meso-America. These and other facts have led some anthropologists to suggest that small pre-conquest communities were patrilineal clans or lineages. Named clans and lineages have actually been reported in a few present-day Tzeltal (Mayan) communities.

Throughout Meso-America generally, newly married couples tend to locate near the groom's family in a slight majority of cases. Inheritance also generally favours the male line, including family names, which are almost invariably inherited from males. Inherited names are now most commonly of Spanish origin, but native surnames are known among some Mayan groups. In certain Mixtec (Oto-Manguan) communities, a man's first name becomes the surname of his offspring.

Marriage, traditionally an alliance between two families, is initiated by the groom's parents and arranged by them directly or through the services of a go-between. A period of bride service by the groom, often involving at least temporary residence with the bride's family, is not uncommon. Polygyny is known and socially acceptable but is not common.

Political and religious institutions are traditionally bound together into a complex of hierarchically arranged year-long offices through which adult males may attain status and power in the community. All males must serve in the lower ranked offices at one time or another, but only the most successful attain the highest positions.

Progress through the ranks typically involves an alternation between civil and religious offices. Successful passage to the highest ranks results in election to the position of elder. Elders form a more or less informal group of

senior men to whom the community looks for experienced guidance in policy matters and in times of crisis.

Meso-American religion, called Christo-pagan by anthropologists, is a complex syncretism of indigenous beliefs and the Christianity of early Roman Catholic missionaries. A hierarchy of indigenous supernatural beings (some benign, others not) have been reinterpreted as Christian deities and saints. Mountain and water spirits are appeased at special altars in sacred places by gift or animal sacrifice. Individuals have companion spirits in the form of animals or natural phenomena, such as lightning or shooting stars. Disease is associated with witchcraft or failure to appease malevolent spirits.

**Economic patterns.** The cultivation of Indian corn, as well as of a number of secondary crops, provides basic subsistence for all Meso-America. Secondary crops include the bean, the squash or pumpkin, the chili pepper for seasoning, and tomatoes of both cooking and eating varieties. Additional foods with a limited distribution because of differing climates and terrain are the pineapple, sweet potato, manioc, chayote, vanilla, maguey, nopal, mesquite, cherimoya, papaya and avocado. Pre-Hispanic commercial plants included cotton, tobacco, henequen for its fibre, and cocoa beans, which served as a medium of exchange. Important commercial crops that have been introduced since European contact include Old World cereals (wheat, barley, oats), bananas, coffee, sugarcane, sesame, and the peanut.

Traditional slash-and-burn agriculture persists in the most isolated areas, but plow agriculture has replaced it in many places. *Chinampa* agriculture is limited to the valley of Mexico: small artificial islands are built up about one foot above the level of shallow waters of a freshwater lake, formed from the mud and vegetation of the lake floor. After settling, this serves as a rich bed for mixed-crop rotation, nurseries, and seed plots.

All Meso-American communities are tied to national and international markets, but the extent of this relationship varies considerably. The Lacandonones of the Chiapas lowland jungles bordering Guatemala lie at one extreme. If the machete, axe, rifle, matches, and similar items from the outside became unavailable to the Lacandonones through some catastrophe, they, of all Meso-Americans,

Agricultural methods

would have perhaps the least difficulty in adjusting to the challenge of their ecological situation. Living members of the community still retain personal knowledge of working flint and stone and of the making of fire, cloth, and pottery. The Cora and Huichol, Uto-Aztecs of northwestern Meso-America, are also reported to be only marginally dependent upon outside markets.

A larger segment of Indian populations is tied to the outside cash economy by one or more products, such as coffee, citrus, vanilla, livestock, or manufactured goods. Specialization is not the norm, but from pre-Hispanic times certain communities have developed products and skills that depend upon trade relations. An entire community may be known for its pottery, weaving, or basketry.

Markets are typically organized into a network in which each of several towns hosts the market in its central plaza, a different town each day of the week. The network may or may not include a central market that is held every day of the week. Such a market consists of a core of local merchants the ranks of which are swollen once a week by merchants from the outlying hamlets of the area. All of the merchants, whether from the central market or from outlying markets, tend to be organized in single household units.

Arts and  
crafts

Craft specializations that figure in marketing operations are also widely practiced to meet family needs only. Before the appearance of inexpensive commercial cloth, it was the norm throughout Meso-America for every young girl to learn to weave cotton cloth and, as a married woman, to provide clothing materials for her family. This skill is declining in the face of easy access to materials of cotton, wool, silk, and synthetic materials and blends. The introduction of the treadle loom by the Spaniards brought men into the weaving industry, especially as a commercial operation.

Both men and women are hat and basket weavers. Commercial products are produced from grasses, reeds, and palms, and lowland peoples also produce baskets of vine for local use.

A variety of pottery-making techniques is known in Meso-America. Before Hispanization, female potters made most ware, forming vessels by hand modelling, by building with coils, or by using a wooden paddle or molds. The Spaniards introduced the potter's wheel. Present-day techniques are a synthesis of indigenous and Spanish methods.

A lacquering art, now an integral part of the tourist trade, was practiced at the time of the conquest. A variety of gourd vessels of many sizes and shapes are artistically painted, using local materials and techniques. The beautifully decorated vessels serve a range of purposes, from simple utilitarian items, such as dippers, to elaborate ceremonial bowls.

**The life cycle.** Christian baptism is the first major event in the life of an individual. Indeed, among Chinantecs, a child is not considered fully human until the rite has been performed. If an unbaptized infant dies, the body is buried immediately without the usual ritual observances—ringing of the church bells, burning of incense, and reading and singing of prayers in the home, at the church, and at the graveside.

Nursing may continue for as long as three or four years, and childhood is a period of little discipline except for the responsibility placed on older children to care for their younger siblings while the parents work. Formal schooling is now available in most areas for at least a few years, but monolingualism in less acculturated areas severely limits the efficacy of the training, which is almost always conducted in Spanish only. There is no puberty rite, so that the transition from infancy to adolescence is unmarked ritually.

Formal  
education

A girl becomes an adult at marriage, but a boy becomes an adult in two ways: through marriage and through citizenship attained when he reaches the proper age, usually 14 or 15 years. At this time he must enter the labour pool of adult men who maintain community property and must contribute his share of any assessment the citizenry may impose upon itself to cover community expenses. He becomes eligible (and obligated) to serve in the lowest

ranking offices of the political and religious institutions of the community.

Death is marked by ritual and burial within 24 hours of death, with repetition of the ritual at periodic intervals after death, sometimes ending on the ninth day, sometimes repeated on the anniversary. An All Saints feast of several days' duration is prepared annually in the fall of the year for all of the dead.

**Modernization.** Indigenous communities have in most cases made a healthy adjustment to the larger non-Indian community around them. Although this has and will continue to involve many kinds of cultural change, the indigenous communities have been able to maintain their cultural integrity with little sign of the kind of disorganization leading to cultural collapse that is often found when two cultures meet. And though the Spanish-speaking community has come to accept (even to take pride in) its Indian heritage, its direct attempts to bring the Indian way of life more in line with that of its own have met with much resistance. While it has been possible to introduce technological changes that have improved the economic position of Indian communities, attempts to change those parts of the culture that have symbolic value—political and religious ideologies that tend to preserve indigenous social systems—have met with less success.

**BIBLIOGRAPHY.** SOL TAX (ed.), *Heritage of Conquest: The Ethnology of Middle America* (1952, reprinted 1968), includes Paul Kirchhoff's ground-breaking article "Mesoamerica" and is the best early synthesis of ethnographic information on the area. A comprehensive statement on all aspects of the subject is found in ROBERT WAUCHOPE (ed.), *Handbook of Middle American Indians* (1964- ), a projected 16-volume reference work and bibliographic sourcebook of which 9 volumes have appeared. Volumes 4 and 11 of THOMAS A. SEBEOK (ed.), *Current Trends in Linguistics* (1968 and 1972), provide the latest syntheses of linguistic relationships. Ethnographic material includes: RALPH L. BEALS, *The Ethnology of the Western Mixe* (1945); GEORGE M. FOSTER, *Empire's Children: The People of Tzintzuntzan* (1948); ROBERT REDFIELD, *A Village That Chose Progress: Chan Kom Revisited* (1950, paperback 1962); WILLIAM MADSEN, *The Virgin's Children: Life in an Aztec Village Today* (1960); OSCAR LEWIS, *Life in a Mexican Village: Tepoztlán Restudied* (1963); EVON Z. VOGT, *Zinacantan: A Maya Community in the Highlands of Chiapas* (1969); and PHILLIP BAER and WILLIAM R. MERRIFIELD, *Two Studies on the Lacandonos of Mexico* (1971). Linguistic descriptions include: RICHARD S. PITTMAN, *A Grammar of Tetelcingo (Morelos) Nahuatl* (1954); VELMA B. PICKETT, *The Grammatical Hierarchy of Isthmus Zapotec* (1960); JOSEPH E. GRIMES, *Huichol Syntax* (1964); MARVIN K. MAYERS (ed.), *Languages of Guatemala* (1966); H. HARWOOD HESS, *The Syntactic Structure of Mezquital Otomi* (1968); WILLIAM R. MERRIFIELD, *Palantla Chinantec Grammar* (1968); and MARION M. COWAN, *Tzotzil Grammar* (1969).

(W.Me.)

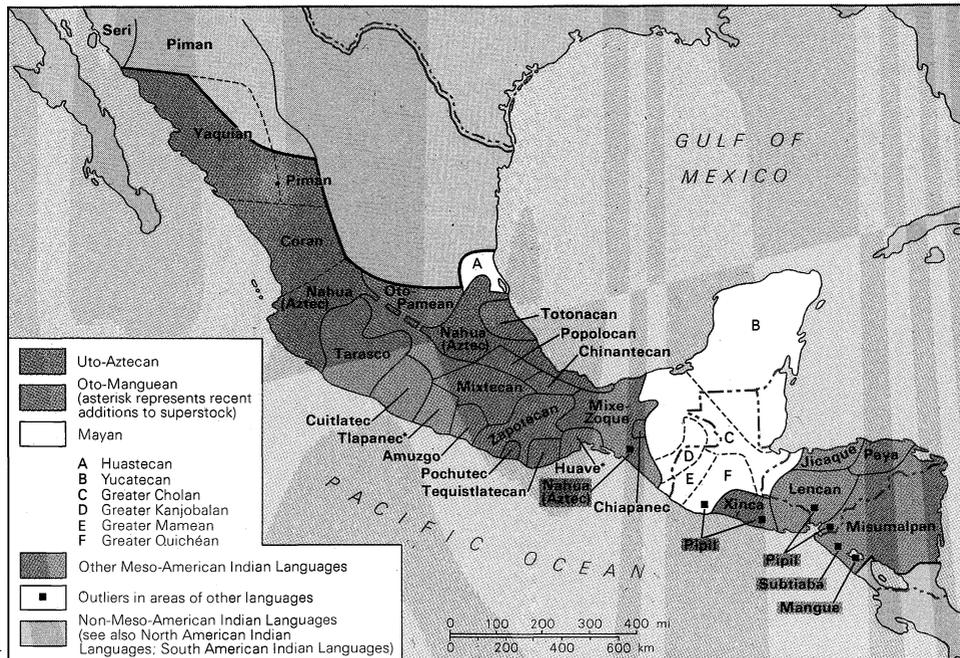

## Meso-American Indian Languages

Meso-American, or Middle American, Indian languages are spoken in Meso-America; *i.e.*, an area of the aboriginal New World that includes central and southern Mexico, Guatemala, British Honduras, El Salvador, parts of Honduras and Nicaragua, and part of northwest Mexico. Though various centres of civilization have flourished in the area, sometimes concurrently, from 1000 BC down to the time of the Spanish conquest of Mexico in 1519, Meso-America as a whole has had a more or less common cultural history for 2,500 years.

Treatments of the languages of Meso-America are customarily organized on the basis of their genetic relationships, and only secondarily on that of geographical distribution. Thus, some languages treated as Meso-American are not in fact spoken in Meso-America proper but form linguistic families with languages that are spoken there. For information about languages of northeast, north central, and northwest Mexico that are not dealt with in this article, see NORTH AMERICAN INDIAN LANGUAGES. For languages of Central America not treated here, see SOUTH AMERICAN INDIAN LANGUAGES.

Some 70 Indian languages are spoken today in Meso-America by perhaps 6,000,000 people. When the Span-

Numbers

languages  
and  
speakers

Distribution of Meso-American Indian languages c. AD 1500. Boundaries are schematic.

ish conquered Mexico in 1519, there may have been 20,000,000 people in Meso-America. Within 100 years of the conquest, the Indian population had decreased by 80 percent as a result of war, disease, forced labour, and starvation. Since then, the Indian population has gone back to a higher level, but several languages—about ten such are documented—have become extinct. Meso-American languages with the greatest number of speakers in the mid-20th century are:

language	number of speakers	family
Aztec	1,000,000	Uto-Aztecan
Yucatec	350,000	
Quiché-Tzutujil-Cakchiquel	900,000	Mayan
Mam	350,000	
Kekchí	300,000	
Mixtec	250,000	
Zapotec	300,000	Oto-Manguean
Otomí	300,000	

*The study of the Meso-American languages.* During the 16th and 17th centuries, some Dominican and Franciscan missionaries devoted themselves to the study of native languages so that priests could deal in religious matters with monolingual Indians. They wrote grammars following a Latin model, devised orthographies applying values used in Spanish or Latin (occasionally inventing new letters), made dictionaries (usually vocabularies or glossaries), and translated Christian texts (confessionals, sacraments, and sermons) into Indian languages. Except for one heroic figure, the Spanish missionary priest Bernardino de Sahagún, they neither collected nor fostered the collection of folklore. During this period grammars and dictionaries were written for such languages as Aztec, Zapotec, Mixtec, Tzeltal, Yucatec, Quiché-Tzutujil-Cakchiquel, Chortí, and Northeastern Otomí. These collections of data served the successors of the first missionaries. During the 18th century, the momentum of such work decreased, and, after Mexican independence in the first part of the 19th century, Spanish clerics were ousted, leaving further work on indigenous languages to travellers and gentlemen scholars—mostly people poorly qualified for such a task.

Modern linguistic techniques for the description of languages were not applied to Meso-American languages until North Americans turned their attention to the area in the 1930s (Protestant missionaries) and 1940s (secular academic linguists). Since then, much professional linguistic work has been done on these languages, especially those of Mexico. Almost every language of Meso-Ameri-

ca has been worked on by at least one linguist, but the time spent and the level of linguistic competence of the investigators have varied greatly. For most of the languages, grammatical and lexical data have been collected, much of which remains unpublished. A number of competent grammars and dictionaries have appeared; none of them, however, is exhaustive or definitive. Folktales have been collected for a smaller number of languages. Spanish-based orthographies have been devised for most of the Meso-American languages in the 20th century, but not much reading matter is available in them. In short, much work remains to be done.

CLASSIFICATION OF THE MESO-AMERICAN LANGUAGES

**Modern genetic groupings.** The classification of Meso-American Indian languages presented here reflects generally accepted genetic groupings (as of the early 1970s), based on similarities in vocabulary and grammar and on the establishment of regular correspondences between sounds in cognate (related) words among the several languages. The languages grouped together are presumed to have developed from a common ancestor, called a protolanguage. Not all of the languages of Meso-America have been convincingly assigned to a specific group. A few are currently thought to be unrelated to any of the established genetic groupings and are listed individually; these are called isolates.

Within a given genetic grouping, there may be several levels of relatedness. Glottochronology (or lexicostatistics), developed by two United States linguists—Morris Swadesh and Robert Lees—is a controversial and not universally accepted procedure for measuring degrees of difference between related languages in terms of years of separation. Based on the assumption that all languages change more or less to the same degree in a given period of time, the method employs a list of 100 items of “basic” or “noncultural” concepts, which are assumed to be expressible by vocabulary items in any language. Over a period of 1,000 years, different words will have been substituted to express 14 percent of the notions on the list, thus leaving fewer cognate (related) words. Since every language replaces 14 percent of the 100 concepts every 1,000 years, two languages that separated 1,000 years ago will share 74 percent cognates (86 percent of 86 is 74 percent). The following are terms and categories for degree of relatedness, correlated with glottochronological time depths, that will be used to describe the various Meso-American language groups. The figures given are minimal bounds.

Extent of the studies of Meso-American languages

\*Indicates centuries of separation. †Not spoken in Meso-America. ‡There is some doubt whether these groups should be given the status of complexes. §Sonoran languages spoken in Meso-America. ||Varieties of the same language spoken in different countries (and having different names).

the position assigned the Nahuatl group. Either Nahuatl is considered as separate and the rest as forming a Sonoran division, thereby producing three divisions—Shoshonean, Sonoran, and Nahuatl—or else Nahuatl is included within Sonoran, thereby producing a Shoshonean versus Sonoran dichotomy, which is the arrangement used in this article. Several scholars believe that the “division” concept is faulty here and that Uto-Aztecan contains eight groups and branches that are not to be further grouped in any special way.

Only some Sonoran languages are spoken in Meso-America (indicated by asterisks [\*] in the Table). The extinct Tubar belongs to the Yaquian branch, but whether to the Tarahumara complex, the Cáhita complex, or neither, is not clear. The Nahuatl group includes the extinct Pochutec, formerly spoken on the coast of Oaxaca, Mexico, and poorly documented; Pochutec is clearly very divergent from the rest of the group. The Aztec complex is considered by some to be a single language with several dialects. The three Aztec languages were spoken within the Aztec Empire as it was constituted in 1519. Pipil speakers, who also refer to their language as *nawat*, were not a part of the Aztec culture and probably represent a Toltec expansion from several centuries earlier.

In 1859, Johann Karl Buschmann, a German philologist, correctly identified all the then-known Uto-Aztecan languages as forming a family. In 1883 a French philologist, Hyacinthe de Charencey, divided Uto-Aztecan into

Oregonian (=Shoshonean) and Mexican (=Sonoran), and, in 1891, in the United States, anthropologist Daniel Brinton recognized Shoshonean and divided the Sonoran division (of this article) into Nahuatl (=Nahuatl) and Sonoran (=the Sonoran of this article minus Nahuatl). Brinton's division was followed by the United States biologist John Wesley Powell in his classification of North American languages.

Buschmann in 1859 and United States anthropological linguist Edward Sapir in 1915 contributed to the comparative study of Uto-Aztecan by assembling sizable numbers of cognate sets.

A number of now-aculturated and racially absorbed Indian ethnic groups of northern Mexico are believed by many to have spoken Uto-Aztecan languages, although only the language names are known, and not the languages themselves. These are: Suma, Jumano, Lagunero, Cazcán, Tecuexe, Guachichil, and Zacatec.

Uto-Aztecan is generally accepted by specialists as related to the Kiowa-Tanoan family of North America and with it to form the Aztec-Tanoan stock (or phylum).

*Cuitlatec* (2). The now extinct Cuitlatec language has not been linked convincingly with any other language or family, though the idea that it might be related to Uto-Aztecan has been entertained.

*The Hokan hypothesis* (3-5). In 1919 two United States anthropologists, Roland Dixon and Alfred Kroeber, tried to improve on an older North American classi-

Various scholars' work on Uto-Aztecan

fiction by reducing the multiplicity of language groupings in California (about 50) to a manageable number of families and stocks. Working over a period of several years, they developed the hypothesis that most California languages belong to one of two great groupings (called phyla or superstocks), Hokan and Penutian. The formulation was accepted and extended by others. Hokan included Shasta, Achumawi, Atsugewi, Chimariko, Karok, Yanan, Pomoan, Washo, Esselen, Yuman, Salinan, and Chumashan. By 1891/92 it had been suggested that Yuman, Seri (3), and Tequistlatec (4) were related. In 1915 the matter was re-examined in the light of the Hokan hypothesis, and it was concluded that all of the languages named above are related. Since then most scholars familiar with Yuman languages have believed that Seri and Yuman are related, and many who accept the Hokan hypothesis believe that Seri and Yuman form a special group within Hokan.

Jicaque (5), which is very poorly documented, though still spoken, has plain, aspirated, and glottalized stops (different varieties of consonant sounds), as do many Hokan languages. In 1953 it was suggested that Jicaque is a Hokan language. The general acceptance of the proposition may have been uncritical, because the available data on Jicaque is hardly reliable.

*Extinct languages of northeast Mexico.* All but one (Tonkawa) of the several languages once spoken in northeast Mexico and South Texas have become extinct. Documented languages of Mexico are: Coahuilteco, Comecrudo, Cotoname, Naolan, and Maratino (or Tamau-lipic). Those of Texas are Karankawa (and Klamkosh), Atakapa, and Tonkawa. John Wesley Powell classified the first three as forming a Coahuiltecan family. The other Mexican languages were unknown until recently. Each of the three Texan languages was considered by Powell to be an isolate. In 1920 Coahuiltecan was redefined to include Karankawa and Tonkawa and to be coordinate with Hokan in a Hokan-Coahuiltecan (=Hokaltecan) superphylum.

*Tlapanec (6).* The Tlapanec complex was first correctly identified by Walter Lehmann, a German physician, in 1920. In 1925 Edward Sapir tried to establish Subtiaba as a Hokan language, proposing some Proto-Hokan reconstructions that could account for the Subtiaba forms. This classification is generally accepted. More recently, however, Calvin Rensch, a U.S. missionary linguist, tried to validate the Oto-Manguean hypothesis (see below) by means of full-scale phonological reconstruction. He believed Tlapanec to be Oto-Manguean; others considered it to be intermediate between Oto-Manguean and Hokan. It must be kept in mind that most of the specialists who have immersed themselves in the study of large numbers of American Indian languages believe that almost all of them are genetically related to one another. This relationship derives from a period, perhaps 20,000 to 30,000 years ago when some of the languages were still spoken in Asia. With such a point of view, correct grouping (or degree of relationship) is a more interesting question than genetic relatedness.

*Oto-Pamean (7).* The Oto-Pamean stock contains four groups and complexes, Chichimec, Pamean, Matlatzinca, and Otomian, of which only the last two are spoken within Meso-America. The exact number of languages within the Otomí complex is not yet determined, though there seem to be four. Oto-Pamean was first correctly identified in 1892.

*Popolocan (8).* The Popolocan family (which might more appropriately be called Mazatecan) was correctly identified in 1926. The exact number of languages within the Mazatec complex has not yet been determined, though there are at least two.

*Mixtecan (9).* There is some difference of opinion as to how the various languages here included within Mixtecan are to be grouped. The main problem is whether Amuzgo is Mixtecan or a separate branch within Oto-Manguean. It has been included within Mixtecan in some systems and excluded from it in others. There seem to be three languages within the Mixtec group, a subdivision of Mixtecan.

*Zapotecan (10).* The Zapotecan family was correctly identified by William Mechling in 1912, but only Francisco Belmar, a Mexican philologist, correctly recognized that Papabuco is a separate language, neither Zapotec nor Chatino (in 1905). Belmar, however, incorrectly included Chinantec within Zapotecan. The Chatino language has several dialects. Within the Zapotec complex there are at least four languages, and perhaps more.

*Chinantecan (11).* The Chinantecan group contains approximately four languages, the exact number as yet undetermined. The separateness of Chinantecan within Oto-Manguean was recognized in 1912.

*Manguean (12).* The Manguean group was correctly identified by Belmar in 1905. Its members, formerly spoken in Chiapas (Mexico), and in Nicaragua, Honduras, and Costa Rica, are now extinct.

*The Oto-Manguean hypothesis (7-12 or 6-13).* Ever since 1891, it has been proposed that two or more of the above families (7-12) should be linked. Since about 1925, it has been generally accepted by specialists that the Oto-Pamean, Popolocan, Mixtecan, Zapotecan, Chinantecan, and Manguean groups form a larger genetic grouping (phylum), commonly labelled Oto-Manguean. This may be called the "classical Oto-Manguean formulation." Since 1950, work has been going on in the reconstruction of parent languages for each of the constituent families and groups. Since 1961, two revisions have been proposed in the formulation of what constitutes Oto-Manguean: the Tlapanec language complex has been recognized as included in or closely related to Oto-Manguean, and Huave has been proposed as an Oto-Manguean language. In the early 1970s, therefore, most Oto-Manguean specialists considered the grouping to consist of groups 6-13.

The comparative study of the Oto-Manguean phylum has resulted in the first case in the Western Hemisphere in which the remote common ancestor of several language families has been phonologically reconstructed. Comparative linguistics at the phylum level has been largely unsuccessful with other postulated superstocks because of the relatively small number of cognates that can be identified. Except for Manguean, all Oto-Manguean languages are spoken in central Mexico.

*Huave (13).* Early proposals linked Huave to Mixe-Zoque and Mayan. Although this has not been generally accepted by many specialists, it has been uncritically repeated in most compilations. Recently, Morris Swadesh presented a reasonably well documented proposal for Huave as an Oto-Manguean language.

*Mixe-Zoque (14).* The Mixe-Zoque family consists of eight languages, which, comparative phonology and grammar suggest, form two branches—a Zoquean group, and a Mixean group including Tapachultec. Glottochronological figures, however, suggest a three-way division, as shown in the Table. The Mixe-Zoque family was correctly identified by Hyacinthe de Charencey in 1883. The Texistepec, Sayula, and Oluta languages of this family are all locally called Popoluca.

*Totonacan (15).* The Totonacan family contains just two languages, of which one (Totonac) has at least three dialects. Possibly, Totonac is a complex.

*Mayan (16).* The Mayan family was correctly identified by a German ethnographer, Otto Stoll, in 1884. This family, with 24 languages and nearly 2,500,000 speakers, is the most diversified and populous language family of Meso-America. The Huastec language is separated by more than 1,000 miles from the nearest other Mayan language. Taken with the fact that the Huastecs did not share in the Classic Maya civilization, this requires a historical explanation involving the separation of Huastec from the rest of the family more than 2,500 years ago. Though the geographical extent of the Mayan languages is considerable, the Mayan peoples, languages, and cultures (as contrasted with those of the Aztecs), have never been particularly expansionist.

A number of attempts have been made to classify the Mayan languages, each one availing itself of more data than the last. The classification given here as of 1971 recognizes, at the lowest level, ten groupings. Specialists have disagreed on the precise positions of Tojolabal and

Chuj, Motozintlec, Aguacatec, Uspantec, and Kekchí and have held no firm opinions about the Yucatec or Huastec complexes. Not much comparative work on the Mayan family has been printed, but much data has recently been collected. The main contributors to Mayan comparative studies have been the U.S. linguists Norman McQuown (1950s and 1960s) and Terence Kaufman (1960s).

Hypotheses concerning superstocks

*The Macro-Mayan and Macro-Penutian hypotheses.* In 1931 L.S. Freeland, a U.S. anthropological linguist, tried to show that Mixe (Zoque) is related to the "Penutian" languages, a superstock that up until then had been limited to California, Oregon, Washington, and British Columbia. In 1935 it was suggested that the similarities between Uto-Aztecan, Tanoan, Kiowa, Penutian, Mixe-Zoque, and Mayan were such as to indicate the existence of a superstock, which it was proposed to call Macro-Penutian. This hypothesis had favour for a period but was never demonstrated nor taken very seriously by specialists. Since then the first three have been generally joined in Aztec-Tanoan. In 1942 it was suggested that Mixe-Zoque and Totonacan might be related genetically to each other and the two in turn might be related to Mayan, the resultant superstock to be called Macro-Mayan. Recently it has been claimed that Tarasco (17) probably belongs in Macro-Mayan as well, though the attempt to prove this has not been convincing to most Mayanists, to whom, minus Tarasco, the Macro-Mayan hypothesis seems as reasonable as the Hokan hypothesis.

*Tarasco (17).* Tarasco has been linked genetically by some not only to Macro-Mayan but also to both Zuni (in North America) and Quechua (in South America), but without general scholarly acceptance.

*Xinca and Lencan (18-19).* It has been suggested that Xinca and Lencan are related and that one or both of them is related to Mayan (16), Chibchan (in South America), or Uto-Aztecan (1). None of these hypotheses has been demonstrated as probable.

*Languages outside Meso-America proper.* The Paya language (20) and the Misumalpan family (21) are Central American languages spoken outside of the cultural area of Meso-America proper, though they have Meso-American outliers in their territory. Paya (20) has been linked in hypotheses to Chibchan and Cariban (both in South America), and perhaps to others, but not convincingly. The Misumalpan family (21) has been recognized since 1895. Since that date some scholars have believed that the three languages and complexes listed are coordinate, and others have believed that the first two constitute one group and the other constitutes a second group. Although the family relationship can be verified on inspection, no supporting comparative work has been published. Previous comprehensive classifications of the Meso-American Indian languages were presented by the U.S. anthropologists Cyrus Thomas and John R. Swanton in 1911 in *Indian Languages of Mexico and Central America and Their Geographical Distribution*, by Edward Sapir in the 14th edition of *Encyclopædia Britannica* (1929), and by Morris Swadesh in 1967 in *Handbook of Middle American Indians*.

**Newly discovered languages and reconstructions.** Although there are probably no uncharted areas in Meso-America, it is not necessarily the case that all the Indian languages of Meso-America have been correctly identified, and there are probably some multilingual Indian communities as well that are not known to be such. In 1967 Terrence Kaufman discovered a hitherto undocumented Mayan language spoken by several hundred Indians in four or five towns in southeast Chiapas and west central Guatemala. Although it appears to be closely related to Mam, Kaufman considered it a separate language and christened it Teco. Kaufman identified two more new Mayan languages in the course of a linguistic survey of Guatemala. These two new languages—Sacapultec (formerly considered Quiché) and Sipacapa (formerly assumed to be Mam)—are not documented in print and both belong to the Quiché complex.

Reconstruction of earlier forms of the Meso-American Indian languages has focussed primarily on phonology and vocabulary. Phonological and lexical comparative

studies as well as reconstruction have been done for the following groups: Uto-Aztecan; Oto-Manguanean—Oto-Pamean, Popolocan, Mixtecan, Zapotecan, Chinantecan, Manguanean; Mixe-Zoque; and Mayan (in part). A small amount of grammatical comparison has been done within Oto-Manguanean and Mixe-Zoque. In addition, some studies have been done of reconstructed vocabulary for the purpose of hypothesizing about the culture of the speakers of the protolanguages.

#### RELATION OF LANGUAGES TO HISTORICAL AND CULTURAL INFLUENCES

**Pre-Columbian diffusion.** The following are some of the important civilizations that have flourished in Meso-America:

civilization	period	location
Olmec	1200 BC-400 BC	Gulf Coast, Mexico
Monte Albán	400 BC-AD 700	Oaxaca, Mexico
Teotihuacán	AD 100-600	Central Mexico
Classic Maya	AD 300-900	Chiapas, Mexico; Petén, Guatemala
Toltec	900-1200	Central Mexico
Aztec	1300-1500	Central Mexico

The Aztecs spoke Nahuatl, as did the Toltecs. The Classic Maya probably spoke two or three Mayan languages, and the people of Monte Albán probably spoke one or more Zapotecan languages. No one knows what either the Teotihuacán people or the Olmecs spoke, but it has been surmised that at least some Olmecs spoke Mixe-Zoque languages and that the Teotihuacán people may have spoken Otomian languages (though an Aztec tradition says Totonac).

In the pre-Columbian period, there was naturally contact among Meso-American languages and occasional borrowing of vocabulary and other linguistic features. Partly because of the unavailability of grammars and dictionaries, actual cases of such diffusion have not been much studied.

Some of the known contacts resulting in borrowing are the following: (1) Mixe-Zoque languages (Olmecs?) have given words to Mayan, Mixtecan, Zapotecan, Otomian, Aztec, Lencan, Xinca, and Jicaque; (2) Zapotecan languages (Monte Albán) have given words to Huastec and Yucatec; (3) Mayan languages (Mayas) have given words to Xinca, Lencan, and Jicaque; and (4) Nahuatl (Toltecs and Aztecs) has given words to Mayan, Lencan, other Uto-Aztecan languages, as well as to other Meso-American languages. Words diffused from these sources provide evidence that contact took place. Scholars know that contact must have taken place at particular times and places, and therefore can form hypotheses about where certain languages may have been spoken in the more remote past.

**External relationships and contacts.** Various scholars have suggested that some Meso-American language or family is related to a language or family (other than Uto-Aztecan) outside of Meso-America. These suggestions are mostly parts of larger attempts to synthesize the language classification of the New World, or of the whole world, and are usually based on the sometimes unexpressed view that all the languages of the Western Hemisphere or even of the whole world are ultimately genetically related. Although the assumption may be true, the proposed connections have been unconvincing to specialists in Meso-American languages. The only generally accepted larger groupings are Hokan and Penutian. Most scholars do not have the breadth of knowledge to be able to evaluate these vast proposals.

One proposal of external relationship probably has some merit. In 1961 it was suggested that Chipaya—a language spoken on the shores of Lake Titicaca in Bolivia—is genetically related to the Mayan languages. The hypothesis, proposed by Ronald Olson, a U.S. missionary linguist, was based on 120 sets of lexical comparisons between Chipaya and Proto-Mayan. The data cited are subject to more than one interpretation, because many of the comparisons involve semantic notions and word forms that are widespread in the Western Hemisphere; also, Chipaya has been so influenced grammatically

Known contacts between various Indian groups

Pre-historic linguistic connection between Meso-America and the Andes

by Aymara (which all Chipayas can speak) that any grammatical peculiarities it may once have shared with Mayan have disappeared. Because a core of data showing regular sound correspondences remains, it is probably necessary to assume that there is a historical connection between Chipaya and Mayan, possibly, but not demonstrably, a genetic relationship. The connection may have been direct—presumably from Meso-America to Bolivia via land—or there may be other languages in western South America that show prehistoric contacts with Mayan. The acceptance of a prehistoric linguistic connection, neither extremely remote nor extremely recent, between Meso-America and the Andes is quite provocative, inasmuch as other evidence exists for early culture contact between Meso-America and the Andes, Meso-America generally being the donor and the Andes generally being the beneficiary; e.g., in the case of corn. Later diffusion from South America to Meso-America also occurred; e.g., witness the transference of peanuts, metallurgy, hammocks.

**Interaction between Spanish and Indian languages.** In modern Meso-America, the dominant European language is Spanish. The speakers of all Meso-American Indian languages include some who are bilingual; and a few languages are spoken by almost totally bilingual populations. Most Indian languages spoken by sizable populations have at least 50 percent monolingual speakers. All Meso-American languages with a significant number of bilingual speakers have been influenced by Spanish, primarily in the areas of vocabulary, particles, and word order. Since the Spanish conquest, Meso-American languages have been borrowing words from Spanish, and, because the kind of Spanish spoken has changed somewhat over the years, both in vocabulary and pronunciation, different historical periods are usually distinguishable in lexical borrowings. For a variety of reasons, certain function words, primarily conjunctions and adverbs, are frequently borrowed from Spanish; e.g., *ya* "already," *pero* "but," *hasta* "until," *y* "and," *o* "or," *ni* "not even," *hasta* "even," *si* "if," *cuando* "when," *porque* "because," *por eso* "therefore, so," *entonces* "then." Some languages have assimilated the Spanish word order of subject-verb-object.

Conversely, the Spanish of Meso-America has been the recipient of vast amounts of lexical material from local languages, primarily Nahuatl. The borrowing has provided names of plants, animals, artifacts, and social forms indigenous to Meso-America and lacking names in Spanish. Among the reasons that Nahuatl has been the primary source is that the Aztecs were the first Meso-American people conquered by the Spaniards; the Aztecs had outposts in many parts of Meso-America; the Spaniards recruited Aztecs, particularly as guides, into their military force to assist their venture of subduing the rest of Meso-America; and, for several decades, Aztec, written in Roman orthography, was used in many parts of Meso-America to keep official records, such as deeds, wills, and censuses.

Many of the words borrowed into Spanish from Aztec have since passed in turn into English; e.g., *chili*, *chile*, or *chilli* (Spanish *chile*), *avocado* (Spanish *aguacate*), *chicle*, *chocolate*, *peyote*, *coyote*, *tomato* (Spanish *tomate*), *ocelot* (Spanish *ocelote*), *guacamole*, *mescal*.

Bilingualism among Indians

In some parts of Meso-America, because of economic and social conditions, an Indian may speak one or more Indian languages besides his own. This is common in Guatemala, where some areas have been recently colonized by speakers of more than one language, or some communities have received outside settlers in the more remote past.

The names used in this article for the Meso-American Indian languages are English versions of the Spanish terms for them. Only in a few cases are these names the ones actually used by the people who speak the languages in question. First, most of the names are of Aztec origin, because at the outset the Spanish learned of local phenomena primarily via Aztec. Secondly, some languages have no special name of their own, simply being called "our language."

**Pre-Columbian writing.** Most of the Meso-American cultures shared a mathematical notation and calendrical system that had been developed and diffused in the distant past, probably before 500 bc. At the time of European contact the Aztecs, Zapotecs, Mixtecs, Otomís, Mayans, and perhaps some others were all producing records on stone (inscriptions) and on a type of homegrown paper (produced from the amate tree, *Ficus glabrata*), these latter being commonly called codices. Except for the Mayan system, which probably originated before AD 1, the records cannot properly be called writing, in that it was not possible to represent all of speech, but only numbers, dates, and names (pictographically). The Mayan system, besides representing all these, was also used to represent morphemes (words and word elements) and phonemes (distinctive sounds). Presumably the symbols used in this system (called glyphs) represent individual phonemes, syllables, and morphemes; and they give semantic information as well to take the ambiguity out of homophonous readings. Several scholars have devoted much time to the study of Mayan writing, but, to date, the results have not been very impressive. A few scholars outside the Meso-American field believe the Mayan writing system is purely ideographic and hence inherently undecipherable without a bilingual inscription or text in a known language. All specialists within the Mayan field hold that the Mayan is a mixed ideographic and phonological system.

What may be delaying progress in the deciphering of Mayan writing is the absence of reconstructions for intermediate groupings within the Mayan family (e.g., Proto-Yucatecan, Proto-Cholan, and others) and ignorance of Mayan languages other than colonial Yucatec on the part of the investigators. Efforts are being made to correct these deficiencies, particularly by Mexican specialists. It is not known whether Mayan writing was used to write more than one language and, if so, what the languages were. If only one, it was probably either Proto-Cholan or Proto-Yucatecan. The symbols used in all the pre-Columbian notation systems are obviously pictographic in origin, as was the case in the ancient Egyptian, Sumerian, ancient Chinese, and Indus Valley writing systems.

#### LINGUISTIC CHARACTERISTICS OF THE MESO-AMERICAN LANGUAGES

In general, all the languages of a particular family are typologically similar to one another both in phonology and grammar. Among the 21 language groupings in Meso-America, there are several types of sound systems and grammatical systems. Because study in this area has hardly begun, nothing very secure can be asserted here, but some general characteristics can be outlined on the basis of data for the following reasonably well-documented languages: Tequistlatec, Otomí, Mazatec, Mixtec, Zapotec, Chinantec, Aztec, Zoque, Totonac, Quiché, and Tarasco.

Phonologically, there is a wide diversity among Meso-American languages. Voiced spirants—i.e., sounds like English *v*, *z*, or *th* in "then"—are missing from all Meso-American languages. Other phonological features in these languages include a voiceless lateral spirant sound, *lh* (in Tequistlatec and Totonac); a lateral affricate, *tl* (in Aztec and Totonac); a postvelar stop, *q*, in contrast with a velar stop, *k* (in Quiché and Totonac); glottalized vowels (in Zapotec, Zoque, Aztec, and Totonac); glottalized consonants (in Tequistlatec, Quiché, Otomí, and Mazatec); aspirated stops (in Tarasco, Otomí, and Mazatec); voiced stops (in Tequistlatec, Otomí, Mazatec, and Chinantec); prenasalized stops (in Otomí, Mazatec, and Mixtec); nasalized vowels (in Otomí, Mazatec, Mixtec, and Chinantec); a labiovelar stop, *kw*, sometimes contrasting with a bilabial stop, *p* (in Otomí, Mazatec, Mixtec, Aztec); tone and stress accent (tone in Otomí, Mazatec, Mixtec, Chinantec, Zapotec; stress in Tarasco and Tequistlatec); and initial and final consonant clusters (in Tequistlatec).

Grammatically, Meso-American languages are rather diverse, but, according to available data, they fall into three main types: Type A, an Oto-Manguan type, is

Diverse types of sound systems and grammars

rightward expanding (*i.e.*, modifiers follow the elements they modify) and synthetic to a low degree (*i.e.*, characterized by relatively few morphemes per word). It employs prefixes and prepositions, and it seldom uses compounding to form words. Type B, an intermediate type, is prepositional, like A, and averagely synthetic, making some use of prefixes (subjects, objects, and possessors) and much use of suffixes. It is mildly leftward expanding (*i.e.*, modifiers precede the elements they modify) and is mainly represented by Mayan and Uto-Aztec languages but partially by Mixe-Zoque and Totonacan. Type C, a leftward expanding type, is highly synthetic with great use of suffixes and postpositions and active ablaut (an interchange among consonants and vowels for the purpose of derivation or inflection). It is represented by Tarasco and, partially, by Totonacan and Mixe-Zoque.

Gram-  
matical  
generaliza-  
tions

There are a number of grammatical generalizations that can be made about all or most Meso-American Indian languages. (1) The genitive relationship between nouns or noun phrases is (except for Tarasco) expressed by means of a possessive pronoun with the possessed noun; *e.g.*, "the dog's fleas" is expressed as "his fleas the dog." (2) Locative notions, such as "above," "below," "in," "on," "beside," are not expressed by prepositions and adverbs, as in European languages, but by means of location nouns (meaning "aboveness," "belowness," "belly," "surface," "side," and so forth), which are always combined with a possessive pronoun, the function of which is to indicate the "object" of the prepositional-adverbial notion. Most languages, however, have at least one generic relational particle that is combined in a phrase with a location noun and its object and has "generic prepositional" function; thus "on the table" is expressed "at (generic particle) its-top the table," or "in the box" is expressed "at its-inside the box." Whereas in most languages the generic relational particles are prepositions, Zoque and Tarasco have postpositions, which are in part related to location nouns.

(3) Within the verbal system, aspect (type of action—*e.g.*, ongoing, habitual, finished, potential, and so forth) is well developed, and tense (time—*e.g.*, now, in the past, in the future) is generally weakly developed. (4) The copula, or equational verb "be," is not expressed in most Meso-American languages. (5) Case suffixes are generally absent, being present in just three languages: Tarasco has a genitive case, an objective case, and various locational cases; Aztec and Zoque have only locational cases, and these are usually related to location nouns. (6) A relative clause that modifies a noun follows it in all the languages of the sample above; *e.g.*, "the man whom I saw (on the street yesterday)." (7) Some Oto-Manguean languages and some Mayan languages distinguish an inclusive pronoun "we" ("I and you") from an exclusive "we" ("I and he/they").

(8) Gender, or inflectional agreement of other word classes in the noun phrase with the noun itself, is rare in Meso-American languages and is limited to some Oto-Manguean languages. (9) Noun subclassification in the context of possession is not uncommon. In some languages, some nouns undergo form changes when possessed; these languages, therefore, have at least two classes of nouns. In other languages, the possessive pronouns differ in form according as they are associated with different classes of nouns. In languages in which the semantic motivation for such a subdivision is clear, the main kind of distinction is between intimate possession (body parts, kinship terms, articles of clothing) and casual possession (domestic animals, tools). (10) Some languages (Mayan, Mixe-Zoque) distinguish between the subject (actor) of a transitive verb and that of an intransitive verb by the form of the associated affixed pronoun. (11) Most Meso-American languages average more than one morpheme per word, and Tarasco and Totonac average more than two morphemes per word. (12) Most Meso-American languages (except Aztec) have consonantal or vocalic ablaut, or else show in their vocabulary sets of words that seem to be related through a formerly functional ablaut system.

(13) The numeral systems are vigesimal-decimal; that

is, counting is from 1 to 10, then from 11 to 20, then from 21 to 40 (adding 1–20 to 20), then from 41–60 (adding 1–20 to 40), and so on, with special terms for 400 ( $20 \times 20$ ), 8,000 ( $20 \times 20 \times 20$ ), 16,000 ( $20 \times 20 \times 20$ ), and so on. In most languages (except Mayan) the numeral expressions for 6 through 9 (sometimes 5 through 9) are compounds of  $5 + 1$ ,  $5 + 2$ ,  $5 + 3$ ,  $5 + 4$ , or the like. (14) In all the languages referred to here, a numeral precedes the noun it quantifies.

**BIBLIOGRAPHY.** Few books ever appear treating the Meso-American Indian languages as a group, although many dictionaries and grammars for individual languages have been prepared. The most up-to-date overview can be gotten from three articles in the *Handbook of Middle American Indians*, vol. 5, *Linguistics* (1967): MARIA TERESA FERNANDEZ DE MIRANDA, "Inventory of Classificatory Materials," which is an annotated bibliography; MORRIS SWADESH, "Lexicostatic Classification," in which the author applies glottochronology to the classification of all the Meso-American Indian languages; and ROBERT LONGACRE, "Systematic Comparison and Reconstruction," a review of what has been accomplished in the historical-comparative field to date. For linguistic characteristics of Meso-American languages, see TERRENCE KAUFMAN, "Areal Linguistics and Middle America," *Current Trends in Linguistics*, vol. 11 (1972). For Uto-Aztec, see CHARLES F. and FLORENCE M. VOEGELIN and KENNETH L. HALE, *Topological and Comparative Grammar of Uto-Aztec* (1962); and WICK R. MILLER, *Uto-Aztec Cognate Sets* (1967). For Mayan and "new languages," see TERRENCE KAUFMAN, "Teco—A New Mayan Language," *Int. J. Am. Linguistics*, 35:154–174 (1969). For "external contacts," see RONALD D. OLSON, "Mayan Affinities with Chipaya of Bolivia," *ibid.*, 30:313–324 (1964) and 31:29–38 (1965).

## Mesopotamia and Iraq, History of

Mesopotamia, most of which is contained within the present Republic of Iraq, was the home of some of the earliest, if not the earliest, civilized (urban and literate) communities in the world. This article, which covers the area's 5,000-year history, is divided into the following sections:

- I. Mesopotamia until 1600 BC
  - The origins of history
  - Sumerian civilization
  - The Old Babylonian Period
- II. Mesopotamia from 1600 BC to AD 630
  - The Kassites, the Mitanni, and the rise of Assyria
  - Assyria and Babylonia at the end of the 2nd millennium
  - Assyria and Babylonia c. 1000–750 BC
  - The Neo-Assyrian Empire (746–609)
  - The Neo-Babylonian Empire (636–539)
  - Mesopotamia under the Persians
  - Babylonia under Alexander, the Seleucids, and the Parthians
- III. Iraq from the Arab conquest to 1918
  - The Arab conquest
  - The Umayyads
  - The 'Abbāsids
  - The Būyids
  - The Seljuqs
  - The Mongols
  - The Ottomans
- IV. Iraq since 1918
  - British occupation and the mandatory regime
  - Independence, 1932–39
  - World War II and British intervention, 1939–45
  - Postwar reconstruction and social upheavals, 1945–58
  - The revolution of 1958
  - Recurrence of military coups, 1963–68
  - The Kurdish question

### I. Mesopotamia until 1600 BC

#### THE ORIGINS OF HISTORY

**The Mesopotamian background.** In the narrow sense, Mesopotamia is the area between the Euphrates and Tigris rivers, north or northwest of the bottleneck at Baghdad; it is al-Jazīrah (The Island) of the Arabs. South of this lies Babylonia, named after the city of Babylon. But in the broader sense the name Mesopotamia has come to be used for the area bounded on the northeast by the Zagros Mountains and on the southwest by the edge of

the Arabian Plateau and that stretches from the Persian Gulf in the southeast to the spurs of the Anti-Taurus Mountains in the northwest. Only from the latitude of Baghdad do the Euphrates and Tigris truly become twin rivers, the *rāfidān* of the Arabs, which have constantly changed their courses over the millennia. The low-lying plain of the River Kārūn in Persia has always been closely related to Mesopotamia; but it is not considered part of Mesopotamia as it forms its own river system.

Mesopotamia, south of ar-Ramādī (about 70 miles, or 110 kilometres, west of Baghdad) on the Euphrates and the bend of the Tigris below Sāmarrā' (about 70 miles north-northwest of Baghdad), is flat alluvial land. Between Baghdad and the mouth of the Shatt al-Arab (the mouth of the Tigris and Euphrates) there is a difference in height only of about 30 feet (or 10 metres). As a result of the slow flow of the water, there are heavy deposits of silt; and the river-beds are raised. Consequently, the rivers often overflow their banks (and may even change their course) when they are not protected by high dikes or—in recent times—can be regulated above Baghdad by the use of escape channels with overflow reservoirs. The extreme south is a region of extensive marshes and reed swamps, *hawrs*, which, probably since early times, have served as an area of refuge for oppressed and displaced peoples. The supply of water is not regular: as a result of the high average temperatures (at Baghdad, July–August 93° F [34° C], December–January 52° F [11°C]) and a very low annual rainfall (less than eight inches—200 millimetres—in southern Mesopotamia), the ground of the plain of latitude 35° S is hard and dry and unsuitable for plant cultivation for at least eight months in the year. Consequently, agriculture without risk of crop failure, which seems to have begun in the higher rainfall zones and in the hilly borders of Mesopotamia in the 10th millennium BC, began in Mesopotamia itself, the real heart of the civilization, only when artificial irrigation had been invented, bringing water to large stretches of territory through a widely branching network of canals. Since the ground is extremely fertile and, with irrigation and the necessary drainage, will produce in abundance, southern Mesopotamia became a land of plenty that could support a considerable population. The cultural superiority of north Mesopotamia, which may have lasted until c. 4000 BC, was finally overtaken by the south when men there had responded to the challenge of their situation.

The present climatic conditions are fairly certainly similar to those of 8,000 years ago. An English survey of ruined settlements in the area 30 miles—about 50 kilometres—around ancient Hatra (180 miles northwest of Baghdad) has shown that the southern limits of the zone in which agriculture is possible without artificial irrigation has remained unchanged since the first settlement of al-Jazīrah.

The availability of raw materials is a historical factor of great importance, as is the dependence on those materials that had to be imported. In Mesopotamia, agricultural products and those from stock breeding, fisheries, date-palm cultivation, and reed industries—in short, corn, vegetables, meat, leather, wool, horn, fish, dates, and reed and plant-fibre products—were available in plenty and could easily be produced in excess of home requirements to be exported. There are bitumen springs at Hit (90 miles west of Baghdad) on the Euphrates (the Is of Herodotus). On the other hand, wood, stone, and metal were rare or even entirely absent. The date palm—virtually the national tree of Iraq—yields a wood suitable only for rough beams and not for finer work. Stone is completely lacking in southern Mesopotamia, although limestone is quarried in the desert about 35 miles to the west; and "Mosul marble" is found not far from the Tigris in its middle reaches. Metal can only be obtained in the mountains, and the same is true of precious and semiprecious stones. Consequently, southern Mesopotamia in particular was destined to be a land of trade from the start. Only rarely could "empires" extending over a wider area guarantee themselves imports by plundering or by subjecting neighbouring regions.

The raw material that epitomizes Mesopotamian civilization is clay: in the almost exclusively mud-brick architecture and in the number and variety of clay figurines and pottery artifacts, Mesopotamia bears the stamp of clay as does no other civilization; and nowhere in the world but in Mesopotamia and the regions over which its influence was diffused was clay used as the vehicle for writing. Such phrases as cuneiform civilization, cuneiform literature, and cuneiform law can apply only where men had held the idea of using soft clay not only for bricks and jars and for the jar stoppers on which a seal could be impressed as a mark of ownership but also as the vehicle for impressed signs to which established meanings were assigned—an intellectual achievement that amounted to nothing less than the invention of writing.

*The character and achievements of ancient Mesopotamia.* Questions as to what ancient Mesopotamian civilization did and did not accomplish, how it influenced its neighbours and successors, and what its legacy has transmitted of value are posed from the standpoint of 20th-century civilization and are in part coloured by ethical overtones, so that the answers can only be relative. Modern scholars assume the ability to assess the sum total of an "ancient Mesopotamian civilization"; but, since the publication of an article by Benno Landsberger, an Assyriologist, on "Die Eigenbegrifflichkeit der babylonischen Welt," it has become almost a commonplace to call attention to the necessity of viewing ancient Mesopotamia and its civilization as an independent entity.

Mesopotamia has many languages, many cultures, is broken up into many historical periods, has no real geographical unity, and above all no permanent capital city, so that by its very variety it stands out from other civilizations with greater uniformity, particularly that of Egypt. The script and the pantheon constitute the unifying factors, but in these also Mesopotamia shows its predilection for multiplicity and variety: written documents turned out in quantities and a pantheon consisting of more than 1,000 deities, even though many names may apply to different manifestations of a single god. Throughout 3,000 years of Mesopotamian civilization, each century gave birth to the next. Thus classical Sumerian civilization influenced that of the Akkadians; and the Ur III Empire, which itself represented a Sumero-Akkadian synthesis, exercised its influence on the first quarter of the 2nd millennium BC. With the Hittites, large areas of Anatolia were infused with the culture of Mesopotamia from 1700 BC onward. The contacts between Syrian and Palestinian scribal schools and Babylonian civilization during the Amarna period (14th century BC) must have led to the enrichment of the literature of the west Semitic lands: this, and not direct borrowing, is the explanation of the similarity of themes in cuneiform literature and the Old Testament, such as the story of the Flood or the motif of the righteous sufferer.

The world of mathematics and astronomy owes much to the Babylonians: for instance, the sexagesimal system for the calculation of time and angles, which is still practical because of the multiple divisibility of the number 60; the Greek day of 12 "double-hours"; and the zodiac and its signs. But often the origins and routes of borrowings are obscure, as in the problem of the survival of ancient Mesopotamian legal theory.

The achievement of the civilization itself may be expressed in terms of its best points—moral, aesthetic, scientific, and, not least, literary. Legal theory flourished and was sophisticated early on, being expressed in several collections of legal decisions, the so-called codes, of which the best known is the Code of Hammurabi. Throughout these codes recurs the concern of the ruler for the weak, the widow, and the orphan—even if, sometimes, the phrases were regrettably only literary clichés. The aesthetics of art are too much governed by subjective values to be assessed in absolute terms; but certain peaks stand out above the rest, notably the art of Uruk IV, the seal engraving of the Akkad period, and the relief sculpture of Ashurbanipal. Nonetheless, there is nothing in Mesopotamia to match the sophistication of Egyptian art. Science the Mesopotamians had, of a kind, though

The importance of clay

The impetus of artificial irrigation

Unique variety of the Mesopotamian civilization

Scientific  
achievements

not as the word is understood of Greek science. From its beginnings in Sumer before the middle of the 3rd millennium BC, Mesopotamian science was characterized by endless, meticulous enumeration and ordering into columns and series, with the ultimate ideal of including all things in the world but without the wish or ability to synthesize and reduce the material to a system. Not a single general law has been found and only rarely the use of analogy. Nevertheless, it remains a highly commendable achievement that Pythagoras' law (that the sum of the squares on the two shorter sides of a right-angled triangle equals the square on the longest side), even though it was never formulated, was being applied as early as the 18th century BC. Technical accomplishments were perfected in the building of the ziggurats (temple towers like pyramids), with their huge bulk, and in irrigation, both in practical execution and in theoretical calculations beforehand. At the beginning of the 3rd millennium BC an artificial stone in use at Uruk (160 miles south-southeast of modern Baghdad) constitutes a forerunner of concrete, but the secret of its manufacture apparently was lost in subsequent years.

Writing pervaded all aspects of life and gave rise to a highly developed bureaucracy—one of the most tenacious legacies of the ancient East. Remarkable organizing ability was required to administer huge estates, in which, under the 3rd dynasty of Ur, for example, it was not unusual to prepare accounts for thousands of cattle or tens of thousands of bundles of reeds. Above all, the literature of Mesopotamia is one of its finest cultural achievements. Though there are many modern anthologies and chrestomathies (compilations of useful learning), with translations and paraphrases of Mesopotamian literature, as well as attempts to write its history, it cannot truly be said that "cuneiform literature" has been resurrected to the extent that it deserves. There are partly material reasons for this: many clay tablets survive only in a fragmentary condition, and duplicates that would restore the texts have not yet been discovered, so that there are still large gaps. A further reason is the inadequate knowledge of the languages: insufficient acquaintance with the vocabulary and, in Sumerian, major difficulties with the grammar. Consequently, another generation of Assyriologists will pass before the great myths, epics, lamentations, hymns, "law codes," wisdom literature, and pedagogical treatises can be presented to the reader in such a way that he can fully appreciate the high level of literary creativity of those times.

*The classical and medieval views of Mesopotamia; its rediscovery in modern times.* Before the first excavations in Mesopotamia, around 1840, nearly 2,000 years had passed during which knowledge of the ancient Near East was derived from three sources only: the Bible, Greek and Roman authors, and the excerpts from the writings of Berosus, a Babylonian who wrote in Greek. In 1800 very little more was known than in AD 800, although these sources had served to stir the imagination of poets and artists, down to *Sardanapalus* by the 19th-century English poet Lord Byron. Apart from the building of the Tower of Babel, the Old Testament mentions Mesopotamia only in those historical contexts in which the kings of Assyria and Babylonia affected the course of events in Israel and Judah: in particular Tiglath-pileser III, Shalmaneser V, and Sennacherib, with their policy of deportation, and the Babylonian Exile introduced by Nebuchadrezzar II. Of the Greeks, Herodotus of Halicarnassus (5th century BC, a contemporary of Xerxes I and Artaxerxes I), was the first to report on "Babylon and the rest of Assyria"; at that date the Assyrian Empire had been overthrown for more than 100 years. The Athenian Xenophon took part in an expedition, during 401–399 BC, of Greek mercenaries who crossed Asia Minor, made their way down the Euphrates as far as the vicinity of Baghdad, and returned up the Tigris after the famous Battle of Cunaxa. In his *Cyropaedia* Xenophon describes the final struggle between Cyrus II and the Neo-Babylonian Empire. Later, the Greeks adopted all kinds of fabulous tales about King Ninus, Queen Semiramis, and King Sardanapalus. These stories are described mainly in

Greek  
views of  
Mesopotamia

the historical work of Diodorus Siculus (1st century BC), who based them on the reports of a Greek physician, Ctesias (405–359 BC). Herodotus saw Babylon with his own eyes, and Xenophon gave an account of travels and battles. But all later historians wrote at second or third hand, with one exception, Berosus (born c. 340 BC), who emigrated at an advanced age to the Aegean island of Cos, where he is said to have composed his three books of *Babylōniaka*. Unfortunately, only extracts from them survive, prepared by one Alexander Polyhistor (1st century BC), who, in his turn, served as a source for the church father Eusebius (who died AD 342). Berosus derided the "Greek historians" who had so distorted the history of his country. He knew, for example, that it was not Semiramis who founded the city of Babylon; but he was himself the prisoner of his own environment and cannot have known more about the history of his land than was known in Babylonia itself in the 4th century BC.

Berosus' first book dealt with the beginnings of the world and with a myth of a composite being, Oannes, half fish, half man, who came ashore in Babylonia at a time when men still lived like the wild beasts. Oannes taught them the essentials of civilization: writing, the arts, law, agriculture, surveying, and architecture. The name Oannes must be derived from the cuneiform U'anna (Sumerian) or Umanna (Akkadian), a second name of the mythical figure Adapa, the bringer of civilization. The second book of Berosus contained the Babylonian king list from the beginning to King Nabonassar (Nabu-našir, 747–734 BC), a contemporary of Tiglath-pileser III. Berosus' tradition, beginning with a list of primeval kings before the Flood, is a reliable one; it agrees with the tradition of the Sumerian king list, and even individual names can be traced back exactly to their Sumerian originals. Even the immensely long reigns of the primeval kings, which lasted as long as "18 sars" ( $= 18 \times 3,600 = 64,800$ ) of years, are found in Berosus. Furthermore, he was acquainted with the story of the Flood, with Cronus as its instigator and Xisuthros (or Ziusudra) as its hero, and with the building of an ark. The third book is presumed to have dealt with the history of Babylonia from Nabonassar to the time of Berosus himself.

Diodorus made the mistake of locating Nineveh on the Euphrates, and Xenophon gave an account of two cities, Larissa and Mespila, which, it is suspected, represented the ancient Kalakh (20 miles southeast of modern Mosul) and Nineveh (just north of modern Mosul), Mespila probably being nothing more than the word of the local Aramaeans for ruins: there can be no clearer instance of the rift that had opened between the ancient Near East and the classical West. In sharp contrast, the East had a tradition that the ruins opposite Mosul (in north Iraq) conceal ancient Nineveh. When a Spanish rabbi from Navarre, Benjamin of Tudela, was travelling in the Near East between 1160 and 1173, Jews and Muslims alike knew the position of the grave of the prophet Jonah. The credit for the rediscovery of the ruins of Babylon goes to an Italian, Pietro della Valle, who correctly identified the vast ruins north of modern al-Hillah (60 miles south of Baghdad); and he must have seen there the large rectangular tower that represented the ancient ziggurat. Previously, other travellers had sought the Tower of Babel in two other monumental ruins: Birs Nimrūd, the massive brick structure of the ziggurat of ancient Borsippa (near al-Hillah), vitrified by lightning, and the ziggurat of the Kassite capital, Dūr Kurigalzu, at Burj 'Aqarqūf, 22 miles west of Baghdad. Pietro della Valle also brought back to Europe the first specimens of cuneiform writing, stamped brick, of which highly impressionistic reproductions were made. Thereafter, European travellers visited Mesopotamia with increasing frequency, among them Carsten Niebuhr (an 18th-century German traveller); Claudius James Rich (a 19th-century Orientalist and traveller); and Ker Porter (a 19th-century traveller).

In modern times, a third Near Eastern ruin drew visitors from Europe—Persepolis, in the land of Persia east of Susiana near modern Shīrāz. In 1602 reports had filtered back to Europe of inscriptions that were not in Hebrew, Arabic, Aramaic, Georgian, or Greek. In 1700 an English-

The work  
of Pietro  
della  
Valle

man, Thomas Hyde, coined the term "cuneiform" for these inscriptions, and by the middle of the 18th century it was known that the Persepolis inscriptions were related to those of Babylon. Carsten Niebuhr distinguished three separate alphabets (Babylonian, Elamite, and Old Persian cuneiform). The first promising attempt at decipherment was made by G.F. Grotefend in 1802, by use of the kings' names in the Old Persian versions of the trilingual inscriptions, although his later efforts led him up a blind alley. Thereafter, the efforts to decipher cuneiform gradually developed in the second half of the 19th century into a discipline of ancient Oriental philology, which was based on results established through the pioneering work of Emile Burnouf, Edward Hincks, Sir Henry Rawlinson, and many others.

Today this subject is still known as Assyriology, because at the end of the 19th century the great majority of cuneiform texts came from the Assyrian city of Nineveh, in particular, from the library of King Ashurbanipal in the mound of Kouyunjik at Nineveh.

*Modern archaeological excavations.* One hundred and thirty years separate the first excavations in Mesopotamia—adventurous expeditions involving great personal risks and far from the protection of helpful authorities—from those of the present day with their specialist staffs, modern technical equipment, and objectives wider than the mere search for valuable antiquities. The progress of five generations of excavators has led to a situation in which less is recovered more accurately; in other words, the finds are observed, measured, and photographed as precisely as possible. At first digging was unsystematic, with the consequence that although huge quantities of clay tablets and large and small antiquities were brought to light, the findspots were rarely described with any accuracy. Not until the beginning of the 20th century did excavators learn to isolate the individual bricks in the walls that had previously been erroneously thought to be nothing more than packed clay; the result was that various characteristic brick types could be distinguished, and successive architectural levels established. Increased care in excavation does, of course, carry with it the risk that the pace of discovery will slow down. Moreover, the eyes of the local inhabitants are now sharpened and their appetite for finds is whetted, so that clandestine diggers have established themselves as the unwelcome colleagues of the archaeologists.

A result of the technique of building with mud brick (mass production of baked bricks was impossible because of the shortage of fuel) was that the buildings were highly vulnerable to the weather and needed constant renewal; layers of settlement rapidly built up, creating a *tall*, a mound of occupation debris that is the characteristic ruin form of Mesopotamia. The word itself appears among the most original vocabulary of the Semitic languages and is attested as early as the end of the 3rd millennium BC. Excavation is made more difficult by this mound formation, since both horizontal and vertical axes have to be taken into account. Moreover, the depth of each level is not necessarily constant, and foundation trenches may be dug down into earlier levels. A further problem is that finds may have been removed from their original context in antiquity. Short-lived settlements that did not develop into mounds mostly escape observation, but aerial photography can now pick out ground discolorations that betray the existence of settlements. Districts with a high water level today, such as the reed marshes (*haws*), or ruins that are covered by modern settlements, such as Arbīl, some 200 miles north of Baghdad, or that are surmounted by shrines and tombs of holy men are closed to archaeological research altogether.

Excavations in Mesopotamia have been almost exclusively national undertakings (France, England, the United States, Germany, Iraq, Denmark, Belgium, Italy, Japan, and the Soviet Union) and the "joint expedition" first sent to Ur (190 miles south-southeast of Baghdad) in the 1920s has remained a rare exception. The history of archaeological research in Mesopotamia falls into four categories, represented by phases of differing lengths: the first, and by far the longest, begins with the French expe-

dition to Nineveh (1842) and Khorsabad (the ancient Dur Sharrukīn, 20 miles northeast of modern Mosul; 1843–55) and that of the English to Nineveh (1846–55) and Nimrūd (ancient Kalakh, biblical Calah; 1845; with interruptions until 1880). This marked the beginning of the "classic" excavations in the important ancient capitals, where spectacular finds might be anticipated. The principal gains were the Assyrian bull colossuses and wall reliefs and the library of Ashurbanipal from Nineveh, whereas the ground plans of temples and palaces were quite as valuable. While these undertakings had restored to life the remains of the Neo-Assyrian Empire from the 1st millennium BC, new French initiatives in Tello (Arabic Tall Lūh), 155 miles southeast of Baghdad, from 1877 onward reached almost 2,000 years further back into the past. There they rediscovered a people whose language had already been encountered in bilingual texts from Nineveh—the Sumerians. Tello (ancient Girsu) yielded not only inscribed material that, quite apart from its historical interest, was critical for the establishment of the chronology of the second half of the 3rd millennium BC but also a large number of artistic masterpieces. Thereafter, excavations in important cities spread to form a network, including Susa, 150 miles west of Isfahan in Iran (France; 1884 onward); Nippur, 90 miles southeast of Baghdad (the United States; 1889 onward); Babylon, 55 miles south of Baghdad (Germany; 1899–1917 and again from 1957 onward); Ashur, modern ash-Sharqāt, 55 miles south of Mosul (Germany; 1903–14); Uruk (Germany; 1912–13 and from 1928 onward); and at Ur (England and the United States; 1918–34). Mention should also be made of the German excavations at Boğazköy in central Turkey, the ancient Hattusa, capital of the Hittite Empire, which have been carried on, with interruptions, since 1906.

The second phase began in 1925 with the commencement of U.S. excavations at Yorgan Tepe (ancient Nuzu), 140 miles north of Baghdad, a provincial centre with Old Akkadian, Old Assyrian, and Middle Assyrian/Hurrian levels. There followed, among others, French excavations at Arslan Tash (ancient Hadatu; 1928); Tall al-Aḥmar (ancient Til Barsib; 1929–31); and above all at Tall Ḥarīrī (ancient Mari; 1933 onward); and U.S. excavations in the Diyālā region, 90 miles northeast of Baghdad: Tall al-Asmar (ancient Eshnunna), Khafājī, and other sites. Thus, excavation in Mesopotamia had moved away from the capital cities to include the "provinces." Simultaneously, it expanded beyond the limits of Mesopotamia and Susiana and revealed outliers of "cuneiform civilization" on the Syrian coast at Ras Shamra (ancient Ugarit; France, 1929 onward) and on the Orontes of northern Syria al'Aṭshānah (ancient Alalakh; England, 1937–39, 1947–49), whereas Danish excavations on the islands of Bahrain and Faylakah, off the Tigris–Euphrates Delta, since 1954 have disclosed staging posts between Mesopotamia and the Indus Valley civilization.

In its third phase, archaeological research in Mesopotamia and its neighbouring lands has probed back into prehistory and protohistory. The objective of these investigations, initiated by U.S. archaeologists, was to trace as closely as possible the successive chronological stages in the progress of man from hunter and gatherer to settled farmer and, finally, to city dweller. These excavations are strongly influenced by the methods of the prehistorian, and the principal objective is no longer the search for texts and monuments. Apart from the United States investigations, Iraq itself has taken part in this phase of the history of investigation, as has Japan since 1956.

Finally, the fourth category, which runs parallel with the first three phases, is represented by "surveys," which do not concentrate on individual sites but attempt to define the relations between single settlements, their positioning along canals or rivers, or the distribution of central settlements and their satellites. Since shortage of time, money, and an adequate task force preclude the thorough investigation of large numbers of individual sites, the method employed is that of observing and collecting finds from the surface. Of these finds, the latest in

Investigations after 1925

Problems of mud-brick buildings

date will give a rough termination date for the duration of the settlement, but, since objects from earlier, if not the earliest, levels work their way to the surface with a predictable degree of certainty or are exposed in rain gullies, an intensive search of the surface of the mound allows conclusions as to the total period of occupation with some degree of probability. If the individual periods of settlement are marked on superimposed maps, a very clear picture is obtained of the fluctuations in settlement patterns, of the changing proportions between large and small settlements, and of the equally changeable systems of riverbeds and irrigation canals—for when points on the map lie in line, it is a legitimate assumption that they were once connected by water courses. During the four phases outlined, the objectives and methods of excavation have broadened and shifted. At first the chief aim was the recovery of valuable finds suitable for museums, but at the same time there was, from early on, considerable interest in the architecture of Mesopotamia, which won for it the place it deserves in architectural history. Alongside philology, art history also made great strides, building up a chronological framework by the combination of evidence from stratigraphical and stylistic criteria, particularly in pottery and cylinder seals. The discovery of graves and a variety of burial customs threw new light on the history of religion, stimulated by the interest of Old Testament studies. Later, an increasing interest from neighbouring disciplines emerged. While pottery had been collected previously for purely aesthetic motives or from the point of view of art history, attention came to be paid increasingly to the everyday wares, and greater insight into social and economic history was based on knowledge of the distribution and frequency of shapes and materials. Finally, the observation and investigation of animal bones and plant remains (pollen and seed analysis) supplied invaluable information on the process of domestication, the conditions of animal husbandry, and the advances in agriculture; such studies demand the co-operation of both zoologists and paleobotanists.

**The emergence of Mesopotamian civilization.** *The Late Neolithic period and the Chalcolithic period.* Between about 10,000 BC and the genesis of large permanent settlements, the following stages of development are distinguishable, some of which run parallel: (1) the change to sedentary life, or the transition from continual or seasonal change of abode, characteristic of hunter-gatherers and the earliest cattle breeders, to life in one place over a period of several years or even permanently; (2) the transition from experimental plant cultivation to the deliberate and calculated farming of grains and leguminous plants; (3) the erection of houses and the associated "settlement" of the gods in temples; (4) the burial of the dead in cemeteries; (5) the invention of clay vessels, made at first by hand, then turned on the wheel and fired to ever greater degrees of hardness, at the same time receiving almost invariably decoration of incised designs or painted patterns; (6) the development of specialized crafts and the distribution of labour; and (7) metal production (the first use of metal—copper—marks the transition from the Late Neolithic to the Chalcolithic period).

These stages of development can only rarely be dated on the basis of a sequence of levels at one site alone. Instead, an important role is played by the comparison of different sites, starting with the assumption that what is simpler and technically less accomplished is older. In addition to this type of dating, which can be only relative, over the last 20 years the carbon-14 method has been of great assistance. By this method the known rate of decay of the radioactive carbon isotope (carbon-14) in wood, horn, plant fibres, and bones allows the time that has elapsed since the "death" of the material under examination to be calculated. Although a plus/minus discrepancy of up to 200 years has to be allowed for, this is not such a great disadvantage in the case of material 6,000 to 10,000 years old. Even when skepticism is necessary because of the use of an inadequate sample, carbon-14 dates are still very welcome as confirmation of dates arrived at by other means.

The first agriculture, the domestication of animals, and the transition to sedentary life took place in regions in which animals that were easily domesticated, such as sheep, goats, cattle, and pigs, and the wild prototypes of grains and leguminous plants, such as wheat, barley, bitter vetch, pea, and lentil, were present. Such centres of dispersion may have been the valleys and grassy border regions of the mountains of Iran, Iraq, Anatolia, Syria, and Palestine; but they could also be, for example, the northern slopes of the Hindu Kush. As settled life, which caused a drop in infant mortality, led to the increase of the population, settlement spread out from these centres into the plains—although it must be remembered that this process, described with the phrase Neolithic revolution, in fact took thousands of years.

Representative of the first settlements on the borders of Mesopotamia are the adjacent sites of Zawi Chemi and Shanidar, which lie northwest of Rawāndūz. They date from the transition from the 10th to the 9th millennium BC and are classified as "pre-pottery." The finds included querns (primitive mills) for grinding grain (whether wild or cultivated is unknown), the remains of huts about 13 feet in diameter, and a cemetery with grave goods. The presence of copper beads is evidence of acquaintance with metal, though not necessarily with the technique of working it into tools; and the presence of obsidian (volcanic glass) is indicative of the acquisition of nonindigenous raw materials by means of trade. The bones found testify that the sheep were already domesticated at Zawi Chemi-Shanidar.

At Karīm Shāhir, a site that cannot be accurately tied chronologically to Shanidar, clear proof was obtained both of the knowledge of grain cultivation, in the form of sickle blades showing sheen from use, and of the baking of clay, in the form of lightly fired clay figurines. Still in the hilly borders of Mesopotamia, a sequence of about 3,000 years can be followed at the site of Qal'at Jarmo, east of Kirkūk, some 150 miles north of Baghdad. The beginning of this settlement can be dated to around 6750 BC; and excavations uncovered 12 archaeological levels of a regular village, consisting of about 20–25 houses built of packed clay, sometimes with stone foundations, and divided into several rooms. The finds included types of wheat (emmer and einkorn) and two-row barley, the bones of domesticated goats, sheep, and pigs, and obsidian tools, stone vessels, and, in the upper third of the levels, clay vessels with rough painted decorations, providing the first certain evidence for the manufacture of pottery. Jarmo must be roughly contemporary with the sites of Jericho (13 miles east of Jerusalem) and of Çatalhöyük in Anatolia (central Turkey). Those sites, with their walled settlements, seem to have achieved a much higher level of civilization; but too much weight must not be placed on the comparison, as no other sites in and around Mesopotamia confirm the picture deduced from Jarmo alone.

About 1,000 years later are two villages that are the earliest so far discovered in the plain of Mesopotamia: Hassūna, near Mosul, and Tall Şawwān, near Sāmarrā'. At Hassūna the pottery is more advanced, with incised and painted designs; but the decoration is still unsophisticated. One of the buildings found may be a shrine, to judge from its unusual ground plan. Apart from emmer there occurs, as the result of mutation, six-row barley, which was later to become the chief grain crop of southern Mesopotamia. In the case of Tall Şawwān, it is significant that the settlement lay south of the boundary of rainfall agriculture; thus, it must have been dependent on some form of artificial irrigation, even if this was no more than the drawing of water from the Tigris. This, therefore, gives a date after which the settlement of parts of southern Mesopotamia would have been feasible.

*The emergence of cultures.* For the next millennium, the 5th, it is customary to speak in terms of various "cultures" or "horizons," distinguished in general by the pottery, which may be classed by its colour, shape, hardness, and, above all, its decoration. The name of each horizon is derived either from the type site or from the place where the pottery was first found: Sāmarrā' on the

Identification of cultural stages through pottery

Tigris, Tall Halaf in the central Jazīrah, Ḥassūna Level V, al-'Ubaid near Ur, and Ḥājj Muḥammad on the Euphrates, not far from as-Samāwah (some 150 miles south-southeast of Baghdad). Along with the improvement of tools, the first evidence for water transport (a model boat from the prehistoric cemetery at Eridu, in the extreme south of Mesopotamia, c. 4000 BC), and the development of terra-cottas, the most impressive sign of progress is the constantly accelerating advance in architecture. This can best be followed in the city of Eridu, which in historical times was the centre of the cult of the Sumerian god Enki.

Originally a small, single-roomed shrine, the temple in the Ubaid period consisted of a rectangular building, measuring 80 by 40 feet (24 by 12 metres), that stood on an artificial terrace. It had an "offering-table" and an "altar" against the short walls, aisles down each side, and a facade decorated with niches. This temple, standing on a terrace probably originally designed to protect the building from flooding, is usually considered the prototype of the characteristic religious structure of later Babylonia, the ziggurat. The temple at Eridu is in the very same place as that on which the Enki-ziggurat stood in the time of the 3rd dynasty of Ur (c. 2112–c. 2004 BC), so the cult tradition must have existed on the same spot for at least 1,500–2,000 years before Ur III itself. Remarkable as this is, however, it is not justifiable to assume a continuous ethnic tradition. The flowering of architecture reached its peak with the great temples of Uruk, built around the turn of the 4th to 3rd millennium BC (Levels Uruk VI to IV).

In extracting information as to the expression of mind and spirit during the six millennia preceding the invention of writing sketched above, it is necessary to take account of four major sources: decoration on pottery, the care of the dead, sculpture, and the designs on seals. There is, of course, no justification in assuming any association with ethnic groups.

The most varied of these means of expression is undoubtedly the decoration of pottery. It is hardly coincidental that in regions in which writing had developed, high-quality painted pottery was no longer made. The motifs in decoration are either abstract and geometrical or figured, although there is also a strong tendency to geometric stylization. An important question is the extent to which the presence of symbols, such as the bucranium (a sculptured ornament representing an ox skull), can be considered as expressions of specific religious ideas, such as a bull cult, and, indeed, how much the decoration was intended to convey meaning at all.

It is not known how ancient is the custom of burying the dead in graves nor whether its intention was to maintain communication (by the cult of the dead) or to guard against the demonic power of the unburied dead left free to wander. A cemetery, or collection of burials associated with grave goods, is first attested at Zawi Chemi-Shanidar. The presence of pots in the grave indicates that the bodily needs of the dead person were provided for, and the discovery of the skeleton of a dog or, at Eridu, of a model boat in the cemetery suggests that it was believed that the activities of life could be pursued in the hereafter.

The earliest sculpture takes the form of very crudely worked terra-cotta representations of women; the "Ubaid horizon," however, has figurines of both women and men, with very slender bodies, protruding features, arms akimbo and the genitals accurately indicated, and also of women suckling children. It is uncertain whether it is correct to describe these statuettes as idols, whether the figures were cult objects, such as votive offerings, or whether they had a magical significance, such as fertility charms, or, indeed, what purpose they did fulfill.

Seals are first attested in the form of stamp seals at Tepe Gawra, north of Mosul. Geometrical designs are found earlier than scenes with figures, such as men, animals, conflict between animals, copulation, or dance. Here again, it is uncertain whether the scenes are intended to convey a deeper meaning. Nevertheless, unlike pottery, a seal has a direct relationship to a particular individual or group; for the seal identifies what it is used to seal (a

vessel, sack, or other container) as the property or responsibility of a specific person. To that extent, seals represent the earliest pictorial representations of persons. The area of distribution of the stamp seal was northern Mesopotamia, Asia Minor, and Iran. Southern Mesopotamia, on the other hand, was the home of the cylinder seal, which was either an independent invention or was derived from stamp seals engraved on two faces. The cylinder seal, with its greater surface area and more practical application, remained in use into the 1st millennium BC. Because of the continuous changes in the style of the seal designs, cylinder seals are among the most valuable of chronological indicators for archaeologists.

In general, the prehistory of Mesopotamia can only be described by listing and comparing human achievements, not by recounting the interaction of individuals or peoples. There is no basis for reconstructing the movements and migrations of peoples unless one is prepared to equate the spread of particular archaeological types with the extent of a particular population or the change of types with a change of population or the appearance of new types with an immigration.

The only certain evidence for the movement of men beyond their own territorial limits is provided at first by material finds that are not indigenous. The discovery of obsidian and lapis lazuli at sites in Mesopotamia or in its neighbouring lands postulates the existence of trade, whether it consisted of direct caravan trade or of a succession of intermediate stages.

Just as no ethnic identity is recognizable, so nothing is known of the social organization of prehistoric settlements. It is not possible to deduce anything of the "government" in a village nor of any supraregional connections that may have existed under the domination of one centre. Constructions that could only have been accomplished by the organization of men in large numbers are first found in Uruk Levels VI to IV: the dimensions of these buildings suggest that they were intended for gatherings of hundreds of people. As for artificial irrigation, which was indispensable for agriculture in south Mesopotamia, the earliest form was probably not the irrigation canal. It is assumed that at first floodwater was dammed up to collect in basins, near which the fields were located. Canals, which led the water farther from the river, would have become necessary when the land in the vicinity of the river could no longer supply the needs of the population.

*Mesopotamian protohistory.* Attempts have been made by philologists to reach conclusions as to the origin of the flowering of civilization in southern Mesopotamia by the analysis of Sumerian words. It has been thought possible to isolate an earlier, non-Sumerian substratum from the Sumerian vocabulary by assigning certain words on the basis of their endings to either a Neolithic or a Chalcolithic language stratum. These attempts are based on the phonetic character of Sumerian at the beginning of the 2nd millennium BC, which is at least 1,000 years later than the invention of writing. Quite apart, therefore, from the fact that the structure of Sumerian words themselves is far from adequately investigated, the enormous gap in time casts grave doubt on the criteria used to distinguish between Sumerian and "pre-Sumerian" vocabulary.

The earliest peoples of Mesopotamia who can be identified from inscribed monuments and written tradition—people in the sense of speakers of a common language—are, apart from the Sumerians, Semitic peoples (Akkadians or pre-Akkadians) and Subarians (the predecessors or near relatives of the Hurrians, who appear in northern Mesopotamia around the end of the 3rd millennium BC). Their presence is known, but no definite statements about their past or possible routes of immigration are possible.

At the turn of the 4th to 3rd millennium BC, the endlessly long span of prehistory is over, and the threshold of the historical era is gained, captured by the existence of writing. Names, speech, and actions are fixed in a system that is composed of signs representing complete words or syllables. The signs may consist of realistic pictures, abbreviated representations, and perhaps symbols selected at

random. Since clay is not well suited to the drawing of curved lines, a tendency to use straight lines rapidly gained ground. When the writer pressed the reed in harder at the beginning of a stroke, it made a triangular "head," and thus "wedges" were impressed into the clay. It is the Sumerians who are usually given the credit for the invention of this, the first system of writing in the Near East. As far as they can be assigned to any language, the inscribed documents from before the dynasty of Akkad (c. 2334–c. 2154 BC) are almost exclusively in Sumerian. The extension, moreover, of the writing system to include the creation of syllabograms by the use of the sound of a logogram (sign representing a word), such as *gi*, "a reed stem," used to render the verb *gi*, "to return," can only be explained in terms of the Sumerian language. It is most probable, however, that Mesopotamia of the 4th millennium BC, just as in later times, was composed of many races. This makes it likely that, apart from the Sumerians, the interests and even initiatives of other language groups may have played their part in the formation of the writing system. A strong argument in favour of this is afforded by the system of numbers and measures, which, in contrast to the rudimentary methods of writing words, was very precise and complex from the beginning. In addition to the sexagesimal system indigenous to Sumerian, which has a progression of alternating tens and sixes (1, 10, 60, 600, 3,600, 36,000, and so on), there is the decimal system (1, 10, 100, and so on). Since the number 100 had no special significance for the Sumerians but was expressed in words as 60 + 40, the decimal system was probably intended to do justice to the numerals of a second, non-Sumerian language.

Sumerian is an agglutinative language: prefixes and suffixes, which express various grammatical functions and relationships, are attached to a noun or verb root in a "chain." Attempts to identify Sumerian more closely by comparative methods have as yet been unsuccessful and will very probably remain so, as languages of a comparable type are only known from AD 500 (Georgian) or AD 1000 (Basque)—that is, 3,000 years later. Over so long a time the rate of change in a language, particularly one that is not fixed in a written norm, is so great that one can no longer determine whether apparent similarity between words goes back to an original relationship or is merely fortuitous. Consequently, it is impossible to obtain any more accurate information as to the language group to which Sumerian may once have belonged.

The most important development in the course of the 4th millennium BC was the birth of the city. There were precursors such as the unwallied prepottery settlement at Jericho of c. 7000 BC, but the beginning of cities with a more permanent character came only later. There is no generally accepted definition of a "city." In this context, it means a settlement that serves as a centre for smaller places, one that possesses one or more shrines of one or more major deities, has extensive granaries, and, finally, displays an advanced stage of specialization in the crafts.

The earliest cities of southern Mesopotamia, as far as their names are known, are Eridu, Uruk, Bad-tibira, Nippur, and Kish (35 miles south-southeast of Baghdad). The archaeological surveys of Robert McCormick Adams and Hans Nissen have shown how the relative size and number of the settlements gradually shifted: the number of small or very small settlements was reduced overall, whereas the number of larger places grew. The clearest sign of urbanization can be seen at Uruk, with the almost explosive increase in the size of the buildings. Uruk Levels VI to IV had rectangular buildings covering areas as large as 275 by 175 feet; they are described as temples, since the ground plans are comparable to those of later buildings whose sacred character is beyond doubt.

The major accomplishments of the period Uruk VI to IV, apart from the first inscribed tablets (Level IV B), are masterpieces of sculpture and of seal engraving and also of the form of wall decoration known as cone mosaics. Together with the everyday pottery of black or red burnished ware, there is a very coarse type known as the *Glockentopf* ("bell pot"). These are vessels of standard

size whose shape served as the original for the sign *sila*, meaning "litre." It is not too rash to deduce from the mass production of such standard vessels that they served for the issue of rations. This would have been the earliest instance of a system that remained typical of the southern Mesopotamian city for centuries: the maintenance of part of the population by allocations of food from the state.

Historians usually date the beginning of history, as opposed to prehistory and protohistory, from the first appearance of usable written sources. If this is taken to be the transition from the 4th to the 3rd millennium BC, it must be remembered that this only applies to part of Mesopotamia: the South, the Diyālā region, Susiana (with a later script of its own invented locally), and the district of the Middle Euphrates. It does not apply to regions that remained without writing for a longer time, such as the Middle Tigris region (Assyria), Syria, Asia Minor, and Iran.

#### SUMERIAN CIVILIZATION

**The Sumerians down to the end of the Early Dynastic period.** Despite the Sumerians' leading role, the historical role of other races should not be underestimated. While with prehistory only approximate dates can be offered, historical periods require a firm chronological framework, which, unfortunately, is not yet established for the first half of the 3rd millennium BC. The basis for the chronology after about 1450 BC is provided by the data in the Assyrian and Babylonian king lists, which can often be checked by dated tablets and the Assyrian lists of eponyms (annual officials whose names served to identify each year). But it is still uncertain how much time separated the middle of the 15th century BC from the end of the 1st dynasty of Babylon, which is therefore variously dated to 1594 BC ("middle"), 1530 BC ("short"), or 1730 BC ("long" chronology). As a compromise, the middle chronology will be used. From 1594 BC several chronologically overlapping dynasties reach back to the beginning of the 3rd dynasty of Ur, c. 2112 BC. From this point to the beginning of the dynasty of Akkad (c. 2334 BC) the interval can only be calculated to within 20–30 years, via the ruling houses of Lagash and the rather uncertain traditions regarding the succession of Gutian viceroys. With Ur-Nanshe (c. 2520 BC), the first king of the 1st dynasty of Lagash, there is a possible variation of 50–60 years, and earlier dates are a matter of mere guesswork: they depend upon factors of only limited relevance, such as the computation of occupation or destruction levels, the degree of development in the script (paleography), the character of the sculpture, pottery, and cylinder seals, and their correlation at different sites. In short, the chronology of the first half of the 3rd millennium is largely a matter for the intuition of the individual author. Carbon-14 dates are at present too few and far between to be given undue weight. Consequently, the turn of the 4th to 3rd millennium is to be accepted, with due caution and reservations, as the date of the flourishing of the archaic civilization of Uruk and of the invention of writing.

In Uruk and probably also in other cities of comparable size, the Sumerians led a city life that can be more or less reconstructed as follows: temples and residential districts; intensive agriculture, stock breeding, fishing, and date-palm cultivation, forming the four mainstays of the economy; highly specialized industries, carried on by sculptors, seal engravers, smiths, carpenters, shipbuilders, potters, and workers of reeds and textiles. Part of the population was supported with rations from a central point of distribution, which relieved people of the necessity of providing their basic food themselves, in return for their work all day and every day, at least for most of the year. The cities kept up active trade with foreign lands.

That organized city life existed is chiefly demonstrated by the existence of inscribed tablets. The earliest tablets contain figures with the items they enumerate and measures with the items they measure, as well as personal names and, occasionally, probably professions. This shows the purely practical origins of writing in Mesopotamia: it did not begin as a means of magic or as a way

nium BC

for the ruler to record his achievements, for example, but as an aid to memory for an administration that was ever expanding its area of operations. The earliest examples of writing are very difficult to penetrate because of their extremely laconic formulation presupposing a knowledge of the context and because of the still very imperfect rendering of the spoken word. Moreover, many of the archaic signs were pruned away after a short period of use and cannot be traced in the paleography of later periods, so that they cannot be identified.

One of the most important questions that has to be met when dealing with "organization" and "city life" is that of social structure and the form of government. But it can only be answered with difficulty, and the use of evidence from later periods carries with it the danger of anachronisms. The Sumerian word for ruler *par excellence* is *lugal*, which etymologically means "big man." The first occurrence comes from Kish around 2700 BC, since an earlier instance from Uruk is uncertain because it could simply be intended as a personal name: "Monsieur Légrand." In Uruk the ruler's special title was *en*. In later periods this word (etymology unknown), which is also found in divine names such as En-lil and En-ki, has a predominantly religious connotation that is translated, for want of a better designation, as "en-priest, en-priestess." *En*, as the ruler's title, is encountered in the traditional epics of the Sumerians (Gilgamesh is the "en of Kullab," a district of Uruk) and particularly in personal names, such as "The-en-has-abundance," "The-en-occupies-the-throne," and many others.

It has often been asked if the ruler of Uruk is to be recognized in artistic representations. A man feeding sheep with flowering branches, who is a prominent personality in seal designs, could thus represent the ruler or a priest in his capacity as administrator and protector of flocks. The same question may be posed in the case of a man depicted on a stele aiming an arrow at a lion. But these questions are purely speculative: even if the "protector of flocks" were identical with the *en*, there is no ground for seeing in the ruler a person with a predominantly religious function.

*Literary and other historical sources.* The picture offered by the literary tradition of Mesopotamia is clearer but not necessarily historically relevant. The Sumerian king list has long been the greatest focus of interest. This is a literary composition, dating from Old Babylonian times, that describes kingship (*nam-lugal* in Sumerian) in Mesopotamia from primeval times to the end of the 1st dynasty of Isin. According to the theory—or rather ideology—of this work, there was officially only one kingship in Mesopotamia, which was vested in one particular city at any one time; hence the change in dynasties brought with it the change of the seat of kingship:

Kish-Uruk-Ur-Awan-Kish-Hamazi-Uruk-Ur-  
Adab-Mari-Kish-Akshak-Kish-Uruk-Akkad-  
Uruk-Gutians-Uruk-Ur-Isin.

The king list gives as coming in succession several dynasties that now are known to have ruled simultaneously. It is a welcome aid to chronology and history, but, so far as the regnal years are concerned, it loses its value for the time before the dynasty of Akkad: for here the lengths of reign of single rulers are given as more than 100 and sometimes even several hundred years. One group of versions of the king list has adopted the tradition of the Sumerian flood story, according to which Kish was the first seat of kingship after the Flood, whereas five dynasties of primeval kings ruled before the Flood in Eridu, Bad-tibira, Larak, Sippar, and Shuruppak. These kings all allegedly ruled for multiples of 3,600 years (the maximum being 64,800 or, according to one variant, 72,000 years). The tradition of the Sumerian king list is still echoed in Berosus.

It is also instructive to observe what the Sumerian king list does not mention. It lacks all mention of a dynasty as important as the 1st dynasty of Lagash (from King Ur-Nanshe to Uru'inimgina, formerly known as Urukagina) and appears to retain no memory of the archaic florescence of Uruk at the beginning of the 3rd millennium BC.

Besides the peaceful pursuits reflected in art and writing,

the art also provides the first information about violent contacts: cylinder seals of the Uruk IV Level depict fettered men lying or squatting on the ground, being beaten with sticks or otherwise maltreated by standing figures. They may represent prisoners of war being killed in order to dispose of them. It is unknown from where these captives came or what form "war" would have taken or how early organized battles were fought. Nevertheless, this does give the first, albeit indirect, evidence for the wars that are henceforth one of the most characteristic phenomena in the history of Mesopotamia; and it makes it all the more surprising that the Mesopotamian cities at the beginning of the 3rd millennium BC were not walled. The earliest city wall so far known, that of Uruk, dates only to 2700–2650 BC.

Just as with the rule of man over man, with the rule of higher powers over man it is difficult to make any statements about the earliest attested forms of religion or about the deities and their names without running the risk of anachronism. Excluding prehistoric figurines, which provide no evidence for determining whether men or anthropomorphic gods are represented, the earliest testimony is supplied by certain symbols that later became the cuneiform signs for gods' names: the "gatepost with streamers" for Inanna, goddess of love and war, and the "ringed post" for the moon god Nanna. A scene on a cylinder seal—a shrine with an Inanna symbol and a "man" in a boat—could be an abbreviated illustration of a procession of gods or of a cultic journey by ship. The constant association of the "gatepost with streamers" with sheep and of the "ringed post" with cattle may possibly reflect the area of responsibility of each deity. The Sumerologist Thorkild Jacobsen sees in the pantheon a reflex of the various economies and modes of life in ancient Mesopotamia: fishermen and marsh dwellers, date-palm cultivators, cowherds, shepherds, and farmers all have their special groups of gods.

Both Sumerian and non-Sumerian languages can be detected in the divine names and place-names. Since the pronunciation of the names is known only from 2000 BC or later, conclusions as to their linguistic affinity are not without problems. Several, for example, have been reinterpreted in Sumerian by popular etymology. It would be particularly important to isolate the Subarian components (related to Hurrian), whose significance was probably greater than has hitherto been assumed. For the south Mesopotamian city HA.A (the noncommittal transliteration of the signs) there is a pronunciation gloss *shubari*, and non-Sumerian incantations are known in the language of HA.A, which have turned out to be Subarian.

There have always been in Mesopotamia speakers of Semitic languages (which belong to the Hamito-Semitic group and also include ancient Egyptian, Berber, and various African languages). This element is easier to detect in ancient Mesopotamia, but whether people began to participate in city civilization in the 4th millennium BC or only during the 3rd is unknown. Over the last 4,000 years Semites (Amorites, Canaanites, Aramaeans, and Arabs) have been partly nomadic, ranging the Arabian fringes of the Fertile Crescent, and partly settled; and the transition to settled life can be observed in a constant, though uneven, rhythm. There are, therefore, good grounds for assuming that the Akkadians (and other pre-Akkadian Semitic tribes not known by name) also originally led a nomadic life to a greater or lesser degree. Nevertheless, they can only have been herders of domesticated sheep and goats, which require changes of pasturage according to the time of year and can never stray more than a day's march from the watering places. The traditional nomadic life of the Bedouin makes its appearance only with the domestication of the camel at the turn of the 2nd to 1st millennium BC.

The question arises as to how quickly writing spread and by whom it was adopted about 3000 BC or shortly thereafter. At Kish, in north Babylonia, almost 120 miles northwest of Uruk, clay tablets have been found with the same repertoire of archaic signs as at Uruk itself. This fact demonstrates that intellectual contacts existed between north and south Babylonia. The dispersion of writ-

Complexities in unravelling the nature of the power structure

The Sumerian king list

Early religious beliefs

The spread of writing

ing in an unaltered form presupposes the existence of schools in various cities that worked according to the same principles and adhered to one and the same canonical repertoire of signs. It would be wrong to assume that Sumerian was spoken throughout the area in which writing had been adopted: it is linguistically significant that even the earliest of the Uruk texts use a sexagesimal and a decimal system side-by-side. Moreover, the use of cuneiform for a non-Sumerian language can be demonstrated with certainty from the 27th century BC.

*First historical personalities.* The specifically political events in Mesopotamia after the flourishing of the archaic culture of Uruk cannot be pinpointed. Not until about 2700 BC does the first historical personality appear—historical because his name, Enmebaragesi (Me-baragesi), was preserved in later tradition. It has been assumed, although the exact circumstances cannot be reconstructed, that there was a rather abrupt end to the high culture of Uruk Level IV. The reason for the assumption is a marked break in both artistic and architectural traditions: cylinder seals were replaced by others with an entirely new style; the great temples were abandoned—flouting the rule of a continuous tradition on religious sites—and on a new site a shrine was built on a terrace, which was to constitute the lowest stage of the later Eanna ziggurat. On the other hand, since the writing system developed organically and was continually refined by innovations and progressive reforms, it would be overhasty to assume a revolutionary change in the population.

In the quarter or third of a millennium between Uruk Level IV and Enmebaragesi, southern Mesopotamia became studded with a complex pattern of cities, many of which were the centres of small independent city-states, to judge from the situation in about the middle of the millennium. In these cities, the central point was the temple, sometimes encircled by an oval boundary wall (hence the term temple oval); but nonreligious buildings, such as palaces serving as the residences of the rulers, could also function as centres.

Enmebaragesi

Enmebaragesi, king of Kish, is the oldest Mesopotamian ruler about whom there are authentic inscriptions. These are vase fragments, one of them found in the temple oval of Khafājī. In the Sumerian king list, Enmebaragesi is listed as the penultimate king of the 1st dynasty of Kish; a Sumerian epic, *Gilgamesh and Agga of Kish*, describes the siege of Uruk by Agga, son of Enmebaragesi. The discovery of the original inscriptions was of great significance because it enabled scholars to ask with somewhat more justification whether Gilgamesh, the heroic figure of Mesopotamia who has entered world literature, had actually been a historical personage. The indirect synchronism notwithstanding, the possibility exists that even remote antiquity knew its "Ninos" and its "Semiramis," figures onto which a rapidly fading historical memory projected all manner of deeds and adventures. Thus, though the historical tradition of the early 2nd millennium believes Gilgamesh to have been the builder of the oldest city wall of Uruk, such may not have been the case. The palace archives of Shuruppak (modern Tall Fa'rah, 125 miles southeast of Baghdad), dating presumably from shortly after 2600, contain a long list of divinities, including Gilgamesh and his father Lugalbanda. More recent tradition, on the other hand, knows Gilgamesh as judge of the nether world. However that may be, an armed conflict between two Mesopotamian cities such as Uruk and Kish would hardly have been unusual in a country whose energies were consumed, almost without interruption from 2500 to 1500, by clashes between various separatist forces. The great "empires," after all, formed the exception, not the rule.

*Emergent city-states.* Kish must have played a major role almost from the beginning. After 2500, southern Babylonian rulers, such as Mesannepada of Ur and Eannatum of Lagash, frequently called themselves king of Kish when laying claim to sovereignty over northern Babylonia. This is not to agree with some recent histories in which Kish is represented as an archaic "empire." It is more likely to have figured as a representative of the

north, calling forth perhaps the same geographical connotation later evoked by "the land of Akkad."

Although the corpus of inscriptions grows richer both in geographical distribution and in point of chronology in the 27th and increasingly so in the 26th century, it is still impossible to find the key to a plausible historical account. Besides, history cannot be written on the sole basis of archaeological findings. Unless clarified by written documents, these findings contain as many riddles as they seem to offer solutions. This applies even to as spectacular a discovery as that of the royal tombs of Ur with their hecatombs (large-scale sacrifices) of retainers who followed their king and queen to the grave, not to mention the elaborate funerary appointments with their inventory of tombs. It is only from c. 2520 to the beginnings of the dynasty of Akkad that history can be written within a framework, with the aid of reports about the city-state of Lagash and its capital of Girsu and its relations with its neighbour and rival, Umma.

Sources for this are, on the one hand, an extensive corpus of inscriptions relating to nine rulers, telling of the buildings they constructed, of their institutions and wars, and, in the case of Uru'inimgina, of their "social" measures. On the other hand, there is the archive of some 1,200 tablets—insofar as these have been published—from the temple of Baba, the city goddess of Girsu, from the period of Lugalanda and Uru'inimgina (first half of the 24th century). For generations, Lagash and Umma contested the possession and agricultural usufruct of the fertile region of Gu'edena. To begin with, some two generations before Ur-Nanshe, Mesilim (another "king of Kish") had intervened as arbiter and possibly overlord in dictating to both states the course of the boundary between them; but this was not effective for long. After a prolonged struggle Eannatum forced the ruler of Umma, by having him take an involved oath to six divinities, to desist from crossing the old border, a canal. The text that relates this event, with considerable literary elaboration, is found on the Stele of Vultures. These battles, favouring now one side, now the other, continued under Eannatum's successors, in particular Entemena, until, under Uru'inimgina, great damage was done to the land of Lagash and to its holy places. The enemy, Lugalzaggesi, was vanquished in turn by Sargon of Akkad. The rivalry between Lagash and Umma, however, must not be considered in isolation. Other cities, too, are occasionally named as enemies, and the whole situation resembles the pattern of changing coalitions and short-lived alliances between cities of more recent times. Kish, Umma, and distant Mari on the Middle Euphrates are listed together on one occasion as early as the time of Eannatum. For the most part, these battles were fought by infantry, although mention is also made of war chariots drawn by onagers (wild asses).

The lords of Lagash rarely fail to call themselves by the title of *ensi*, of as yet undetermined derivation; "city ruler," or "prince," would only be approximate translations. Only seldom do they call themselves *lugal*, or "king," the title given the rulers of Umma in their own inscriptions. In all likelihood, these were local titles that were eventually converted, beginning perhaps with the kings of Akkad, into a hierarchy in which the *lugal* took precedence over the *ensi*.

*Territorial states.* More difficult than describing its external relations is the task of shedding light on the internal structure of a state like Lagash. For the first time, a state consisting of more than a city with its surrounding territory came into being because aggressively minded rulers had managed to extend that territory until it comprised not only Girsu, the capital, and the cities of Lagash and Nina (Zurghul) but also many smaller localities and even a seaport, Guabba. But it is not clear to what extent the conquered regions were also integrated administratively. On one occasion Uru'inimgina uses the formula "from the limits of the Ningirsu [that is, the city god of Girsu] to the sea," having in mind a distance of up to 125 miles. It would be unwise to harbour any exaggerated notion of well-organized states exceeding that size.

For many years views were conditioned by the slogan of

Intercity rivalry between Lagash and Umma

The  
Sumerian  
temple city

the Sumerian temple city, used to convey the idea of an organism whose ruler, as representative of his god, theoretically owned all land, privately held agricultural land being a rare exception. The image of the temple city had its origin partly in the overinterpretation of a passage in the so-called reform texts of Uru'ningina, which state that "on the field of the *ensi* [or else, his wife and the crown prince], the city god Ningirsu [or else, the city goddess Baba and the divine couple's son]" had been "reinstated as owners." On the other hand, the statements in the archives of the temple of Baba in Girsu, dating from Lugalanda and Uru'ningina, were held to be altogether representative. Here is a system of administration, directed by the *ensi's* spouse or by a *sangu* (head steward of a temple), in which every economic process, including commerce, stands in a direct relationship to the temple: agriculture, vegetable gardening, tree farming, cattle raising and the processing of animal products, fishing, and the payment in merchandise of workers and employees.

The conclusion from this analogy proved to be dangerous because the archives of the temple of Baba provide information about only a portion of the total temple administration and that portion, furthermore, is limited in time. Understandably enough, the private sector, which of course was not controlled by the temple, is scarcely mentioned at all in these archives. The existence of such a sector is nevertheless documented by bills of sale for land purchases of the pre-Sargonic period and from various localities. Written in Sumerian as well as in Akkadian language, they prove the existence of private land ownership or, in the opinion of some scholars, of lands predominantly held as undivided family property. Although a substantial part of the population was forced to work for the temple and drew its pay and board from it, it is not yet known whether it was year-round work.

It is probable, if unfortunate, that there will never exist a detailed and numerically accurate picture of the demographic structure of a Sumerian city. It is assumed that in the oldest city the government was in a position to summon sections of the populace for the performance of public works. The construction of monumental buildings or the excavation of long and deep canals could be carried out only by means of such a levy. The large-scale employment of indentured persons and of slaves are of no concern in this context. Evidence of male slavery is fairly rare before Ur III, and even in Ur III and in the Old Babylonian period slave labour was never an economically relevant factor. It was different with female slaves. According to one document, the temple of Baba employed 188 such women; the temple of the goddess Nanshe, 180, chiefly in grinding flour and in the textile industry; and this continued to be the case in later times. For accuracy's sake it should be added that the terms male slave and female slave are used here in the significance they possessed around 2000 and later, designating persons in bondage who were bought and sold and who could not acquire personal property through their labour. A distinction is made between captured slaves (prisoners of war and kidnapped persons) and others who had been sold.

In one inscription, Entemena of Lagash boasts of having "allowed the sons of Uruk, Larsa, and Bad-tibira to return to their mothers" and of having "restored them into the hands" of the respective city god or goddess. Read in the light of similar but more explicit statements of later date, this laconic formula represents the oldest known evidence of the fact that the ruler occasionally endeavoured to mitigate social injustices by means of a decree. Such decrees might refer to the suspension or complete cancellation of debts or to exemption from public works. Whereas a set of inscriptions of the last ruler from the 1st dynasty of Lagash, Uru'ningina (possibly the correct reading in lieu of the former "Urukagina"), has long been considered a prime document of social reform in the 3rd millennium, the designation "reform texts" is only partly justified. Reading between the lines, it is possible to discern that tensions had arisen between the "palace"—the ruler's residence with its annex, administrative staff, and landed properties—and the "clergy"; that is, the

stewards and priests of the temples. In seeming defiance of his own interests, Uru'ningina, who in contrast to practically all of his predecessors lists no genealogy and has therefore been suspected of having been a usurper, defends the clergy, whose plight he describes somewhat tearfully. If the foregoing passage about restoring the *ensi's* fields to the divinity is interpreted carefully, it would follow that the situation of the temple was ameliorated and that palace lands were assigned to the priests. Along with these measures, which resemble the policies of a newcomer forced to lean on a specific party, are found others that do merit the designation of "measures taken toward the alleviation of social injustices"—for instance, the granting of delays in the payment of debts or their outright cancellation and the setting up of prohibitions to keep the economically or socially more powerful from forcing his inferior to sell his house, his ass's foal, and the like. Besides this, there were tariff regulations, such as newly established fees for weddings and burials, as well as the precise regulation of the food rations of garden workers, called blind men.

These conditions, described on the basis of source materials from Girsu, may well have been paralleled elsewhere; but it is equally possible that other archives, yet to be found in other cities of pre-Sargonic southern Mesopotamia, may furnish entirely new historical aspects. At any rate, it is wiser to proceed cautiously, by keeping to analysis and evaluation of the available material rather than to construct generalizations.

This, then, is the horizon of Mesopotamia shortly before the rise of the Akkadian Empire. In Mari, writing was introduced at the latest around the mid-26th century BC; and from that time this city, situated on the Middle Euphrates, forms an important centre of cuneiform civilization, especially in regard to its Semitic component. Reaching out across the Diyālā region and the Persian Gulf, Mesopotamian influences extended to Iran, where Susa is mentioned along with Elam and other, not yet localized, towns. In the west, the Amanus Mountains were known; and under Lugalzagesi, the "upper sea" in other words, the Mediterranean, is mentioned for the first time. To the east, the inscriptions of Ur-Nanshe of Lagash already name the isle of Tilmun (modern Bahrain), which may have been even then a transshipment point for trade with the Oman coast and the Indus region, the Magan and Meluhha of more recent texts. Trade with Asia Minor and Afghanistan was nothing new to the 3rd millennium, even if these regions are not yet listed by their names. It was the task of the Akkadian dynasty to unite, within these boundaries, a territory that transcended the dimensions of a state of the type represented by Lagash.

**Sumer and Akkad in 2350–2000 BC.** There are several reasons for taking the year 2350 as a turning point in the history of Mesopotamia. For the first time, an empire arose on Mesopotamian soil. The driving force of that empire was the "Akkadians," so called after the city of Akkad, which Sargon chose for his capital (it has not yet been identified but was presumably located on the Euphrates between Sippar and Kish). The name Akkad becomes synonymous with a population group that stands side-by-side with the Sumerians. The "land of Sumer and Akkad" becomes a name for southern Mesopotamia; "Akkadian" becomes the name of a language; and the arts rise to new heights. But even this turning point was not the first time the Akkadians had emerged in history. Semites—whether Akkadians or a Semitic language group that had settled before them—perhaps had had a part in the urbanization that took place at the end of the 4th millennium. The earliest Akkadian names and words occur in written sources of the 27th century. The names of several Akkadian scribes are found in the archives of Tell Abu Šalābikh near Sippar, synchronous with those of Shuruppak (shortly after 2600). The Sumerian king list places the 1st dynasty of Kish, together with a series of kings bearing Akkadian names, immediately after the Flood. In Mari, Akkadian script was probably used from the very beginning. Thus, the founders of the dynasty of Akkad were presumably members of a people who had

Conscript  
of labour

been familiar for centuries with Mesopotamian culture in all its forms.

*Sargon's reign.* According to the Sumerian king list, the first five rulers of Akkad (Sargon, Rimush, Manishtusu, Naram-Sin, and Shar-kali-sharri) ruled for a total of 142 years; Sargon alone ruled for 56. Although these figures cannot be checked, they are probably trustworthy, because the king list for Ur III, even if 250 years later, did transmit dates that proved to be accurate.

As stated in an annotation to his name in the king list, Sargon started out as a cupbearer to King Ur-Zababa of Kish. There is also an Akkadian legend about Sargon, who is supposed to have been exposed after birth, brought up by a gardener, and beloved of the goddess Ishtar. Nevertheless, there are no historical dates about his career. Yet it is feasible to assume that in his case a high court office served as springboard for a dynasty of his own. The original inscriptions of the kings of Akkad that have come down to posterity are brief, more informative for geographical distribution than content. The main source material for Sargon's reign, with its high points and catastrophes, are copies made by Old Babylonian scribes in Nippur, from the very extensive originals that presumably had been kept there. They are in part Akkadian, in part bilingual Sumerian-Akkadian texts. According to these texts, Sargon is said to have fought against the Sumerian cities of southern Babylonia, thrown down city walls, taken prisoner 50 *ensis*, and have "cleansed his weapons in the sea." He is also supposed to have captured Lugalzagesi of Uruk, the former ruler of Umma, who had vigorously attacked Uru'inimgina in Lagash, forcing his neck under a yoke and leading him thus to the gate of the god Enlil at Nippur. "Citizens of Akkad" filled the offices of *ensi* from the "nether sea" (the Persian Gulf) upward, which was perhaps a device used by Sargon to further his dynastic aims. Aside from the 34 battles fought in the south, Sargon also tells of conquests in northern Mesopotamia: Mari, Tuttul on the Balikh, where he venerated the god Dagan (Dagon), Ebla (Tall Mardikh of Syria), the "cedar forest" (Amanus or Lebanon), and the "silver mountains"; battles in Elam and the foreshore of the Zagros are mentioned. Sargon also relates that ships from Meluhha (Indus region), Magan (possibly the coast of Oman), and Tilmun (Bahrain) made fast in the port of Akkad.

Impressive as they are at first sight by way of a terse synopsis, these reports have only a limited value because they cannot be arranged chronologically, and it is not known whether Sargon built a large empire. Akkadian tradition itself saw it in this light, however, and a learned treatise of the late 8th or the 7th century lists no fewer than 65 cities and lands belonging to that empire. But even if Magan and Kapturu (Crete) are given as the eastern and western limits of the conquered territories, it is impossible to transpose this to the 3rd millennium.

Sargon appointed one of his daughters priestess of the moon god in Ur. She took the name of Enkheduana and was succeeded in the same office by Enmenana, a daughter of Naram-Sin. Enkheduana must have been a very gifted woman; two Sumerian hymns by her have been preserved, and she is also said to have been instrumental in starting a collection of songs dedicated to the temples of Babylonia.

Sargon died in very old age. The inscriptions, likewise preserved only in copies, of his son Rimush are full of reports about battles fought in Sumer and Iran, just as if there had never been a Sargonic empire. It is not known in detail how rigorously Akkad wished to control the cities to the south and how much freedom had been left to them; but they presumably clung tenaciously to their inherited local autonomy. From a practical point of view, it was probably in any case impossible to organize an empire that would embrace all of Mesopotamia.

Since the reports (that is, copies of inscriptions, as was their later elaboration into legend) left by Manishtusu, Naram-Sin, and Shar-kali-sharri speak time and again of rebellions and victorious battles and since Rimush, Manishtusu, and Shar-kali-sharri are themselves said to have died violent deaths, the problem of what remained of

Akkad's greatness obtrudes. Wars and disturbances, the victory of one and the defeat of another, and even regicide constitute only one of the aspects suggested to us by the sources. Whenever they extended beyond the immediate Babylonian neighbourhood, the military campaigns of the Akkadian kings were dictated primarily by trade interests instead of being intended to serve the conquest and safeguarding of an empire. Akkad, or more precisely, the king, needed merchandise, money, and gold in order to finance wars, buildings, and the system of administration that he had instituted.

On the other hand, the original inscriptions that have been found so far of a king like Naram-Sin are scattered over a distance of some 620 miles as the crow flies, following the Tigris downriver: Diyarbakir on the Upper Tigris, Nineveh, Tall Birak on the upper Khabur (which had an Akkadian fortress and garrison), Susa in Elam, as well as Marad, Puzurish-Dagan, Adab (Bismayah), Nippur, Ur, and Girsu in Babylonia. Even if all this was not part of an empire, it surely constituted an impressive sphere of influence.

Also to be considered are other facts that weigh more heavily than high-sounding reports of victories that cannot be checked. After the first kings of the dynasty had borne the title of king of Kish, Naram-Sin had himself addressed as "king of the four quarters of the earth"; that is, of the universe. As if he were in fact divine, he also had his name written with the cuneiform sign "god," the divine determinative that was customarily used in front of the names of gods; furthermore, he assumed the title of "god of Akkad." It is legitimate to ask whether the concept of deification may be used in the sense of elevation to a rank equal to that of the gods. At the very least it must be acknowledged that in relation to his city and his subjects, the king saw himself in the role played by the local divinity as protector of the city and guarantor of its well-being. In synchronous judicial documents from Nippur, the oath is often taken "by Naram-Sin," with a formula identical with that used in swearing by a divinity. Documents from Girsu contain Akkadian date formulas of the type "in the year in which Naram-Sin laid the foundations of the Enlil temple at Nippur and of the Inanna temple at Zabalam." As evidenced by the dating procedures customary in Ur III and in the Old Babylonian period, the use of such formulas presupposes that the respective city acknowledged as its overlord the ruler whose name is invoked.

*Ascendancy of Akkad.* Under Akkad, the Akkadian language acquired a literary prestige that made it the equal of Sumerian; under the influence, perhaps, of an Akkadian garrison at Susa, it spread beyond the borders of Mesopotamia. After having employed for several centuries an indigenous script patterned after cuneiform writing, Elam adopted Mesopotamian script during the Akkadian period and with a few exceptions used it even when writing in Elamite rather than Sumerian or Akkadian. The so-called Old Akkadian manner of writing is extraordinarily appealing from the aesthetic point of view; as late as in the Old Babylonian era, it served as a model for monumental inscriptions. This bears out the fact that the plastic and graphic arts, especially sculpture in the round, relief work, and cylinder seals reached a high point of perfection.

Thus the reign of the five kings of Akkad may be considered one of the most productive periods of Mesopotamian history. Although separatist forces opposed all unifying tendencies, Akkad brought about a broadening of political horizons and dimensions. The period of Akkad fascinated historiographers as did few other eras; having contributed its share to the storehouse of legend, it has never disappeared from memory. With a phrase such as "There will come a king of the four quarters of the earth," liver omens (sooth-saying done by analyzing the shape of a sheep's liver) of the Old Babylonian period express the yearning for unity at a time when Babylonia had once again disintegrated into a dozen or more small states.

*The end of the dynasty.* Of the kings after Shar-kali-sharri (c. 2217-c. 2193), only the names and a few brief

Source materials on Sargon

Divine kingship

Sargon's daughter

The Gutians' obscure role

inscriptions have survived. Quarrels arose over the succession, and the dynasty went under, although modern scholars know as little about the individual stages of this decline as about the rise of Akkad. Two factors contributed to its downfall: the invasion of the nomadic Amurru (Amorites), called Martu by the Sumerians, from the northwest, and the infiltration of the Gutians, who came, apparently, from the region between the Tigris and the Zagros Mountains eastward. This argument, however, may be a vicious circle, as these invasions were provoked and facilitated by the very weakness of Akkad. In Ur III, the Martu, in part already sedentary, form one ethnic component along with Sumerians and Akkadians. The Gutians, on the other hand, played only a temporary role, even if the memory of a Gutian dynasty persisted until the end of the 17th century BC. As a matter of fact, the wholly negative opinion that even some modern historians have of the Gutians is based solely on a few stereotyped statements by the Sumerians and Akkadians, especially on the victory inscription of Utu-khegal of Uruk (2116–10). While Old Babylonian sources give the region between the Tigris and the Zagros Mountains as the home of the Gutians, these people probably also lived on the Middle Euphrates during the 3rd millennium. According to the Sumerian king list, the Gutians held the “kingship” in southern Mesopotamia for about 100 years. It has long been recognized that there is no question of a whole century of undivided Gutian rule and that some 50 years of this rule coincided with the final half century of Akkad. From this period there has also been preserved a record of a “Gutian interpreter.” As it is altogether doubtful whether the Gutians had made any city of southern Mesopotamia their “capital” instead of controlling Babylonia more or less informally from outside, scholars cautiously refer to “viceroys” of this people. The Gutians have left no material records, and the original inscriptions about them are so slight that no binding statements about them are possible.

The Gutians' influence probably did not extend beyond Umma. The neighbouring state of Lagash enjoyed a century of complete independence, between Shar-kali-sharri and Ur III, during which time it showed expansionist tendencies and had widely ranging trade connections. Of the *ensi* Gudea (c. 2144–c. 2124) there are extant writings, exclusively Sumerian in language, which are of inestimable value. He had the time, power, and means to carry out an extensive program of temple construction during his reign; and in a hymn divided into two parts and preserved in two clay cylinders 12 inches (30 centimetres) high he describes explicitly the reconstruction of Eninnu, the temple of the god Ningirsu. Comprising 1,363 lines, the text is second in length only to Eannatum's Stele of Vultures among the literary works of the Sumerians up to that time. While Gudea forges a link, in his literary style, with his country's pre-Sargonic period, his work also bears the unmistakable stamp of the period of Akkad. Thus, the regions that furnish him building materials reflect the geographical horizon of the empire of Akkad, and the *ensi's* title “god of his city” recalls the “god of Akkad” (Naram-Sin). The building hymn contains interesting particulars about the work force deployed. “Levies” were organized in various parts of the country, and the city of Girsu itself “followed the *ensi* as though it were a single man.” Unfortunately, synchronous administrative archives of sufficient length to provide less summarily compiled information about the social structure of Lagash shortly before the 3rd dynasty of Ur are lacking. After the great pre-Sargonic archives of the Baba temple at Girsu, only the various administrative archives of the king of Ur III give a closer look at the functioning of a Mesopotamian state.

**The 3rd dynasty of Ur.** Utu-khegal of Uruk is given credit for having overthrown Gutian rule by vanquishing their king Tiriqan along with two generals. Utu-khegal calls himself lord of the four quarters of the earth in an inscription; but this title, adopted from Akkad, is more likely to signify political aspiration than actual rule. If another inscription has been correctly restored, Utu-khegal was a brother of the Ur-Nammu who

founded the 3rd dynasty of Ur (“3rd” because it is the third time that Ur is listed in the Sumerian King List). Under Ur-Nammu and his successors Shulgi, Amar-Su'en (Amar-Sin), Shu-Sin, and Ibbi-Sin, this dynasty lasted for a century (c. 2112–2004). Ur-Nammu was at first “governor” of the city of Ur under Utu-khegal. How he became king is not known, but there may well be some parallels between his rise and the career of Ishbi-Era of Isin or, indeed, that of Sargon. By eliminating the state of Lagash, Ur-Nammu caused the coveted overseas trade (Tilmun, Magan, and Meluhha) to flow through Ur. As evidenced by a new royal title that he was the first to bear—that of “king of Sumer and Akkad”—he had built up a state that comprised at least the southern part of Mesopotamia. Like all great rulers, he built much, including the very impressive ziggurats of Ur and Uruk, which acquired their final monumental dimensions in his reign.

Assyriologists have given the name of Codex of Ur-Nammu to a literary monument that is the oldest hitherto-known example of a genre extending through the Code of Lipit-Ishtar in Sumerian to the Code of Hammurabi, written in Akkadian. It is a collection of sentences or verdicts mostly following the pattern of “If A [assumption], it follows that B [legal consequence].” The collection is framed by a prologue and an epilogue. The original was most likely a stele, but all that is known of the Code of Ur-Nammu so far are Old Babylonian copies. The term code as used here is conventional terminology and should not give the impression of any kind of “codified” law; furthermore, the content of the Code of Ur-Nammu is not yet completely known. It deals, among other things, with adultery by a married woman, the deforation of someone else's female slave, divorce, false accusation, the escape of slaves, bodily injury, the granting of security, as well as with legal cases arising from agriculture and irrigation.

Before its catastrophic end, under Ibbi-Sin, the state of Ur III does not seem to have suffered setbacks and rebellions as grievous as those experienced by Akkad. There are no clear indications pointing to inner unrest, although it must be remembered that the first 20 years of Shulgi's reign are still hidden in darkness. But from that point on until the beginning of Ibbi-Sin's reign, or for a period of 50 years at least, the sources give the impression of peace enjoyed by a country that lived undisturbed by encroachments from abroad. Some expeditions were sent into foreign lands, to the region bordering on the Zagros, to what later became Assyria, and to the vicinity of Elam, in order to secure the importation of raw materials, in a fashion reminiscent of Akkad. Force seems to have been employed only as a last resort; and every attempt was made to bring about peaceful conditions on the other side of the border through the dispatch of embassies or the establishment of family bonds, for example, by marrying the king's daughters to foreigners.

Shulgi, too, called himself king of the four quarters of the earth. Although he resided in Ur, another important centre was in Nippur, whence—according to the prevailing ideology—Enlil, the chief god in the Sumerian state pantheon, had bestowed on him the royal dignity. Shulgi and his successors enjoyed divine honours, as Naram-Sin of Akkad had before them; by now, however, the process of deification had taken on clearer outlines in that sacrifices were offered and chapels built to the king and his throne, while the royal determinative turned up in personal names. Along with an Utu-khegal (The Sun God Is Exuberance) there appears a Shulgi-khegal (Shulgi Is Exuberance), and so forth.

**Administration.** The highest official of the state was the *sukkal-makh*, literally “supreme courier,” whose position may be paraphrased with “(state) chancellor.” The empire was divided into some 40 provinces ruled by as many *ensis*, who, despite their far-reaching authority (civil administration and judicial powers), were no longer autonomous, even if only indirectly, although the office was occasionally handed down from father to son. They could not enter into alliances or wage wars on their own. The *ensis* were appointed by the king and could

The Codex of Ur-Nammu

probably also be transferred by him to other provinces. Each of these provinces was obliged to pay a yearly tribute, the amount of which was negotiated by emissaries. Of special significance in this was a system called *bala*, "cycle" or "rotation," in which the *ensis* of the southern provinces took part; among other things, they had to keep the state stockyards supplied with sacrificial animals. Although the "province" often corresponded to a former city-state, many others were no doubt newly established. The so-called land-register text of Ur-Nammu describes four such provinces north of Nippur, giving the precise boundaries and ending in each case with the statement: "King Ur-Nammu has confirmed the field of the god XX for the god XX." In some cities, notably in Uruk, Mari, or Der (near Badrah, Iraq), the administration was in the hands of a *shakana*, a man whose title is rendered partly by "governor" and partly by "general."

The available histories are practically unanimous in seeing in Ur III a strongly centralized state marked by the king's position as absolute ruler. Nevertheless, some caution is indicated. For one thing, the need to deal as tactfully as possible with the *ensis* must not be underestimated. A further question arises from the borders between and relative extent of the "public" and the "private" sector; the latter's importance may have been underrated as well. What is meant by "private" sector is a population group with land of its own and with revenues not directly granted by a temple or a "palace," such as by the king's or an *ensis*'s household. The traditional picture is derived from the sources, the state archives of Puzurish-Dagan, a gigantic "stockyard" situated outside the gates of Nippur, which supplied the city's temples with sacrificial animals but inevitably also comprised a major wool and leather industry; other such archives are those of Umma, Girsu, Nippur, and Ur. All these activities were overseen by a finely honed bureaucracy that stressed the use of official channels, efficient administration, and precise accounting. The various administrative organs communicated with one another by means of a smoothly functioning network of messengers. Although almost 23,000 documents referring to the economy of Ur III have so far been published, they are still waiting to be properly evaluated. Nor is there yet a serviceable typology for them; only when that has been drawn up will it be possible to write a book entitled "*The Economic System of Ur III*." Represented in the main by contracts (loans, leases of temple land, the purchase of slaves, and the like), the "private" sector makes up only a small part of this mass of textual material. Neither can the sites at which discoveries have been made so far be taken as representative; in northern Babylonia, for example, scarcely any contemporary written documents have yet been recovered.

*Ethnic, geographic, and intellectual constituents.* From the ethnic point of view, Mesopotamia was as heterogeneous at the end of the 3rd millennium as it had been earlier. The Akkadian element predominated, and the proportion of speakers of Akkadian to speakers of Sumerian continued to change in favour of the former. Some scholars consider it altogether wrong to speak of "Sumerians" and "Akkadians" at this point, since the Sumerians had been living in southern Mesopotamia for at least 1,000 years, without any contact with possibly related peoples, whereas the Semitic population regenerated itself continually from the ranks of nomads who became sedentary. The third group, first mentioned under Sharkali-sharri of Akkad, are the Amorites. In Ur III, some members of this people are already found in the higher echelons of the administration, while the bulk, organized in tribes, still led a nomadic life. Their great days came in the Old Babylonian period. While clearly differing linguistically from Akkadian, the Amorite language, which can be reconstructed to some extent from hundreds of proper names, is fairly closely related to the so-called Canaanite branch of the Semitic languages, of which it may in fact represent an older form. The fact that King Shu-Sin had a regular wall built clear across the land, the "wall that keeps out the Tidnum" (name of a tribe), shows how strong the pressure of the nomads was in the 21st century and what efforts were being made to

check their influx. The fourth major ethnic group comprised the Hurrians, who were especially important in northern Mesopotamia and in the vicinity of modern Kirkūk.

It is likely that the geographical horizon of the empire of Ur III did not materially exceed that of the empire of Akkad. No names of localities in the interior of Asia Minor have been found, but there was much coming and going of messengers between Mesopotamia and Iran, far beyond Elam. There is also one mention of Gubla (Byblos) on the Mediterranean coast. Oddly enough, there is no evidence of any relations with Egypt, either in Ur III or in the Old Babylonian period. It is odd if no contacts existed at the end of the 3rd millennium between the two great civilizations of the ancient Near East.

Intellectual life at the time of Ur III must have been very active in the cultivation and transmission of older literature, as well as in new creations. Although its importance as a spoken tongue was diminishing, Sumerian still flourished as a written language, a state of affairs that continued into the Old Babylonian period. As shown by the hymn on the deified king, new literary genres arose in Ur III. If Old Babylonian copies are any indication, the king's correspondence with leading officials was also of a high literary level.

In the long view, the 3rd dynasty of Ur did not survive in historical memory as vigorously as did Akkad. To be sure, Old Babylonian historiography speaks of Ur III as *bala-Shulgi*, the "(reigning) cycle of Shulgi"; but there is nothing that would correspond to the epic poems about Sargon and Naram-Sin. The reason is not clear, but it is conceivable that the later, purely Akkadian population felt a closer identification with Akkad than with a state that to a large extent still made use of the Sumerian language.

*Ur III in decline.* The decline of Ur III is an event in Mesopotamian history that can be followed in greater detail than other stages of that history. There are some clear sources, such as the royal correspondence, two elegies on the destruction of Ur and Sumer, and an archive from Isin that shows how Ishbi-Erra, as usurper and king of Isin, eliminated his former overlord in Ur. Ibbi-Sin was waging war in Elam when an ambitious rival came forward in the person of Ishbi-Erra from Mari, presumably a general or high official. By emphasizing to the utmost the danger threatening from the Amorites, Ishbi-Erra urged the King to entrust to him the protection of the neighbouring cities of Isin and Nippur. Ishbi-Erra's demand came close to extortion, and his correspondence shows how skillfully he dealt with the Amorites and with individual *ensis*, some of whom soon went over to his side. Ishbi-Erra also took advantage of the depression that the King suffered because the god Enlil "hated him": a phrase presumably referring to bad omens resulting from the examination of sacrificed animals, on which procedure many rulers based their actions (or, as the case may be, their inaction). Ishbi-Erra fortified Isin and, in the 10th year of Ibbi-Sin's reign, began to employ his own dating formula on documents, an act tantamount to a renunciation of loyalty. Ishbi-Erra, on his part, believed himself to be the favourite of Enlil, the more so as he ruled over Nippur, where the god had his sanctuary. In the end, he claimed suzerainty over all of southern Mesopotamia, including Ur.

While Ishbi-Erra purposefully strengthened his domains, Ibbi-Sin continued for 14 more years to rule over a decreasing portion of the land. The end of Ur came about through a concatenation of misfortunes: a famine broke out; and Ur was besieged, taken, and destroyed by the invading Elamites and their allies among the Iranian tribes. Ibbi-Sin was led away captive, and no more was heard of him. The elegies record in moving fashion the unhappy end of Ur, the catastrophe that had been brought about by the wrath of Enlil.

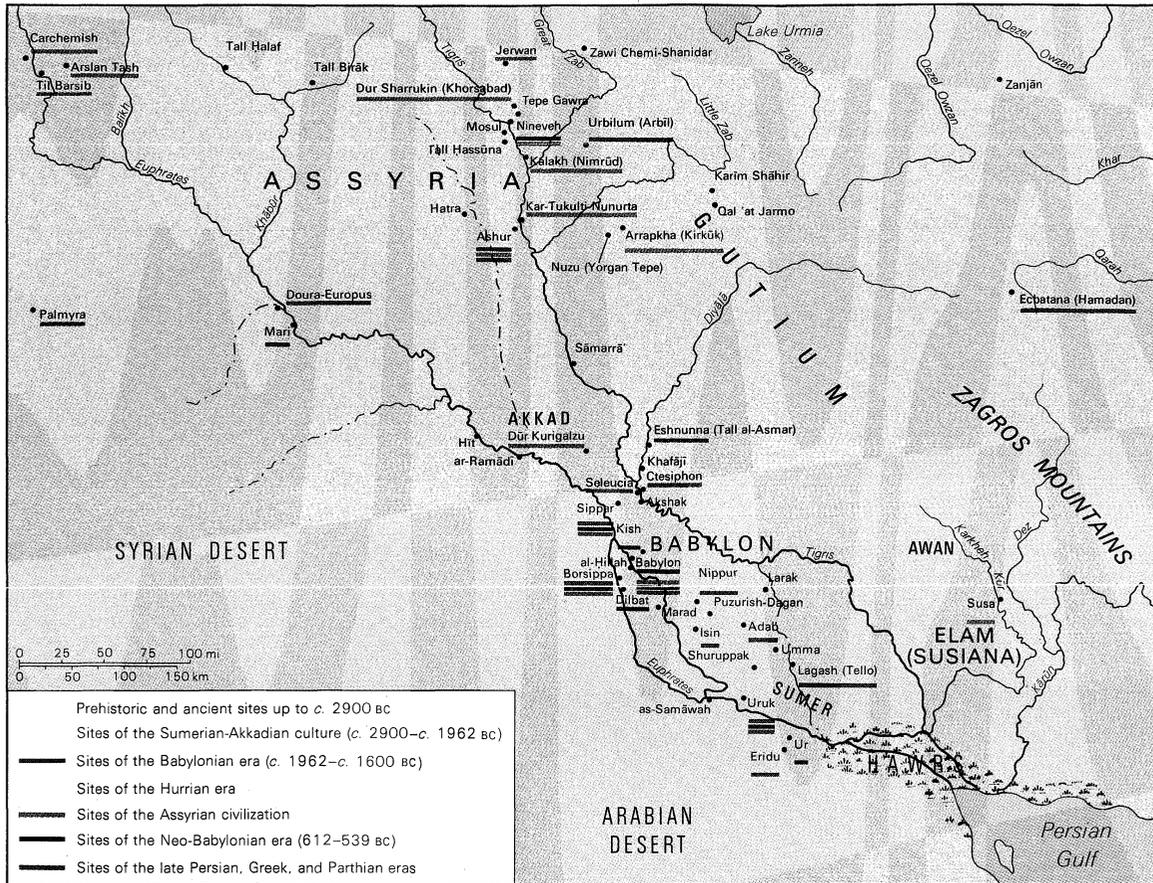

#### THE OLD BABYLONIAN PERIOD

*Isin and Larsa.* During the collapse of Ur III, Ishbi-Erra established himself in Isin and founded a dynasty there that lasted from 2017 to 1794; his example was fol-

The  
bureau-  
cracy

Literature  
of Ur III

Ur's end

Sites associated with ancient Mesopotamian history.

lowed elsewhere by local rulers, as in Der, Eshnunna, Sippar, Kish, and Larsa. In many localities an urge was felt to imitate the model of Ur; Isin probably took over unchanged the administrative system of that state. Ishbi-Erra and his successors had themselves deified, as did one of the rulers of Der on the Iranian border. For almost a century Isin predominated within the mosaic of states that were slowly re-emerging. Overseas trade revived after Ishbi-Erra had driven out the Elamite garrison from Ur, and under his successor, Shu-ilishu, a statue of the moon god Nanna, the city god of Ur, was recovered from the Elamites who had carried it off. Up to the reign of Lipit-Ishtar (c. 1934–c. 1924), the rulers of Isin so resembled those of Ur, so far as the King's assessment of himself in the hymns is concerned, that it seems almost arbitrary to postulate a break between Ishbi-Sin and Ishbi-Erra. As a further example of continuity it might be added that the Code of Lipit-Ishtar stands exactly midway chronologically between the Code of Ur-Nammu and the Code of Hammurabi. Yet it is much closer to the former in language and especially in legal philosophy than to Hammurabi's compilation of judgments. For example, the Code of Lipit-Ishtar does not know the *lex talionis* (or "an eye for an eye and a tooth for a tooth"), the guiding principle of Hammurabi's penal law.

**Political fragmentation.** It is probable that the definitive separation from Ur III came about through changing components of the population, from "Sumerians and Akkadians" to "Akkadians and Amorites." An Old Babylonian liver omen states that "He of the steppes will enter, and chase out the one in the city." This is indeed an abbreviated formula for an event that took place more than once: the usurpation of the king's throne in the city by the "sheikh" of some Amorite tribe. These usurpations were regularly carried out as part of the respective tribes became settled, although this was not so in the case of Isin because the house of Ishbi-Erra came from Mari and was of Akkadian origin, to judge by the rulers' names. By the same linguistic token the dynasty of Larsa was Amor-

ite. The fifth ruler of the latter dynasty, Gungunum (ruled c. 1932–c. 1906), conquered Ur and established himself as the equal and rival of Isin; at this stage—the end of the 20th century BC—if not before, Ur had certainly outlived itself. From Gungunum until the temporary unification of Mesopotamia under Hammurabi, the political picture was determined by the disintegration of the balance of power, by incessant vacillation of alliances, by the presumption of the various rulers, by the fear of encroachments by the Amorite nomads, and by increasingly wretched social conditions. The extensive archive of correspondence from the royal palace of Mari (c. 1810–1750) is the best source of information about the political and diplomatic game and its rules, whether honoured or broken: treaties, the dispatch and reception of embassies, agreements about the integration of allied armies, espionage, "situation reports" from "foreign" courts. Devoid of exaggeration or stylization, these letters, dealing as they do with everyday events, are preferable to the numerous royal inscriptions on buildings even when the latter contain historical allusions.

**Literary texts and increasing decentralization.** Another indirect but far from negligible source for the political and socio-economic situation in the 20th–18th centuries BC is the literature of omens. These are long compendiums in which the condition of a sheep's liver or some other divinatory object (for instance, the behaviour of a drop of oil in a beaker filled with water, the appearance of a newborn baby, and the shape of rising clouds of incense) are described at length and commented on with the appropriate prediction: "The king will kill his dignitaries and distribute their houses and property among the temples"; "A powerful man will ascend the throne in a foreign city"; "The land that rose up against its 'shepherd' will continue to be ruled by that 'shepherd'"; "The king will depose his chancellor"; and "They will lock the city gate and there will be a calamity in the city."

Beginning with Gungunum of Larsa, the texts allow greater insight into the private sector than in any other

The literature of omens as a source

previous period. There is a considerable increase in the number of private contracts and private correspondences. Especially frequent among the private contracts are those concluded about loans of silver or grain (barley), illustrating the common man's plight, especially when driven to seek out a creditor, the first step on a road that in many instances led to ruin. The rate of interest, murderously high at 20 percent in the case of silver and 33 percent in that of grain, increased further if the deadline for repayment, usually at harvest time, was not kept. Insolvency resulted in imprisonment for debt, slavery by mortgage, and the sale of children and even the debtor's own person. Many private letters contain entreaties for the release of family members from imprisonment at the creditor's hands. Yet considerable fortunes were also made, in "liquid" capital as well as landed property. As these tendencies threatened to end in economic disaster, the kings prescribed as a corrective the liquidation of debts, by way of temporary alleviation at least. The exact wording is known of one such decree from the time of Ammisaduqa of Babylon.

Until the Ur III period, the only archives so far recovered dealt with temples or the palace. But belonging to the Old Babylonian period, along with documents pertaining to civil law, were an increasing number of administrative records of privately managed households, inns, and farms: settlements of accounts, receipts, and notes on various transactions. Here was clearly a regular bourgeoisie, disposing of its own land and of means independent of temple and palace. Trade, too, was now chiefly in private hands; the merchant travelled (or sent his partners) at his own risk, not on behalf of the state. Among the civil-law contracts there was a substantial increase in records of land purchases. Also significant for the economic situation in the Old Babylonian era was a process that might be summarized as "secularization of the temples," even if all the stages of this development cannot be traced. The palace had probably possessed for centuries the authority to dispose of temple property, but, whereas Uru'inimgina of Lagash had still branded the tendency as leading to abuses, the citizen's relationship to the temple now took on individual traits. Revenues from certain priestly offices—benefices, in other words—went to private individuals and were sold and inherited. The process had begun in Ur, where the king bestowed benefices, although the recipients could not own them. The archives of the "canonesses" of the sun god of Sippar furnish a particularly striking example of the fusion of religious service and private economic interest. These women, who lived in a convent called *gagim*, came from the city's leading families and were not allowed to marry. With their property, consisting of land and silver, they engaged in a lively and remunerative business by granting loans and leasing out fields.

The tendency toward decentralization had begun in the Old Babylonian period with Isin. It concluded with the 72-year reign of the house of Kudur-Mabuk in Larsa (c. 1834–c. 1763). Kudur-mabuk, sheikh of the Amorite tribe of the Jamutbal, despite his Elamite name, helped his son Warad-Sin to secure the throne. This usurpation allowed Larsa, which had passed through a period of internal unrest, to flourish one more time. Under Warad-Sin and in the long reign of his brother Rim-Sin, large portions of southern Babylonia, including Nippur, were once again united in one state of Isin in 1794. Larsa on its part was conquered by Hammurabi in 1763.

**Early history of Assyria.** In contrast to southern Mesopotamia or the mid-Euphrates region (Mari), written sources in Assyria do not begin until very late, shortly before Ur III. By Assyria—a region that does not lend itself to precise geographical delineation—is understood the territory on the Tigris north of the river's passage through the mountains of the Jabal Ḥamrīn to a point north of Nineveh, as well as the area between Little and Great Zab (a tributary of the Tigris in northeast Iraq) and to the north of the latter. In the north, Assyria was later bordered by the mountain state of Urartu; to the east and southeast, its neighbour was the region around the old Nuzu (near modern Kirkūk, "Arrapachitis" [Ar-

rapkha] of the Greeks). In the early 2nd millennium the main cities of Assyria were Ashur (160 miles north-northwest of modern Baghdad), the capital (synonymous with the city god and national divinity); Nineveh, lying opposite modern Mosul; and Urbilum, the later Arbela (today Arbil, some 200 miles north of Baghdad).

In Assyria, inscriptions were composed in Akkadian from the beginning. Under Ur III, Ashur was the provincial capital. Assyria as a whole, however, is not likely to have been a permanently secured part of the empire, since two date formulas of Shulgi and Amar-Su'ena mention the destruction of Urbilum. Ideas of the population of Assyria in the 3rd millennium are necessarily very imprecise. It is not known how long Semitic tribes had been settled there. The inhabitants of southern Mesopotamia called Assyria Shubir in Sumerian and Subartu in Akkadian; these names may point to an older Subarean population that was related to the Hurrians. Gasur, the later Nuzu, belonged to the Akkadian language region about the year 2200 but was lost to the Hurrians in the first quarter of the 2nd millennium. The Assyrian dialect of Akkadian found in the beginning of the 2nd millennium differs strongly from the dialect of Babylonia. These two versions of the Akkadian language continue into the 1st millennium.

In contrast to the kings of southern Mesopotamia, the Assyrian rulers styled themselves, not king but partly *īššiakum*, in short, the Akkadian for the Sumerian word *ensi*, partly *rubā'um*, or "great one." Unfortunately, the rulers cannot be synchronized precisely with the kings of southern Mesopotamia before the Assyrian Shamshi-Adad I (c. 1813–c. 1781 BC). For instance, it has not yet been established just when Ilushuma's excursion into Babylon, recorded in an inscription, actually took place. Ilushuma boasts of having freed of taxes the "Akkadians and their children." While he mentions the cities of Nippur and Ur, the other localities listed were situated in the region east of the Tigris. The event itself may have taken place in the reign of Ishme-Dagan of Isin (c. 1953–c. 1935 BC), although how far Ilushuma's words correspond to the truth cannot be checked; in the Babylonian texts, at any rate, no reference is made to Assyrian intervention. The whole problem of dating is aggravated by the fact that the Assyrians did not, unlike the Babylonians, use date formulas that often contain interesting historical details; instead, every year was designated by the name of a high official (eponymic dating). The conscious cultivation of an old tradition is mirrored in the fact that two rulers of 19th-century Assyria called themselves Sargon and Naram-Sin, after famous models in the Akkadian dynasty.

Aside from the generally scarce reports on projected construction, there is at present no information about the city of Ashur and its surroundings. There is, however, unexpectedly rewarding source material from the Assyrian trading colonies in Asia Minor. The texts come mainly from Kanesh (near modern Kayseri, in southeast Turkey) and from Hattusas (also southeast Turkey), the later Hittite capital. In the 19th century BC three generations of Assyrian merchants engaged in a lively commodity trade (especially in textiles and metal) between the homeland and Anatolia, also taking part profitably in internal Anatolian trade. Like their contemporaries in southern Mesopotamia, they did business privately and at their own risk, living peacefully and occasionally intermarrying with the "Anatolians." As long as they paid taxes to the local rulers, the Assyrians were given a free hand.

It is obvious that these forays by Assyrian merchants led to some transplanting of Mesopotamian culture into Asia Minor. Thus the Anatolians adopted cuneiform writing and used the Assyrian language as a means of communication. While this influence doubtless already affected the first Hittites arriving in Asia Minor, a direct line from the period of these trading colonies to the Hittite Empire cannot yet be traced.

From c. 1813 to c. 1781 Assyria was ruled by Shamshi-Adad I, a contemporary of Hammurabi and a personality in no way inferior to him. Shamshi-Adad's father—an

Changing relationship between religious institutions and individuals

Language differences

Amorite, to judge by the name—had ruled near Mari. The son, not being of Assyrian origin, ascended the throne of Assyria as a foreigner and on a detour, as it were, after having spent some time as an exile in Babylonia. He had his two sons rule as viceroys, in Ekallatum on the Euphrates and in Mari, respectively, until the older of the two, Ishme-Dagan, succeeded his father on the throne. Through the archive of correspondence in the palace at Mari, scholars are particularly well informed about Shamshi-Adad's reign and many aspects of his personality. Shamshi-Adad's state had a common border for some time with the Babylonia of Hammurabi; in the west, it reached to the Mediterranean. Soon after Shamshi-Adad's death, Mari broke away, regaining its independence under an Amorite dynasty that had been living there for generations; in the end, Hammurabi conquered and destroyed Mari. After Ishme-Dagan's death, Assyrian history is lost sight of for over 100 years.

**The Old Babylonian Empire.** *Political fortunes.* Hammurabi (c. 1792–50 BC) is surely the most impressive and by now the most popular figure of the ancient Near East of the first half of the 2nd millennium BC. He owes his posthumous reputation to the great stele into which the “Code of Hammurabi” has been carved and indirectly also to the fact that his dynasty has made the name of Babylon famous for all time. In much the same way in which pre-Sargonic Kish exemplified the non-Sumerian area north of Sumer and Akkad lent its name to a country and a language, Babylon became the symbol of the whole country that the Greeks called Babylonia. This term has already been used anachronistically as a geographical concept in reference to the period before Hammurabi. Originally the city's name was probably Babilla, which was reinterpreted in popular etymology as Bab-ilu (Gate of the God).

The 1st dynasty of Babylon rose from insignificant beginnings. The history of the erstwhile province of Ur is traceable from about 1894 onward, when the Amorite Samu'abum came to power there. What is known of these events fits altogether into the modest proportions of the period when Mesopotamia was a mosaic of small states. Hammurabi played skillfully on the instrument of coalitions and became more powerful than his predecessors had been. But it was only in his 30th year, after his conquest of Larsa, that he gave concrete expression to the idea of ruling all of southern Mesopotamia by “strengthening the fundament of Sumer and Akkad,” in the words of that year's dating formula. In the prologue to the Code of Hammurabi the King lists the following cities as belonging to his dominions: Eridu near Ur, Ur, Lagash and Girsu, Zabalani, Larsa, Uruk, Adab, Isin, Nippur, Keshi, Dilbat, Borsippa, Babylon itself, Kish, Malgium, Mashkan-shapir, Kutha, Sippar, Eshnunna in the Diyālā region, Mari, Tuttul on the lower Balikh (a tributary of the Euphrates), and finally Ashur and Nineveh. This was on a scale reminiscent of Akkad or Ur III. Yet Ashur and Nineveh cannot have formed part of this empire for long because at the end of Hammurabi's reign mention is made again of wars against Subartu—that is, Assyria.

Decline of  
Babylonia  
under  
Samsuiluna

Under Hammurabi's son Samsuiluna (c. 1749–c. 1712 BC) the Babylonian Empire greatly shrank in size. Following what had almost become a tradition, the south rose up in revolt; Larsa regained its autonomy for some time, and the walls of Ur, Uruk, and Larsa were levelled to the ground. Eshnunna, which evidently had also seceded, was vanquished in c. 1730. Later chronicles mention the existence of a state in the Sealand, with its own dynasty; by “sealand” is understood the marshlands of southern Babylonia. Knowledge of this new dynasty is unfortunately very vague, only one of its kings being documented in contemporary texts. In c. 1741 Samsuiluna mentions the Kassites for the first time; in c. 1726 he constructed a stronghold, “Fort Samsuiluna,” as a bulwark against them on the Diyālā near its confluence with the Tigris.

Like the Gutians before them, the Kassites were at first prevented from entering Babylonia and pushed into the mid-Euphrates region; there, in the kingdom of Khana (centred on Mari and Terqa, both below the junction

with the Khābūr), a king appears with the Kassitic name of Kashtiliashu, who ruled toward the end of the Babylonian dynasty. From Khana the Kassites moved south in small groups, probably as harvest workers. After the Hittite invasion under Mursilis I, who is said to have de-throned Samsuditana, the last king of Babylon, in 1595, the Kassites assumed the royal power in Babylonia. So far, the contemporary sources do not mention this epoch, and the question arises as to how the Kassite rulers named in king lists mesh with the end of the 2nd millennium BC.

*Babylonian law.* The Code of Hammurabi is the most frequently cited cuneiform document in specialized literature. Its first scholarly examination in 1902 led to the development of a special branch of comparative jurisprudence, the study of cuneiform law. Following the division made by the first editor, Jean-Vincent Scheil, the Code of Hammurabi contains 280 judgments, or “paragraphs,” on civil and criminal law, dealing in the main with cases from everyday life in such a manner that it becomes obvious that the “lawgiver” or compiler had no intention of covering all possible contingencies. In broad outline, the themes treated in the Code of Hammurabi are: libel; corrupt administration of justice; theft, receiving stolen goods, robbery, looting, and burglary; murder, manslaughter, and bodily injury; abduction; judicature of tax lessees; liability for negligent damage to fields and crop damage caused by grazing cattle; illegal felling of palm trees; legal problems of trade enterprises, in particular, the relationship between the merchant and his employee travelling overland, and embezzlement of merchandise; trust monies; the proportion of interest to loan money; the legal position of the female publican; slavery and ransom, slavery for debt, runaway slaves, the sale and vindication of slaves, and disclaimer of slave status; the rent of persons, animals, and ships and their respective tariffs, offenses of hired labourers, and the vicious bull; family law: the price of a bride, dowry, the married woman's property, wife and concubine, and the legal position of the respective issue, divorce, adoption, the wet nurse's contract, and inheritance; and the legal position of certain priestesses.

A similar if much shorter compendium of judgments, probably antedating that of Hammurabi by a generation or two, has been discovered in Eshnunna.

Hammurabi, who called his own work *dīnāt mišarim*, or “verdicts of the just order,” states in the epilogue that it was intended as legal aid for persons in search of advice. It is nevertheless doubtful whether these judgments were meant to have binding force in the sense of modern statutes. The Code of Hammurabi differs in many respects from the Code of Lipit-Ishtar, which was written in Sumerian. Its most striking feature lies in the extraordinary severity of its penalties and in the principle of the *lex talionis*. The same attitude is reflected in various Old Babylonian treaties in which defaulters are threatened with bodily punishment. It is often said, and perhaps rightly so, that this severity, which so contrasts with Sumerian judicial tradition, can be traced back to the Amorite influence.

There is yet another way in which the Code of Hammurabi has given rise to much discussion. Many of its “paragraphs” vary according to whether the case concerns an *awilum*, a *muškēnum*, or a *wardum*. A threefold division of the populace had been postulated on the basis of these distinctions. The *wardum* is the least problematic of them all: he is the slave—that is, a person in bondage who could be bought and sold, unless he was able to regain his freedom under certain conditions as a debtor-slave. The *muškēnum* were, under King Hammurabi at least, persons employed by the palace who could be given land in usufruct without receiving it as property. *Awilum* were the citizens who owned land in their own right and depended neither on the palace nor the temple. As the scholar I.M. Diakonoff points out, the distinction cannot have been very sharply drawn because the classes *awilum* and *muškēnum* are not mutually exclusive: a man in high palace office could fairly easily purchase land as private property, whereas the free citizen who got into debt as a

The Code  
of  
Ham-  
murabi

result of a bad harvest or some other misfortune had one foot in the slave class. Still unanswered is the question as to which segment of the population could be conscripted to do public works, a term that included the levy in case of war.

Ammisaduqa (c. 1646–c. 1626 BC) comes a century and a half after Hammurabi. His edict, already referred to, lists, among others, the following social and economic factors: private debts in silver and grain, if arising out of loans, were cancelled; also cancelled were back taxes that certain officials owed the palace and that had to be collected from the people; the “female publican” had to renounce the collection of outstanding debts in beer and barley and was, in turn, excused from paying amounts of silver and barley to the king; taxes on leased property were reduced; debt slaves who had formerly been free (as against slaves made over from debtor to creditor) were ransomed; and high officials were forbidden on pain of death to press those who held property in fee into harvest work by prepayment of wages. The phrase “because the king gave the land a just order” serves as a rationale for many of these instances. In contrast to the “codes,” about whose binding force there is much doubt, edicts such as those of Ammisaduqa had legal validity since there are references to the edicts of other kings in numerous legal documents of the Old Babylonian period.

*Babylonian literature.* The literature and the literary languages of Babylonia during the three centuries following Ur III deserve attention. When commenting on literary and historical texts such as the inscriptions of the kings of Akkad, it was pointed out that these were not originals but copies of Old Babylonian vintage. So far, such copies are the main source for Sumerian literature. But, while the Old Babylonian period created much literature itself (royal hymns of the kings of Isin, Larsa, and Babylon and elegies), it was above all a time of intensive cultivation of traditional literature. The great Sumerian poems, whose origins or first written version, respectively, can now be traced back to about 2600, were copied again and again. After 2000, when Sumerian as a spoken language rapidly receded to isolated regions and eventually disappeared altogether, texts began to be translated, line by line, into Akkadian until there came to be bilingual versions. An important part of this, especially in the instructional program in schools, were the so-called lexicographic texts. Sumerian word lists are almost as old as cuneiform writing itself because they formed the perfect material for those learning to write. In the Old Babylonian period, the individual lexical entries were translated and often annotated with phonetic signs. This led to the creation of “dictionaries,” the value of which to the modern philologist cannot be exaggerated. Since Sumerian had to be taught much more than before, regular “grammatical treatises” also came into being: so far as it was possible, in view of the radically different structure of the two languages, Sumerian pronouns, verb forms, and the like were translated into Akkadian, including entire “paradigms” of individual verbs.

In belles-lettres, Sumerian still predominates, although there is no lack of Akkadian masterpieces, including the oldest Akkadian version of the *Epic of Gilgamesh*. The very high prestige still enjoyed by Sumerian should not be underestimated, and it continued to be used for inscriptions on buildings and the yearly dating formulas. Aside from being the language of practical affairs (letters and contracts), there was a high incidence of Akkadian in soothsaying and divinatory literature. To be sure, the Sumerians also practiced foretelling the future from the examination of animal entrails, but as far as is known they did not write down the results. In Akkadian, on the other hand, there are extensive and “scientifically” arranged compendiums of omens based on the liver (as well as other omens), reflecting the importance that the divination of the future had in religion, in politics, and in all aspects of daily life.

Judging by its continually more refined juridical thought, its ability to master in writing ever more complicated administrative procedures, its advanced knowledge of mathematics, and the fact that it marks the beginning

of the study of astronomy, the Old Babylonian period appears to have been a time of exceedingly active intellectual endeavour—despite, if not because of, its lack of political cohesiveness.

**The Hurrians.** The Hurrians enter the orbit of ancient Near Eastern civilization toward the end of the 3rd millennium BC. They arrived in Mesopotamia from the north or the east, but it is not known how long they had lived in the peripheral regions. There is a brief inscription in Hurrian language from the end of the period of Akkad, while that of King Arishen (or Atalshen) of Urkish and Nawar is written in Akkadian. The language of the Hurrians must have belonged to a widespread group of ancient Near Eastern languages. The relationship between Hurrian and Subarean has already been mentioned, and the language of the Urartians, who played an important role from the end of the 2nd millennium to the 8th century BC, is likewise closely related to Hurrian. Soviet scholars claim to be able to show that the “Veinakh” group of north-eastern Caucasian languages is an offspring of the Hurrian–Urartean group.

It is not known whether the migrations of the Hurrians ever took the form of aggressive invasion: 18th-century-BC texts from Mari speak of battles with the Hurrian tribe of Turukku south of Lake Urmia (some 150 miles from the Caspian Sea’s southwest corner); but these were mountain campaigns, not the warring off of an offensive. Proper names in cuneiform texts, increasing in the period of Ur III, constitute the chief criterion for the presence of Hurrians. Nevertheless, there is no clear indication that the Hurrians had already advanced west of the Tigris at that time. An entirely different picture results from the 18th-century palace archives of Mari and from texts originating near the upper Khābūr. Northern Mesopotamia, west of the Tigris, and Syria now appear settled by a population that is mainly Amorite and Hurrian; and the latter have already reached the Mediterranean littoral, as shown by texts from Alalakh on the Orontes. In Mari, literary texts in Hurrian have also been found, indicating that Hurrian had by now become a full-fledged written language as well.

The high point of the Hurrian period was not reached until about the middle of the 2nd millennium. In the 15th century, Alalakh was heavily Hurrianized; and in the empire of Mitanni the Hurrians represented the leading and perhaps the most numerous population group.

(D.O.E.)

## II. Mesopotamia from 1600 BC to AD 630

### THE KASSITES, THE MITANNI, AND THE RISE OF ASSYRIA

About 150 years after the death of Hammurabi, his dynasty was destroyed by an invasion of new peoples. Because there are hardly any written records of this era, the time from about 1600 BC to about 1450 BC (in some areas until 1400 BC) is called the dark ages. The remaining Semitic states, such as the state of Ashur, became minor states within the sphere of influence of the new states of the Kassites and the Hurrians-Mitanni. But the languages of the older cultures, the Akkadian and Sumerian, continued or were soon re-established. The cuneiform script persisted as the only type of writing in the entire area. Cultural continuity was not broken off, either, particularly in Babylonia. A matter of importance was the emergence of new Semitic leading classes from the ranks of the priesthood and the scribes. These gained increasing power.

**The Kassites in Babylonia.** The Kassites had settled by 1800 BC in what is now western Iran in the region of Hamadan-Kermanshah. The first to feel their forward thrust was Samsuiluna, who had to repel groups of Kassite invaders. Increasing numbers of Kassites gradually reached Babylonia and southern Mesopotamia. There they founded principalities, of which little is known. No inscription or document in the Kassite language has been preserved. Some 300 Kassite words have been found in Babylonian documents. Nor is much known about the social structure of the Kassites or their culture. There seems to have been no hereditary kingdom. Their religion was polytheistic; the names of 30 gods are known.

The people and the language of the Kassites

The beginning of Kassite rule in Babylonia cannot be dated exactly. A king called Agum II ruled over a state that stretched from western Iran to the middle part of the Euphrates Valley; 24 years after the Hittites had carried off the statue of the Babylonian god Marduk, he regained possession of the statue, brought it back, and renewed the cult, making the god Marduk the equal of the Kassitic equivalent god, Shuqamuna. Meanwhile, native princes continued to reign in southern Babylonia. It was Ulamburiash who finally annexed this area around 1450 and began negotiations with Egypt in Syria. Karaindash built a temple with bas-relief tile ornaments in Uruk (Erech) around 1420. A new capital west of Baghdad, Dur Kurigalzu, was named after Kurigalzu I (c. 1415–c. 1390). His successors Kadashman-Enlil I (c. 1390–c. 1375) and Burnaburiash II (c. 1375–c. 1347) were in correspondence with the Egyptian rulers Amenhotep III and Akhenaton (Amenhotep IV). They were interested in trading their lapis lazuli and other items for gold as well as in planning political marriages. Kurigalzu II (c. 1345–c. 1324) fought against the Assyrians but was defeated by them. His successors sought to ally themselves with the Hittites in order to stop the expansion of the Assyrians. During the reign of Kashtiliash IV (c. 1242–c. 1235), Babylonia waged war on two fronts at the same time—against Elam and Assyria—ending in the catastrophic invasion and destruction of Babylon by Tukulti-Ninurta I. Not until the time of the kings Adad-shum-nasir (c. 1218–c. 1189) and Melishipak (c. 1188–c. 1172) was Babylon again able to experience a period of prosperity and peace. Their successors were again forced to fight, facing the conqueror, King Shutruk-Nahhunte of Elam (c. 1185–c. 1155). Cruel and fierce, the Elamites finally destroyed the dynasty of the Kassites during these wars (about 1155). Some poetical works lament this catastrophe.

Babylonia  
under the  
Kassites

Letters and documents of the time after 1380 show that many things had changed after the Kassites took power. The Kassite upper class, always a small minority, had been largely babylonized. Babylonian names were to be found even among the royalty, and they predominated among the civil servants and the officers. The new feudal character of the social structure showed the influence of the Kassites. Babylonian town life had revived on the basis of commerce and handicrafts. The Kassitic nobility, however, maintained the upper hand in the rural areas, their wealthiest representatives holding very large landed estates. Many of these holdings came from donations of the king to deserving officers and civil servants, considerable privileges being connected with such grants. From the time of Kurigalzu II these were registered on stone tablets or, more frequently, on boundary stones. After 1200 the number of these increased substantially, because the kings needed a steadily growing retinue of loyal followers. The boundary stones had pictures in bas-relief, very often a multitude of religious symbols, and frequently detailed inscriptions giving the borders of the particular estate; sometimes the deserts of the recipient were listed and his privileges recorded; finally, trespassers were threatened with the most terrifying curses. Agriculture and cattle husbandry were the main pursuits on these estates, and horses were raised for the light war chariots of the cavalry. There was an export trade in horses and vehicles, in exchange for raw material.

The decline of the Babylonian culture at the end of the Old Babylonian period continued for some time under the Kassites. Not until approximately 1420 did the Kassites develop a distinctive style in architecture and sculpture. Kurigalzu I played an important part, especially in Ur, as a patron of the building arts. Poetry and scientific literature developed only gradually after 1400. The existence of earlier work is clear from poetry, philological lists, and collections of omens and signs that were in existence by the 14th century or before and have been discovered in the Hittite capital of Hattusas, in the Syrian capital of Ugarit, and even as far away as Palestine. Somewhat later, new writings appear—medical diagnoses and recipes, more Sumerian–Akkadian word lists, and collections of astrological and other omens and signs with

their respective interpretations. Most of these works are known today only from copies of more recent date. The most important of them all is the Babylonian epic of the creation of the world, *Enuma elish*. Composed by an unknown poet, in all probability in the 14th century, it tells the story of the god Marduk. He began as the god of Babylon and was elevated to be king over all other gods after having successfully accomplished the destruction of the powers of chaos. For almost 1,000 years this epic was recited during the new year's festival in the spring as part of the Marduk cult in Babylon. The literature of this time contains hardly any Kassitic words. Many scholars believe that the essential groundwork for the development of the subsequent Babylonian culture was laid during the later epoch of the Kassite era.

**Kingdom of the Hurrians and the Mitanni.** The weakening of the Semitic states in Mesopotamia after 1600 enabled the Hurrians to penetrate deeper into this region, where they founded numerous small states in the eastern parts of Asia Minor, Mesopotamia, and Syria. The Hurrians came from northwestern Iran, but their early history is almost unknown. After 1500, isolated dynasties appeared with Indo-Aryan names, but the significance of this is disputed. The fact that Old Indian technical terms appear in later records about horse breeding and that the names of Indian gods are used in some compacts of state led many scholars to assume that numerous groups of Aryans, closely related to the Indians, pushed into Asia Minor from the northeast. They were also credited with the introduction of the light war chariot with spoke wheels. This conclusion, however, is by no means established fact. So far it has not been possible to appraise the quantity and the political and cultural influence of the Aryans in Asia Minor relative to that of the Hurrians.

Shortly after 1500 the kingdom of the Mitanni arose near the sources of the Khābūr River in Mesopotamia. Since no record or inscription of their kings has been unearthed, there is hardly anything known about the development and history of the Mitanni before King Tushratta. The Mitanni were known to the Egyptians under the name of Naharina, and Thutmose III fought frequently against them after 1468 BC. By 1440 the domain of the Mitanni king Saustatar (Saushtar) stretched from the Mediterranean all the way to the Zagros Mountains, in western Iran, including Alalakh, in northern Syria, as well as Nuzu and Arrapkha. The northern boundary dividing the Mitanni from the Hittites and the Hurrians was in all probability not fixed even under his successors Artatama and Shuttarna II, who married their daughters to the pharaohs Thutmose IV (1425–1417) and Amenhotep III (1417–1379). Tushratta (c. 1390–c. 1340), the son of Shuttarna, was able to maintain the kingdom he had inherited from his predecessors for many years. In his sometimes very long letters to Amenhotep III and Akhenaton he writes about commerce, his desire for gold, and marriage. Weakened by internal strife, the Mitanni kingdom eventually became a pawn between the rising kingdoms of the Hittites and the Assyrians.

The kingdom of the Mitanni was a feudal state led by a warrior nobility of Aryan or Hurrian origin. Frequently horses were bred on their large landed estates. Documents and contract agreements in Syria often mention a chariot-warrior caste that also constituted the social upper class in the cities. The aristocratic families usually received their landed property as an inalienable fief. Consequently, no documents on the selling of landed property are to be found in the great archives of Akkadian documents and letters discovered in Nuzu, near Kirkūk. The prohibition against selling landed property was often dodged, however, with a stratagem: the previous owner "adopted" a willing buyer against an appropriate sum of money. The wealthy lord Tehiptilla was "adopted" almost 200 times, acquiring tremendous holdings of landed property in this way without interference by the governmental authorities. He had gained his wealth through trade and commerce and in agriculture. For a long time, a prince was in charge of the royal governmental administration in the district capital. Society was highly struc-

Empire  
of the  
Mitanni

tured in classes, ranks, and professions. The judiciary, patterned after the Babylonian model, was well organized; the documents place heavy emphasis on correct procedure.

Temple monuments of modest dimensions have been unearthed; in all probability, specific local traditions played a deciding factor in their design. The dead were probably buried outside the settlement. There is evidence that members of the royal family were cremated. Small artifacts, particularly seals, show a peculiar continuation of Babylonian and Assyrian traditions in their preference for the naturalistic representation of figures. There were painted ceramics with finely drawn decorations (white on a dark background). The strong position of the royal house was evident in the large palaces, existing even in district capitals. The palaces were decorated with frescoes. Because only a few settlements of the Mitanni have been unearthed in Mesopotamia, knowledge of the Mitanni arts and culture is as yet insufficient.

Assyria  
under  
Mitanni  
rule

**The rise of Assyria.** Very little can be said about northern Assyria during the 2nd millennium BC. Information on the old capital, Ashur, located in the south of the country, is somewhat more plentiful. The old lists of kings suggest that the same dynasty ruled continuously over Ashur from about 1670 on. All the names of the kings are given. But little else is known about Ashur before 1420. Almost all the princes had Akkadian names, and it can be assumed that their sphere of influence was rather small. Although Assyria belonged to the kingdom of the Mitanni for a long time, it seems that Ashur retained a certain autonomy. Located close to the boundary with Babylonia, it played that empire off against the Mitanni whenever possible. Puzur-Ashur III concluded a border treaty with Babylonia in 1490 as did Ashur-bel-nisheshu in 1415. Ashur-nadin-akhe II (c. 1402–c. 1393) was even able to obtain support from Egypt, which sent him a consignment of gold.

Ashur-uballit I (c. 1365–c. 1330) was at first subject to King Tushratta of the Mitanni. After 1350, however, he attacked Tushratta, presumably together with Suppiluliumas of the Hittites. Taking away from the Mitanni parts of northeastern Mesopotamia, Ashur-uballit I now called himself "Great King" and socialized with the King of Egypt on equal terms—arousing the indignation of the King of Babylonia. Ashur-uballit was the first to name Assyria the Land of Ashur, because the old name, Subartu, was often used in a derogatory sense in Babylonia. He ordered his short inscriptions to be partly written in the Babylonian language rather than the Assyrian, since this was considered refined. Marrying his daughter to a Babylonian, he intervened there energetically when Kassite nobles murdered his grandchild. Future generations came to consider him rightfully as the real founder of the Assyrian Empire. His son Enlil-nirari (c. 1328–c. 1320) also fought against Babylonia. Arik-den-ili (c. 1319–c. 1308) turned westward where he encountered Semitic tribes of the so-called Akhlamu-group.

Still greater successes were achieved by Adad-nirari I (c. 1307–c. 1275). Defeating the Kassite king Nazimarruttash, he forced him to retreat. After that he defeated the kings of the Mitanni, at first Shattuara I, then Wasashatta. This enabled him for a time to incorporate all of Mesopotamia into his empire as a province, although in later struggles he lost large parts to the Hittites. In the east, he was satisfied with the defense of his lands against the mountain people.

Adad-nirari's inscriptions were more elaborate than those of his predecessors and were written in the Babylonian language. In them he declares that he feels called to these wars by the gods, a statement that was to be repeated by other kings after him. Assuming the old title of great king, he called himself "King of All." He enlarged the temple and the palace in Ashur and also developed the fortifications there, particularly at the banks of the Tigris River. He worked on large building projects in the provinces.

His son Shalmaneser I (c. 1274–c. 1245) attacked Urartu (later called Urartu) in southern Armenia, which had allegedly broken away. But Shattuara II of Hanigalbat

put him into a difficult situation, cutting his forces off from their water supplies. With courage born of despair, the Assyrians fought themselves free. They then set about reducing what was left of the Mitanni kingdom into an Assyrian province. The king claimed to have blinded 14,400 enemies in one eye—psychological warfare of a similar kind was used more and more as time went by. The Hittites tried in vain to save Hanigalbat. Together with the Babylonians they fought a commercial war against Ashur for many years. Like his father, Shalmaneser was a great builder. At the juncture of the Tigris and the Great Zab rivers he founded a strategically situated second capital, Kalakh (biblical Calah; modern Nimrud).

His son was Tukulti-ninurta (c. 1244–c. 1208), the Ninos of Greek legends. Gifted but extravagant, he made his nation a great power. He carried off thousands of Hittites from eastern Anatolia. He fought particularly hard against Babylonia, deporting Kashtiliash IV to Assyria. When the Babylonians rebelled again, he plundered the temples in Babylon, an act regarded as a sacrilege, even in Assyria. The relationship between the king and his capital deteriorated steadily. For this reason the king began to build a new city, Kar-Tukulti-Ninurta, on the other side of the Tigris River. Ultimately, even his sons rebelled against him and laid siege to him in his city; in the end he was murdered. His victorious wars against Babylonia were glorified in an epic poem, but his empire broke up soon after his death. Assyrian power declined for a time, while that of Babylonia rose.

Assyria had suffered under the oppression of both the Hurrians and the Mitannis. Its struggle for liberation and the bitter wars that followed had much to do with its development into a military power. In his capital of Ashur, the king depended on the citizen class and the priesthood, as well as on the landed nobility that furnished him with the war-chariot troops.

Documents and letters show the important role agriculture played in the development of the state. Assyria was less dependent on artificial irrigation than was Babylonia. The breeding of horses was carried on intensively; remnants of elaborate directions for their training are extant. Trade and commerce were also of notable significance: metals were imported from Asia Minor or Armenia, tin from northwestern Iran, and lumber from the west. The opening up of new trade routes was oftentimes a cause and the purpose of war.

Assyrian architecture, derived from a combination of Mitannian and Babylonian influences, developed early quite an individual style. The palaces often had colourful wall decorations. The art of seal cutting, taken largely from the Mitanni, continued creatively on its own. The schools for scribes, where all the civil servants were trained, taught both the Babylonian and the Assyrian dialects of the Akkadian tongue. Babylonian works of literature were assimilated into Assyrian, often reworked into a partially different form. The Hurrian tradition remained strong in the military and political sphere while at the same time influencing the language.

#### ASSYRIA AND BABYLONIA AT THE END OF THE 2ND MILLENNIUM

**Babylonia under the 2nd dynasty of Isin (c. 1156–c. 1025).** In a series of heavy wars about which not much is known, Marduk-kabit-akhesu (c. 1156–c. 1139) established what came to be known as the 2nd dynasty of Isin. His successors were often forced to continue the fighting. The most famous king of the dynasty was Nebuchadrezzar I (c. 1124–c. 1103). He fought mainly against Elam, which had conquered most of Babylonia. His first attack miscarried because of an epidemic among his troops, but in a later campaign he conquered Susa, the capital of Elam, and returned the previously stolen statue of the god Marduk to its proper place. Soon thereafter the king of Elam was assassinated, and his kingdom fell apart into small states. This enabled Nebuchadrezzar to turn west, using the later years of peace to complete extensive building projects. After him, his son became king, succeeded by his brother Marduk-nadin-ahhe (c. 1098–c. 1081). At first successful in his wars against

Organiza-  
tion of  
the  
Assyrian  
state

Assyria, he later experienced heavy defeat. A famine of catastrophic proportions triggered an attack from Aramaean tribes, the ultimate blow. His successors made peace with Assyria, but the country suffered more and more from repeated attacks by Aramaeans and other Semitic nomads. Even though some of the kings still had grand titles, they were unable to stem the progressive disintegration of their empire. There followed the era known as the 2nd dynasty of the Sealand (c. 1024–c. 1004), which included three usurpers. The first of these had the Kassitic name of Simbar-shikhu (c. 1024–c. 1007).

Toward the end of its reign, the dynasty of the Kassites became completely babylonized. The changeover to the dynasty of Isin, actually a succession of kings from different families, brought no essential transformation of the social structure. The feudal order remained. New landed estates came into existence in many places through grants to deserving officers; many boundary stones (*kudurru*) have been found that describe them. The cities of Babylonia retained much of their former autonomy. The border provinces, however, were administered by royally appointed governors with civil and military functions.

This was a period of creativity in the literary arts. The successes of Nebuchadnezzar I provided new material. One heroic epic, modelled upon older epics, celebrates his deeds, but unfortunately little of this is extant. Other material came from ancient myths. The best known poet is Sinleqeunnini (c. 1100–?) of Uruk (Erech), the poet of the later version of the *Epic of Gilgamesh* known as the Twelve-Tablet Poem. This version is distinguished by its greater stress on the human qualities of Gilgamesh and Enkidu, making it one of the great works of world literature. Another poet working at about the same time was the author of verses meditating on the workings of divine justice, a matter that had acquired vital importance in the contemporary religion of Babylon. This poem elaborates on the great suffering of a high official and his subsequent salvation by the god Marduk. Other religious poems have been preserved, but their time of origin is not certain. The later Babylonians with good reason regarded the time of Nebuchadnezzar I as one of the great eras of their history.

**Assyria between 1200 and 1000.** After a period of decline following Tukulti-Ninurta I, Assyria was consolidated and stabilized under Ashur-dan I (c. 1179–c. 1134) and Ashur-resh-ishi I (c. 1133–c. 1116). Several times forced to fight against Babylonia, the latter was even able to defend himself against an attack by Nebuchadnezzar I. According to the inscriptions, most of his building efforts were in Nineveh, rather than in the old capital of Ashur.

His son Tiglath-pileser I (Tukulti-apal-Esharra, c. 1115–c. 1077) raised the power of Assyria to new heights. First he turned against a large army of the Mushki that had entered into southern Armenia from Asia Minor, defeating them decisively. After this he forced the small Hurrian states of southern Armenia to pay him tribute. Trained in mountain warfare themselves and helped by capable pioneers, the Assyrians were now able to advance far into the distant valleys of the interior. Their main enemies were the Aramaeans, the Semitic camel Bedouins whose many small states often combined against the Assyrians. Tiglath-pileser I also went to Syria and even reached the Mediterranean, where he took a sea voyage. After 1100 these campaigns led to conflicts with Babylonia. Tiglath-pileser conquered northern Babylonia and plundered Babylon, without decisively defeating Marduk-nadin-ahhe. In his own country the King paid particular attention to agriculture and fruit growing, improved the administrative system, and developed more thorough methods of training scribes.

Three of his sons reigned after Tiglath-pileser, including Ashur-bel-kala (c. 1074–c. 1057). Like his father, he fought in southern Armenia and with Babylonia as his ally, against the Aramaeans. Disintegration of the empire could not be arrested, however. The grandson of Tiglath-pileser, Ashurnasirpal I (c. 1050–c. 1032), was sickly and unable to do more than defend Assyria proper against his enemies. Fragments of three of his prayers

to the goddess Ishtar are preserved; among them is a penitential prayer in which he wonders about the cause of so much adversity. Referring to his many good deeds but admitting his guilt at the same time, he asks for forgiveness and health. According to the king, part of his guilt lay in neglecting to teach his subjects the fear of god in sufficient measure. After him, little is known for 100 years.

State and society during the time of Tiglath-pileser were not essentially different from those of the 13th century. Collections of laws, drafts, and edicts of the court exist that go back as far as the 14th century BC. Presumably, most of these remained in effect. One tablet defining the marriage laws shows that the social position of women in Assyria was lower than in Babylonia or Israel or among the Hittites. A man was allowed to send away his wife at his own pleasure with or without divorce money. In case of adultery, he was permitted to kill or maim her. Outside of her house the woman was forced to observe many restrictions, such as the wearing of a veil. It is not clear whether these regulations carried the weight of law, but they seem to have represented a reaction against practices that were more favourable to women. Two somewhat older marriage contracts, for example, grant equal rights to both partners, even in divorce. The women of the king's harem were subject to severe punishment, including beating, maiming, and death, along with those who guarded and looked after them. The penal laws of the time were generally more severe in Assyria than in other countries of the East. The death penalty was not uncommon. In less serious cases the penalty was forced labour after flogging. In certain cases there was trial by ordeal. One tablet treats the subject of landed property rights. Offenses against the established boundary lines called for extremely severe punishment. A creditor was allowed to force his debtor to work for him, but he could not sell him.

The greater part of Assyrian literature was either taken over from Babylonia or written by the Assyrians in the Babylonian dialect, who modelled their works upon Babylonian originals. The Assyrian dialect was used in legal documents, court and temple rituals, and collections of recipes—as, for example, in directions for manufacturing perfumes. A new art form was the picture tale: a continuing series of pictures carved on square steles of stone. The pictures, showing war or hunting scenes, begin at the top of the stele and run down around it, with inscriptions under the pictures explaining them. These and the finely cut seals show that the fine arts of Assyria were beginning to surpass those of Babylonia. Architecture and other forms of the monumental arts also began a further development, such as the double temple with its two towers (*ziggurat*). Colourful, enamelled tiles were used to decorate the façades.

#### ASSYRIA AND BABYLONIA C. 1000–750 BC

**Assyria and Babylonia until Ashurnasirpal II.** The most important factor in the history of Mesopotamia in the 10th century was the continuing threat from the Aramaean seminomads. Again and again, the kings of both Babylonia and Assyria were forced to repel their invasions. Even though the Aramaeans were not able to gain a foothold in the main cities, there are evidences of them in many rural areas. Ashur-dan II (934–912) succeeded in suppressing the Aramaeans and the mountain people, in this way stabilizing the Assyrian boundaries. He was the first to use the Assyrian dialect in his written records.

Adad-nirari II (c. 911–891) left very detailed accounts of his wars and his efforts to improve agriculture. He led six campaigns against Aramaean intruders from northern Arabia. In two campaigns against Babylonia he forced Shamash-mudammîq (about 930–904) to surrender extensive territories. Shamash-mudammîq was murdered, and a treaty with his successor, Nabu-shum-ukin (904–888) secured peace for many years. Tukulti-Ninurta II (890–884), the son of Adad-nirari II, reigned only for a short time. He preferred Nineveh to Ashur. His wars led him to southern Armenia. He was portrayed on steles in blue–yellow enamel in late Hittite style, showing

nirari II

him under the winged sun—a theme adopted from Egyptian art. His son Ashurnasirpal II (883–859) continued the policy of conquest and expansion. He left a very detailed account of his campaigns, which were impressive in their cruelty. Defeated enemies were impaled, flayed, or beheaded in great numbers. But mass deportations were found to serve the interests of the growing empire better than terror. Through the systematic exchange of native populations, conquered regions were denationalized. The result was a servile, submissive, mixed population in which the Aramaean element became the preponderant majority. This provided the labour force for the various public works in the metropolitan centres of the Assyrian Empire. Ashurnasirpal II rebuilt Kalakh, founded by Shalmaneser I, and made it his capital. Ashur remained the centre of the worship of the god Ashur—in whose name all the wars of conquest were fought. A third capital was Nineveh.

The reign  
of  
Ashur-  
nasirpal II

Ashurnasirpal II was the first to use cavalry units to any large extent in addition to infantry and war-chariot troops. He was also the first to employ heavy, mobile battering rams and wall breakers in his sieges. Following after the conquering troops came officials from all branches of the civil service, because the king wanted to lose no time in incorporating the new lands into his empire. The supremacy of Assyria over its neighbouring states owed much to the proficiency of the government service under the leadership of the minister Gabbilani'ersh. The campaigns of Ashurnasirpal II lead him mainly to southern Armenia and Mesopotamia. After a series of heavy wars, he incorporated Mesopotamia as far as the Euphrates River. A campaign to Syria encountered little resistance. There was no great war against Babylonia. Ashurnasirpal, like other Assyrian kings, may have been moved by religion not to destroy Babylonia, which had almost the same gods as Assyria. Both empires must have profited from mutual trade and cultural exchange. The Babylonians, under the energetic Nabu-apal-iddin (c. 887–855) attacked the Aramaeans in southern Mesopotamia and occupied the valley of the Euphrates River to about the mouth of the Khābūr River.

Ashurnasirpal, so brutal in his wars, was able to inspire architects, structural engineers, and artists and sculptors to heights never before achieved. He built and enlarged temples and palaces in several cities. His most impressive monument was his own palace in Kalakh, covering a space of 25,000 square metres (269,000 square feet). Hundreds of large limestone slabs were used in murals in the state rooms and living quarters. Most of the scenes were done in relief, but painted murals have also been found. Most of them depict mythological themes and symbolic fertility rites, with the king participating. Brutal war pictures were aimed to discourage enemies. The chief god of Kalakh was Ninurta, god of war and the hunt. The tower of the temple dedicated to Ninurta served also as an astronomical observatory. Kalakh soon became the cultural centre of the empire. Ashurnasirpal claimed to have entertained 69,574 guests at the opening ceremonies of his palace.

**Shalmaneser III and Shamshi-Adad V of Assyria.** The son and successor of Ashurnasirpal was Shalmaneser III (858–824). His father's equal in both brutality and energy, he was less realistic in his undertakings. His inscriptions, in a peculiar blend of Assyrian and Babylonian, record his considerable achievements but are not always able to conceal his failures. His campaigns were directed mostly against Syria. While he was able to conquer northern Syria and make it a province, in the south he could only weaken the strong state of Damascus and was unable, even after several wars, to eliminate it. In 841 he laid unsuccessful siege to Damascus. Also in 841 King Jehu of Israel was forced to pay tribute. In his invasion of Cilicia, Shalmaneser had only partial success. The same was true of the kingdom of Urartu in Armenia, from which, however, the troops returned with immense quantities of lumber and building stones. The king and, in later years, the general Daian-Ashur, went several times to western Iran, where they found such states as Mannai in northwestern Iran and, further away in the

Conquest  
of  
northern  
Syria

southeast, the Persians. They also encountered the Medes during these wars. Horse tribute was collected.

In Babylonia, Marduk-zakir-shumi I ascended the throne around the year 855. His brother Marduk-bel-usate rebelled against him, and in 851 the king was forced to ask Shalmaneser for help. Shalmaneser was only too happy to oblige; when the usurper had been finally eliminated (850), Shalmaneser went to southern Babylonia, which at that time was almost completely dominated by Aramaeans. There he encountered, among others, the Chaldeans, mentioned for the first time in 878 BC, who were to play a leading role in the history of later times; Shalmaneser made them tributaries.

During his long reign he built temples, palaces, and fortifications in Assyria as well as in the other capitals of his provinces. His artists created many statues and steles. Among the best known is the Black Obelisk, which includes a picture of Jehu of Israel paying tribute. The bronze doors of Imgur-Enlil in Assyria portray the course of his campaigns and other undertakings in rows of pictures, often very lifelike. Hundreds of delicately carved ivories were carried away from Phoenicia, and many of the artists along with them; these later made Kalakh a centre for the art of ivory sculpture.

In the last four years of the reign of Shalmaneser, the crown prince Ashur-danin-apal led a rebellion. The old King appointed his younger son Shamshi-Adad as the new crown prince. Forced to flee to Babylonia, Shamshi-Adad V (823–811) finally managed to regain the kingship with the help of Marduk-zākir-shumi I under humiliating conditions. As king he campaigned with varying success in southern Armenia and Azerbaijan, later turning against Babylonia. He won several battles against the Babylonian kings Marduk-balassu-iqbi and Baba-ahaididdina (about 818–12) and pushed through to Chaldea. Babylonia remained independent, however.

**Adad-nirari III and his successors.** Shamshi-Adad V died while Adad-nirari III (810–783) was still a minor. His Babylonian mother, Sammu-ramat, took over the regency, governing with great energy until 806. The Greeks, who called her Semiramis, credited her with legendary accomplishments, but historically little is known about her. Adad-nirari later led several campaigns against the Medes and also against Syria and Palestine. In 804 he reached Gaza, but Damascus proved invincible. He also fought in Babylonia, helping to restore order in the north.

Shalmaneser IV (c. 783–773) fought against Urartu, then at the height of its power under King Argishti (about 780–755). He successfully defended eastern Mesopotamia against attacks from Armenia. On the other hand, he lost most of Syria after a campaign against Damascus in 773. The reign of Ashur-dan III (772–755) was shadowed by rebellions and by epidemics of plague. Of Ashur-hirari V (754–746) little is known.

In Assyria, the feudal structure of society remained largely unchanged. Many of the conquered lands were combined to form large provinces. The governors of these provinces sometimes acquired considerable independence, particularly under the weaker monarchs after Adad-nirari III. Some of them even composed their own inscriptions. The influx of displaced peoples into the cities of Assyria created large metropolitan centres. The spoils of war, together with an expanding trade, favoured the development of a well-to-do commercial class. The dense population of the cities gave rise to social tensions that only the strong kings were able to contain. A number of the former capitals of the conquered lands remained important as capitals of provinces. There was much new building. A standing occupational force was needed in the provinces, and these troops grew steadily in proportion to the total military forces. The civil service also expanded, the largest administrative body being the royal court, with thousands of functionaries and craftsmen in the several residential cities.

The cultural decline around the year 1000 was overcome during the reigns of Ashurnasirpal II and Shalmaneser III. The arts in particular experienced a tremendous resurgence. Literary works continued to be written in

Assyrian and were seldom of great importance. The literature that had been taken over from Babylonia was further developed with new writings, although one can rarely distinguish between works written in Assyria and works written in Babylonia. In religion, the official cults of Ashur and Ninurta continued, while the religion of the common people went its separate way.

In Babylonia, not much was left of the feudal structure; the large landed estates almost everywhere fell prey to the inroads of the Aramaeans, who were at first half nomadic. The leaders of their tribes and clans slowly replaced the former landlords. Agriculture on a large scale was no longer possible except on the outskirts of metropolitan areas. The predominance of the Babylonian schools for scribes may have prevented the emergence of an Aramaean literature. In any case, the Aramaeans seem to have been absorbed into the Babylonian culture. The religious cults in the cities remained essentially the same. The Babylonian Empire was slowly reduced to poverty, except perhaps in some of the cities. In 764, after an epidemic, the myth of pest god Erra was written by the poet Kabt-ilani-Marduk.

#### THE NEO-ASSYRIAN EMPIRE (746-609)

**Tiglath-pileser III and Shalmaneser V.** The decline of Assyrian power after 780 was notable; Syria and considerable lands in the north were lost. A military coup deposed king Ashur-nirari V and raised a general to the throne. Under the name of Tiglath-pileser III (746-727) he brought the empire to its greatest expanse. He reduced the size of the provinces in order to break the independence of the governors. He also invalidated the tax privileges of cities such as Ashur and Haran, in order to distribute the tax load more evenly over the entire realm. Military equipment was improved substantially. In 746 he went to Babylonia to aid Nabu-nasir (747-734) in his fight against Aramaean tribes. Tiglath-pileser beat the Aramaeans and then made visits to the large cities of Babylonia. Here he tried to get the support of the priesthood by patronizing their building projects. Babylonia retained its independence.

His next undertaking was to throw back Urartu. His campaigns in Azerbaijan were designed to drive a wedge between Urartu and the Medes. In 743 he went to Syria, defeating there an army of Urartu. The Syrian city of Arpad, which had formed an alliance with Urartu, did not surrender so easily. It took Tiglath-pileser three years of siege to conquer Arpad, whereupon he massacred the inhabitants and destroyed the city. In 738 a new coalition formed against Assyria under the leadership of Samal of northern Syria. It was defeated, and all the princes from Damascus to eastern Anatolia were forced to pay tribute. Another campaign in 735, this time directed against Urartu itself, was only partly successful. In 734 Tiglath-pileser invaded Palestine, going as far as the Egyptian border. Damascus and Israel tried to organize resistance against him, seeking to bring Judah into their alliance. But Ahaz of Judah asked Tiglath-pileser for help. In 733 Tiglath-pileser devastated Israel and forced it to surrender large territories. In 732 he advanced upon Damascus, first devastating the gardens outside the city and then conquering the capital and killing the king, whom he replaced with a governor. The Queen of southern Arabia, Samsia, was now obliged to pay tribute, being permitted in return to use the harbour of the city of Gaza, which was in Assyrian hands.

The death of King Nabonassar of Babylonia caused a chaotic situation to develop there, and the Aramaean Ukin-zer crowned himself king. In 731 Tiglath-pileser fought and beat him and his allies, but he did not capture Ukin-zer until 729. This time he did not appoint a new king for Babylonia but assumed the crown himself under the name Pulu (Pul in the Old Testament). In his old age he abstained from further campaigning, devoting himself to the improvement of his capital Kalakh. He rebuilt the palace of Shalmaneser III, filled it with treasures from his wars, and decorated the walls with bas-reliefs. The latter were almost all of warlike character, as if designed to intimidate the onlooker with their presentation of grue-

some executions. These pictorial narratives on slabs have also been found in several provincial capitals of Assyria.

Tiglath-pileser was succeeded by his son Shalmaneser V (726-722), who continued the policy of his father. As king of Babylonia he called himself Ululai. Almost nothing is known about his enterprises, since his successor destroyed all his inscriptions. The Old Testament relates that he marched against Hoshea of Israel in 724 after Hoshea had rebelled. He was probably assassinated during a three-year siege of Samaria. His successor maintained that the god Ashur had withdrawn his support of Shalmaneser V for acts of disrespect.

**Sargon II (721-705) and Marduk-apal-iddina of Babylonia.** It was probably a younger brother of Shalmaneser who ascended the throne of Assyria. Assuming the old name of Sharru-kin (Sargon in the Bible), meaning Legitimate King, he assured himself of the support of the priesthood and the merchant class by restoring privileges they had lost, particularly the tax exemptions of the great temples. The change of sovereign in Assyria triggered another crisis in Babylonia. An Aramaean prince from the south, Marduk-apal-iddina II (the biblical Mero-dach-Baladan), seized power in Babylon in 721 and was able to retain it until 710 with the help of Humbanigash I of Elam. A first attempt by Sargon to recover Babylonia miscarried when Elam defeated him in 721. During the same year the three-year siege of Samaria was brought to a close. The Samarian upper class was deported, and Israel became an Assyrian province. Samaria was repopulated with Syrians and Babylonians. Judah remained independent by paying tribute. In 720 Sargon squelched a rebellion in Syria that had been supported by Egypt. Then he defeated both Hanunu of Gaza and an Egyptian army near the Egyptian border. In 717 and 716 he campaigned in northern Syria, making the hitherto independent state of Carchemish one of his provinces. He also went to Cilicia in an effort to prevent further encroachments of the Phrygians under their king Midas.

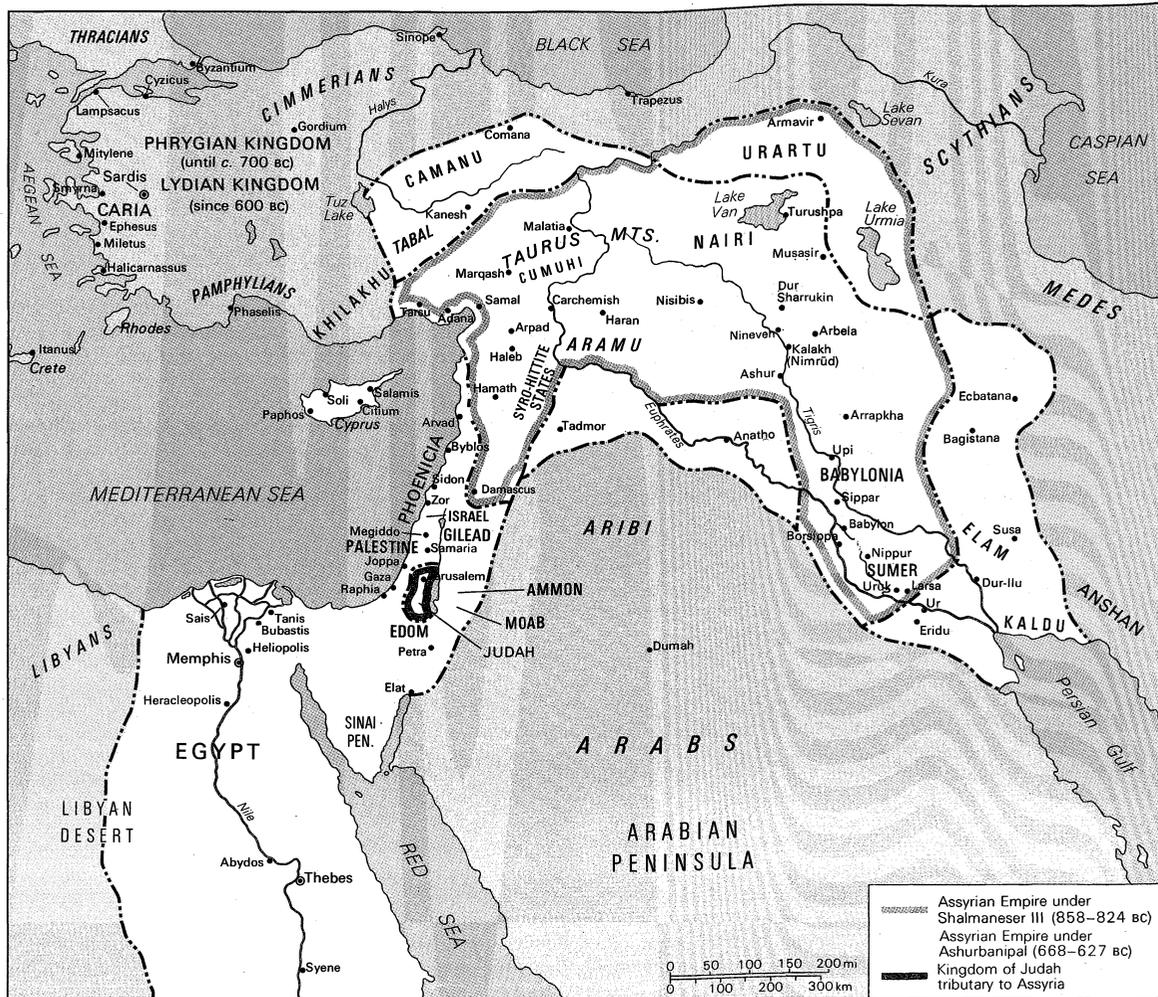

In order to protect his ally, the state of Mannai, in Azerbaijan, Sargon embarked on a campaign in Iran in 719 and incorporated parts of Media as provinces of his empire. But in 716 another war became necessary. At the same time, he was busy preparing a major attack against Urartu. Under the leadership of the crown prince Sennacherib, armies of agents infiltrated Urartu, which was also threatened from the north by the Cimmerians. Many of their messages and reports have been preserved. The longest inscription ever composed by the Assyrians about a year's enterprise (430 very long lines) is dedicated to this Urartu campaign of 714. Phrased in the style of a first report to the god Ashur, it is interlaced with stirring descriptions of natural scenery. The strong points of Urartu must have been well fortified. Sargon tried to avoid them by going through the province of Mannai and attacking the Median principalities on the eastern side of Lake Urmia. In the meantime, hoping to surprise the Assyrian troops, Rusas of Urartu had closed the narrow pass lying between Lake Urmia and Sahand Mount. Sargon, anticipating this, led a small band of cavalry in a surprise charge that developed into a great victory for the Assyrians. Rusas fled and died. The Assyrians pushed forward, destroying all the cities, fortifications, and even irrigation works of Urartu. They did not conquer Mannai itself but took possession of the mountain city of Muşaşir. The spoils were immense. The following years saw only small campaigns in Media, eastern Asia Minor, and against Ashdod, in Palestine. King Midas of Phrygia and some cities on Cyprus were quite ready to pay tribute.

Sargon was now free to settle accounts with Marduk-apal-iddina of Babylonia. Abandoned by his ally Shurruk-Nahhunte II of Elam, Marduk-apal-iddina found it best to flee: first to his native land on the Persian Gulf and later to Elam. Because the Aramaean prince had made himself very unpopular with his subjects, Sargon was hailed as the liberator of Babylonia. He complied with the wishes of the priesthood while at the same time putting down the Aramaean nobility. The modest title of governor of Babylonia was enough for him.

At first Sargon resided in Kalakh, but he then decided to

### The founding of Dur Sharrukin

found an entirely new capital north of Nineveh. He called the city Dur Sharrukin—Sargonsburg (now Khorsabad). He erected his palace on a high terrace in the northeastern part of the city. The temples to the main gods, smaller in size, were built within the palatial rectangle, which was surrounded by a special wall. This arrangement enabled Sargon to supervise the priests better than had been possible in the old, large temple complexes. One consequence of this design was that the figure of the king pushed the gods somewhat into the background, thereby gaining in importance. Wanting his palace to match the vastness of his empire, the King planned it in monumental dimensions. Stone reliefs of two winged bulls with human heads flanked the entrance—much larger than anything comparable built before. The walls were decorated with long rows of bas-reliefs showing scenes of war and festive processions. A comparison with a well-executed stele of the Babylonian king Marduk-apal-iddina shows that the fine arts of Assyria had far surpassed those of Babylonia. Sargon never completed his capital, though from 713 to 705 BC tens of thousands of labourers and hundreds of artisans worked upon the great city. Yet, with the exception of some magnificent buildings for public officials, only a few durable edifices were completed in the residential section. In 705, in a campaign in northwestern Iran, the King was ambushed and killed. His corpse remained unburied, food for birds of prey. His son Sennacherib, who had quarrelled with his father, was inclined to believe with the priests that the death of the King was a punishment from the gods.

**Sennacherib.** Sennacherib (Assyrian Sin-akhkhe-eriba; 704–681) was well prepared for his position as sovereign. With him Assyria acquired an exceptionally clever and

gifted, though often extravagant, ruler. His father, interestingly enough, is not mentioned in any of his many inscriptions. He left the new city of Dur Sharrukin at once and resided in Ashur for a few years, until in 701 he made Nineveh his capital.

Sennacherib had considerable difficulty with Babylonia. In 703 Marduk-apal-iddina again crowned himself king with the aid of Elam, proceeding at once to ally himself with other enemies of Assyria. After nine months he was forced to withdraw when Sennacherib defeated a coalition army consisting of Babylonians, Aramaeans, and Elamites. The new puppet king of Babylonia was Bel-ibni (702–700), who had been raised in Assyria.

In 702 Sennacherib undertook a predatory raid into western Iran, then moved against Syria and Palestine in 701 to smash a coalition of Phoenicians, Palestinians, and Egyptians. Sidon immediately expelled its ruler, who was hostile to Assyria. The other allies surrendered or were beaten. One Egyptian army was defeated at Eltekeh. Only Hezekiah of Judah did not surrender, fearing grave judgment and retribution. Failing in their efforts to incite the people of Jerusalem against their king, the Assyrians laid siege to the city. The Old Testament relates these events in great detail. The most likely reconstruction of events is that, when an epidemic broke out among the Assyrian troops during the siege of Jerusalem, Sennacherib found it advisable to return to Assyria. In the course of time several generations of storytellers in Judah swelled the number of Assyrian dead to 185,000. Hezekiah nevertheless paid tribute to Nineveh.

Bel-ibni of Babylonia seceded from the union with Assyria in 700. Sennacherib moved quickly, defeating Bel-ibni and replacing him with Sennacherib's oldest son, Ashur-

### The siege of Jerusalem

nadin-shum. The next few years were relatively peaceful. The King used this time to prepare a decisive attack against Elam, which time and again had supported Babylonian rebellions. The overland route to Elam had been cut off and fortified by the Elamites. Sennacherib had ships built in Syria and at Nineveh. The ships from Syria were moved on rollers from the Euphrates to the Tigris. The fleet sailed downstream and was quite successful in the lagoons of the Persian Gulf and along the southern coastline of Elam. The Elamites launched a counter-offensive by land, occupying Babylonia and putting a man of their choice on the throne. Not until 693 were the Assyrians again able to fight their way through to the north. Finally, in 689, Sennacherib had his revenge. Babylon was conquered and completely destroyed, the temples plundered and levelled with the ground. The waters of the Arakhtu Canal were diverted over the ruins, and the inner city remained almost totally uninhabited for eight years. Even many Assyrians were indignant at this, believing that the Babylonian god Marduk must be grievously offended at the destruction of his temple and the carrying off of his image. Marduk was also an Assyrian deity, to whom many Assyrians turned in time of need. A political-theological propaganda campaign was launched to explain to the people that what had taken place was in accord with the wish of most of the gods. A story was written in which Marduk, because of a transgression, was captured and brought before a tribunal. Only a part of the commentary to this botched piece of literature is extant. Even the great poem of the creation of the world, the *Enuma elish*, was altered: the god Marduk was replaced by the god Ashur. Sennacherib's boundless energies brought no gain to his empire, however, and probably weakened it. The tenacity of the king can be seen in his building projects: for example, when Nineveh needed water for irrigation, Sennacherib had his engineers divert the waters of a tributary of the Great Zab River. The canal had to cross a valley at Jerwan. An aqueduct was constructed, consisting of about 2,000,000 blocks of limestone, with five huge, pointed archways over the brook in the valley. The bed of the canal on the aqueduct was sealed with cement containing magnesium. Parts of this aqueduct are still standing today. The King wrote of these and other technological accomplishments in minute detail, with illustrations.

Sennacherib built a huge palace in Nineveh, adorned with reliefs, some of them depicting the transport of colossal bull statues by water and by land. Many of the rooms were decorated with pictorial narratives in bas-relief telling of war and of building activities. Considerable advances can be noted in artistic execution, particularly in the portrayal of landscapes and animals. Outstanding are the depictions of the battles in the lagoons, the life in the military camps, and the deportations.

In 681 BC there was a rebellion. Sennacherib was assassinated by one or two of his sons in the temple of the god Ninurta. This god, along with the god Marduk, had been badly treated by Sennacherib, and the event was widely regarded as punishment of divine origin.

**Esarhaddon.** Ignoring the claims of his older brothers, an imperial council appointed Esarhaddon (Ashur-akhiddina, 680–669) as the successor. The choice is all the more difficult to explain in that Esarhaddon, quite unlike his father, was friendly toward the Babylonians. It can be assumed that his energetic and designing mother, Nakija, who hailed from Syria or Judah, used all her influence in his behalf to override the national party of Assyria. He may very well have been a partner in plotting the murder of his father; at any rate, he was able to procure the loyalty of his father's army. His brothers had to flee to Urartu. In his inscriptions, Esarhaddon always mentions both his father and grandfather.

Defining the destruction of Babylon explicitly as punishment by the god Marduk, the new king soon ordered the reconstruction of the city. He referred to himself only as governor of Babylonia and by his policies obtained the support of the cities of Babylonia. At the beginning of his reign the Aramaean tribes were still allied with Elam against him, but Urtaku of Elam (675–664) signed a

peace treaty and freed him for campaigning elsewhere. In 679 he stationed a garrison at the Egyptian border, because Egypt, under its Ethiopian king Taharqa, was intervening in Syria. He put down with great severity a rebellion of the combined forces of Sidon, Tyre, and other Syrian cities. The time was ripe to attack Egypt, which was suffering under the rule of the Ethiopians and by no means a united country. Esarhaddon's first attempt in 674/673 miscarried. In 671 BC, however, his forces took Memphis, the Egyptian capital. Assyrian consultants were assigned to assist the princes of the 22 provinces, their main duty being the collection of tribute.

Occasional threats came from the mountainous border regions of eastern Anatolia and Iran. Pushed forward by the Scythians, the Cimmerians in northern Iran and Transcaucasia tried to get a foothold in Syria and western Iran. Esarhaddon allied himself with the Scythian king Partatua by giving him one of his daughters in marriage. In so doing he checked the movement of the Cimmerians. Nevertheless, the apprehensions of Esarhaddon can be seen in his many offerings, supplications, and requests to the sun-god. These were concerned less with his own enterprises than with the plans of enemies and vassals and the reliability of civil servants. The priestesses of Ishtar had to reassure the King constantly by calling out to him, "Do not be afraid." Previous kings had never needed this kind of encouragement.

At home the King was faced with serious difficulties from factions in the court. His oldest son had died early. The national party suspected his second son Shamash-shum-ukin of being too friendly with the Babylonians; he may also have been considered unequal to the task of kingship. The king's third son, Ashurbanipal, was given the succession in 672, Shamash-shum-ukin remaining crown prince of Babylonia. This arrangement caused much dissension, and some farseeing civil servants warned of disastrous effects. Nevertheless, the Assyrian nobles, priests, and city leaders were sworn to just such an adjustment of the royal line; even the vassal princes had to take an oath of allegiance to Ashurbanipal.

Another matter of deep concern for Esarhaddon was his failing health. He regarded eclipses of the moon as particularly alarming omens, and in order to prevent a fatal illness from striking him at such times he had substitute kings chosen who ruled during the three such critical periods that occurred during his 12-year reign. The replacement kings died or were put to death after their brief term of office. During his off terms Esarhaddon called himself "Mister Peasant." This practice implied that the gods could not distinguish between the real king and a false one—quite contrary to the usual assumptions of the religion.

Esarhaddon enlarged and improved the temples in both Assyria and Babylonia. He also constructed a palace in Kalakh, using many of the picture slabs of Tiglath-pileser III. The works that remain are not on the level of those of either his predecessors or of Ashurbanipal. He died while on an expedition to put down a revolt in Egypt.

**Ashurbanipal (668–627) and Shamash-shum-ukin (668–648).** Although the death of his father occurred far from home, Ashurbanipal assumed his kingship as planned. He may have owed his fortunes to the intercession of his grandmother Nakija, who had recognized his superior capacities. He tells of his diversified education by the priests and his training in armour making as well as in other military arts. He may have been the only king in Assyria with a scholarly background. As crown prince he had also studied the administration of the vast empire. The record notes that the gods granted him a record harvest during the first year of his reign. There were also good crops in subsequent years. During these first years he was also successful in foreign policy, and his relation to his brother in Babylonia was good.

In 668 he put down a rebellion in Egypt and drove out the Ethiopian king, Taharqa. But in 664 the nephew of Taharqa, Tanutamun, gathered forces for a new rebellion. Ashurbanipal went to Egypt, pursuing the Ethiopian prince far into the south. His smashing victory moved

Tyre and other parts of the empire to resume regular payments of tribute. Ashurbanipal installed Psamtik as prince over the Egyptian region of Sais. In 656 Psamtik dislodged the Assyrian garrisons with the aid of Carian and Ionian mercenaries, making Egypt again independent. Ashurbanipal did not attempt to reconquer it again. A former ally of Assyria, Gyges of Lydia had now aided Psamtik in his rebellion. In return, Assyria did not help Gyges when he was attacked by the Cimmerians. Gyges lost his throne and his life. His son Ardys decided that the payment of tribute to Assyria was a lesser evil than conquest by the Cimmerians.

Graver difficulties loomed in southern Babylonia, which was attacked by Elam in 664. Another attack came in 653, whereupon Ashurbanipal sent a large army that decisively defeated the Elamites. Their king was killed, and some of the Elamite states were encouraged to secede. Elam was no longer strong enough to assume an active part on the international scene. This victory had serious consequences for Babylonia. Shamash-shum-ukin had grown weary of being patronized by his domineering brother. He formed a secret alliance in 656 with the Iranians, Elamites, Aramaeans, Arabs, and Egyptians, directed against Ashurbanipal. The withdrawal of defeated Elam from this alliance was probably the reason for a premature attack by Shamash-shum-ukin at the end of the year 652, without waiting for the promised assistance from Egypt. Ashurbanipal, taken by surprise, soon pulled his troops together. The Babylonian army was defeated and Shamash-shum-ukin was surrounded in his fortified city of Babylon. His allies were not able to stand on their own against the Assyrians. Reinforcements of Arabian camel troops were also defeated. The city of Babylon was under siege for three years. It fell in 648 amid scenes of horrible carnage, Shamash-shum-ukin dying in his burning palace.

After 648 the Assyrians made a few punitive attacks on the Arabs, breaking the forward thrust of the Arab tribes for a long time to come. The main objective of the Assyrians, however, was a final settlement of their relationship with Elam. The refusal of Elam in 647 to extradite an Aramaean prince was used as pretext for a new attack that drove deep into its territory. The assault on the solidly fortified capital of Susa followed, probably in 646. The Assyrians destroyed the city, including its temples and palaces. Vast spoils were taken. As usual, the upper classes of the land were exiled to Assyria and other parts of the empire, and Elam became an Assyrian province. Assyria had now extended its domain to southwestern Iran. Cyrus I of Persia sent tribute and hostages to Nineveh, hoping perhaps to secure protection for his borders with Media. Little is known about the last years of Ashurbanipal's reign.

Ashurbanipal left more inscriptions than any of his predecessors. His campaigns were not always recorded in chronological order but clustered in groups according to their purpose. The accounts were highly subjective. One of his more remarkable accomplishments was the founding of the great library in Nineveh, which is today one of the most important sources for the study of that era. The King himself supervised its construction. Important works were kept in more than one copy, some intended for the King's personal use. The work of arranging and cataloging drew upon the experience of centuries in the management of collections in huge temple archives such as the one in Ashur. In his inscriptions Ashurbanipal tells of becoming an enthusiastic hunter of big game, acquiring a taste for it during a fight with marauding lions. In his palace at Nineveh the long rows of hunting scenes show what a masterful artist can accomplish in bas-relief; with these reliefs Assyrian art reached its peak. In the series picturing his wars, particularly the wars fought in Elam, the scenes are overloaded with human figures. Those portraying the battles with the Arabian camel troops are magnificent in execution.

One reason for the durability of the Assyrian Empire was the practice of deporting large numbers of people from conquered areas and resettling others in their place. This kept many of the conquered nationalities from re-

gaining their power. Equally important was the installation in conquered areas of a highly developed civil service under the leadership of trained officers. The highest ranking civil servant carried the title of *tartan*, a Hurrian word. The *tartans* also represented the king during his absence. In descending rank were the palace overseer, the main cupbearer, the palace administrator, and the governor of Assyria. The generals often held high official positions, particularly in the provinces. The civil service numbered about 100,000, many of them former inhabitants of subjugated provinces. Prisoners became slaves but were later often freed.

No laws are known for the empire, although documents point to the existence of rules and standards for justice. Those who broke contracts were subject to severe penalties, even in cases of minor importance: the sacrifice of a son or the eating of a pound of wool and drinking of a great deal of water afterward, which led to a painful death. The position of women was inferior, except for the queen and some priestesses.

Good estimates of the economic situation of the period do not exist. The arts and crafts experienced a golden age in Assyria; many qualified artists and artisans went there, bringing renewed creativity and new ideas. Finds of Aramaic texts from the Assyrian era are notably few because neither papyrus nor parchment preserved well in the climate; evidence of literary efforts in other languages is lacking, except of course in the border areas of Syria-Palestine and Judah.

Babylonia lagged behind Assyria during the period. Many small wars severely hampered the development of the country, undermining agricultural production and commerce. The temples fared best because many Assyrians supported them, but they left no document—a fact that can hardly be regarded as accidental. The continuing existence of scholarly study can be inferred from extant letters and the continuation of old traditions. The pictorial arts, however, were neglected, and the Babylonian artists may have found better jobs in Assyria. This period saw the first use of ancestral names as family appellations.

The era apparently was not fruitful for literary accomplishments either in Babylonia or Assyria. The large inscriptions of the kings were the most important achievements in Assyria; there were also hymns and prayers, executed mostly in the traditional style, and unusual oracle texts in the Assyrian language. Both countries saw the beginnings of a historical literature, going far beyond the ordinary chronicals.

**Decline of the Assyrian Empire.** Few historical sources remain for the last 30 years of the Assyrian Empire. There are no extant inscriptions of Ashurbanipal after 640 BC, and the few surviving inscriptions of his successors contain only vague allusions to political matters. In Babylonia the silence is almost total until 625 BC, when the chronicles resume. The rapid downfall of the Assyrian Empire was formerly attributed to military defeat, although it was never clear how the Medes and the Babylonians alone could have accomplished this. More recent work has established that after 635 a civil war occurred, weakening the empire, so that it could no longer stand up against a foreign enemy. Ashurbanipal had twin sons. Ashur-etel-ilani was appointed successor to the throne, but his twin brother Sin-shar-ishkun did not recognize him. The fight between them and their supporters forced the old king to withdraw to Haran, in 632 at the latest, perhaps ruling from there over the western part of the empire until his death in 627. Ashur-etel-ilani governed in Assyria from about 633 on, but a general, Sin-shum-lisher, soon rebelled against him and proclaimed himself counterking. Some years later (629?) Sin-shar-ishkun finally succeeded in obtaining the kingship. In Babylonian documents dates can be found for all three kings. To add to the confusion, until 626 there are also dates of Ashurbanipal and a king named Kandalanu. In 626 the Chaldean Nabopolassar revolted from Uruk and occupied Babylon. There were several changes in government. King Ashur-etel-ilani was forced to withdraw to the west, where he died sometime after 625.

State and culture in the Neo-Assyrian Empire

Defeat of Shamash-shum-ukin

Internal struggles in the last years of the empire

Around the year 626 the Scythians laid waste to Syria and Palestine. In 625 the Medes became united under Cyaxares and began to conquer the Iranian provinces of Assyria. One chronicle relates of wars between Sin-shar-ishkun and Nabopolassar in Babylonia in 625–623. It was not long until the Assyrians were driven out of Babylonia. In 616 the Medes struck against Nineveh, but, according to the Greek historian Herodotus, were driven back by the Scythians. In 615, however, the Medes conquered Arrapkha (Kirkūk) and in 614 the old capital of Ashur, looting and destroying the city. Now Cyaxares and Nabopolassar made an alliance for the purpose of dividing Assyria. In 612 Kalakh and Nineveh succumbed to the superior strength of the allies. The revenge taken on the Assyrians was terrible: 200 years later Xenophon found the country still sparsely populated.

Sin-shar-ishkun, king of Assyria, found death in his burning palace. The commander of the Assyrian army in the west crowned himself king in the city of Haran, assuming the name of the founder of the empire, Ashuruballit II (611–609 BC). Ashuruballit had to face both the Babylonians and the Medes. They conquered Haran in 610, without, however, destroying the city completely. In 609 the remaining Assyrian troops had to capitulate. With this event, Assyria disappeared from history. The great empires that succeeded it learned a great deal from the hated Assyrians, both in the arts and in the organization of their states.

#### THE NEO-BABYLONIAN EMPIRE (626–539)

The Chaldeans, who inhabited the coastal area near the Persian Gulf, had never been entirely pacified by the Assyrians. About 630 Nabopolassar became king of the Chaldeans. In 626 he forced the Assyrians out of Uruk and crowned himself king of Babylonia. He took part in the wars aimed at the destruction of Assyria. At the same time, he began to restore the dilapidated network of canals in the cities of Babylonia, particularly those in the city of Babylon. He fought against the Assyrian Ashuruballit II and then against Egypt, his successes alternating with misfortunes. In 605 Nabopolassar died in Babylon.

**Nebuchadrezzar (Nabu-kudurri-usur) II.** Nabopolassar had named his oldest son after the famous king of the second dynasty of Isin, had trained him carefully for his prospective kingship, and had shared responsibility with him. When the father died in 605, Nebuchadrezzar was with his army in Syria; he had just crushed the Egyptians in a cruel, bloody war and pursued them into the south. On receiving the news of his father's death, Nebuchadrezzar returned immediately to Babylon. In his numerous inscriptions he tells but rarely of his many wars. The Babylonian chronicle is extant only for the years 605–594, and not much is known from other sources about the later years of this famous king. He went very often to Syria and Palestine—at first to drive out the Egyptians. In 604 he took the Philistine city of Ashkelon. In 601 he tried to push forward into Egypt but was forced to pull back after a very bloody, undecided battle and to regroup his army in Babylonia. After smaller incursions against the Arabs of Syria, he attacked Palestine at the end of 598. Joiakin of Judah had rebelled, counting on help from Egypt. According to the chronicle, Jerusalem was taken on March 16, 597, and King Joiakin, together with at least 3,000 Jews, were led into exile in Babylonia. They were treated well there, according to the documents. Zedekiah was appointed the new king. In 596, when danger threatened from the east, Nebuchadrezzar marched to the Tigris River and induced the enemy to withdraw. After a revolt in Babylonia had been crushed with much bloodshed, there were other campaigns in the west.

According to the Old Testament, Judah rebelled again in 589; Jerusalem was under siege. The city fell after 18 months of siege and was completely destroyed. Many thousands of Jews were forced into "Babylonian exile," and their country was reduced to a province of the Babylonian Empire. The revolt had been caused by an Egyptian invasion that pushed as far as Sidon. Nebuchadrezzar laid siege to Tyre for 13 years without taking the city,

because there was no fleet at his disposal. In 568/567 he attacked Egypt, again without much success, but from then on the Egyptians refrained from further attacks on Palestine. Nebuchadrezzar lived at peace with Media throughout his reign and acted as a mediator after the Median–Lydian war of 590–585.

The Babylonian Empire under Nebuchadrezzar extended to the Egyptian border. It had a well-functioning administrative system. Though he had to collect extremely high taxes and tributes in order to maintain his armies and carry out his building projects, Nebuchadrezzar made Babylonia one of the richest lands in western Asia—the more astonishing because it had been rather poor when it was ruled by the Assyrians. Babylon was the largest city of the "civilized world." The King maintained the existing canal systems and built many supplementary canals, making the land even more fertile. Trade and commerce flourished.

Nebuchadrezzar's building activities surpassed those of most of the Assyrian kings. He fortified the old double walls of Babylon, adding another triple wall outside the old wall. In addition, he erected another wall, the Median Wall, north of the city between the Euphrates and the Tigris rivers. According to Greek estimates, the Median Wall may have been about 30 metres (100 feet) high. He enlarged the old palace and added many wings, so that hundreds of rooms with large inner courts were now at the disposal of the central offices of the empire. Colourful glazed-tile bas-reliefs decorated the walls. Terrace gardens, called hanging gardens in later accounts, were added. Hundreds of thousands of workers must have been required for these projects. The temples were objects of special concern. He devoted himself first and foremost to the completion of the Tower of Babel. Its base measured 91 metres (about 300 feet) on each side and 91 metres in height. There were five terrace-like gradations surmounted by a temple, the whole tower being about twice the height of those of other temples. The wide street used for processions led along the eastern side by the inner city walls and crossed at the enormous Ishtar Gate with its world-renowned bas-relief tiles. The King also built many smaller temples throughout the country.

**The last kings of Babylonia.** Awil-Marduk (in the Old Testament Evil-Merodach, 561–560), the son of Nebuchadrezzar, was unable to win the support of the priests of Marduk. His reign did not last long, and he was soon eliminated. His brother-in-law and successor, Nergal-shar-usur (in classical sources, Neriglissar, 559–556), was a general who undertook a campaign in 557 into the "rough" Cilician land, which may have been under the control of the Medes. His land forces were assisted by a fleet. His still-minor son Labashi-Marduk was murdered not long after that, allegedly because he was not suitable for his job.

The next king was the Aramaean Nabonidus (555–539) from Haran, one of the most interesting and enigmatical figures of ancient times. His mother, Addagoppe, was a priestess of the god Sin in Haran, who came to Babylon and managed to get responsible offices for her son at court. The god of the moon rewarded her piety with a long life—she lived to be 102—and she was buried in Haran with all the honours of a queen in 547. It is not clear which powerful faction in Babylon supported the kingship of Nabonidus; it may have been one opposing the priests of Marduk, who had become extremely powerful. The King raided Cilicia in 555 and secured the surrender of Haran, which had been ruled by the Medes. He concluded a treaty of defense with Astyages of Media against the Persians, who had become a growing threat since 559 under their king Cyrus II. He also devoted himself to the renovation of many temples, taking an especially keen interest in old inscriptions. He gave preference to his god Sin and had powerful enemies in the priesthood of the Marduk temple. Modern excavators have found fragments of propaganda poems written against Nabonidus and also in support of him. Both traditions continued in Judaism.

Internal difficulties and the recognition that the narrow strip of land from the Persian Gulf to Syria could not be

defended against a major attack from the east induced Nabonidus to leave Babylonia around 552 and to reside in Taima in northern Arabia. There he organized an Arabian province with the assistance of Jewish mercenaries. His viceroy in Babylonia was his son Bel-shar-usur, the Belshazzar of the Book of Daniel in the Bible. Cyrus turned this to his own advantage by annexing Media in 550. Nabonidus, in turn, allied himself with Croesus of Lydia in order to fight Cyrus. But, when Cyrus attacked Lydia and annexed it in 546, Nabonidus was not able to help Croesus. Cyrus bode his time. In 542 Nabonidus returned to Babylonia, where his son had been able to maintain good order in external matters but had not overcome a growing internal opposition to his father. Consequently, Nabonidus' career after his return was of short duration, though he tried very hard to regain the support of the Babylonians. He appointed his daughter to be high priestess of the god Sin in Ur, thus returning to the Sumerian-Old Babylonian religious custom. The priests of Marduk looked to Cyrus, hoping to have better relations with him than with Nabonidus; they promised Cyrus the surrender of Babylon without a fight if he would grant them their privileges in return. In 539 Cyrus attacked northern Babylonia with a large army, defeating Nabonidus, and entered the city of Babylon without a battle. The other cities did not offer any resistance, either. Nabonidus surrendered, receiving a small territory in eastern Iran. Tradition has confused him with his great predecessor Nebuchadrezzar II. The Bible refers to him as Nebuchadrezzar in the Book of Daniel.

Babylonia's peaceful submission to Cyrus saved it from the fate of Assyria. It became a territory under the Persian crown but kept its cultural autonomy. Even the racially mixed western part of the Babylonian Empire submitted without resistance.

Culture  
of the  
Neo-  
Babylonian  
Empire

The Babylonians by 620 had grown tired of Assyrian rule. They were also weary of internal struggle. They were easily persuaded to submit to the order of the Chaldean kings. The result was a surprisingly quick social and economic consolidation, helped along by the fact that after the fall of Assyria no external enemy threatened Babylonia for over 60 years. In the cities, the temples were an important element of the economy, having vast benefices at their disposal. The business class regained its strength, not only in the trades and commerce but also in the management of agriculture in the metropolitan areas. Livestock breeding—sheep, goats, beef cattle, and also horses—flourished, as did poultry farming. The cultivation of corn, dates, and vegetables grew in importance. Much was done to improve communications, both by water and by land, with the western provinces of the empire. The collapse of the Assyrian Empire had the consequence that many trade arteries were rerouted through Babylonia instead. Another consequence was that the city of Babylon became a world centre.

The immense amount of documentary material and correspondence that have survived has not yet been fully analyzed. No new system of law or administration seems to have developed during that time. The Babylonian dialect gradually became Aramaicized, still written primarily on clay tablets that often bore added material in Aramaic lettering. Parchment and papyrus documents have not survived. There is no evidence of much artistic creativity. Aside from some of the inscriptions of the Kings, especially Nabonidus, which were not comparable from a literary standpoint with those of the Assyrians, the main efforts were devoted to the rewriting of old texts. In the fine arts, only few monuments have any suggestion of new tendencies.

#### MESOPOTAMIA UNDER THE PERSIANS

Cyrus  
as king of  
Babylonia

Cyrus united Babylonia with his country in a personal union, assuming the title of "King of Babylonia, King of the Lands." His son Cambyses was appointed vice king and resided in Sippar. The Persians relied on the support of the priests and the business class in the cities. In a Babylonian inscription, Cyrus relates with pride his peaceful, bloodless conquest of the city of Babylon. At the same time, he speaks of Marduk as the king of gods.

His moderation and restraint were rewarded: Babylonia became the richest province of his empire. There is no indication of any national rebellion in Babylonia under Cyrus and Cambyses (529–522). That there must have been an accumulation of discontent became clear at the ascension to the throne of Darius I (522–486), when a usurper seized the throne of Babylonia under the name of Nebuchadrezzar (III), only to lose both the throne and his life after ten weeks. Darius waived any punitive action. He had to take more drastic measures in 521, when a new Nebuchadrezzar incited another rebellion against him. This usurper's reign lasted for two months. Executions and plundering followed; Darius ordered the inner walls of Babylon to be demolished and reformed the organization of the state. But Babylon remained the capital of the new satrapy and also became the administrative headquarters for the satrapies of Assyria and Syria. One result was that the palace had to be enlarged.

Babylonia remained a wealthy and prosperous land, in contrast to Assyria, which was still a poor country. At the same time, the administration was more and more in the hands of the Persians, and the tax burdens grew heavier. This produced discontent, centring especially on the large temples in Babylon. Xerxes (486–465) had his residence in Babylon while he was crown prince and knew the country very well. When he assumed his kingship, he immediately curtailed the autonomy of the satrapies. This, in turn, gave rise to many rebellions. In Babylonia there were two short interim governments of Babylonian pretenders during 484–482. Xerxes retaliated by desecrating and partially destroying the holy places of the god Marduk and the Tower of Babel in the city of Babylon. Priests were executed, and the statue of Marduk was melted down. The members of the royal family still resided in the palaces of the city of Babylon, but Aramaic became more and more the language of the official administration. One source of information for this period are the clay-tablet archives of the commercial house of Murashu and Sons of Nippur for the years of 455–403, which tell much about the important role the Iranians played in the country. The state domains were largely in their hands. They controlled many minor feudal tenants, grouped into social classes according to ancestry and occupation. The business people were predominantly Babylonians and Aramaeans, but there were also Jews. The documents become increasingly sparse after 400. The cultural life of Babylon became concentrated in a few central cities, particularly Babylon and Uruk; Ur and Nippur were also important centres. The work of astronomers continued, as evidenced in records of observations. Nabu-rimanni, living and working around 500, and Kidinnu, 5th or 4th century BC, were also known to the Greeks; both astronomers are famous for their methods of calculating the courses of the Moon and the planets. In the field of literature, religious poetic works as well as texts of omens and Sumero-Akkadian word lists were constantly copied very often with commentaries. (W.T.v.S.)

#### BABYLONIA UNDER ALEXANDER, THE SELEUCIDS, AND THE PARTHIANS

Babylonia was once more to become the centre of the civilized world. Alexander the Great decided to make Babylon one of the capitals of his empire after he conquered the Persians. He began to build a large harbour. In 331 he ordered the restoration of the Marduk temples, among them also the high temple of Etemenanki; Marduk was henceforth recognized as the equal of the Greek god Zeus. After Alexander's death, Babylon lost its position of importance. In 312 Seleucus I Nicator entered Babylon. But soon he founded a new capital, Seleucia, on the Tigris River. Babylon's temples and scholarly institutions continued to receive the care and consideration of the kings of the Seleucid dynasty as well as of some of the later Parthian kings. Antiochus I Soter (281–261) even ordered a Babylonian inscription to be included in the walls of the Temple of Nabu when he undertook the rebuilding of the city of Borsippa. Babylonian business documents from the time of the Seleucids,

The  
end of  
Babylonian  
culture

written on clay tablets, are still extant. Greek and Aramaean documents did not survive. The city of Uruk was second in importance to Babylon as a cultural centre at this time. Uruk's god Anu—the god of the heavens—was recognized along with Marduk as the equal of the Greek Zeus. Two large temples were built for Anu and Ishtar. Written rituals indicate that the cult had remained true to the old traditions. The citizens of Uruk participated in these rituals in various functions, lucrative as well as honourable and respected. Some documents indicate that religious benefices were handled as stock and often sold in shares. Other documents deal with the selling of promises. The exact measurements and markings of the boundary lines are stated on these. While the names of the parties are mostly Babylonian, it is not unusual to find a second, Greek name added to the original Babylonian one.

The  
Babylonian  
astronomers

An important result of the mixture of Babylonian and Greek culture in Babylon and Uruk was the further development of the science of astronomy. The Babylonians contributed their methods of mathematical calculation, as well as an accumulation of observations covering several centuries. The Greeks contributed their training in logical thinking. Many documents of the Hellenistic princes who ruled in Asia Minor and along the Aegean Sea during this time show the cooperative efforts of the Greek and Babylonian astronomers. They laid the basis upon which astronomers of later times were able to build. One of them deserves particular mention: the Marduk priest Berosus, who founded a school for astrology and astronomy on the island of Kos around the year 280. He was also the author of a book about Babylonia, its history, and its religion (*Babyloniaka*). The book was written in Greek, and fragments of it still exist.

The decline of the empire of the Seleucids after 150 led to the incorporation of Babylonia into the empire of the Parthians in eastern Iran between 141 and 129. The result was by no means a great political catastrophe. Nevertheless, it hastened the decline of the late Babylonian city culture. There had been no new creative or cultural ideas for a long time, and the old schools for scribes slowly became extinct. Few literary texts and documents survive from the time between 140 bc and 80 bc. The knowledge of the cuneiform script was lost under the Greeks, who were hardly interested in foreign languages. Not until the 19th and 20th centuries did the discovery of tens of thousands of cuneiform texts lead to the decoding of this entirely forgotten writing. This permitted scholars to repossess a large part of the lost literature of Mesopotamia.

**Parthian and Sāsānian periods.** Mesopotamia (especially the district of Nisibis) was attached to the growing dominions of Armenia temporarily in the 1st century bc but was recovered for Parthia by Phraates III (reigned 70–58/57 bc). With the rise of Roman power in the Near East, it assumed the character of a border territory between the Roman and Parthian spheres of influence, though it usually remained under Parthian control. The Roman leader Crassus led an army into Mesopotamia in 54 bc but was defeated by the Parthians at Carrhae in 53. In ad 114–117 the emperor Trajan conquered the area and made it a Roman province, but it was abandoned once again to Parthia by Hadrian after Trajan's death. Beginning in 165, the Romans once more occupied the northwest portion of Mesopotamia.

During most of the period from the early 3rd century until the rise of Islām in the early 7th century, Mesopotamia remained a battleground between the Romans (in the 6th and 7th centuries, the Byzantines) and the Sāsānian successors of the Parthians. As during the Parthian period, Roman influence was for the most part confined to the extreme northwestern part of the country—the area around Carrhae, Edessa, and Nisibis, near the Syrian and Anatolian borders. The Sāsānian kings made their capital at Ctesiphon, near the midpoint of the Tigris, and their influence predominated in the rest of Mesopotamia. During this period, Mesopotamia became one of the chief centres of Nestorian Christianity and had a sizable Jewish community. (For the history of the Parthian and Sāsānian empires, see IRAN, HISTORY OF.) (Ed.)

### III. Iraq from the Arab conquest to 1918

From the Arab conquest in the 7th century to the second decade of the 20th century, Iraq existed not as an independent state but as a geographical expression for the flatlands between Baghdad and the Persian Gulf—an area of unavoidable passage between Central Asia and the Mediterranean. The history of Iraq in this period is dominated by the rivalry of the three strongest ethnic elements of the Muslim world: the Arabs, the Iranians, and the Turks. During this period Iraq was also a great centre of Islāmic culture as well as the place of origin of several religious sects that divided the community of Islām. The political history of the area may be summarized as follows: after being the metropolitan province of the Arabo-Islāmic Empire under the caliphs' more or less effective authority, Iraq fell successively under the control of the Būyid dynasty of Iran and the Seljuq Turks; and then, after the Mongol invasion, which hastened its decline, it became a dominion of Mongol and later Turkmen and Persian dynasties established in Iran and remained for almost four centuries under Ottoman rule, to emerge again as an independent state as a result of World War I. Further information about Iraq's history during this period is contained in the following articles: IRAN, HISTORY OF; CALIPHATE, EMPIRE OF THE; SELJUQS; MONGOLS; OTTOMAN EMPIRE AND TURKEY, HISTORY OF THE.

#### THE ARAB CONQUEST

From the 3rd century ad, the Lakhmids, a small dynasty of South Arabian origin, ruled al-Hīrah, on the Euphrates, as vassals of the Sāsānid rulers of Iran, who had entrusted them with keeping the Bedouins in check and holding the borders of Iran against the Byzantines; the Lakhmid capital was a flourishing centre of trade between Persia and Arabia as well as a focus of Arabic culture. In addition, some elements of such important Arab tribes as the Taghlib, the Bakr, and the Tamīm had taken the steppes of Lower Mesopotamia for pastureland, and relations had been established between the Prophet and those Bedouins, perhaps with a view to subsequent operations in the area.

The rich area stretching south of al-Hīrah was protected by strongholds that were easily reduced on the occasion of mere reconnaissances made by Arab parties under al-Muthannā ibn Hārithah, a leader of the Bakr, who is said to have called in the famous general Khālid ibn al-Walīd to help him. Khālid seized Al-Hīrah in 633–634, but he was sent to Syria. Al-Muthannā was left in charge of the Arab forces in Lower Iraq. For three years, the progress of the conquest proceeded slowly, until 637, when Sa'd ibn Abī Waqqāsh won a decisive victory over the Sāsānids at al-Qādisiyah, 20 miles (32 kilometres) southeast of al-Hīrah. The Arabs sacked Ctesiphon, the Persian capital, and seem to have been welcomed by the native population of the region. Those successes marked the beginning of the collapse of the Sāsānid Empire and made it possible for the Arabs to spread eastward. In 641 both Nineveh and Mosul fell to the Arabs. Sāsānid power was eventually destroyed in 642 at the battle of Nehāvand. This victory enabled the Arabs to control western and central Persia in addition to Mesopotamia.

At that time two military camps, Basra and Kūfah, had been established, the former on the right bank of the Shatt al-Arab in 638 and the latter on the right bank of the Euphrates, near al-Hīrah, in 638–639. Both camps were to develop into large cities and play an outstanding part in the history of Iraq until the foundation of Baghdad in 762. Both towns received new inhabitants either from Arabia or the East as a result of conquests that brought them captives and booty as well as revenue from two Persian provinces (*māh al-Basrah* and *māh al-Kūfah*) within their scope. The area to the east of Basra and Kūfah was called as-Sawād (the Black Region), in reference to its fertility. The mixing of various ethnic elements promoted economical and intellectual development in the rival cities, while political events gave rise to the great politico-religious parties that were to divide Islām into discordant groups. Moreover, it was in Basra and Kūfah that all literary, philological, and his-

Establishment of Basra and Kūfah

torical materials that were to form the basis of Arabo-Islamic culture were collected from Bedouins: it was there that Islamic sciences such as grammar and lexicography came into existence. Qur'anic exegesis and science of traditions developed, while several schools of thought, particularly Mu'tazilism (see below), took shape. It is true that Kūfah did not outlive for long the founding of Baghdad, but Basra was far enough from the capital to retain its identity. The whole history of Islām has been to some extent conditioned by events that occurred at Basra and Kūfah or were in connection with either city. 'Uthmān ibn 'Affān, the third orthodox caliph, was murdered in 656. 'Ā'ishah, a Prophet's widow, set out for Basra with her followers with the object of avenging the caliph and fighting 'Alī ibn Abī Tālib, the latter's successor. With the help of troops from Kūfah, 'Alī defeated the rebels in the so-called Battle of the Camel (for 'Ā'ishah was riding a camel) fought in Basra in December of 656. Here two parties of Muslims struggled against each other for the first time. In the following year 'Alī tried to subdue Mu'āwiyah, the powerful governor of Syria who had refused to obey an order of dismissal. Leaving Kūfah, where he had established the seat of his government, he met his rival at Šiffin, on the right bank of the Euphrates. When 'Alī was about to win the day, Mu'āwiyah's troops raised leaves of the Qur'an on their spears, meaning that they wished to leave it to God's decision. 'Alī agreed to stop fighting and both parties agreed to arbitration. On his return to Kūfah, 'Alī had to suppress a rebellion instigated by some soldiers who contested the very principle of arbitration, and he crushed these Khārijites ("Seceders") on July 17, 658, in an-Nahrawān. The survivors, however, continued the movement, scattering in various areas and recruiting new followers; thus, it was in Iraq that Khārijism, the earliest sect to rise within Islām, came into existence.

#### THE Umayyads

After being deposed in January 659 by the arbitrators met in Adhruh, 'Alī tried to preserve the caliphate, but he was murdered by a Khārijite on January 24, 661, and Mu'āwiyah, who had asserted his dominion over Syria and Egypt, was proclaimed in the Arabian province of Hejaz. Mu'āwiyah moved the seat of the Umayyad caliphate to Damascus in Syria. Iraq became a single province but a privileged one, as it developed into the military base for the Muslim conquest of Eastern countries. Iraq continued to play a major political role in the empire of the caliphate.

In Umayyad times and afterward, the limits of Iraq were roughly marked out by a line running some distance to the west of the Shatt al-Arab and the Euphrates up to al-Anbār (sometimes up to al-Hādīthah), thence to Takrit on the Tigris, then on through Hulwān to the Persian Gulf east of 'Abbādān (now Abadan, in Iran); al-Jazīrah and Mosul were not included in Iraqi provinces except during certain periods.

Under the Umayyads, Kūfah inclined toward 'Alī and his party; it was there that revolts raised by his descendants or their followers, the Shī'ah, broke out. Basra seemed to be in favour of a more democratic regime, but it was anxious to preserve independence and scarcely accepted governors sent from Damascus. It was at Basra that the Khārijites, the most vehement opponents to the established order, caused disturbances. After the murder of 'Alī and the failure of a plot woven simultaneously by them against Mu'āwiyah and the Governor of Egypt, they constantly threatened Iraq and especially Basra during the following decades. While Iraqi troops were launched to the conquest of Oriental areas as far away as India, Basra had to defend itself against the rebels. Mu'āwiyah publicly recognized Ziyād (an alleged illegitimate son of his father) as his brother and appointed him governor of Basra in 665 and then of Basra and Kūfah from 670 to 675. Ziyād fought both Khārijites and Shī'is with efficiency and, by promoting important drainage projects, did much to restore the economic life of Lower Iraq. His son, 'Ubayd Allāh, continued to rule firmly in Iraq, but, when Mu'āwiyah died in 680, the succession of his son

engendered further revolts. Al-Husayn, 'Alī's second son, was invited by his followers to Kūfah, where a revolt had been initiated in his support; on October 10, 680, al-Husayn was intercepted at Karbalā', near Kūfah, and slaughtered, together with his small escort. This event had an enormous impact on the Muslim world: it inspired unspeakable abhorrence among the Shī'ah and other orthodox Muslims toward the Umayyads. A few years after Karbalā', in January 685, the so-called Penitents (Tawwābūn) tried, with little success, to foster disturbances in Iraq with a view to avenging the murder of al-Husayn; next, a rebellion broke out under al-Mukhtar, who backed the cause of Muḥammad, another son of 'Alī. Al-Mukhtār succeeded in winning the support of some 'Alids (supporters of 'Alī) and *mawālī* (non-Arabs who had accepted Islām) and gained control over Kūfah for a few months. At that time, the anti-caliph 'Abd Allāh ibn az-Zubayr, who had revolted in Medina and established himself in Mecca, had appointed Muṣ'ab, his brother, as governor of Basra. Muṣ'ab suppressed the uprising, and al-Mukhtār was killed in 687. Four years later, the Umayyads recovered their control over Iraq.

Despite this internecine warfare, Iraq prospered. The province profited by remote conquest, carried out by its armies, and witnessed an important development. In 694, the caliph 'Abd al-Malik ibn Marwān appointed an outstanding statesman, al-Ḥajjāj, as governor of Kūfah. With the support of Syrian forces, he established respect for the caliphal authority and restored order throughout the country. Eager to achieve some sort of a balance between the two cities of Basra and Kūfah, he founded a new city, which he called Wāsiṭ (intermediary), and made it the seat of his governorship. At the same time, important public utility works were undertaken: canals were dug, swamps drained, and agriculture revitalized. Arabic replaced Persian as the official language of government administration. New coins with Arabic inscriptions were minted at Wāsiṭ to replace Sāsānid money.

A serious problem arose concerning the tax system. According to a general rule, those lands that had been left to their non-Muslim owners were subjected to the *kharāj* (land tax), while Muslim landowners paid only the tithe; thus, a large number of peasants embraced Islām in order to escape paying the *kharāj*. But some tax collectors continued to levy the land tax; this caused a mass movement of the peasantry into the towns. Al-Ḥajjāj forcibly resettled them on the land, and their embittered discontent erupted into several revolts against the Umayyads. Under the caliph Hishām ibn 'Abd al-Malik (724–743) it was decided that land tax should be imposed independently of the religion of *kharāj* landowners.

After al-Ḥajjāj's death (714), Yazīd ibn al-Muḥallab, one of his successors, who had been put in jail and escaped, fomented a rebellion that was crushed in 721; order was temporarily restored by Khālīd ib 'Abd Allāh al-Qasri, but increasing disturbances stirred up by Khārijites and 'Abbāsīd followers as well brought the Umayyad rule to an end. In Khorāsān a campaign aiming at overthrowing the Umayyads in favour of the 'Abbāsīds, who inclined more toward the Persian element, was successful; the example of Khorāsān was followed in other areas; Kūfah was the first town to rise, and it was in its great mosque that as-Saffāh, the first 'Abbāsīd caliph, was proclaimed on October 30, 749. Thenceforth, the history of Iraq intermingles with the 'Abbāsīds'.

#### THE 'ABBASIDS

The reign of Abū al-'Abbās as-Saffāh (749–754) was taken up with fighting the last Umayyads and asserting 'Abbāsīd power. His successor, al-Manṣūr (754–775), ruthlessly harried the Shī'is, whose revolts he suppressed in 755 and 762–763; in 755 he put to death Abū Muslim, to whom the 'Abbāsīds were principally indebted for their accession to power. His fame rests on his founding of the new capital, Baghdad, completed in 766, and in laying the foundations on which his successors were to build an elaborate administration. Al-Mahdī (775–785) distinguished himself in fighting the so-called *zanādiqah* —i.e., heterodox sects and individuals, especially Mani-

The founding of Wāsiṭ

Movement of the caliphate to Damascus

The founding of Baghdad

chaeans. He was succeeded by al-Hādī (785–786) and Hārūn ar-Rashīd (786–809). The latter's image has been somewhat idealized by the *Thousand and One Nights*.

The Umayyads had been an Arab dynasty; the 'Abbāsids, however, who often had Iranian blood on their mothers' side, naturally turned east and organized their administration and court on the same lines as the Sāsānids'. The first 'Abbāsīd period was the golden age of Persian officials. Although deeply Arabicized, they did not fail to remember the old glory of their fatherland and to assume hostile attitudes toward the Arabs, which produced a racial movement known as Shu'ūbiyah and various conflicts between Arabs and non-Arabs. On the other hand, it is obvious that converts to Islām were not always absolutely sincere, and many of them secretly retained their own faiths. That is the reason al-Mahdī hunted out the *zanā-diqāh* and put a great many of them to death. Al-Mahdī acted in self-defense; it is not preposterous to discern a feeling of the same kind in ar-Rashīd's reaction against the Barmakids.

As-Saffāh had taken as his chief associate Khālid ibn Barmak, a noble Persian who remained in the service of the caliphs. Yahyā, Khālid's son, became the vizier of ar-Rashīd, while al-Faḍl and Ja'far, Yahyā's sons, were entrusted with high government offices. Suddenly, ar-Rashīd decided to execute Ja'far (January 803). He imprisoned Ja'far's father and brothers and seized the property of the whole family. The reason for ar-Rashīd's actions is not quite made clear by the sources, which speak of an affair between Ja'far and 'Abbāsah, ar-Rashīd's sister; whether this was so or not, such an act of cruelty was regarded as an unbearable slur cast on Persians, at a time when the Shī'īs, after some unsuccessful attempts at seizing power, fostered deep resentment against the 'Abbāsids.

On ar-Rashīd's death, his succession gave rise to bloody conflicts between his sons al-Amīn (809–813) and al-Ma'mūn (813–833); the latter defeated his brother but was compelled to besiege Baghdad to recover the throne. Aiming at reconciling Shī'īs and Sunnīs, al-Ma'mūn contemplated the designation of 'Alī ar-Riḍā, the eighth Shī'ī *imām*, or leader of the community of Islām, as heir apparent; he was forced, however, to go back on his decision in view of the strong Sunnī opposition in Baghdad, a fact that was again jeopardizing the balance between Arabs and Persians, the latter supporting the Shī'īs; such policy was all the more a failure as Shī'īs suspected the caliph of having poisoned ar-Riḍā (died 818). In 815, Abū as-Sarāyā, allegedly backing the 'Alids Ibn Ṭabāṭabā and Muḥammad ibn Zayd, occupied Kūfah, where he minted money, seized Wāsiṭ, Basra, and other towns; and set out for Baghdad. He was eventually defeated and was beheaded on October 18, 815.

Later, however, the political power of the caliphate asserted itself. Economic prosperity grew, and the Arabo-Islāmic civilization centred in Baghdad radiated far beyond the limits of the empire. The seventh 'Abbāsīd caliph, al-Ma'mūn, founded, or at least developed, in Baghdad the Bayt al-Ḥikmah (The House of Wisdom), where Greek philosophical and scientific works were translated into Arabic. A rich library was attached to the House of Wisdom, as were several astronomical observatories. A harmonious blending of cultural factors, borrowed from Greece, Persia, and India, enabled Arabo-Islāmic culture to rise to a high degree of refinement in such fields as medicine, mathematics, philosophy, theology, literature, and poetry. Iraq came to regard itself as a kind of privileged heir to all former civilizations and felt bound to accept, sort out, and develop their legacies. Aristotle was considered the master by an intellectual elite fascinated by his method of logical reasoning. The influence of Aristotle was reflected in Mu'tazilism, a school of thought that flourished in Basra before reaching its peak in Baghdad. Without breaking with orthodoxy, the Mu'tazilīs aimed at harmonizing reason and faith; therefore, they assigned free will to man and regarded the Qui'an as created by God, unlike strict orthodox Sunnīs, who hold it uncreated, coeternal with God. Anticipating that he could rely on the support of the

intellectual elite against his opponents, al-Ma'mūn embraced the Mu'tazilī doctrine, but he came up against difficulties when he wanted to enforce the createdness of the Qui'an as a formal tenet. Al-Ma'mūn's religious policy alienated both the Shī'īs and the Sunnīs, and in order to maintain his precarious position he inaugurated a severe inquisition (*miḥnah*).

In ordering the *miḥnah* al-Ma'mūn had proved that the 'Abbāsīd caliph could become an *imām*, a spiritual ruler, although without any right of legislation on purely religious matters such as worship and canon law; in addition, he was a monarch whose powers were fixed by the Shar'īah, the Islāmic law. Though these powers were held in the person of the caliph, he frequently delegated them to a vizier placed at the head of the hierarchical central administration, which included the army, the chancery, the ministry of finance, the postal system, and the intelligence service. A great *qāḍī*, with his seat at Baghdad, headed the administration of justice. Provincial towns often were governed by 'Abbāsīd princes, who were closely connected with the central government, the orders of which they carried out.

From the economic point of view, the founding of Baghdad shifted international trade toward Iraq and developed Basra as an emporium and transit centre. The capital was the hub of Middle Eastern trade. From Baghdad, merchants sailed to India, Ceylon, and even China, while overland trade routes converged on Baghdad from Asia Minor, Syria, Egypt, Arabia, and Persia.

It was not long, however, before Iraq shared in the political and economic decline of the caliphate. Religious conflicts had to some extent weakened the authority of the caliph and divided the Muslim community. Yet a powerful administration for some time kept up a semblance of cohesion, in spite of centrifugal forces tending to detach several outlying provinces from Baghdad.

When al-Mu'tasim (833–842) succeeded to power, he enrolled a number of foreign mercenaries, mainly Turkish slaves, in his bodyguard. The officers of the new Turkish guard rapidly distinguished themselves in war and rose to influential positions. Since the excesses of these troops created a dangerous state of tension in Baghdad, al-Mu'tasim in 836 moved his residence to a new city, Sāmarrā', about 60 miles (97 kilometres) north of Baghdad. Henceforth, Turkish mercenaries dominated the empire and controlled the succession of caliphs. Under al-Wāthiq (842–847), the commander of the Turkish guard was even given the title of sultan. Al-Mutawakkil (847–861) succeeded to the throne with the help of two Turkish chiefs. In a desperate attempt to restore the caliph's authority, al-Mutawakkil endeavoured to conciliate the orthodox Muslims (Sunnīs). He persecuted not only the Mu'tazilites but also the Shī'īs and imposed severe restrictions on Jews and Christians, compelling them to wear distinctive dress.

These measures did not prevent the decline of the dynasty. Between 861 and 870 four caliphs appeared in succession; they were to suppress a revolt of the Turks leading to the siege of Baghdad in 865–866 and, more especially, a serious uprising of Negro slaves (the Zanj) settled in the swamps of Lower Mesopotamia; the operations launched against them during 15 years (869–883) wore out the resources of the government. Basra was sacked (871), Lower Iraq occupied, Wāsiṭ taken (878), and the country devastated. This social revolt threatened the caliphate, which at the same time was faced with other rebellions in Khorāsān, Egypt, Ṭabaristān, and in other areas.

About 890 Lower Iraq was again shaken by revolt, this time by Ḥamdān Qarmat, whose followers won tremendous victories and gained control over parts of Iraq, Syria, and Palestine. Al-Mu'tamid (870–892) re-established the seat of the caliphate in Baghdad (892) shortly before he died, and his successors did not return to Sāmarrā'. Al-Muktafi (902–908) stopped the Qarmaṭian movement temporarily, but the rebels resumed their activity and plundered Kūfah in 925.

In addition to such factors of internal decay, centrifugal forces compelled the 'Abbāsīds to grant independence to some provinces, even on the borders of Iraq. As early as

decline

890, the Ḥamdānids, who were to come into prominence in Aleppo during the 10th century, created an independent amirate in Mosul, and the Caliph himself was sometimes induced to ask their help. Less than two centuries after the beginning of 'Abbāsīd rule, Iraq became practically the sole possession of the caliphate. Struggles among the Turkish commanders and between the Turks and the Daylamite and other elements of the army reduced even Baghdad and the neighbourhood to anarchy.

#### THE BUYIDS

In 936 the caliph ar-Rādī (934–940) introduced the title of *amīr al-umara'*, (amir of the amirs) and bestowed it on Muḥammad ibn Rā'iq, governor of Basra, retaining for himself only the religious leadership of the Muslim community. The new title brought about serious rivalries between several pretenders to it, until the Būyids, a Shī'ī family from Daylam, a mountainous region in Iran, made themselves masters of Basra, Wāsiṭ, and Baghdad, ushering in a new stage and giving the caliphate, which had retained part of its previous prestige, a still unknown character. Although it reached its lowest ebb during the period of Būyid supremacy, the caliphate was not entirely eliminated by the Būyids, who probably hoped to use such glamour as the 'Abbasids still possessed. Moreover, the survival of a sunnī caliphate left them with a free hand for their own political and religious aims. They were content with the rank of *amīr al-umara'* and with honorary titles ending with ad-Dawlah ("of the dynasty," e.g., "friend of the dynasty," or "support of the dynasty"), but it is obvious that they held all powers in their hands.

The reign of the first of them, Mu'izz ad-Dawlah (945–967), was largely occupied by internal rebellions and a series of expeditions against the Ḥamdānids; confiscations of the property of officials on death or dismissal were common, and offices were put up to the highest bidder. The Amīr al-Umarā' did nothing to improve conditions and had no care for the local population; he also made grants of land to his troops, the result of which was to bring agriculture into a hopeless state of disorganization. Under his successor 'Izz ad-Dawlah (967–977), Turkish mercenaries revolted and seized power. In 977 'Aḍud ad-Dawlah became the chief of the family; he ruled first in Fars, and then in Fars and Iraq (977–983). A capable ruler, 'Aḍud ad-Dawlah kept up some prosperity, improved roads, dug canals, reorganized the postal system, stamped out brigandage, and fostered trade. After his death the Būyid dynasty rapidly declined; the western provinces of their dominions were torn by internecine strife, the administrative system collapsed, and agriculture fell into decay.

In the field of finance, reforms initiated by the Būyids were connected with the pay of troops: the caliphs had tended to grant to the military an increasing amount of lands subject to the tithes. When the treasury proved unable to cover the cost of the army, the Būyids introduced the practice of granting *iqṭā's*, or lands hitherto subject to land tax (*kharāj*). The beneficiaries of *iqṭā's* levied the revenue of the *kharāj* themselves and paid nothing to the treasury. The debilitating consequences of such a system contributed to the political disintegration of the empire.

As for religion, the Būyids did not fail to spread their Shī'ī doctrines and practices, erecting in particular mausoleums on the tombs of the *imāms*. In spite of their Daylamite origin, the Būyids were eager supporters of Arabic culture, although they also favoured the development of new Iranian influences. It was at that time that rhymed prose gained ground in the Chancery and literature, the *maqāmah* appeared, and a new style was initiated in epistolography, yet most of that activity took place beyond Iraq. Baghdad, where Arabic culture had reached its height—with prose writers such as al-Jāhīz, Ibn Qutaybah, al-Mas'ūdī, and many others; historians such as al-Ya'qūbī, aṭ-Ṭabarī, or ad-Dīnawarī; poets such as Abū Nuwās, Abū Tammām, al-Buḥturī, and others; philosophers such as al-Fārābī; and scientists such as al-Khwārizmī—was not quite superseded, but it was challenged by other centres, such as Shirāz and Isfahan, let alone Cairo, where the Faṭimids established themselves in 969, attract-

ing a large part of the flow of trade that previously had converged on Iraq.

In fact, a large district of Iraq escaped Būyid control; just as Mosul was in the hands of the 'Uqaylids, so, as early as 1012, the Mazyadids were recognized as *amīrs* over an area extending from Basra to Hīt; they threatened Baghdad itself, where the 'ayyārūn were terrorizing the inhabitants, being actually the masters of the capital. The activities of the 'ayyārūn lasted until 1055—when the Seljuq ruler, Toghrīl Beg, entered Baghdad—and perhaps a little longer.

#### THE SELJUQS

A former high official of the Būyids, al-Basāsīrī, who had risen to power in Baghdad, fled on Toghrīl's coming, but it was not long before he marched on the city, occupied it on December 27, 1058, and proclaimed the Faṭimid al-Mustansīr caliph; the 'Abbāsīd al-Qā'im took refuge with the 'Uqaylids, and al-Basāsīrī extended his control over Basra and Wāsiṭ, with Mazyadid support. In 1059 Toghrīl reconquered Baghdad, and the caliph returned.

While the power of the Būyids had been usurped, that of the Seljuq Turks was given a legal basis. Unlike the Būyids, the Seljuqs were Sunnī, hence the caliph recognized them as sultans and delegated all his powers to them, entrusting them with eradicating Shī'ism from Iraq and other parts of the empire. With their eagerness to restore and assert Sunnism, they must be credited with the founding of *madrāsahs*—high colleges intended for training future officials in both religious and secular matters. The most famous among those *madrāsahs* is the Nizāmīyah, founded at Baghdad in 1067. Nevertheless, the Seljuqs did not take Baghdad as their capital, since they lived at Isfahan and later (from 1157 onward) at Hamadan. During the Seljuq period, the history of Iraq is that of a succession of Turkish sultans who regarded the ancient centre of the Islāmic Empire as a kind of protectorate under religious leadership of the caliph, who was not more than a local ruler, certainly less powerful, in the political and military field, than the Zangids in Mosul or the Mazyadids in Lower Iraq. The Arab dynasty of the Mazyadids came to prominence in al-Jāmi'ān (called al-Ḥillah from 1101 onward); they were Shī'ī, as were the majority of the Arab tribes in the region, and ready to support 'Alid movements against the Seljuqs or play off some of them against the others. Profiting by the struggles between Berk-yaruq and his brother Muḥammad, Ṣadaqah ibn Manṣūr extended his power over almost all Iraq by the end of the 11th century; the towns of Hīt, Wāsiṭ, Basra, and Takrīt fell into his hands, but he was killed in a battle against the Seljuqs in 1108, and the dynasty of the Mazyadids eventually came to an end in 1163.

In 1118 there came to power a branch of Seljuqs who established an autonomous principality in Iraq that lasted until 1194. During this period the caliphs made some attempts to dispute the supremacy of the sultans and shake off their tutelage, but these actions resulted in struggles, notably in the reign of Sultan Mas'ūd (1134–52). Al-Mustarshid (1118–35) was the first caliph in Seljuq times to assemble an army and lead it in person. But al-Mustarshid was executed in 1135, as was his successor, ar-Rashīd, in 1136. Subsequently, on the death of Mas'ūd, al-Muqtafī (1136–60) established himself as the legitimate sovereign in Iraq, exercising both temporal and religious power. Later, the caliph an-Nāṣir (1180–1225) tried to restore some importance to the caliphate by conciliating Sunnīs and Shī'īs and using associations of various kinds (grouped under the general name of *futūwah*) as instruments of moral and social education, hoping to restore the moral and political unity of the 'Abbāsīd Empire. Furthermore, about 1192, he appealed to the *khwārezm-shāh* Tekesh for help against Toghrīl III, the last of the Seljuq sultans of Iraq, who was defeated in 1194 and his dynasty overthrown. An-Nāṣir contended with Tekesh for Seljuqs' spoils and succeeded in taking Khuzistan and other Persian provinces. But Tekesh proved a more dangerous rival than Toghrīl; shortly

culture

before his death (1200), he demanded that the *khuṭbah* (the Friday sermon in the great mosques) should be read in Baghdad in the name of the Khwārezm-Shāh. An-Nāṣir refused, and in 1196 fighting took place between the Khwārezm-Shāh's army and the Caliph's, to the disadvantage of the latter. Some years later, Muḥammad ibn Tekesh reiterated his father's demand and met with an uncompromising refusal. The conflict culminated in 1216, when the Caliph had a former official of Tekesh assassinated. In the following year Muḥammad ibn Tekesh set out for Baghdad but was unable to take the city, his army being annihilated by the Kurds. An-Nāṣir played off the Mongol leader Genghis Khān against the Khwārezm-Shāh, and the latter was defeated in 1219.

#### THE MONGOLS

Unfortunately, an-Nāṣir's successors, az-Zāhir (1225–26), al-Mustanṣir (1226–42), and al-Musta'ṣim (1242–58), were weak and unable to carry on his policy. In the meantime, Hülegü, a descendant of Genghis Khan, who established Mongol power in Iran, invited the caliph al-Musta'ṣim to surrender and, on his refusal, marched on Baghdad, which he took on February 10, 1258, after a siege of some seven weeks. Al-Musta'ṣim and several members of his family were put to death; the city was sacked and its inhabitants slaughtered. Iraq, the core of the 'Abbāsid Empire, was devastated and depopulated. It did not recover for centuries.

Until 1339 the province of Iraq remained under the domination of the Īl-Khāns, a Mongol dynasty founded in Persia by Hülegü. Under the Īl-Khāns, the western frontier of Mesopotamia was the political boundary of Persia, Baghdad being the capital of Lower Mesopotamia and Mosul the seat of another government. In 1295, Baydu, a grandson of Hülegü and governor of Iraq, seized power, but he was overthrown in the same year by Ghāzān, governor of Khorāsān. When Abū Sa'īd, the 9th Īl-Khān, died in 1335, Ḥasan Buzurg (died 1356) founded in Baghdad the dynasty of the Jalāyirids, who achieved some success, chiefly in Fars and Upper Mesopotamia, but they were compelled to suppress a succession of revolts in Baghdad. Restless Bedouin tribes in the south and Turkmens and Kurds in the north complicated the state of affairs and hastened the decline of a moribund country. This small dynasty of Mongol origin ruled from 1339 to 1410 and incorporated Mosul into its dominions in 1364. On two occasions, however, in 1393 and particularly in 1401, Timur (Tamerlane) took and sacked Baghdad, slaughtered its inhabitants, and pulled down a great part of the town. Aḥmad the Jalāyirid (died 1410), driven out by Timur, recovered Baghdad in 1394 and again in 1405 and tried to make good the damages. Until 1432, Jalāyirid rulers retained some power in Lower Mesopotamia (al-Ḥillah, Basra, Khuzistan) but were unable to preserve Baghdad, which fell (1411) into the hands of the Kara Koyunlu (the Black Sheep), a Turkmen dynasty that ruled Asia Minor from 1375 to 1468. This period is also marked by political fragmentation and rivalries between Baghdad and Mosul. The rule of the Turkmens was challenged by the politico-religious movement of the Musha'sha', who came into prominence in Khuzistan, attempted to extend their control over Lower Iraq, and harried the Kara Koyunlu as far as the outskirts of Baghdad, which they were not able to take. In 1468, the Ag Koyunlu (the White Sheep) took over from the Kara Koyunlu, ruling from Tabriz; in 1503, the last member of the dynasty was compelled to seek refuge at Baghdad, where he ruled till 1508, when Iraq, including Mosul, fell under the sway of the Shī'ī Ṣafavids and remained in their possession until the Ottomans conquered it. In spite of the weakness of the local government, Iraq enjoyed a fairly prosperous economy during this short period.

#### THE OTTOMANS

Although Sultan Selim I (1512–20) had crushed the Ṣafavid armies at Chāldirān in 1514 and taken Tabriz, Mosul, Diyarbakır, and several Kurdish areas east of the Tigris in 1515–17, Iraq proper remained under Persian control for some time. In Baghdad, the Kurdish

leader Dhū al-Faqār raised a revolt in 1527 that induced Shāh Ṭahmāsp (1524–76) to assert Persian authority over central Iraq more firmly than ever, but hostilities started again between him and Süleyman (Sulayman the Magnificent, 1520–66); the latter entered Baghdad in 1534, and Iraq remained in the possession of the Ottomans until March 1917, though not without trouble: the peace was somewhat disturbed by intermittent struggles between Turks and Iranians, resulting in the occupation of Baghdad by the Ṣafavids from 1623 to 1638; the Turkish communications were at the mercy of turbulent tribesmen; and parts of the country were semi-independent at one time or another. The long period of Ottoman rule, however, witnessed some revival of Baghdad, improvement of living conditions, and administrative reorganization on Western lines as well as the beginning of European penetration.

The Ottomans had assumed the title of caliph, and the capture of the last 'Abbāsid puppet in Cairo (1517) had emphasized their feeling that they were the successors of the great Baghdadian dynasty; therefore, the conquest of Baghdad increased Süleyman's prestige, but it had another consequence: on the one hand, it temporarily brought to an end the rivalries between Shī'īs and Sunnīs and materialized the triumph of Sunnism in the country where such religious conflicts were frequent; on the other hand, the conquest of Egypt had made the Ottomans the masters of the Red Sea, which retained, in spite of the discovery of the Cape route around Africa at the end of the 15th century, much of its former importance in international trade. As masters of the Persian Gulf, the Ottomans could control all the traffic in the Middle East. Last but not least, Iraqi territories were a kind of buffer against not only the rulers of Iran but also the restless tribes of Kurds and Arabs.

Basra, always eager to preserve independence, played a certain part under the Ottoman rule. At first a vassal of the Sultan, it tried to shake his suzerainty, but two expeditions sent from Baghdad in 1546 resulted in its incorporation into the Ottoman possessions in Iraq, which was divided at the time into five *eyalets*: Baghdad, Basra, Mosul, Shahrazūr, and al-Ḥasā, on the western shore of the Persian Gulf.

For almost two centuries the Ottomans tried to exercise a sort of direct rule over Iraq. Süleyman organized local administration, made a survey of the lands, appointed governors, sent Janissaries, and displayed some building activity, mainly in Baghdad, which became a prosperous centre of trade much admired by European travellers. Early in the 17th century, however, a Janissary officer named Bakr Şū Bāshī revolted, held sway over Baghdad—which he terrorized—and entered upon negotiations with Shāh 'Abbās I (1587–1629) in order to strengthen his position, but Iraq was taken by the Ṣafavids in 1623, the Ottomans being able to preserve only Mosul and Shahrazūr. The Persians destroyed many buildings, including Sunnī mosques, and several thousands of inhabitants were killed or sold as slaves.

Just as in al-Ḥasā a family of governors ruled from the late 16th century until 1663, so in Basra Afrāsiyāb an army officer of unknown origin purchased the governorship from the local pasha in 1612 and founded a small dynasty of governors who ruled the town until 1668 and favoured European penetration by opening the doors to English, Portuguese, and Dutch merchants trading in the Persian Gulf. Afrāsiyāb offered strong resistance to the Ṣafavids but did not support Baghdad against them.

In the meantime, Baghdad had been retaken in 1638 by Sultan Murad IV (1612–40), and a great many Shī'īs were massacred. A treaty concluded in 1639 at Qasr-e Shīrīn between the Ottomans and Ṣafavids fixed the boundaries of the two states.

This Ottoman victory did not bring stability to Iraq, and the rulers had to suppress many disturbances caused by the turbulent garrison troops and unruly Arab and Kurdish tribes. In Lower Iraq, after the Afrāsiyāb dynasty was overthrown, the Arab tribes of al-Muntafiq and Ḥuwayza threatened the Ottoman supremacy, while Iranians penetrated into this region. After the Treaty of Karlowitz

Beginning  
of  
European  
penetration

(1699) with Austria, Russia, Poland, and Venice, the Ottomans were able to send some troops to Iraq and recover Basra. In spite of the 1639 settlement, Baghdad was still the stake of struggles between Turks and Persians because of its being the most important city in the east of the Ottoman possessions.

From 1704 a new government system was introduced in Iraq by Hasan Paşa (governor from 1704 to 1724), his son Ahmad Paşa (1724–1747), and their successors. Themselves of Georgian origin, they relied on young Georgian slaves, trained in a special school, to become the chiefs of the main administrative services; those *mamlüks* (slaves), known in Turkish as *kölemen*, sometimes reached governorship in Baghdad and applied personal policies; they suppressed revolts, restored order, annexed Basra, and promoted some prosperity in the country. In 1733, however, Nāder Shāh (later ruler of Iran from 1736 to 1747) besieged Baghdad but was compelled to withdraw from the capital; in 1742, he also failed to seize Mosul, governed by a native pasha, 'Abd al-Jalīl, whose family, the Jalīlis, ruled there from 1726 to 1834, and an agreement in 1746 confirmed the terms of the Qasr-e Shīrīn settlement. In 1775, Basra, where an agency of the British East India Company had been established as early as 1763, was lost for five years to Šādīq Khān, a brother of Karīm Khān Zand, the ruler of Persia. Süleyman Paşa (later known as Büyükle the Great), governor of Basra, was transported to Shīrāz and came back on Karīm's death, took possession of Baghdad, and was given the governorship of Baghdad, Basra, and Shahrazūr by the Sultan. Under Büyükle (1780–1802), the *kölemen* rule reached its zenith. He fostered agriculture and trade, built several monuments, and, in 1798, permitted a permanent British resident to be appointed in the capital. Shortly before he died, however, Iraq was attacked by the Wahhābīs of Arabia, who penetrated into al-Hasā and, with their iconoclastic zeal, raided and sacked in 1802 Karbalā', the holy city of Shī'īs, despite the support of the Muntafiq confederacy to Baghdad.

The *kölemen* regime lasted until 1831, when Sultan Mahmud (1730–54) turned out Dawud Paşa from Baghdad after famine and flood had devastated and depopulated the city. From 1831, the Sublime Porte had high hand over Iraq, the history of which is henceforth characterized by administrative, economic, and social reform, together with European penetration. English, French, and Italian agencies and consulates were established in Basra. A company for river traffic between Basra and Baghdad was created; a telegraphic line linked Istanbul with Baghdad; but the Ottoman authority over the tribesmen was still weak. A new stage came with the governorship of Midhat Paşa (1869–72), who enforced the Ottoman law of *vilyets*, introduced a new administrative system, including an elected town council, created a press and the earliest Iraqi newspaper (*az-Zawwā'*, 1869), founded primary and secondary military schools, and inaugurated the Baghdad–Kāzīmāyn tramway line. This was a meritorious attempt at modernizing the country, at least Baghdad. Progress continued until the early 20th century, when Arabic-speaking Iraqi leaders began to lose confidence in the Ottomans and to dream about independence within the framework of a Pan-Arab and anti-Ottoman movement.

On November 20, 1914, an Anglo-Indian expeditionary force occupied Basra; Gen. Charles Townshend seized Kūt al-'Amārah in 1915 but was compelled to surrender on April 29, 1916; finally, the British took possession of Baghdad in March 1917, Mosul remaining in the hands of the Ottomans until the armistice of Mudros (October 30, 1918). (C.L.P.P.)

#### IV. Iraq since 1918

##### BRITISH OCCUPATION AND THE MANDATORY REGIME

The merging of the three provinces of Mosul, Baghdad, and Basra into one political entity and the creation of a nation out of the diverse religious and ethnic elements inhabiting these lands was accomplished by the events and circumstances following World War I. Action undertaken

by the British military authorities during the war and the upsurge of nationalism after the war helped determine the shape of the new Iraqi state and the course of events during the postwar years, until Iraq finally emerged as an independent political entity in 1932.

British control of Iraq, however, proved to be short-lived. After the war Britain debated both its general policy in Iraq and the specific type of administration to establish. Two schools of thought influenced policy makers in London. The first, advocated by the Colonial Office, stressed a policy of direct control to protect British interests in the Persian Gulf and India. Assessing British policy from India, this school may be called the Indian school of thought. The other school, hoping to reconcile Arab nationalism, advised indirect control. In Iraq itself, British authorities were divided on the issue. Some, under the influence of Sir Arnold Wilson, the acting civil commissioner, advocated direct control; others, alarmed by growing dissatisfaction with the British administration, advised indirect control and suggested the establishment of an indigenous regime under British supervision. Britain was still undecided on which policy it should follow in 1920 when external events in other Arab countries radically changed the internal conditions of Iraq.

Early in 1920 the *amīr* Fayṣal I, son of the *sharīf* Ḥusayn, who had led the Arab Revolt in 1916, established an Arab government in Damascus and was proclaimed king of Syria. Meanwhile, a group of Iraqi nationalists met in Damascus to proclaim the *amīr* 'Abd Allāh, older brother of Fayṣal, as king of Iraq. Under the influence of nationalist activities in Syria, nationalist agitation followed first in northern Iraq and then in the tribal areas of the Middle Euphrates. By the summer of 1920 the revolt had spread to all parts of the country except the big cities of Mosul, Baghdad, and Basra, where British forces were stationed.

In July 1920, Fayṣal came into conflict with the French authorities over control of Syria. France had been given the mandate over Syria and Lebanon in April and was determined to obtain Fayṣal's acceptance of the mandate. Nationalists urged Fayṣal to reject the French demands, and conflict ensued between him and the French, resulting in his expulsion from Syria. Fayṣal went to London to complain about the French action.

Although the revolt in Iraq was suppressed by force, it prompted both Iraq and Great Britain to reconcile their differences. In Britain a segment of public opinion wanted to "get out of Mesopotamia" and urged relief from further commitments. In Iraq, the nationalists were demanding independence. When Fayṣal arrived in London, the question of Iraq had been the subject of discussion between the Colonial and Foreign offices. In 1921 Britain offered the Iraqi throne to Fayṣal along with the establishment of an Arab government under British mandate. Fayṣal wanted the throne if it were offered to him by the Iraqi people. He also suggested the replacement of the mandate by a treaty of alliance. These proposals were accepted by the British government, and Winston Churchill, then colonial secretary, promised to carry them out. He was advised by T.E. Lawrence, known for his sympathy for the Arabs.

In March 1921 a conference presided over by Churchill was held in Cairo to settle Middle Eastern affairs. Fayṣal was nominated to the Iraqi throne, provided that a plebiscite be held to confirm the nomination. Sir Percy Cox, recently appointed a high commissioner for Iraq, was entrusted with carrying out the plebiscite before Fayṣal's accession to the throne. A provisional government set up by Cox shortly before the Cairo Conference passed a resolution on July 11, 1921, declaring Fayṣal king of Iraq, provided that his "Government shall be constitutional, representative and democratic." The plebiscite confirmed this proclamation, and Fayṣal was formally crowned king on August 23, 1921.

The establishment of the monarchy was the first step in the establishment of a national regime. Two other steps followed immediately: the signing of a treaty of alliance with Great Britain and the drafting of a constitution. It was deemed necessary that a treaty should precede the constitution and define relations between Iraq and

Amīr 'Abd Allāh proclaimed king

Treaty of  
alliance  
with  
Britain

Britain. The treaty was signed on October 10, 1922. Without direct reference, it reproduced most of the provisions of the mandate. Iraq undertook to respect religious freedom and missionary enterprises and the rights of foreigners, to treat all states equally, and to cooperate with the League of Nations. Britain was obligated to offer advice on foreign and domestic affairs, such as military, judicial, and financial matters (defined in separate and subsidiary agreements). Although the terms of the treaty were open to periodic revision, they were to last 20 years. In the meantime, Britain agreed to prepare Iraq for membership in the League of Nations "as soon as possible."

It soon became apparent that the substance, though not the form, of the mandate was still in existence and that complete independence had not been achieved. Strong opposition to the treaty in the press made it almost certain it would not be ratified by the Constituent Assembly. Nor was British public opinion satisfied with the commitments to Iraq. During the general elections of 1922 there was a newspaper campaign against British expenditures in Iraq. In deference to public opinion, both in Britain and Iraq, a protocol to the treaty was signed on April 30, 1923, reducing the period of the treaty from 20 to four years. Despite the shortening of British tutelage, the Constituent Assembly demanded complete independence when the treaty was put before it for approval. Ratification of the treaty was accomplished on June 11, 1924, after England's warning that nonapproval would lead to the referral of the matter to the League of Nations.

The Constituent Assembly then moved to consider a draft constitution drawn up by a constitutional committee. The committee tried to give extensive powers to the king. Discussion on the draft constitution by the Constituent Assembly lasted a month, and, after minor modifications, it was adopted in July 1924. The Organic Law, as the constitution was then called, went into effect right after it was signed by the King on March 21, 1925. It provided for a constitutional monarchy, a parliamentary government, and a bicameral legislature. The latter was composed of an elected House of Representatives and an appointed Senate. The lower house was to be elected every four years in a free manhood suffrage. The first Parliament met in 1925. Ten general elections were held before the downfall of the monarchy in 1958, and over 50 Cabinets formed during the same period reflected the instability of the system.

From the establishment of a national government, there was keen interest in organizing political parties. Three parties, organized in 1921, one by the group in power and two by opposition parties, had similar social and economic views and essentially the same political objective: termination of the mandate and the winning of independence. They differed, however, in the means of achieving the objective. After the achievement of independence in 1932, these parties dissolved, because their *raison d'être* had disappeared. It was only when social issues were discussed that new political groupings, even if not formally organized as political parties, began to emerge. The power struggle among these groups became exceedingly intense after World War II.

The Iraqi nationalists, though appreciating the free expression of opinion permitted under a parliamentary system, were far from satisfied with the mandate. They demanded independence as a matter of right, as promised in war declarations and treaties, rather than as a matter of capacity for self-government as laid down in the mandate. Various attempts were made to redefine Anglo-Iraqi relations, as embodied in the 1926 and 1927 treaties, without fundamentally altering Britain's responsibility. The British treaties were deemed by the nationalists as not only impeding the realization of Iraq's nationalist aspirations, but also inimical to the economic development of the country. The nationalists viewed the situation as a "perplexing predicament" (*al-waḍ'ash-shadh*)—a term that became popular in Parliament and the press. It referred to the impossibility of government by the dual authority of the mandate. The nationalists argued that there were two governments in Iraq, one foreign and the other national, and that such a regime was

The

"per-  
plexing  
predica-  
ment"

an abnormality that, though feasible in theory, was unworkable in practice.

In 1929 Britain decided to end this stalemate and reconcile its interests with Iraq's national aspirations. It notified Iraq that the mandate would be terminated in 1932 and a new treaty of independence negotiated. A new government was formed, headed by Gen. Nūrī as-Sa'īd, who helped in achieving Iraq's independence.

The new treaty was signed on June 30, 1930. It provided for the establishment of a "close alliance" between Britain and Iraq, with "full and frank consultation between them in all matters of foreign policy which may affect their common interests." Iraq would maintain internal order and defend itself against foreign aggression, supported by Britain. Any dispute between Iraq and a third state, involving the risk of war, was to be discussed with Britain in the hope of a settlement in accordance with the Covenant of the League of Nations. In the event of an imminent menace of war, the two parties would take a common defense position. Iraq recognized that the maintenance and protection of essential British communications was in the common interest of both parties. Air-base sites for maintaining British troops were therefore granted and installed near Basra and west of the Euphrates, but these forces "shall not constitute in any manner an occupation, and will in no way prejudice the sovereign rights of Iraq." This treaty, valid for 25 years, was to come into effect after Iraq had become a member of the League of Nations. On October 3, 1932, Iraq was admitted to the League of Nations as an independent state.

#### INDEPENDENCE, 1932-39

Since conflict among Iraq's political leaders centred essentially on how to end the mandate rather than on the right of independence, King Fayṣal sought the cooperation of opposition leaders after independence. Shortly after Iraq's admission to the League, General Nūrī, who had been prime minister since 1930, resigned. After an interim administration, King Fayṣal invited Rashīd 'Alī al-Gaylānī, one of the opposition leaders, to form a new government. For a short while it seemed that all the country's leaders would close ranks and devote all their efforts to internal reforms.

But internal dissension soon developed. The first incident was the Assyrian uprising of 1933. The Assyrians, a small Christian community living in Mosul Province, were given assurances of security by both Britain and Iraq. When the mandate was ended, the Assyrians began to feel insecure and demanded new assurances. Matters came to a head in the summer of 1933 when King Fayṣal was in Europe. The opposition, now in power, wanted to impress the public through a high-handed policy toward a minority group. In clashes with the Iraqi troops several hundred Assyrians were brutally killed. The incident was brought to the attention of the League less than a year after Iraq had given assurances that it would protect minority rights. Had King Fayṣal been in the country, he would have counselled moderation. Upon his hasty return to Baghdad, he found deep-seated divisions and events beyond his control. Suffering from heart trouble, he returned to Switzerland, where he died in September 1933. The Assyrian incident brought about the fall of Rashīd 'Alī and his replacement by a moderate government.

Fayṣal was succeeded by his son, King Ghāzī (1912-39), who was still young and inexperienced—a situation that gave political leaders an opportunity to compete for power. Without political parties to channel their activities through constitutional processes, politicians resorted to extraconstitutional, or violent, methods. One extraconstitutional method involved clever political manoeuvring. Opposition leaders tried to embarrass those in power by press attacks, palace intrigues, or incidents that would cause Cabinet dissension and force the prime minister to resign. The first five governmental changes after independence, from 1932 to 1934, were produced by these methods.

The second device used was the incitement of tribal

The  
Assyrian  
uprising  
of 1933

uprisings in areas where there were tribal chiefs unfriendly to the group in power. Tribes, though habitually opposed to authority, had been brought under control and remained relatively quiet after 1932. When opposition leaders began to incite them against the government in 1934, however, they rebelled and caused the fall of three governments from 1934 to 1935.

The third method was military intervention. The opposition tried to obtain the loyalty of army officers, plan a coup d'état, and force those in power to resign. This method, often resorted to by the opposition, proved to be the most dangerous because, once the army intervened in politics, it became increasingly difficult to re-establish civilian rule. From 1936 until the army was defeated in a war with Britain, in 1941, the army dominated domestic politics. The army again intervened in 1958, and it continues to dominate the political scene.

The  
coup d'état  
of 1936

Two different sets of opposition leaders produced the first military coup d'état in 1936. The first group, led by Hikmat Sulaymān, was a faction of old politicians who sought power by violent methods. The other was the Ahālī group, composed mainly of young men who advocated Socialism and democracy and sought to carry out reform programs. It was Hikmat Sulaymān, however, who urged Gen. Bakr Ṣiqī, commander of an army division, to stage a surprise attack on Baghdad, in cooperation with another military commander, and forced the cabinet to resign. It seems that young King Ghāzī had also been disenchanted with the group in power and so allowed the government to resign. Hikmat Sulaymān became prime minister in October 1936, and Bakr Ṣidqī was appointed chief of the general staff. Neither the Ahālī group nor Hikmat Sulaymān could improve social conditions, however, because the army gradually dominated the political scene. Supported by opposition leaders, a dissident military faction assassinated Bakr Ṣidqī, but civilian rule was not re-established. The significance of this first military coup lies in the fact that it introduced a new factor in politics. Lack of leadership after the assassination of Bakr Ṣidqī left the army divided, while jealousy among leading army officers induced each faction to support a different set of civilian leaders. The army continued to influence political decisions behind the scenes and became virtually the deciding factor in Cabinet changes from 1936 to 1941.

Despite political instability, material progress continued under King Ghāzī's short reign: the Kūt al-'Amarah irrigation project, begun in 1934, was completed; other projects, to be financed by oil royalties, were laid down; the pipelines from the Kirkūk oil fields to the Mediterranean were opened in 1935; the railroads, still under British control, were purchased in 1935, and the Ba'ījī-Tal Küçük section, the only missing railway link between the Persian Gulf and Europe, was completed in 1938; and there was a noticeable increase in construction, foreign trade, and in educational facilities. Several outstanding disputes with Iraq's neighbours were settled, including the dispute with Iran over the Shatt al-Arab in 1936 and the boundary with Syria, which was settled in Iraq's favour to include within its boundary the Jabal Sinjār. A nonaggression pact, called the Sa'dābād Pact, between Turkey, Iran, Afghanistan, and Iraq was signed in 1937. Arab cooperation was stressed in a nonaggression agreement with Saudi Arabia and Yemen. In 1939, shortly before the outbreak of World War II, King Ghāzī was killed in a car accident and his son Fayṣal II ascended the throne. As Fayṣal was only four years old, Fayṣal's uncle, Amīr 'Abd al-Ilāh, was appointed regent and served in this capacity for the next 14 years.

#### WORLD WAR II AND BRITISH INTERVENTION, 1939-45

General Nūrī, author of the 1930 treaty, was prime minister when World War II broke out. Believing that the Anglo-Iraqi alliance was the best guarantee for Iraqi security, he wanted to declare war on Germany, but his ministers counselled caution as British victory was then in doubt. General Nūrī accordingly declared Iraq nonbelligerent and severed diplomatic relations with Germany. When Italy entered the war, however, Nūrī, then

Minister of Foreign Affairs in Rashīd 'Alī al-Gaylān's Cabinet, was unable to persuade the Cabinet to break off diplomatic relations with Italy. Under the influence of Pan-Arab leaders, public opinion in Iraq radically changed after France's fall, becoming especially hostile to Britain because other Arab countries remained under foreign control. Pan-Arabs urged Iraqi leaders to free Syria and Palestine and achieve unity among Arab countries. Extremists advocated alliance with Germany as the country that would foster independence and unity among Arabs.

Rashīd 'Alī was at first unwilling to side with the extremists and gave lip service to the Anglo-Iraqi alliance. But dissension among the Iraqi leaders forced Rashīd 'Alī to side with the Pan-Arabs. Leading army officers also fell under Pan-Arab influences and encouraged Rashīd 'Alī to detach Iraq from the British alliance. During 1940 and 1941 Iraqi officers were unwilling to cooperate with Britain, and the Pan-Arab leaders began secret negotiations with the Axis Powers. Britain decided to send reinforcements to Iraq. Rashīd 'Alī, while allowing the landing of a small British force in 1940, was overthrown from power early in 1941, but he was reinstated by the army in April and refused further British requests for reinforcements.

British contingents entered Iraq from the Persian Gulf as well as from the Ḥabbānīyah air base during April and May 1941; armed conflict with the Iraqi forces followed. The hostilities lasted only 30 days, during which period a few Iraqi leaders, including the regent and General Nūrī, fled the country. By the end of May the Iraqi Army capitulated, and Rashīd 'Alī and his Pan-Arab supporters left the country.

The return of the regent and moderate leaders through British intervention had far-reaching consequences. Britain was given what it demanded: the use of transportation and communication facilities and a declaration of war on the Axis Powers in January 1942. Rashīd 'Alī's supporters were dismissed from the service and some of them interned for the duration of the war. Four officers who were responsible for the war were hanged.

#### POSTWAR RECONSTRUCTION AND SOCIAL UPHEAVALS, 1945-58

During World War II, liberal and moderate Iraqi elements began to play an active political role. The entry of the United States and the Soviet Union into the war on the side of Britain and their declarations in favour of democratic freedoms greatly enhanced the position of the Iraqi democratic elements. The people endured shortages and regulations restricting personal liberty and the freedom of the press, trusting that the end of the war would bring the promised better way of life. The government, however, paid no attention to the new spirit, and the wartime regulations and restrictions continued after the war. The regent called a meeting of the country's leaders in 1945 and made a speech in which he attributed public disaffection to the absence of a truly parliamentary system. He called for the formation of political parties and promised full freedom for their activities and the launching of social and economic reforms.

The immediate reactions to the regent's speech were favourable, but, when political parties were formed in 1946 and certain regulations abolished, the older politicians and vested interests resisted, and the new government formed in January 1946 to honour the regent's promises was overthrown within a few months of its inception. General Nūrī then became prime minister and tried to enlist the cooperation of political parties, but the general elections held under his government's supervision were no different from previously controlled elections. The parties boycotted the elections. General Nūrī resigned in March 1947, and Ṣāliḥ Jabr formed a new government.

Jabr, the first Shī'ī politician to become a prime minister, included in his cabinet a number of young men, but he himself was unacceptable to some liberal and nationalist elements who had been roughly handled when he was wartime Minister of Interior. Jabr tried to help the Arabs in Palestine in order to improve his image in national-

Hostility  
toward  
Britain

Ṣāliḥ  
Jabr's  
government

ist circles, but he mishandled opposition leaders. Most damaging was his attempt to replace the Anglo-Iraqi treaty of 1930 by another—without consultation with the country's leaders. When his attention was called to the need for consultation, he consulted only with older politicians and excluded younger leaders.

Jabr entered into negotiations with Britain with the intention of enhancing his own position. When he found that Britain wanted to retain control of its air bases in Iraq, he insisted that Britain accept the principle of Iraqi control of the bases and allow Iraq the use of the bases for defensive purposes. He threatened to resign if Britain refused his proposals. It was with this understanding that Jabr proceeded to London early in 1948 to negotiate a new treaty. Jabr and Ernest Bevin, the British foreign secretary, quickly came to an agreement and signed a new 20-year treaty at Portsmouth on January 15, 1948. It provided for a new alliance between Iraq and Britain on the basis of equality and complete independence and stated "each of the high contracting parties undertake not to adopt in foreign countries an attitude which is inconsistent with the alliance or which might create difficulties for the other party." The annex to the treaty stressed the importance of the air bases as "an essential element in the defense of Iraq," but Britain's use of the air bases in the event of war, or threat of war, would be dependent on Iraq's invitation. The treaty also provided for the establishment of "a joint defence board," equally represented by Britain and Iraq, for common defense and consultation. Both parties agreed to grant each other necessary facilities for defense purposes. An improvement of the 1930 treaty, this treaty sought an alliance on the basis of mutual interests. The two air bases, which were often the subject of criticism, were returned to Iraq. British forces were to be evacuated, and Iraq would be supplied with arms and military training.

Anti-British rioting

Despite these advances, the treaty was repudiated immediately in a popular uprising. Street demonstrations had been going on before the treaty was signed, in defense of Arab rights in Palestine, but, when the news of the signing of the new treaty was broadcast in London, rioting and demonstrations in Baghdad led to clashes between students and the police. The regent called a meeting at the royal household on January 21, which was attended by the country's leaders. After deliberations, it was decided to repudiate the treaty. Jabr returned to Baghdad to defend his position but to no avail. Rioting, demonstrations, and clashes with the police increased, and Jabr was forced to resign. Obviously the new treaty was not the root cause of the uprising. The uprising was the culmination of events in a struggle between the liberal and young leaders who wanted to participate in political activities and the older leaders who insisted on excluding the younger elements from public affairs. The conflict between the older and younger leaders continued after the treaty had been rejected. The older politicians returned to power under General Nūrī's leadership. By 1952 another popular uprising, stirred by opposition leaders and carried out by students and extremists, again manifested itself in rioting and street demonstrations. The police were unable to control the mob, and the regent called on the army to maintain public order. The chief of the general staff governed the country under martial law for more than two months. Civilian rule was restored at the beginning of 1953, but there was no sign that the country's older leaders were prepared to share authority with their opponents. Meanwhile, King Fayṣal II, who had come of age, began to exercise his formal powers, and the period of regency came to an end. It was hoped that the regent would withdraw from active politics and allow the political forces of the country to create a new order. The former regent, who became the crown prince, continued to control political events from behind the scene. The struggle for power among the leaders continued with increasing intensity until the downfall of the monarchy in 1958.

Despite political instability, Iraq achieved material progress during the 1950s, thanks to a new oil agreement that increased royalties and the establishment of the Develop-

ment Board. The oil agreement between the Iraqi government and the Iraq Petroleum Company (IPC), originally signed in 1925, had yielded relatively modest royalties, owing to certain technical limitations, such as construction of pipelines, and to war conditions. It was not until 1952 that construction of pipelines to Baniyas was completed. There were certain points of dispute between the government and the IPC that were not entirely resolved. The nationalization of the oil industry in Iran and the announcement of the 1950 agreement between Saudi Arabia and Aramco (Arabian American Oil Company), on a half-and-half basis of payment, induced the Iraqi government and IPC to negotiate a new agreement on the new pattern of the division of profits. Some of the opposition leaders demanded the nationalization of the oil industry, but the Iraq government and IPC, forestalling any serious move for nationalization, agreed to negotiate on the basis of the fifty-fifty formula, to the mutual advantage of Iraq and the company. The new agreement was signed in 1952, allowing Iraq to take in kind as part of its share and to receive an increasing amount of royalties specifically agreed upon between the two parties. It was then estimated that Iraq would receive no less than £30 million in 1953 and 1954 and no less than £50 million in 1955 and subsequent years.

Development of Iraq oil in the 1950s

In 1950 the government created the independent Development Board, an agency immune from political pressures and responsible directly to the prime minister. This agency provided for a body of six executive members, three of whom were to be experts in some branch of the development program. The prime minister, as chairman, and the minister of finance were ex-officio members. An amendment to the law increased membership by two and provided for a minister of development responsible directly to the head of the Cabinet. These members were appointed by the Cabinet, given equal voting rights, and might not hold any other official position. Two foreign members held positions as experts, and the Iraqi members were selected on merit and past experience. The board was composed of a council and ministry. Its staff was divided into technical sections and the ministry into a number of departments. The technical sections were for irrigation, flood control, water storage, drainage, transportation, and industrial and agricultural development. The board was financed from 70 percent of oil royalties and from loans and revenues from the board's own projects. The estimated expenditure of the first six-year program (1951–56) was £155,000,000, and in 1950 the World Bank provided a loan of \$12,800,000 for the Wādī ath-Tharthār flood-control project.

Creation of the Development Board

The Tharthār project, completed in 1956, connects the River Tigris at Samarrā' (some 60 miles north of Baghdad) with the Wādī ath-Tharthār Depression. A barrage was constructed on the Euphrates at Ramādī, making it possible to divert water into Lake Ḥabbāniyah. Other flood-control plans, such as that at Bakhma (completed after the revolution of 1958), were laid down. Extensive work on bridges and public buildings, including schools, hospitals, a new Parliament building, and a royal house, was started, and it was completed after 1958. This work, especially the work on dams and irrigation projects, was a long-term investment, and many short-term projects of more direct benefit to the population were neglected. Opposition leaders attacked the Development Board for the stress on long-term projects whose beneficiary, they held, were the vested interests—landowners and tribal chiefs. Despite criticism, the board maintained an independent status rarely enjoyed by any other government department. Nevertheless, the public remained unaware of the far-reaching effects of the projects undertaken, while the opposition attacked the board for squandering funds on contracts given to wealthy landlords and influential politicians.

#### THE REVOLUTION OF 1958

Despite material progress, the monarchy failed to win public support and, in particular, the confidence of the younger generation. Before the revolution, Iraq lacked an enlightened leadership capable of achieving progress

and inspiring public confidence. The new generation offered such leadership, but the older leaders resisted. Moreover, the older leaders embarked on an unpopular foreign policy, including an alliance with Britain and participation in a regional security plan, the Baghdad Pact. Above all, Iraq's opposition to the establishment of the United Arab Republic (U.A.R.) was viewed in Iraqi nationalist circles as opposed to Arab nationalist aspirations. These conflicts created a climate of opinion favourable to revolutionary change as the older leaders tried to suppress this opposition.

The failure of younger civilians to obtain power aroused the concern of the young officers, whose sympathies lay with their own age group. The young officers, watching the struggle among civilian leaders, began secretly to engage in underground activities to overthrow the old leaders. Required by military discipline to take no part in politics, these officers, calling themselves the Free Officers, began to organize in small groups and to lay down revolutionary plans. The number of officers who took part in clandestine activities was relatively small, but a considerably larger number of sympathizers, either directly or indirectly, supported the Free Officers movement. The officers worked in cells, and the identity of the participants was kept secret. Only the Central Organization, which supplied leadership of the movement, was known to all the Free Officers. The Central Organization was composed of 14 officers, headed by 'Abd al-Karīm Qāsim, who held the highest military rank. The officers were secretly in touch with some of the civilian leaders, but the plot was laid down by the officers themselves. In secret meetings the Free Officers made several decisions concerning the regime to be established by the revolution, such as the abolition of the monarchy and the establishment of a republic and a new democratic and representative, rather than authoritarian, system.

Several plots were laid down to overthrow the monarchy but were called off because circumstances seemed unfavourable; the plan that was laid down by Qāsim and his close collaborator 'Abd as-Salām 'Arif proved the most appropriate. The general staff issued an order to one of the brigades, in which 'Arif served, to proceed to Jordan on July 14, 1958, to reinforce the Jordanian forces against alleged threats by Israel. Brigadier Qāsim, in command of another brigade, was to protect the brigades going to Jordan. Qāsim and 'Arif agreed that as the brigade proceeding to Jordan passed through Baghdad it would capture the city.

On July 14 the Iraqi forces captured the capital by surprise and declared the downfall of the monarchy and the proclamation of a republic. A faction of the army took control of the radio-broadcasting building and other key government buildings; another surrounded the royal palace and put to death the leading members of the royal house, including the King and Crown Prince. Still another small force proceeded to surround the house of General Nūrī. Nūrī left his house from a back door and remained hiding in the city for two days; he was found and shot while he was trying to escape. Qāsim, head of the revolutionary force, proceeded to the Ministry of Defence and established headquarters. He formed a Cabinet, over which he presided, and appointed himself Commander of the National Forces. He also assumed the portfolio of defense and appointed 'Arif both Minister of the Interior and Deputy Commander of the National Forces. The vacancy created by the destruction of the monarchy was filled by a Council of Sovereignty, composed of three persons, to act as head of state.

The initial public reaction was favourable, and there were demonstrations in support of the revolutionary change. Qāsim responded by releasing political prisoners and allowing those in exile to return to the country. All parties and political groupings that had been banned were allowed to resume activities. A provisional constitution was promulgated until a new one could be drawn up by a national assembly. This constitution declared that Iraq formed an integral part "of the Arab nation," and "Arabs and Kurds are considered partners in this homeland." Iraq was declared a republic, Islām the religion of

the state, and all executive and legislative powers entrusted to the Sovereignty Council and the Cabinet during the transitional period. It soon became clear that power rested in Qāsim's hands, supported by the army whose immediate command was entrusted to Brigadier Ahmad Salih al-Abdi, one of Qāsim's protégés, and ultimately under Qāsim's own control. A military court, presided over by Colonel Fadil Abbas al-Mahdawi, another protégé, was designed to try political leaders of the old regime and others who conspired against the new regime.

Conflicts among the officers developed, first between Qāsim and 'Arif, and then between Qāsim and his supporters. 'Arif championed the Pan-Arab cause and advocated Iraq's union with the U.A.R. Qāsim rallied the forces against Arab unity—Kurds, Communists, and others—and stressed Iraq's own identity and internal unity. These forces supported Qāsim's drive against joining Egypt in an Arab union. 'Arif was dropped from power in December, but in the following year Qāsim became deeply involved in a power struggle with other factions. Qāsim's military opponents tried first to oust him through a plot in Baghdad and then by a military uprising in Mosul; both failed because Qāsim was able to manipulate forces and liquidate one opponent after another. He dealt ruthlessly with his foes and went so far as to execute some of his closest military supporters. He survived a plot to assassinate him in October 1959 by rallying Communist against nationalist factions. Qāsim might have committed himself to one ideological group and ruled the country in its name. He was, however, distrustful of both nationalists and Communists and tried to play off one against the other. In the last analysis, he had to rely on the army and tried to purge from it unreliable elements. Qāsim tried to divert public opinion from domestic conflicts to foreign affairs by putting forth Iraq's claim to Kuwait's sovereignty in June 1961. This claim brought him into conflict not only with Britain and Kuwait but also with the other Arab countries. He opened negotiations with the Iraq Petroleum Company to increase Iraq's royalties, but his extreme demands resulted in the breakdown of negotiations in 1961. A law, called Public Law 80, was enacted to prohibit the granting of concessions to any foreign company and to transfer control over all matters connected with oil to an Iraq National Oil Company (INOC).

By 1963 Qāsim had become isolated internally as well as externally. Even the Communists, who enjoyed more freedom under him than before, had certain reservations about him. He also came into conflict with most of Iraq's neighbours and with the Western powers. The only great power with which he remained on friendly terms was the Soviet Union because of financial assistance he had received. When one faction of the army, in cooperation with one nationalist group—the Ba'th—started a rebellion in February 1963, the Qāsim regime suddenly collapsed, and Qāsim was executed.

#### RECURRENCE OF MILITARY COUPS, 1963-68

The military faction that brought about the collapse of the Qāsim regime preferred to remain behind the scenes rather than to assume direct responsibility. The Ba'th Party, a group of young nationalists who advocated nationalism and socialism, was entrusted with power. Ba'th leaders invited 'Abd as-Salām 'Arif, an officer retired by Qāsim, to assume the presidency of the republic. A National Council for Revolutionary Command (NCR), composed of civil and military leaders, was established to assume legislative and executive powers. The premiership was entrusted to Col. Ahmad Hassan al-Bakr, a Ba'thist officer, with whom a number of civil and military leaders cooperated.

At the outset the Ba'th Party disclosed no new revolutionary principles, since its main purpose was to discredit Qāsim and to win over public opinion. The NCR issued a set of proclamations to enforce public order, and the National Guard, a civil militia, was instructed to pursue Communists and their sympathizers who had persecuted Arab nationalists. Like the militia under Qāsim, the National Guard often committed excesses that reflected on Ba'thist leadership. The Ba'th Party tried to infuse new

blood in the administration by appointing Ba'athist members to high posts but most of the appointees were very young—some had hardly completed high school—and obviously lacked experience.

Some of the Ba'ath leaders wanted to carry out Ba'ath Socialist ideas; others advised more caution. A compromise was finally reached in which the party's goals—Arab unity, freedom, and Socialism—were reaffirmed in principle, but it was decided to adopt a transitional program to prepare the country for Ba'ath principles. In this program, the industrialization and economic development of Iraq were stressed, and the role of the middle class recognized. These steps were regarded as necessary prerequisites to the adoption of Socialism. A number of influential Ba'ath leaders, however, pressed for immediate implementation of certain measures that caused disension among the leaders.

President 'Arif, whose powers were initially restricted by the Ba'ath leaders, seized the opportunity by rallying the military to his side. On November 18, 1963, in agreement with Tahir Yahya, chief of the general staff, he placed the leaders of the Ba'ath Party under arrest and took over control. 'Arif became in fact, as in name, the real ruler of the country. From November 1963 until his accidental death in April 1966, 'Arif governed the country through Cabinets that were directly responsible to him, while the army, which he was able to manipulate, was completely dominated by him. Before he was appointed president, 'Arif was known in nationalist circles as an advocate of Pan-Arabism, but after he became president he was in no great hurry to join the U.A.R. Negotiations with Egypt stressed the need for preparing Iraq step by step for unity, and it was made clear that before Iraq joined the U.A.R., it should adopt Arab Socialism. In May 1964, a new provisional constitution was promulgated in which the principles of Arab unity and Socialism were adopted, and, in July, Socialist decrees were issued in which the banks and a number of the country's industries were nationalized. These steps were followed by the establishment of a Socialist union, like Egypt's Arab Socialist Union, to prepare the country for Arab unity. Despite these measures, unity was not forthcoming.

The idea of Arab Socialism attracted only a small group in Iraq, and 'Arif began to discover its unfavourable effects on the country. 'Arif himself had never been a believer in Socialism, but he had adopted it under the influence of Egypt. The adverse impact of nationalization gave 'Arif an excuse to replace the ideological group that supported Socialism with others who would pay attention to the reality of Iraq's economic conditions. Nor had 'Arif been happy with the group of officers who had elevated him to power. 'Arif must have realized that a stable regime would have to depend on popular rather than military support, and he began to prepare the way to entrust power to civilian hands willing to be guided by him as chief executive.

In September 1965 'Arif invited Abd ar-Rahman al-Bazzaz to form a new government. Bazzaz had distinguished himself as an able lawyer and a writer on Arab nationalism, and he had served as Iraq's ambassador to Egypt and England. Bazzaz did not feel that he should abolish Arab Socialism, but he offered to increase production and create a balance between public and private sectors. He also offered to establish a permanent regime by holding general elections and setting up a parliament.

'Arif died in a helicopter accident in April 1966, and Bazzaz, though continuing in office until August under the presidency of 'Arif's older brother, Abd ar-Rahman, was forced to resign under military pressure. Abd ar-Rahman 'Arif owed his election as president to army support, and, therefore, he had to listen to the officers' complaints when it became evident that Bazzaz was intent on keeping the army out of politics. Bazzaz was succeeded by an officer who was active in military circles, and the premiership remained in military hands until July 1968, when the Ba'ath, supported by a dissident military faction, staged a coup d'etat that eliminated both 'Arif and his military supporters. Ahmad Hasan al-Bakr, a Ba'athist officer, assumed the presidency.

#### THE KURDISH QUESTION

The Kurds were given the opportunity to form a separate political entity under the Treaty of Sèvres (1920), before Iraq was created as a state. The Kemalist movement, however, shattered their hopes by rejecting the Treaty of Sèvres, and the Treaty of Lausanne (1923), which superseded the Sèvres arrangement, made no room for Kurdish nationhood. After the national regime was established in Iraq, the Kurds were persuaded to live under the Iraqi political system.

But neither the Arabs nor the Kurds were prepared to merge into one nationality and create a new Iraqi nation. The Arabs, divided into two unequal communities on religious grounds (Sunnis and Shi'is), were consciously discouraged to move too swiftly to form an Iraqi nation. The merging of the Kurds—a solidly Sunni community—with the Sunni Arabs was considered by the Shi'ah to weaken their position and therefore was resisted by almost half of the population of the country. Moreover, the Sunni Arabs themselves were reluctant to merge with the Kurds by the upsurge of Arab nationalism. This move discouraged the Kurds from uniting with a people unprepared to maintain Iraq as a separate national identity distinct from Arab nationalism, and it encouraged Kurdish leaders to advocate Kurdish nationalism for survival. Thus, both Arab and Kurdish nationalism grew in strength in the last days of the monarchy.

The Kurds welcomed the revolution of 1958 since they had suffered certain restrictions imposed on their national activities. The Free Officers sympathized with the Kurds, and Qāsim offered to cooperate with their leaders as co-partners with Arabs within the framework of Iraqi unity. The Kurds formed a Kurdish Democratic Party, advocating Kurdish nationalism and Communism. The party became active in politics and hoped that the new regime would sympathize with Kurdish national aspirations.

The Qāsim regime, however, failed to give assurances that the Kurds would be free and equal partners with the Arabs. The Kurds hoped for administrative autonomy in the Kurdish provinces, for a fair share of economic development projects and social services, and for promotion of Kurdish language and cultures. Qāsim did little or nothing to improve the social and economic conditions of the Kurds, and their leaders despaired of any improvement under the new regime.

Mulla Mustafa of Barzan, a Kurdish leader exiled under the monarchy for political activities, returned in 1958 to lead the Kurdish nationalist movement. At first he offered to cooperate with Qāsim but soon found Qāsim instigating rival leaders against him. In June 1961 matters came to a head, and a clash between a few Kurds and the Iraqi Army took place in Rānyah, a small Kurdish town. Mulla Mustafa, who was not directly involved in the Ranya incident, supported Kurdish demands and led a protracted war against Qāsim. Unable to defeat Mulla Mustafa's forces, the successor Ba'ath government decided to come to terms with the Kurds, having been in touch with some of their leaders before Qāsim's fall in 1963. It was agreed that a democratic regime would be established and the Kurds would enjoy autonomy but not independence. No sooner had Qāsim been overthrown than Mulla Mustafa sent a telegram to the Ba'ath government congratulating its leaders and ordering a cease-fire. Mulla Mustafa's action was premature, as negotiations led to no agreement on Kurdish autonomy, even after the Mulla's acceptance of administrative decentralization instead of autonomy. In resumed fighting, the Kurds inflicted heavy damages on the Iraqi Army. It was only when Bazzaz came to power and realized the strength of Kurdish nationalism that a settlement of the Kurdish question was possible. Negotiations were resumed, and an agreement was reached, embodied in a public declaration made by Bazzaz on June 29, 1966. The agreement, among other things, included the following points:

1. The Iraq government recognized Kurdish nationality and the national rights of the Kurds within one Iraqi homeland, and Arabs and Kurds were to enjoy equal rights and duties.
2. Kurdish nationality and national rights were to be

Arab-Kurd religious differences

'Arif's alliance with the military

Return to civilian rule

Outbreak of civil war in 1961

implemented in a provincial law based on the principle of decentralization. Each province was to have an elected council that would exercise wide power on education, health, and local affairs.

3. The Iraq government would recognize the Kurdish language as an official language, in addition to Arabic, in regions where the majority of the population is Kurdish.

4. The Kurds were to be represented in proportion to their numerical strength in the parliamentary system that would be established in forthcoming general elections for both national and provincial councils. The Kurds would also be adequately represented in all the departments of government.

5. The Kurdish provinces would have their share in all social and economic reconstruction to be undertaken by the government. Moreover, the government was to compensate all those who had suffered damage during the military operations.

Before Bazzaz had an opportunity to implement this agreement, his government fell, and its provisions were never fully carried out. There were complaints of violations on both sides, but in reality Mulla Mustafa remained in control of the Kurdish provinces. Attempts were made to resume negotiations to implement the agreement but to no avail. The Ba'th government announced, in March 1970, that it had reached an agreement on points of difference that would allow the Kurds to maintain their own forces and give them adequate representation in high government posts. Since Kurdish forces in the early 1970s were in de facto control of the Kurdish provinces, it was likely that Kurdish national demands would increase. Unless an assurance of Kurdish autonomous rule is given, conflict with the Iraq government is likely to continue. Continuation of the conflict might eventually push the Kurds toward independence, to the disadvantage of both Arabs and Kurds. (M.Kh.)

## Mesopotamian Religions

The term Mesopotamian religions serves generally to designate the religious beliefs and practices of the Sumerians and Akkadians, who inhabited ancient Mesopotamia (modern Iraq) in the millennia before the Christian era. These beliefs and practices form a single stream of tradition. Sumerian in origin, it was added to and subtly modified by the Akkadians (Semites immigrating into the country from the West at the end of the 4th millennium BC), whose own beliefs were in large measure assimilated to, and integrated with, those of their new environment.

#### NATURE AND SIGNIFICANCE

As the only available intellectual framework that could provide a comprehensive understanding of the forces governing existence and also guidance for right conduct in life, religion ineluctably conditioned all aspects of ancient Mesopotamian civilization. It yielded the forms in which that civilization's social, economic, legal, political, and military institutions were, and are, to be understood, as well as providing the significant symbols for poetry and art. In many ways it even influenced peoples and cultures outside of Mesopotamia, such as the Elamites to the east, the Hurrians and Hittites to the north, and the Aramaeans and Israelites to the west. Of lesser importance in evaluating the degree of such influence are, perhaps, the direct or indirect borrowings of individual Mesopotamian gods or myths, and the adjustments and subtle reinterpretations that the gods and myths have undergone to fit into the borrowing culture and its special system of values and meanings. Far more significant is the aspect of new religious insights and attitudes that arose in Mesopotamia and that spread from there to neighbouring cultures, modifying their religious beliefs and practices and indigenous cultures.

#### SOURCES

Present knowledge of ancient Mesopotamian religion rests almost exclusively on archaeological evidence recovered from the ruined city-mounds of Mesopotamia during the last century or so. Most significant is the literary evidence, texts written in cuneiform (wedge-shaped) script

Uruk Vase decorated with an offering scene to a goddess, rows of porters, and animals and plants; bas-relief, early 3rd millennium BC. In the Iraq Museum, Baghdad.

By courtesy of the Directorate General of Antiquities, Baghdad

on tablets made of clay or, for monumental purposes, on stone. Central, of course, are the specifically religious texts comprising god lists, myths, hymns, laments, prayers, rituals, omen texts, incantations, and other forms; but since religion permeated the culture, giving form and meaning to all aspects of it, any written text, any work of art, or any of its material remains, are directly or indirectly related to the religion and may further scholarly knowledge of it.

Importance of archaeological discoveries

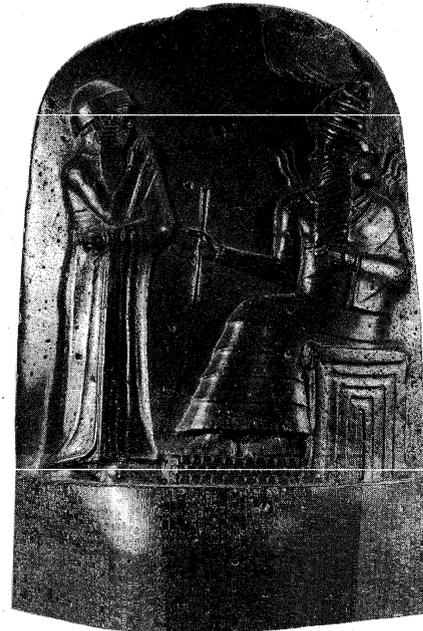

Among the archaeological finds that have particularly helped to throw light on religion are the important discoveries of inscribed tablets with Sumerian texts in copies of Old Babylonian date (c. 1800–c. 1600 BC) at Nippur and Ur, the Sumerian and Akkadian texts of the 2nd and 1st millennia from Ashur and Sultantepe, and particularly the all-important library of the Assyrian king Ashurbanipal (reigned 668–627 BC) from Nineveh. Of nonliterary remains, the great temples and temple towers (ziggurats) excavated at almost all major sites—e.g., Eridu, Ur, Nippur, Babylon, Ashur, Calah, Nineveh—as well as numerous works of art from various periods, are important sources of information. The Uruk Vase, with its representation of the rite of the sacred marriage, the Naram-Sin stele (inscribed commemorative pillar), the Ur-Nammu stele, and the stele with the Code of Hammurabi (Babylonian king, 18th century BC), which shows at its top the royal lawgiver before the sun god Shamash, the divine guardian of justice, are important works of art that may be singled out. Also among important sources are the representations on cylinder seals and on boundary stones (*kudurru*s), both of which provide rich materials for religious iconography in certain periods.

In working with, and seeking to interpret, these varied sources two particular difficulties stand out: the incompleteness of the data, and the remoteness of the ancients from modern man, not only in time but also in experience and in ways of thought. Thus, for all periods before the

3rd millennium scholars must rely on scarce, nonliterary data only, and even though writing appears shortly before that millennium, it is only in its latter half that written data become numerous enough and readily understandable enough to be of significant help. It is generally necessary, therefore, to interpret the scarce data of the older periods in the light of survivals and of what is known from later periods, an undertaking that calls for critical acumen if anachronisms are to be avoided. Also, for the later periods, the evidence flows unevenly, with perhaps the middle of the 2nd millennium the least well documented and hence least known age.

As for the difficulties raised by differences in the ways of thinking between modern man and the ancients, they are of the kind that one always meets in trying to understand something unfamiliar and strange. A contemporary inquirer must keep his accustomed values and modes of thought in suspension and seek rather the inner coherence and structure of the data with which he deals, in order to

Difficulties in interpretation of sources

Giraudon

enter sympathetically into the world out of which they came, just as, for example, in entering the sometimes intensely private world of a poem, or, on a slightly different level, in learning the new, unexpected meanings and overtones of the words and phrases of a foreign language.

#### HISTORICAL DEVELOPMENT

**Cultural background.** Human occupation of Mesopotamia—"the land between the rivers" (i.e., the Tigris and Euphrates)—seems to reach back furthest in time in the north (Assyria) where the earliest settlers built their small villages some time around 6000 BC. The prehistoric cultural stages of Hassuna-Samarra and Halaf (named after the sites of archaeological excavations) succeeded each other here before there is evidence of settlement in the south—Sumer. There, the earliest settlements, such as Eridu, appear to have been founded around 5000 BC, in the late Halaf Period. From then on the cultures of the north and south move through a succession of major archaeological periods that in their southern forms are known as Ubaid, Warka, Protoliterate (during which writing was invented), and Early Dynastic, at the end of which—shortly after 3000 BC—recorded history begins. The historical periods of the 3rd millennium are, in order: Akkad, Gutium, 3rd dynasty of Ur; those of the 2nd millennium: Isin-Larsa, Old Babylonian, Kassite, and

Periodization of Mesopotamian history

Middle Babylonian; and those of the 1st millennium: Assyrian, Neo-Babylonian, Achaemenian, Seleucid, and Parthian.

Politically, an early division of the country into small independent city-states, loosely organized in a league with the centre in Nippur, was followed by a unification by force under King Lugalzagesi (c. 2400 BC) of Uruk, just before the Akkad Period (2371–2230 BC). The unification was maintained by his successors, the kings of Akkad, who built it into an empire, and—after a brief interruption by Gutian invaders—by Utuhegal (2120–2114) of Uruk and the rulers of the 3rd dynasty of Ur (c. 2112–c. 2004 BC). When Ur fell, around 2000 BC, the country again divided into smaller units, with the cities Isin and Larsa vying for hegemony. Eventually Babylon established a lasting national state in the south, while Ashur dominated a similar rival state, Assyria, in the north. From the middle of the 1st millennium onward, Assyria built an empire comprising, for a short time, all of the ancient Near East. This political and administrative achievement remained essentially intact under the following Neo-Babylonian and Persian kings down to Alexander's conquest (331 BC).

**Stages of religious development.** The religious development—as indeed that of the Mesopotamian culture generally—was not significantly influenced by the movements of the various peoples into and within the area—the Sumerians, Akkadians, Gutians, Cassites, Hurrians, and Aramaeans (or Chaldeans). Rather it forms a uniform, consistent, and coherent Mesopotamian tradition changing in response to its own internal needs of insights and expression. It is possible to discern a basic substratum involving worship of the forces in nature—often visualized in nonhuman forms—especially those that were of immediate import to basic economic pursuits. Many of these figures belong to the type of the “dying god” (a fertility deity displaying death and regeneration characteristics as in agriculture) but show variant traits according to whether they are powers of fertility worshipped by marsh men, orchard growers, herders, or farmers. This stage may be dated tentatively back to the 4th millennium BC and even earlier. A second stage, characterized by a view of the gods as human in shape and organized in a polity of a primitive democratic cast in which each deity had his or her special offices and functions, overlaid and conditioned the religious forms and characteristics of the earlier stage during the 3rd millennium BC. Lastly, a third stage, characterized by a growing emphasis on personal religion involving concepts of sin and forgiveness, and by a change of the earlier democratic divine polity into an absolute monarchical structure dominated by the god of the national state—to the point of pious abstention from all human initiative, in absolute faith and reliance on divine intervention—characterizes the 2nd and 1st millennia BC. As a result of this development, since the ancient Mesopotamians were intensely conservative in religious matters and unwilling to discard anything of a hallowed past, the religious data of any period, and particularly those of the later periods, are a condensed version of earlier millennia that must be carefully analyzed and placed in proper perspective before it can be evaluated.

#### WORLD VIEW

**Myth: its role in the expression of the world view.** The more completely a given culture is embraced, the more natural will its basic tenets seem to the people involved. The most fundamental of its presuppositions are not even likely to rise into awareness and be consciously held but are tacitly taken for granted. It takes a degree of cultural decline, of the loosening of the culture's grip on thought and action, before its most basic structural lines can be recognized and, if need be, challenged. Since culture, the total pattern within which man lives and acts, is thus not likely to be conceived of consciously and as a whole until it begins to lose its obvious and natural character, it is understandable that those myths of a culture that may be termed existential—in the sense that they articulate human existence as a whole in terms of the culture and show

its basic structure—are rarely encountered until comparatively late in the history of a culture. Before that occurs, it is, rather, the particular aspects and facets of existence that are apt to claim attention.

In ancient Mesopotamia the oldest known materials, the Sumerian myths, have relatively little to say about creation; scholars must, for the most part, turn to the introductions of tales and disputations to infer how things were believed to be in the beginning. Thus, a story about the hero Gilgamesh refers in its introductory lines to the times: “after heaven had been moved away from earth, after earth had been separated from heaven.” The same notion that heaven and earth were once close together occurs also in a bilingual Sumerian-Akkadian text from Ashur about the creation of man. The actual act of separating them is credited to the storm god Enlil of Nippur in the introduction to a third tale that deals with the creation of the first hoe. From similar passing remarks scholars have inferred that the gods, before man came into being, had to labour hard at the heavy works of irrigation agriculture and dug out the beds of the Tigris and the Euphrates.

Not creation but the ordering of the cosmos gave rise to separate myths. In one such myth, “Enki and World Order,” the god Enki organized the cosmos on behalf of Enlil much as a steward would organize a large estate, ordering its various economic functions—herding, agriculture, building, and other operations—and appointing gods to oversee them. Another, but rather differently oriented myth, “Lugal-e,” viewed the ordering of the world under the image of the reorganization of a conquered province by a victorious young king, Enlil's son, the god Ninurta. The “Eridu Genesis” is a myth that presumably began with an account of the creation of the world by the deities An, Enlil, Enki, and Ninhursag. As preserved, it relates stories about the creation of man and animals, the founding of the first cities, and the sending of the flood. In all of these myths, except the last, a single god is the hero, and the “horizon” of the story—*i.e.*, the kind of creative acts with which it deals—is limited by his particular character and powers.

**Cosmogony and cosmology.** Though the “Eridu Genesis” may have come close to treating existence as a whole, a true cosmogonic and cosmological myth that deals centrally with the origins, structuring, and functional principles of the cosmos does not actually appear until Old Babylonian times, when Mesopotamian culture was entering a millennium and a half of doubts about the moral character of world government and even of divine power itself. Yet, the statement is a positive one, almost to the point of defiance. *Enuma elish*, the Babylonian creation story, tells of a beginning when all was a watery chaos and only the sea, Tiamat, and the sweet waters under ground, Apsu, mingled their waters together and the original watery form that was personified served as Apsu's page. In their midst the gods were born. The first pair, Lahmu and Lahamu, represented the powers in silt; the next, Anshar and Kishar, those in the horizon. They engendered the god of heaven, Anu, and he in turn the god of the flowing sweet waters, Ea.

The tradition here used is known in a more complete form from an ancient list of gods known as *An: Anum*. There, after a different beginning, Lahmu and Lahamu give rise to Duri and Dari, “the time-cycle”; and these in turn give rise to the powers for a circle to be Enshar and Ninshar, “Lord and Lady Circle.” Enshar and Ninshar engender the concrete circle of the horizon, Anshar and Kishar, probably conceived of as silt deposited along the edge of the universe. Next on the list is the horizon of the greater heaven and earth, and then—omitting an intrusive line—heaven and earth, probably conceived as two juxtaposed flat disks formed from silt deposited inward from the horizons. *Enuma elish* truncates these materials and violates their inner logic considerably. Though they are clearly cosmogonic and assume that the cosmic elements and the powers informing them come into being together, *Enuma elish* seeks to utilize them for a pure theogony (account of the origin of the gods). The creation of the actual cosmos is dealt with much later. Also, the intro-

Myths of the ordering of creation

*Enuma elish*, the Babylonian creation story

Characteristics of the stages of religious development

duction of Mummu, the personified "original form," which in the circumstances can only be that of water, may have led to the omission of Ki, "Earth" who—as nonwater—did not fit in.

Marduk as creator

The gods, who in *Enuma elish* come into being within Apsu and Tiamat, are viewed as dynamic creatures, who contrast strikingly with the older generation. Apsu and Tiamat stand for inertia and rest. This contrast leads to a series of conflicts in which first Apsu is killed by Ea; then Tiamat, who was roused later to attack the gods, by Ea's son Marduk. It is Marduk, the hero of the story, who creates the extant universe out of the body of Tiamat after he kills her. Marduk cuts her, as a dried fish, in two, making one-half of her into heaven—appointing there sun, moon, and stars to execute their prescribed motions—and her other half into the earth. He pierces her eyes to let the Tigris and Euphrates flow forth, and then, heaping mountains on her body in the east, he makes the various tributaries of the Tigris flow out from her breasts. The remainder of the story deals with Marduk's organization of the cosmos, his creation of man, and his assigning to the gods their various cosmic offices and tasks. The cosmos is viewed as structured as, and functioning as, a benevolent absolute monarchy.

**The gods and demons.** The gods were, as mentioned previously, organized in a polity of a primitive democratic cast. They constituted, as it were, a landed nobility, each god owning and working an estate—his temple and its lands—and controlling the city in which it was located. On the national level he attended the general assembly of the gods, which was the highest authority in the cosmos, to vote on matters of national import such as, for example, election or deposing of kings. The major gods also served on the national level as officers having charge of cosmic offices. Thus, for example, Utu, the sun god, was, in addition to taking care of the sun, the judge of the gods and in charge of justice and righteousness generally.

Hierarchy of the gods

Highest in the pantheon—and presiding in the divine assembly—ranked An (Akkadian Anu), god of Heaven and responsible for the calendar and the seasons as they were indicated by their appropriate stars. Next came Enlil of Nippur, god of winds and of agriculture, creator of the hoe. Enlil executed the verdicts of the divine assembly. Equal in rank to An and Enlil was the goddess Ninhursag (also known as Nintur and Ninmakh), goddess of stony ground: the near mountain ranges in the east and the stony desert in the west with its wildlife—wild asses, gazelles, wild goats, etc. She was also the goddess of birth. With these was joined—seemingly secondarily—the god Enki (Ea), god of the sweet waters of rivers and of the fertile male semen; he was the cleverest of the gods and a great troubleshooter often appealed to both by gods and by men. Of other gods may be mentioned Enlil's sons: the moon god Nanna or Sin; the god of thunderstorms, floods, and the plough, Ninurta; and the underworld figures Meslamtaea, Ninazu, and Ennugi. Sin's sons were the sun god and judge of the gods, Utu (the Akkadian Shamash), the rain god Ishkur (the Akkadian Adad), and his daughter, the goddess of war, love, and morning and evening star, Inanna (the Akkadian Ishtar). Inanna's ill-fated young husband was the herder god Dumuzi (the Akkadian Tamuz). The dread Nether World was ruled by the goddess Ereshkigal and her husband Nergal, a figure closely related to Meslamtaea and Ninurta. Earlier tradition mentions Ninazu as her husband.

Demons played little or no role in the myths or lists of the Mesopotamian pantheon. Their domain was that of incantations. Mostly, they were depicted as outlaws; the demoness Lamashtu, for instance, was hurled from Heaven by her father An because of her wickedness. The demons attacked man by causing all kinds of diseases and were, as a rule, viewed as wind and storm beings. Consistent with the classical view of the universe as a cosmic state, it was possible for a person to go to the law courts against the demons; *i.e.*, to seek recourse before Utu and obtain judgments against them. Various rituals for such procedure are known.

**Man: his origin, nature, and destiny.** Two different notions about man's origin seem to have been current in

ancient Mesopotamian religions. Brief mentions in Sumerian texts indicate that the first men grew forth from the earth in the manner of grass and herbs. One of these texts, the "Myth of the Creation of the Hoe," adds a few details: Enlil removed heaven from earth in order to make room for seeds to come up and, after he had created the hoe, he used it to break the hard crust of earth in Uzumua ("the flesh-grower"), a place in the Temple of Inanna in Nippur. Here, out of the hole made by Enlil's hoe, man grew forth.

The other notion presented the view that man was created by Enki, or by Enki and his mother Nammu, or by Enki and the birth goddess called variously Ninhursag, Nintur, and Ninmakh. In a Sumerian myth known as "Enki and Ninmakh," Enki made man from the "engendering clay of the Apsu"—*i.e.*, of the waters underground—and was borne by Nammu. The Akkadian tradition, as represented by the "Myth of Atrakhasis," had Enki advise that a god—presumably a rebel—be killed and that the birth goddess Nintur mix his flesh and blood with clay. This was done, after which 14 womb goddesses gestated the mixture and gave birth to seven human pairs. A similar—probably derived—form of this motif is found in *Enuma elish*, in which Enki (Ea) alone fashioned man out of the blood of the slain rebel leader Kingu. The creation of man from the blood shed by two slain gods is yet another version of the motif that appears in a bilingual myth from Assur.

Man's nature, then, is part clay (earthly) and part god (divine). The divine aspect, however, is not that of a living god but rather that of a slain, powerless divinity. The Atrakhasis story relates that the *etemmu* (ghost) of the slain god was left in man's flesh and thus became part of man. It is this originally divine part of man, his *etemmu*, that was believed to survive at his death and to give him a shadowy afterlife in the Nether World. No other trace of a notion of divine essence in man is discernible; in fact, man by himself was viewed as being utterly powerless to act effectively or to succeed in anything. For anything he might wish to do or achieve, man needed the help of a personal god or goddess, some deity in the pantheon who for one reason or other had taken an interest in him and helped and protected him, for "Without his personal god a man eats not."

The divine and earthly nature of man

About man's destiny all sources agree. However man may have come into being, he was meant to toil in order to provide food, clothing, housing, and service for the gods, so that they, relieved of all manual labour, could live the life of a governing upper class, a landed nobility. In the scheme of existence man was thus never an end, always just a means.

#### INSTITUTIONS AND PRACTICES

**City-state and national state.** In early dynastic times, probably as far back as historians can trace its history, Mesopotamia was divided into small units, the so-called city-states, consisting of a major city with its surrounding lands. The ruler of the city—usually entitled *ensi*—was also in charge of the temple of the city god. The spouse of the *ensi* had charge of the temple of the city goddess, and the children of the *ensi* administered the temples of the deities who were regarded as children of the city god and the city goddesses. After the foundation of larger political units, such as leagues or empires, contributions were made to a central temple of the political unit, such as the temple of Enlil at Nippur in the Nippur league. On the other hand, however, the king or other central ruler might also contribute to the shrines of local cults. When, in the 2nd and 1st millennia, Babylonia and Assyria emerged as national states, their kings had responsibility for the national cult and each monarch supervised the administration of all temples in his domain.

**Cult.** In the cultic practices man fulfilled his destiny: to take care of the gods' material needs. Man therefore provided the gods with houses (the temples) that were richly supplied with lands, which man cultivated for them. In the temple the god was present in—but not bounded by—a statue made of precious wood overlaid with gold. For this statue the temple kitchen staff prepared daily meals from

The purpose of man in relation to the gods

victuals grown or raised on the temple's fields, in its orchards, in its sheepfolds, cattle pens, and game preserves, brought in by its fishermen, or delivered by farmers owing it as a temple tax. Not only was the statue fed but it was also clad in costly raiments, bathed, and escorted to bed in the bedchamber of the god, often on top of the temple tower, or ziggurat. To see to all of this the god had a corps of house servants; *i.e.*, priests trained as cooks, bakers, waiters, and bathers, or as *encomiasts* (singers of praise) and musicians to make the god's meals festive, or as elegists to soothe him in times of stress and grief. Diversions from the daily routine were the great monthly festivals, and also a number of special occasions. Such special occasions might be a sudden need to go through the elaborate ritual for purifying the king when he was threatened by the evils implied in an eclipse of the moon, or in extreme cases there might be a call for the ritual installation of a substitute king to take upon himself the dangers threatening, and various other nonperiodic rituals.

Partly regular, partly impromptu, were the occasions for audiences with the god in which the king or other worshippers presented their petitions and prayers accompanied by appropriate offerings. These were mostly edibles, but not infrequently the costly containers in which they were presented, stone vases, golden boat-shaped vessels, etc., testified to the ardour of the givers. Appropriate gifts other than edibles were also acceptable—among them cylinder seals for the god's use, superhuman in size, and weapons for him, such as maceheads, also outside.

To the cult, but as private rather than as part of the temple cult, may be counted also the burial ritual, concerning which, unfortunately, there is little known. In outgoing early dynastic times in Girsu two modes of burial were current. One was ordinary burial in a cemetery; the other, laying the body "in the reeds of Enki," is not clear, perhaps it denoted the floating of the body down the river into the canebrakes. Elegists and other funerary personnel were in attendance and conducted the laments seeking to give full expression to the grief of the bereaved and propitiate the spirit of the dead. In later times burial in a family vault under the dwelling house was frequent.

**Sacred times.** During most of the 2nd millennium each major city had its own calendar. The months were named from local religious festivals celebrated in the month in question. Only by the 2nd millennium did the Nippur calendar attain general acceptance. The nature of the festivals in these various sacred calendars sometimes reflected the cycle of agricultural activities, such as celebrating the ritual hitching up of the plows and, later in the year, their unhitching, or rites of sowing, harvesting, and other activities. The sacred calendar of Girsu at the end of the early dynastic period is rich in its accounting of festivals. During some of these festival periods the queen travelled through her domain to present funerary offerings of barley, malt, and other agricultural products to the gods and to the spirits of deceased charismatic human administrators.

The cycles of festivals celebrating the marriage and early death of Dumuzi and similar fertility figures in spring are structured according to the backgrounds of the various communities of farmers, herders, or date growers. The sacred wedding—sometimes a fertility rite, sometimes a harvest festival with overtones of thanksgiving—was performed as a drama: the ruler and a high priestess took on the identity of the two deities and so ensured that their highly desirable union actually took place. In many communities the lament for the dead god took the form of a procession out into the desert to find the slain god in his gutted fold, a pilgrimage to the accompaniment of harps and heart-rending laments for the god.

Of major importance in later times was the New Year Festival, or Akitu, celebrated in a special temple out in the fields. Originally an agricultural festival connected with sowing and harvest, it became the proper occasion for the crowning and investiture of a new king. In Babylon it came to celebrate the sun god Marduk's victory over Tiamat, the goddess of the watery deep. Besides the yearly festivals there were also monthly festivals at New Moon, the 7th, the 15th, and the 28th of the month. The last—

when the moon was invisible and thought to be dead—had a distinctly funereal character.

**Administration.** Supreme responsibility for the correct carrying out of the cult, on which the welfare of the country depended, was entrusted to the city ruler, or, when the country was united, the king. The city ruler and the king were, however, far more than administrators; they also were charismatic figures imparting their individual magic into their rule, thus creating welfare and fertility. In certain periods the king was deified; throughout the 3rd millennium, he became, in ritual action, the god Dumuzi in the rite of the sacred marriage and thus insured fertility for his land. The rulers of the entire 3rd dynasty of Ur (c. 2112–c. 2004 BC) and most of the dynasty of Isin (c. 2020–c. 1800 BC) were treated as embodiments of the dying god Damu and invoked in the ritual laments for him. As a vessel of sacred power the king was surrounded by strict ritual to protect that power, and he had to undergo elaborate rituals of purification if the power became threatened.

The individual temples were usually administered by officials called *sanga* ("bishops"), who headed staffs of accountants, overseers of agricultural and industrial works on the temple estate, and *gudu* (priests), who looked after the god as house servants. Among the priestesses the highest ranking were termed *en* (Akkadian *entu*). They were usually princesses of royal blood and were considered the human spouses of the gods they served, participating as brides in the rites of the sacred marriage. Other ranks of priestesses are known, most of them to be considered orders of nuns. The best known are the votaries of the sun god, who lived in a cloister (*gagu*) in Sippar. Whether, besides nuns, there were also priestesses devoted to sacred prostitution is a moot question; what is clear is that prostitutes were under the special protection of the goddess Inanna (Ishtar).

**Sacred places.** Mesopotamian worshippers might worship in open-air sanctuaries, chapels in private houses, or small separate chapels located in the residential quarters of town; but the sacred place par excellence was the temple. Archaeology has traced the temple back to the earliest periods of settlement, and though the very early temple plans still pose many unsolved problems, it is clear that from the early dynastic period onward the temple was what the Sumerian (*e*) and Akkadian (*bitum*) terms for it indicate; *i.e.*, the temple was the god's house or dwelling. In its more elaborate form such a temple would be built on a series of irregular artificial platforms, one on top of the other; by the 3rd dynasty of Ur, near the end of the 3rd millennium, these became squared off to form a ziggurat. On the lowest of these platforms a heavy wall—first oval, later rectangular—enclosed storerooms, the temple kitchen, workshops, and other such rooms. On the highest level, approached by a stairway, were the god's living quarters centred in the cella, a rectangular room with an entrance door in the long wall near one corner. The god's place was on a podium in a niche at the short wall farthest from the entrance; benches with statues of worshippers ran along both long walls, and a hearth in the middle of the floor served for heating. Low pillars in front of the god's seat seem to have served as stoppers for a hanging that shielded him from profane eyes. Here, or in a connecting room, would be the god's table, bed, and bathtub.

At a later time in Babylonia the dimensions of the cella with its adjoining rooms were greatly enlarged so that it became an open court surrounded by rooms. Only the section separated by the hanging remained roofed and became a new cella, entered from the middle of its long side and with the god in his niche in the wall directly opposite. The development in Assyria took a slightly different course. Here the original door in the long side moved around the corner to the short side opposite the god, creating a rectangular cella entered from the end wall.

The function of the temple, as of all of the other sacred places in ancient Mesopotamia, was primarily to ensure the god's presence and to provide a place where he could be approached. The providing of housing, food, and service for the god achieved the first of these purposes. His

The role and functions of the priesthood

The structure and function of the temple

New Year Festival

presence was also assured by a suitable embodiment—the cult statue, and, for certain rites, the body of the ruler. To achieve the second purpose, greeting gifts, praise hymns as introduction to petitions, and other actions were used to induce the god to receive the petitioner and to listen to, and accept, his prayers.

In view of the magnitude of such an establishment provided for the gods and the extent of lands belonging to them and cultivated for them—partly with temple personnel, partly by members of the community holding temple land in some form of tenure or another—it was unavoidable that temples should vie in economic importance with similar large private estates or with estates belonging to the crown. This importance, one may surmise, would lie largely in the element of stability that an efficiently run major estate provided for the community. With its facilities for producing large storable surpluses that could be used to offset bad years and with its facilities—such as its weaveries—the temple estates could absorb and utilize elements of the population, such as widows, waifs, captives, and others, who otherwise would have perished or become a menace to the community in one way or other. The economic importance of the temple primarily was local. The amount of foreign trade carried on by them apparently was small. The power behind foreign trade seems rather to have been the king.

**The magical arts.** In the ancient Mesopotamian view, gods and humans shared one world. The gods lived among men on their great estates (the temples), ruled, upheld law and order for men, and fought their wars. In general, knowing and carrying out the will of the gods was not a matter for doubt: they wanted the practice of their cult performed faultlessly, work on their estates done willingly and well, and they disapproved, in greater or lesser degree, of breaches of the moral and legal order. On occasion, however, man might well be uncertain: did a god want his temple rebuilt or did he not? In all such cases, and others like them, the Mesopotamians sought direct answers from the gods through divination, and conversely the gods might take the initiative and convey specific wishes through dreams, signs, or portents.

There were many forms of divination. Of interest to students of biblical prophecy is recent evidence that prophets and prophetesses were active at the court of Mari on the Euphrates in Old Babylonian times (c. 1800–c. 1600 BC). In Mesopotamia as a whole, however, the forms of divination most frequently used seem to have been incubation—i.e., sleeping in the temple in the hope that the god would send an enlightening dream—and hepatoscopy; i.e., examining the entrails, particularly the liver, of a lamb or kid sacrificed for a divinatory purpose, to read what the god had “written” there by interpreting variations in form and shape. In the 2nd and 1st millennia large and detailed handbooks in hepatoscopy were composed for consultation by the diviners. Though divination in historical times was regularly presented in terms of ascertaining the divine will, there are internal indications in the materials suggesting that it was originally less theologically elaborated. Apparently it was a mere attempt to read the future from “symptoms” in the present, much as a physician recognizes the onset of a disease. This is particularly made clear in that branch of divination that deals with unusual happenings believed to be ominous. Thus, if a desert plant sprouted in a city—indicating that desert essence was about to take over—it was considered an indication that the city would be laid waste.

Related to the observation of unusual happenings in society or nature, but far more systematized, was astrology. The movements and appearance of the sun, the moon, and the planets were believed to yield information about future events affecting the nation or, in some cases, the fate of individuals. Horoscopes, predicting the character and fate of a person on the basis of the constellation of the stars at his birth, are known to have been constructed in the late 1st millennium, but the art may conceivably be older.

Witchcraft was apparently at all times considered a crime punishable by death. Frequently, however, it probably was difficult to identify the witch in individual cases,

or even to be sure that a given evil was the result of witchcraft rather than of other causes. In such cases the expert in white magic, the *ashipu* or *mashmashshu*, was able to help both in diagnosing the cause of the evil and in performing the appropriate rituals and incantation to fight it off. In earlier times the activities of the magicians seem generally to have been directed against the lawless demons who attacked man and caused all kinds of diseases. In the later half of the 2nd, and all through the 1st millennium, however, the fear of man-made evils grew, and witchcraft vied with the demons as the chief source of all ills.

#### RELIGIOUS ART AND ICONOGRAPHY

The earliest periods in Mesopotamia have yielded figurines of clay or stone, some of which may conceivably represent gods or demons; certainty of interpretation in regard to these figurines is, however, difficult to attain. With the advent of the Protoliterate period toward the end of the 4th millennium BC, the so-called cylinder seal came into use. In the designs on these seals—often, it would seem, copies from monumental wall paintings now lost—ritual scenes and divine figures, recognizable from what is known about them in historical times, make their first appearance. To this period also belongs the magnificent Uruk Vase, with its representation of the sacred marriage rite. Until the early centuries of the 2nd millennium the cylinder seal remains one of the most prolific sources of religious motifs and representations of divine figures, but larger reliefs, wall paintings, and sculpture in the round greatly add to modern historians' understanding of who and what is rendered. In the 2nd and 1st millennia, the humble categories of clay plaques and clay figurines often contained representations of deities, and the numerous sculptured boundary stones (*kudurrus*) furnish representations of symbols and emblems of gods, at times identified by labels in cuneiform. To the 1st millennium belong also the magnificent colossal statues of protective genii (spirits) in the shape of lions or human-headed bulls that guarded the entrances to Assyrian palaces, and also, on the gates of Nebuchadrezzar's (died 562 BC) Babylon, the reliefs in glazed tile of lions and dragons that served the same purpose.

#### CONCLUSION

A religious development covering four millennia such as one finds in ancient Mesopotamian religions is obviously of interest in and of itself. The tendencies that lead from a central concern with salvation from famine to salvation from attack, and finally to salvation from a sense of personal guilt, with the attendant deepening and enriching of the concept of the divine, invites close study. So also do the many moving and profound expressions of religious faith in the hymns, laments, and prayers of these religions. As one of the earliest religious systems in history to structure, and be itself structured by, the complexities of a high civilization, Mesopotamian religions are of significant interest to historians, historians of religion, and theologians. As a source from which religious insights, attitudes, and problems flowed into all of Western tradition, Mesopotamian religions are of lasting and great interest beyond themselves.

## Mesopotamian Religious Literature and Mythology

The large body of written remains that has been preserved from ancient Mesopotamian civilization is here termed religious literature, because its core, the part of it that by form and expressiveness qualifies as literature in the strict sense (*belle lettres*), is predominantly religious in nature. This core comprises the genres (literary kinds or forms) of myth, epic, hymn, lamentations, penitential psalm, incantation, and wisdom literature. Outside the core literature there are several more practically oriented handbook genres. Only two of these, those dealing with rituals and omens (signs, or omens), are clearly religious; the rest, consisting of historical, juridical, economical, mathematical, astronomical, lexical, grammatical, and epistolary collections, tend toward the secular. Because religion provided the only total view of existence in ancient Mesopotamian civilization, however, religious themes, attitudes, and presuppositions turn up quite frequently in these quasi-secular writings.

### NATURE AND SIGNIFICANCE

**Sumerian literature.** Mesopotamian literature originated with the Sumerians, whose earliest known written records are from the middle of the 4th millennium BC. It constitutes the oldest known literature in the world; moreover, inner criteria indicate that a long oral-literary tradition preceded, and probably coexisted with, the setting down of its songs and stories in writing. It may be assumed, further, that this oral literature developed the genres of the core literature. The handbook genres, however, in spite of occasional inclusions of oral formula—*e.g.*, legal or medical—may generally be assumed to have been devised after writing had been invented, as a response to the remarkable possibilities that writing offered for amassing and organizing data.

Functions of Mesopotamian religious literature

The purpose underlying the core literature and its oral prototypes would seem to have been as much magical as aesthetic, or merely entertaining in origin. In magic, words create and call into being what they state—the more vivid and expressive they are the more they are believed to be efficacious—so by its expressiveness literature forms a natural vehicle of such creativity. In ancient Mesopotamia its main purpose appears to have been the enhancement of what was seen as beneficial. With the sole exception of wisdom literature, the core genres are panegyric in nature (*i.e.*, they praise something or other), and the magical power and use of praise is to instill, call up, or activate the virtues presented in the praise.

That praise is of the essence of hymns, for instance, is shown by the fact that over and over again the encomiast, the official praiser, whose task it was to sing these hymns, closed with the standing phrase: "O [the name of a deity], thy praise is sweet." The same phrase is common also at the end of myths and epics, two further praise genres that also belonged in the repertoire of the encomiast. They praise not only in description but also in narrative, by recounting acts of valour done by the hero, thus sustaining and enhancing his power to do such deeds, according to the magical view.

In time, possibly quite early, the magical aspect of literature must have tended to fade from men's consciousness, yielding to more nearly aesthetic attitudes that viewed the praise hymns as expressions of allegiance and loyalties, and accepted the narrative genres of myth and epic for the enjoyment of the story and the values expressed, poetic and otherwise.

Hymns, myths, and epics all were believed to sustain existing powers and virtues by means of praise, but laments were understood to praise blessings and powers lost, originally seeking to hold on to and recall them magically, through the power in expression of intense longing for them and vivid representation of them. The lamentation genre was the province of a separate professional, the elegist. It contained dirges for the dying gods of the fertility cults and laments for temples and cities destroyed and desecrated. The laments for temples—which go back no earlier than to the 3rd dynasty of Ur (c. 2112–c. 2004

BC)—were used to recall the beauties of the lost temple as a kind of inducement to persuade the god and owner of the temple to restore it.

Penitential psalms lament private illnesses and misfortunes and seek to evoke the pity of the deity addressed and thus to gain divine aid. The genre apparently is late in date, most likely Old Babylonian (c. 19th century BC), and in it the element of magic has, to all intents and purposes, disappeared.

The core genres of Mesopotamian literature were developed by the Sumerians apparently as oral compositions. Writing, which is first attested at the middle of the 4th millennium BC, was in its origins predominantly ideographical (picture or symbol writing) and long remained a highly imperfect means of rendering the spoken word. Even as late as the beginning of the Early Dynastic III Period in south Mesopotamia at the end of that millennium, the written literary texts preserved have the character of mnemonic (memory) aids only and seem to presuppose that the reader has prior oral knowledge of the text.

As writing developed more and more precision during the 3rd millennium BC, more and more oral compositions seem to have been put into writing and with the 3rd dynasty of Ur (c. 2112–c. 2004 BC) a considerable body of literature had come into being and was being added to by a generation of highly gifted authors. Fortunately for its survival, this literature became part of the curriculum in the Sumerian scribal schools, studied and copied by student after student so that an abundance of such copies, reaching a peak in old Babylonian times, duplicated and supplemented each other as witnesses to the text of the major works. As many as 50 or more copies or fragments of copies of a single composition may support a modern edition, and many thousands more such copies probably still lie unread, buried in the earth.

**Akkadian literature.** The first centuries of the 2nd millennium BC witnessed the demise of Sumerian as a spoken language and its replacement by Akkadian. Because of its role as bearer of Sumerian culture, as the language of religion, literature, and many arts, however, Sumerian (much as Latin in the Middle Ages) continued to be taught and spoken in the scribal schools throughout the 2nd and 1st millennia BC. New compositions were even composed in it, grammatically more and more barbarous the greater the distance in time from when it was still alive.

Akkadian, when it supplanted Sumerian as the spoken language of Mesopotamia, was not without its own literary tradition. Writing, to judge from Akkadian orthographical peculiarities, was very early borrowed from the Sumerians. By old Babylonian times (c. 19th century BC), the literature in Akkadian, partly under the influence of Sumerian models and Sumerian literary themes, had developed myths and epics of its own, among them the superb Old-Babylonian Gilgamesh epic (dealing with the problem of death) as well as hymns, disputation texts (evaluations of elements of the cosmos and society), penitential psalms, and not a few independent new handbook genres—*e.g.*, omens, rituals, laws and legal phrasebooks (often translated from Sumerian), mathematical texts, and grammatical texts. A noticeable amount of translations from Sumerian is observable: incantation series like the *utukke limnuti* ("The Evil Spirits"), laments for destroyed temples, penitential psalms, and others. The prestige of Sumerian as a literary language, however, is indicated by the fact that translations were rarely, if ever, allowed to supersede the original Sumerian text. The Sumerian text was kept with an interlinear translation to form a bilingual work.

The continued study and copying of literature in the schools, both Sumerian and Akkadian, by the middle of the 2nd millennium led to a remarkable effort of standardizing, or canonizing. Texts of the same genre were collected, often under royal auspices and with royal support, and were then sifted and finally edited in series that from then on were recognized as the canonical form. Authoritative texts were established for incantations, laments, omens, medical texts, lexical texts, and others. In

The significance of writing

Canonization of Mesopotamian religious literature

myths and epics, such major and lengthy compositions as the Akkadian creation story *Enuma elish*, the Erra myth, Nergal and Ereshkigal, the Etana legend, the Gilgamesh epic, and the Tukulti-Ninurta epic were reworked or re-created.

Of special interest are philosophical compositions, in Akkadian called *Ludlul bel nemeqi*, "Let me praise the expert," and theodicies (justification of divine ways) that deal with the problem of the just sufferer, similar to the biblical Job. They constitute a high point in the genre of wisdom literature. From the 1st millennium BC the rise of factual historical chronicles and a spate of political and religious polemical writings reflecting the rivalry between Assyria and Babylonia deserve mention. Very late in the millennium, the first astronomical texts appeared.

**The influence of Mesopotamian literature.** That Mesopotamian literature influenced the later literatures that grew up in surrounding countries (e.g., Syria, the land of the Hittites, Israel, Phoenicia, and Greece), is unmistakable, but little work has been done to trace its influence in detail. The Mesopotamian story of the flood told in the old Babylonian Atrahasis (hero of the flood) myth and secondarily incorporated in the Gilgamesh epic shows such close correspondence in details with the biblical account of Noah and the Flood that direct influence must be assumed, even though the setting of the story and its ultimate significance was viewed very differently by the Mesopotamian and the biblical narrators. The Babylonian account of the ruling generations of gods—the dynasty of Dunnum—is traceable to Phoenicia and from there on to Greece, in which it underlies Hesiod's Theogony (birth of the gods). A variant form found its way to the Hittites. Not only individual works and literary motifs seem to have spread but also borrowings of literary forms may be assumed in the case of the biblical book of Lamentations, which clearly stands in the tradition of the Mesopotamian genre of lamentations for temples and cities. A similar case is the genre of penitential psalm developed in Mesopotamia early in the 2nd millennium, spreading to the Hittites and to Egypt in the middle and latter half of that millennium, and then continuing in Israel as a type of psalm. More easy to trace—though the cuneiform (wedge-shaped writing) original has not yet been uncovered—is the distribution of the book about the wise Achiqar, a minister of the Assyrian king Sennacherib (died 681 BC), which was spread in its Aramaic form throughout the Near East. The spread of fables about animals and trees is traceable from Mesopotamia to Greece in the West and to India in the East.

Besides core literature, "handbook" literature also spread, but it is often difficult to distinguish whether what was borrowed was literature, or content and data only. Here must be mentioned first of all the early and broad spread of written legal and business forms, contracts, account types, legal phraseology, and other Sumerian and Akkadian forms to ancient Iran in the East, and to Syria and Asia Minor in the West. Clear links with the earlier Mesopotamian legal tradition are also evident in the laws of the Hebrews. In the 2nd and 1st millennia Babylonian mathematics and astronomy also spread. Babylonian terms, formulations, and inventions found their way to Egypt and Greece and—transmitted by the Greeks—to India. Further evidence and further study will most likely amplify and clarify much, in the matter of the diffusion of Mesopotamian cultural achievement, both literary and otherwise, to its neighbours and heirs.

#### THE LITERATURE AND ITS TEXTS

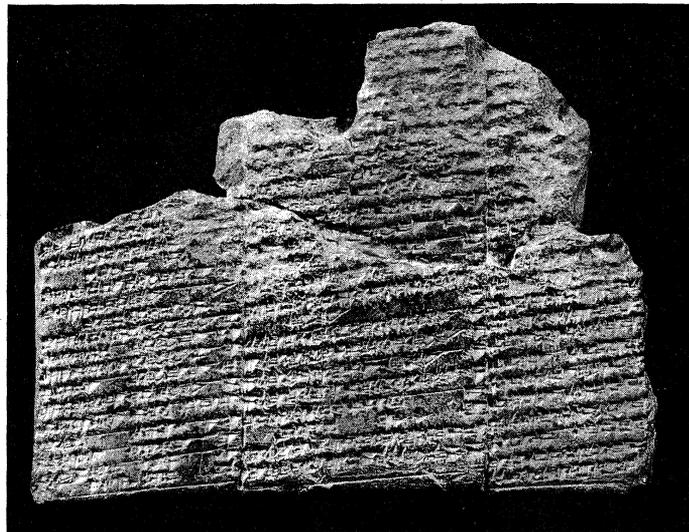

Present knowledge of ancient Mesopotamian literature is due almost exclusively to archaeological excavations, which began probing the ruined city-mounds of ancient Mesopotamia—present-day Iraq—around the middle of the 19th century. Thousands of ancient documents have been exhumed.

Of greatest importance was the early discovery of the Assyrian king Ashurbanipal's library in Nineveh in 1849, at a time when the decipherment of cuneiform writing was still in its infancy. This library, collected by Ashurbanipal (668–627 BC), contained specimens of al-

most all genres of Ancient Mesopotamian literature and apparently had copies—unfortunately not always completely recovered—of most of its greatest works. Of particular practical importance were the lexical texts found in it. Without them and the information about the many different possible values of each cuneiform sign that the ancient scribes had here organized, it is doubtful that cuneiform could ever have been fully deciphered. Similar though less extensive libraries of about the same period have been found in Nimrud (Assyria) and Sultan Tepe. In ancient Ashur (ash-Sharqāt) German excavators unearthed a number of private libraries in which literary texts were well represented.

Whereas the Ashurbanipal library was a true library, another large find of texts, the so-called temple library at Nippur in Mesopotamia, constituted the waste from scribal schools of the Old Babylonian Period. These texts and fragments of texts were found in the foundations of private houses and apparently had been carted there from the school's waste heaps to serve simply as fill, for which they were, of course, eminently well suited. Since the first finds of literary texts in Nippur (1889–1900), similar finds in Old Babylonian private houses have been made on other sites, most extensively by the archaeologist Leonard Woolley at Ur (1930–31). The Old Babylonian literary texts from Nippur and elsewhere represent copies of Sumerian literature as it was preserved and handed on in the scribal schools of the period. A majority of its greatest works apparently date back to the time of the 3rd dynasty of Ur and the centuries immediately preceding and following it; but relatively few copies of that period have yet been found. The famous Cylanders of Gudea (rulers of Lagash c. 2050 BC) from Tello and an as yet unpublished group of literary texts of the Ur III Period from Nippur may be mentioned. The oldest collections of literary works so far discovered were found at Fara and at Ishan Abu Salabikh; they date to the borderline between Early Dynastic II and III (c. 2750–c. 2334 BC).

Relatively little is known about the verse style of ancient Mesopotamian literary compositions. The Sumerians, it seems, often used syllabic verse with a constant or regularly alternating number of syllables to each line. Often the line appears to be divided by a medial caesura (poetical interruption). The lines are usually grouped into stanzas consisting of strophe (two or more lines repeated as a unit) and antistrophe (distich), or strophe and two antistrophes (tristich). Stanzas of four or six lines also occur. A much used device is the "particularizing" stanza in which a person or thing is mentioned under a general term in the strophe, to be then named or similarly particularized in the otherwise identical antistrophe. Larger sections, or

Use of verse styles

"cantos," with short responses following them are often indicated in hymns and laments by the following notations: *ki-ru-gu* ("place in which to counter") after the canto, and *gis-gi-gal-bi-im* ("is its antiphone") after the antiphon. Occasionally, very elaborate patterns were developed, such as in the myth of "Inanna and Bilulu" in which the lines are grouped in stanzas as strophe and antistrophe, or strophe and two antistrophes. These stanzas are themselves grouped into larger "megastrophes" (great strophes).

In Akkadian, the verse is accentual verse. The line is usually divided by a medial caesura into halves, each of which has two stresses. All lines end in a trochee; *i.e.*, metrical unit of one stressed and one unstressed syllable. As in Sumerian poetry, distichs and tristichs are frequent and may be enlarged to four- or six-line stanzas. The tristichs and longer stanzas seem to be characteristic of the later periods after old Babylonian times. To these later times belong also lines with more than four stresses. In the last millennium BC the highly artificial form of the acrostic came into use and enjoyed a fair measure of popularity.

#### REPRESENTATIVE TYPES OF LITERATURE

**Myths.** The genre of myths in ancient Mesopotamian literature centres on praises that recount and celebrate great deeds. The doers of the deeds (creative or otherwise decisive acts), and thus the subjects of the praises, are the gods.

**Sumerian myths.** In the oldest myths, the Sumerian, these acts tend to have particular rather than universal relevance, which is understandable since they deal with the power and acts of a particular god with a particular sphere of influence in the cosmos. An example of such myths is the myth of "Dumuzi's Death" that relates how Dumuzi (the Quickener of the Young), the power in the fertility of spring, dreamed of his own death at the hands of a group of deputies from the Nether World and how he tried to hide himself but was betrayed by his friend after his sister had resisted all attempts at making her reveal where he was.

A similar, very complex myth, "Inanna's Descent," relates how the goddess Inanna (Lady of the Date Clusters) set her heart on ruling the Nether World and tried to depose her older sister, the queen of the Nether World, Ereshkigal (Lady of the Greater Earth). Her attempt failed, she was killed, and changed into a piece of rotting meat in the Nether World. It took all the ingenuity of Enki (Lord of the Earth) to bring Inanna back to life, and even then she was released only on condition that she furnish a substitute to take her place. On her return, finding her young husband Dumuzi feasting instead of mourning for her, Inanna was seized with jealousy and designated him as that substitute. Dumuzi tried to flee the force of deputies who had accompanied Inanna, and with the help of the sun god Utu ("Sun"), who changed Dumuzi's shape, he managed to escape, was recaptured, escaped again, and so on, until he was finally taken to the Nether World, where the fly told his little sister Geshtinanna where he was, and she went in search of him. The myth ends with Inanna rewarding the fly and decreeing that Dumuzi and his little sister could alternate as her substitute, each of them spending half a year in the Nether World, the other half above with the living.

A third myth built over the motif of journeying to the Nether World is the myth of "The Engendering of the Moongod and his Brothers," which tells how Enlil (Lord Wind), when still a youngster, came upon young Ninlil (the Varicoloured Ear; goddess of grain) as she—disobeying her mother—was bathing in a canal. He lay with her in spite of her protests and thus engendered the moon god Suen. For this offense Enlil was banished from Nippur and took the road to the Nether World. Ninlil, carrying his child, followed him. On the way Enlil took the shape first of the Nippur gatekeeper, then of the man of the river of the Nether World, and lastly of the ferryman of the river of the Nether World. In each such disguise Enlil persuaded Ninlil to let him lie with her to engender a son who might take Suen's place in the Nether World and

leave him free for the world above. Thus three further deities, all underworld figures, were engendered: Meslamtaea (he who comes out of temple), Ninazu (Water Knower), and Ennugi (the God who returns not). The myth ends with a paean to Enlil as a source of abundance and to his divine word, which always comes true. Most likely all of these myths have backgrounds in fertility cults and concern the disappearance of nature's fertility with the onset of the dry season or with the underground storage of food.

As Enlil is celebrated for engendering other gods that embody other powers in nature, so also was Enki in the myth of "Enki and Ninhursag," in which myth Enki lay down with Ninhursag (Lady of the Stony Ground) on the island of Dilmun (modern Bahrein), which had been allotted to them. At that time all was new and fresh, inchoate, not yet set in its present mold. There Enki provided water for the future city of Dilmun, lay with Ninhursag, and left her. She gave birth to a daughter, Ninshar (Lady Herb), on whom Enki in turn engendered the spider Uttu, goddess of spinning and weaving. Ninhursag warned Uttu, but Enki, proffering marriage gifts, persuaded her to open the door to him. After Enki had had his will of her and abandoned her, Ninhursag found her and removed Enki's semen from her body. From the semen seven plants sprouted forth. These plants Enki later saw and ate and so became pregnant from his own semen. Unable as a male to give birth, he fell fatally ill, until Ninhursag relented and—as birth goddess—placed him in her vulva and helped him to give birth to seven daughters, whom Enki then happily married off to various gods.

Not only the birth of gods but also the birth, or creation, of man is treated in the myths. The myth of "Enki and Ninmakh" relates how the gods originally had to toil for their food, dig irrigation canals, and perform other acts until, in their distress, they complained to Enki's mother Nammu, who took the complaints to Enki. Enki remembered the engendering clay of the Apsu (*i.e.*, the fresh underground waters that fathered him) and from his clay, with the help of the womb goddesses and eight midwife goddesses led by Ninmakh (another name for Ninhursag) he had his mother become pregnant with, and give birth to man so that he could relieve the gods of their toil. At the celebration of the birth, however, Enki and Ninmakh both drank too much beer and began to quarrel. Ninmakh boasted that she could impair man's shape at will and Enki countered that he could temper even the worst that she might do. So she made seven freaks, for each of which Enki found a place in society and a living. He then challenged her to alleviate the mischief he could do, but the creature he fashioned (one suffering from all the ills and debilities of extreme old age) was far beyond her powers to cope with. Thus the many imperfections in man came into being.

The ordering, rather than the creation, of the world is the subject of another myth about Enki, called "Enki and World Order." Beginning with long praises and self-praises of Enki, it tells how he blessed Nippur (Sumer), Ur, Meluhha (Ethiopia), and Dilmun (Bahrein) and gave them their characteristics, after which he turned his attention to the Euphrates and the Tigris rivers, to the marshes, the sea, and the rains, and then to instituting one facet after another of the economic life of Sumer: agriculture, housebuilding, herding, and so forth. The story ends with a complaint by Enki's granddaughter Inanna that she has not been given her due share of offices, at which he patiently pointed to various offices she had in fact been given and kindly added a few more.

Another myth about the world order but dealing with it from a very different point of view is about Enlil's son, the rain god Ninurta, called from its opening word "Lugal-e" (O King). This myth begins with a description of the young king, Ninurta, sitting at home in Nippur when, through his general, reports reach him of a new power that has arisen in the mountains to challenge him—*i.e.*, Azag, son of Anu (Sky) and Ea (Earth), chosen king by the plants and raiding the cities with his warriors, the stones. Ninurta sets out in his boat to give battle, and a fierce engagement ensues in which Azag is killed. After-

ward Ninurta reorganizes his newly won territory, builds a stone barrier, the *hursag*, the near mountain ranges, gathers the waters that used to go up into the mountains and directs them into the Tigris to flood it and provide plentiful irrigation water from Sumer. The *hursag* he presents as a gift to his mother, who had come to visit him, naming her Ninhursag, Lady of the Hursag; and lastly he sits in judgment on the stones who had formed the Azag's army. Some of them, who had shown special ill will toward him, he curses, and others he trusts and gives high office in his administration. These judgments give the stones their present characteristics so that, for example, the flint is condemned to break before the much softer horn, as it indeed does when the horn is pressed against it to flake it. Noteworthy also is the way in which order in the universe, the yearly flood and other seasonal events, is seen—consonantly with Ninurta's role as "king" and leader in war—under the pattern of a reorganization of conquered territories.

Other myths about Ninurta are "An-gim dim-ma" and a myth of his contest with Enki. The first of these tells how Ninurta, on returning from battle to Nippur, was met by Enlil's page Nusku, who ordered him to cease his boastful clamor and not scare Enlil and the other gods. After long speeches of self-praise, by Ninurta, further addresses to him calmed him and made him enter Nippur gently. The second tale relates how he conquered the Thunderbird Ansud with Enki's help but missed the powers it had stolen from him, and how, resentful at this, he plotted against Enki but was outsmarted and trapped. Another Sumerian myth, the "Eridu Genesis," tells of the creation of man and animals, of the building of the first cities, and of the flood.

**Akkadian myths.** The Akkadian myths are in many ways dependent on Sumerian materials, but they show an originality and a broader scope in their treatment of the earlier Sumerian concepts and forms; they address themselves more often to existence as a whole. Fairly close to Sumerian prototypes is an Akkadian version of the myth of "Inanna's Descent." An old Babylonian myth about the Thunderbird Ansud, who stole the tablets of fates, was conquered by Ninurta, and who was guided by Enki's counsel, is probably closely related to the Sumerian story of Ninurta's contest with Enki.

Also important is an old Babylonian "Myth of Atrahasis," which, in motif, shows a relationship with the account of the creation of man to relieve the gods of toil in the "Enki and Ninmakh" myth, and with a Sumerian account of the flood in the "Eridu Genesis"; but the myth treats of these themes with noticeable originality and remarkable depth. It relates, first, how the gods originally had to toil for a living, how they rebelled and went on strike, how Enki suggested that one of their number—apparently the ringleader who "had the idea," one We—be killed and mankind created from clay mixed with his flesh and blood, so that the toil of the gods could be laid on man and the gods left to go free. But after Enki and the birth goddess Nintur (another name for Ninmakh) had created man, man multiplied at such a rate that the din he made kept Enlil

sleepless. At first Enlil had Namtar, the god of death, cause a plague to diminish mankind's numbers, but the wise Atrahasis, at the advise of Enki, had man concentrate all worship and offerings on Namtar, and Namtar, embarrassed at hurting people who showed such love and affection for him, stayed his hand. Next Enlil had Adad, the god of rains, hold back the rains and thus cause a famine, but because of the same strategem, Adad was embarrassed and released the rains. After this, Enlil, next planned a famine by divine group action that would not be vulnerable as the earlier actions by individual gods had been. Anu and Adad were to guard the heavens, he himself earth, and Enki the waters underground and the sea so that no gift of nature could come through to man. The ensuing famine was terrible. By the seventh year one house consumed the other and people began eating their own children. At that point Enki—accidentally he maintained—let through a wealth of fish from the sea and so saved man. With this, however, Enlil's patience was at an end and he thought of the flood as a means to get rid of humanity once and for all. Enki, however, warned Atrahasis and had him build a boat in which he saved himself, his family, and all animals. After the flood had abated and the ship was grounded, Atrahasis sacrificed, and the hungry gods, much chastened, gathered around the offering. Only Enlil was unrelenting until Enki upbraided him for killing innocent and guilty alike and—there is a gap in the text—suggested other means to keep man's numbers down. In consultation with the birth goddess Nintur, Enki then developed a scheme of birth control by inventing the barren woman, the demon Pashittu who kills children at birth, and the various classes of priestesses to whom birth giving was taboo.

The myth uses the motif of the protest of the gods against their hard toil and the creation of man to relieve it, which was depicted earlier in the Sumerian myth of "Enki and Ninmakh," and also the motif of the flood, which occurred in the "Eridu Genesis." The import of these motifs here is, however, new: they bring out the basic precariousness of man's existence and man's usefulness to the gods will not protect him unless he takes care not to annoy them, however innocently. He must stay within bounds; there are limits set for his self-expression.

A far more trustful and committed attitude to the powers that rule existence finds expression in the seemingly slightly later Babylonian creation story, *Enuma elish*, which may be dated to the later part of the 1st dynasty of Babylon (c. 1894–c. 1595 BC). Babylon's archenemy then was the Sealand, which controlled Nippur and the country south of it—the ancestral country of Sumerian civilization. This lends political point to the battle of Marduk (thunder and rain deity), the god of Babylon, with the Sea, Tiamat; it also accounts for the odd, almost complete silence about Enlil of Nippur in the tale.

The myth tells how in the beginning there was nothing but Apsu, the sweet waters underground, and Tiamat, the sea, mingling their waters together. In these waters the first gods came into being and generation followed generation. The gods represented energy and activity, and thus differed markedly from Apsu and Tiamat, who stood for rest and inertia. True to their nature the gods gathered to dance, and in so doing, surging back and forth, they disturbed the insides of Tiamat. Finally, Apsu's patience was at an end, and he thought of doing away with the gods, but Tiamat, as a true mother, demurred at destroying her own offspring. Apsu, however, did not swerve from his decision and he was encouraged in this by his page Mummu, "the original (watery) form." When the youngest of the gods, the clever Ea (Sumerian Enki), heard about the planned attack he forestalled it by means of a powerful spell with which he poured slumber on Apsu, killed him, and built his temple over him. He seized Mummu and held him captive by a nose rope.

In the temple thus built the hero of the myth, Marduk, was born. From the first he was the darling of his grandfather, the god of heaven, Anu, who engendered the four winds for him to play with. As they blew and churned up waves, the disturbing of Tiamat—and of a faction of the gods who shared her desire for rest—became more and

The role of Atrahasis as the hero of the flood

The *Enuma elish*

more unbearable. At last these gods succeeded in rousing her to resistance and she created a mighty army with a spearhead of monsters to destroy the gods. She placed her consort Kingu ("Task[?]") at the head of it and gave him absolute powers.

When news of these developments reached the gods there was consternation. Ea was sent to make Tiamat desist, and then Anu, but to no avail. Finally Anshar, god of the horizon and king of the gods, thought of young Marduk. Marduk proved willing to fight Tiamat but demanded absolute authority. Accordingly, a messenger was sent to the oldest of the gods, Lahmu and Lahamu ("Silt[?]?"), to call the gods to assembly, and in the assembly the gods conferred absolute authority on Marduk, tested it by seeing whether his word of command alone could destroy a constellation and then again make it whole, hailed him king, and set him on the road of "security and obedience," a formula of allegiance that placed his power and authority on the pressing need for protection of the moment.

In the ensuing encounter with Tiamat's forces Kingu and his army lost heart when they saw Marduk. Only Tiamat stood her ground, seeking first to throw him off his guard by flattery about his quick rise to leadership, but Marduk angrily denounced her and the older generation: "The sons (had to) withdraw (for) the fathers were acting treacherously, and (now) you, who gave birth to them, bear malice to the offspring." At this Tiamat, furious, attacked, but Marduk loosed the winds against her, pierced her heart with an arrow, and killed her. Kingu and the gods who had sided with her he took captive.

Having thus won a lasting victory for his suzerain, King Anshar, he gave thought to what he might do further. Cleaving the carcass of Tiamat, he raised half of her to form heaven, ordered the constellations, the calendar, the movements of sun and moon, and, keeping control of atmospheric phenomena for himself, made the earth out of the other half of her, arranging its mountains and rivers. Having organized the various administrative tasks, he put their supervision in Ea's hands; to Anu he gave the tablets of fate he had taken from Kingu. His prisoners he paraded in triumphal procession before his fathers, and as a monument to his victory he set up images of Tiamat's monsters at the gate of his parental home. The gods were overjoyed to see him; Anshar rushed toward him and Marduk formally announced to him the state of security he had achieved. He then bathed, dressed, and seated himself on his throne, with the spear "Security and Obedience," named from his mandate, at his side. By now, however, the situation had subtly altered. The old fear and urgent need for protection was gone, but in its stead had come a promise held out by Marduk's organizational powers; so when the gods reaffirmed their allegiance to him as king they used a new formula: "benefits and obedience." From then on Marduk would take care of their sanctuaries and they, in turn, would obey him.

The building of Babylon

Marduk then announced his intention of building a city for himself, Babylon, with room for the gods when they come there for assembly; and his fathers suggested that they move there themselves to be with him and help in the administration of the world he had created. Next, he pardoned the gods who had sided with Tiamat and had been captured, charging them with the building tasks. Grateful for their lives, they prostrated themselves before him, hailed him as king, and promised to do the building.

Pleased with their willingness, Marduk magnanimously wanted to relieve them even from this chore and planned to create man to do the toil for them. At the advice of his father Ea, he then had them indict Kingu as instigator of the rebellion. Kingu was duly sentenced and executed, and from his blood Ea created man. Then Marduk divided the gods into a celestial and a terrestrial group, assigned them their tasks in the cosmos, and allotted them their stipends. Thus freed from all burdens, the gods wanted to show their gratitude to Marduk and as a token they took, of their own free will, for one last time, spade in hand to build Babylon and Marduk's temple Esagila. In the new temple the gods then assembled, distributed the celestial and terrestrial offices, the "great gods" went into

session and permanently appointed the "seven gods of destinies," or better "of the decrees," who would formulate in final form the decrees enacted by the assembly. Marduk then presented his weapons and Anu adopted the bow as his daughter and gave it a seat among the gods. Lastly, Marduk was enthroned, and after the gods had prostrated themselves before him they bound themselves by oath—touching their throats with oil and water—and formally gave him kingship, appointing him permanently lord of the gods of heaven and earth. After this they solemnly named his 50 names expressive of his power and achievements. The myth ends with a plea that it be handed on from father to son and told to future rulers, that they may heed Marduk: it is the song of Marduk who bound Tiamat and assumed the kingship.

The motifs from which this myth is built up are in large measure known from elsewhere. The initial generation of the gods is a variant form of the genealogy of Anu in the great god list *An: Anum*; the threat to annihilate the disturbances of sleep are known from the Atrahasis and the Sumerian flood traditions; the battle of Marduk with Tiamat seems to stem from western myths of a battle between the thunder god and the sea; the organization of the universe after victory recalls the organization of conquered territory in "Lugal-e"; and the killing of a rebel god to create man to take over the gods' toil is found in the Atrahasis myth and—without the rebel aspect—in a bilingual creation myth found in Assur. New and original, however, is the way in which they have all been grouped and made dependent on the figure of the young king. The political form of the monarchy is seen as embracing the universe; it was the prowess of a young king that overcame the forces of inertia; it was his organizational genius that created and organized all; and it is he that—as his counterpart on earth, the human king—grants benefits in return for obedience. The high value set on the monarchy as a guarantor of security and order in the *Enuma elish* can hardly have seemed obvious in Babylonia in the first troubled years of Assyrian rule in the second quarter of the 1st millennium BC. From this period (c. 700 BC) comes a myth usually called the Erra epic, which reads almost like a polemic against *Enuma elish*. It tells how the god of affray and indiscriminate slaughter, Erra, persuaded Marduk to turn over the rule of the world to him while Marduk was having his royal insignia cleaned, and how Erra, true to his nature, used his powers to institute indiscriminate rioting and slaughter. Royal power here stands no longer for security and order, but for the opposite: license to kill and destroy.

The value of the monarchy

Two other Akkadian myths may be mentioned—both probably dating from the middle of the 2nd millennium—the myth of the "Dynasty of Dunnum" and the myth of "Nergal and Ereshkigal." The first of these tells of succeeding divine generations ruling in Dunnum, the son usually killing his father and marrying, sometimes his mother, sometimes his sister, until—according to a reconstruction of the broken text—more acceptable mores came into vogue with the last generation of gods, Enlil and Ninurta. This myth, as has been mentioned, underlies the Greek poet Hesiod's Theogony. The myth of Nergal and Ereshkigal relates the unorthodox way in which the god Nergal became the husband of Ereshkigal and king of the Nether World.

**Epics.** The genre of epics appears generally to be younger in origin than that of myths and apparently was linked—in subject matter and values—to the emergence of monarchy at the middle of the Early Dynastic Period. The works that have survived seem, however, all to be of later date. A single short epic tale, "Gilgamesh and Agga of Kish," is told in the style of primary epic. It deals with Gilgamesh's successful rebellion against his overlord and former benefactor, Agga of Kish. More in the style of romantic epic are the stories of "Enmerkar and the Lord of Aratta," "Enmerkar and Ensuhkeshdanna," and the "Lugalbanda epic," all of which have as heroes rulers of the 1st dynasty of Uruk (c. 3500 BC) and deal with wars between that city and the fabulous city of Aratta in the eastern highlands. Gilgamesh, also of that dynasty, figures as the hero of a variety of short tales;

some, such as "Gilgamesh and Huwawa" and "Gilgamesh and the Bull of Heaven" in romantic epic style, and others, such as "The Death of Gilgamesh" and "Gilgamesh, Enkidu and the Nether World," concern the inescapable fact of death and the character of afterlife.

A much later dynasty, which similarly inspired epic tales, was the dynasty of Akkad (c. 2334–c. 2154 BC). The quick rise of its founder Sargon from obscurity to fame and his victory over Lugalzagesi of Uruk form the theme of several tales. The sudden eclipse of the Akkadian empire under Naramsin, attributed to that ruler's pride and the gods' retaliation, is the theme of "The Fall of Akkad." Akkadian epic tradition continues and gives focus to the Sumerian tales of Gilgamesh.

The  
Gilgamesh  
epic

The Akkadian *Epic of Gilgamesh* seems to have been composed in old Babylonian times but was reworked by a certain Sin-liqi-unninni later in the 1st millennium BC. It tells how Gilgamesh, the young ruler of Uruk, drives his subjects so hard that they appeal to the gods for relief. The gods create a wild man, Enkidu, who at first lives with the animals in the desert but is lured away from them and becomes Gilgamesh's friend. Together they vanquish the terrifying Huwawa, set by Enlil to guard the cedar forest in the West, and when on their return the goddess of Uruk, Ishtar, falls in love with Gilgamesh, is jilted by him, and sends the dread "bull of heaven" to kill him, he and Enkidu manage to kill the bull. At this point, however, their fortunes change. Enlil, angered at the killing of Huwawa, causes Enkidu to fall ill and die, and Gilgamesh, inconsolable at the death of his friend and terrified at the realization that he himself must someday die sets out to find eternal life.

After many adventures he reaches an ancestor of his, Utnapishtim, to whom the gods have granted eternal life, but his case proves to be a unique one and so of no help to Gilgamesh. Utnapishtim was rewarded for having saved human and animal life at the time of the great flood. Eventually, just as Gilgamesh is ready to return home he is told about a plant that rejuvenates and makes old men children again. Gilgamesh finds it and begins his return journey. But as the day is warm, when he passes an inviting pool, he leaves his clothes and the plant on the shore and goes in for a swim. A serpent smells the plant, comes out of its hole and eats it. Thus Gilgamesh's quest comes to naught. Eternal life is beyond man's grasp. The Gilgamesh epic is perhaps the most moving work in Ancient Mesopotamian literature with its sharp contrast of values: the warrior's disdain of death and danger, which informs the early parts of the epic, and the haunting fear that drives Gilgamesh in the later parts.

Other Akkadian epics that deserve to be mentioned are the Etana epic, which tells how Etana, the first king, was carried up to heaven on the back of an eagle to obtain the plant of birth, so that his son could be born; and epic tales about Sargon of Akkad, one of which, the birth legend, tells of his abandonment in a casket on the river by his mother—much as the Hebrew Moses was abandoned—and his discovery by an orchardman, who raised him as his son. Another Sargon tale is "The King of Battle," which tells about conquests in Asia Minor to protect foreign trade. Naramsin is the central figure in another tale dealing with that king's pride and also relating the destructive invasions by barbarous foes. A late flowering of primary epic is the Assyrian Tukulti-Ninurta epic that deals with that king's wars with Babylonia. He reigned from 1245 to 1208 BC.

**Other genres.** In addition to the genres of myth and epic, ancient Mesopotamian literature comprises much else of note, which should be at least briefly touched upon. The genre of cult literature reaches its high point in the Tammuz compositions; *i.e.*, love songs and descriptive compositions accompanying the rite of the sacred marriage, and, often deeply moving, laments—narrative or purely lyrical—used in the yearly ritual of wailing for the dead god. Of different character, practical rather than literary, are cult texts meant as instructional guides, outlining the sequence and nature of ritual acts. The earliest known text of this type is from Sumer (c. 2000 BC), but the great majority of what is known is relatively late.

Cult  
literature

Outstanding among them is a detailed description of the great New Year festival in Babylon.

Hymns and prayers, sometimes meant for public, sometimes for private, worship may also be considered as cult texts. Among the hymns the superb poem in praise of the temple Eninnu in Girsu, known as Gudea's Cylinders A and B, must rank foremost. Among hymns to the gods, the great Sumerian hymn to Enlil stands out. Prayers, both Sumerian and Akkadian, are often remarkable in the intensity of religious feeling they convey. Another cult genre is that of lamentations for temples and cities. Here the "Lament for the Destruction of Ur" is the masterpiece, unequalled for poignancy and power of expression.

It remains to mention the more secular genres of didactic and wisdom literature. Besides proverbs and fables, this genre has characteristic "disputation texts," serving as vehicles of evaluation of various elements in the cosmos or in society: summer and winter, copper and silver, shepherd and farmer, a father and his wayward son, and other opposing elements argue their respective merits. Sometimes—*e.g.*, in disputes between schoolboys or between common scolds (those addicted to reprimand harshly)—sheer enjoyment of the slanging match seems to take over. The genre of juridical literature—*i.e.*, extensive and varied collections of formulas for contracts, records of lawsuits, law codes, and other juridical works—is perhaps best represented by the famous Reform Texts of Urukagina (24th century BC) and the even more famous Code of Hammurabi (1792–1750 BC), both of which stand in a tradition of equity over against the common law.

Lastly, the genre of historical texts must be briefly mentioned. It may perhaps be thought of as including building and votive inscriptions, especially the Assyrian annalistic inscriptions of the 1st millennium BC, although these are commemoratively rather than historically oriented in the strict sense. Of truly historical works the earliest known example is the Sumerian king list composed around 2300 BC and chronicles that—though perhaps they are earlier in origin—appear fully developed in the 1st millennium BC. The most impressive example is the Babylonian Chronicle that presents a remarkably concise, factual, and unbiased account of contemporary events.

#### CONCLUSION

The wealth and the richness of ancient Mesopotamian literature makes it impossible to deal with it here in any great degree of detail. Nor can its works—even at best—be given in other than outline. It seems proper, however, that in conclusion at least one sample of its powers of expression should be quoted in translation. The lines below are from a lament for the dying god, whose mother is seeking for him in the desert as he speaks from the grave:

I am not one who can answer my mother,  
who cries for me in the desert,  
Who makes the cry for me echo in the desert,  
She will not be answered.  
I am not the grass, may not grow up (again) for her,  
I am not the waters, may not rise (again) for her,  
I am not the grass sprouting in the desert,  
I am not the new grass, growing up in the desert.

(From *Most Ancient Verse*; selected and translated by T. Jacobsen and J.A. Wilson, The University of Chicago Press, 1963, p. 29.)

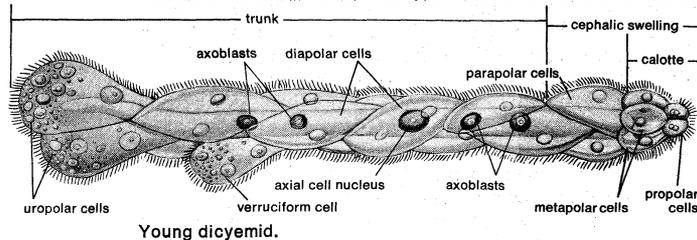

**BIBLIOGRAPHY.** A. LEO OPPENHEIM, *Ancient Mesopotamia* (1964), provides a good general account of the cultural background. Reliable translations of most of the relevant texts may be found in J.B. PRITCHARD (ed.), *Ancient Near Eastern Texts Relating to the Old Testament*, 3rd ed. (1969). Special groups of texts, such as hymns and prayers, are covered in A. FALKENSTEIN and W. VON SODEN, *Sumerische und Akkadische Hymnen und Gebete* (1953); and in W.G. LAMBERT, *Babylonian Wisdom Literature* (1960). Both of these works have introductions dealing with the history of that particular branch of literature. T. JACOBSEN and J.A. WILSON, *Most Ancient Verse* (1963), seeks to render the poetic qualities of ancient passages. Interpretative works include: H. FRANKFORT *et al.*, *Before Philosophy* (1951); T. JACOBSEN, *Toward the Image of Tammuz*, ed. by W.L. MORAN (1970); and S.N. KRAMER, *Sumerian Mythology* (1944) and *The Sumerians* (1963).

## Mesozoa

In 1876 the name Mesozoa was proposed for dicyemids, a group of minute multicellular parasites that seem to represent a true "missing link" between the Protozoa and the Metazoa. There is no sign, in either the adult or embryonic stages of dicyemids, of the discrete systems (e.g., muscular, reproductive, digestive) typical of metazoans. Although all dicyemid functions are carried out at the cellular level, as in protozoans, dicyemids are too complex to be colonial protozoans. The name Mesozoa and the concepts associated with it have persisted. Sometimes the term mesozoan is expanded to include another parasitic group, the orthonectids.

From *The Encyclopaedia of the Biological Sciences* by Peter Grey © 1961 by Litton Educational Publishing, Inc. Reprinted by permission of Van Nostrand Reinhold Co.

Young dicyemid.

**General features.** Mesozoans, minute, wormlike parasites of marine invertebrates, range from less than a millimetre to a few millimetres in length. Orthonectids, often considered mesozoans, occur as multinucleate ameboid masses (known as plasmodia) in the incubatory pouches of ophiuroids, such as brittle stars, as well as in the tissue spaces of diverse groups that include turbellarian, nemertean, and polychaete worms, and gastropod and bivalve mollusks. The plasmodia of orthonectids give rise to free-swimming sexual adults. Dicyemid mesozoans occur only in the renal chambers of cephalopods. A single, long reproductive cell, the axial cell, is surrounded by a single layer of ciliated somatic cells, those at the anterior end forming a sort of head (the calotte) by which the dicyemid clings to the renal tissue of its host.

In both the dicyemids and the orthonectids, the number and arrangement of cells is relatively constant for any given species. This definitive cell number is attained during embryonic development. Growth, therefore, consists of the enlargement and differentiation of existing cells. In both groups chromatin (the material that comprises chromosomes) elimination occurs during early cleavage divisions from the cell line that will give rise to somatic cells.

Both groups are very widely distributed wherever appropriate hosts occur in shallow bottom environments of the sea. They are not found in hosts in open sea environments, nor have they been found in hosts from tropical coral islands. In many regions dicyemids infect entire populations of bottom-dwelling cephalopods, such as squids and octopuses. On the other hand, orthonectids infect only a small percentage of their hosts in a given region. In orthonectids agametes (asexual reproductive cells), formed during the plasmodial stage, give rise to sexual adults that leave the host for a brief free-swimming period, during which the females are impregnated. The zygotes develop into ciliated larvae that infect new hosts, giving rise to new plasmodia. While in the host, the plasmodia pass through a period of asexual reproduction forming agametes before adults appear once more.

Dicyemids have a more complex life cycle, one that is not yet fully understood. Two reproductive phases occur in the cephalopod host. During a phase called the nematogen phase, agametes give rise to wormlike larvae similar to their parents. These nematogens remain in the same host, thus increasing the parasite population. In the next phase, known as the rhombogen phase, a few axoblasts give rise to minute organisms known as infusorigens; these are reduced hermaphroditic individuals that remain in the axial cell of the rhombogen and give rise to sperm and egg cells. The zygotes develop into ciliated infusori-forms, or swarm larvae, which escape from the parent rhombogen and from the cephalopod. Their fate is unknown.

In some species the first nematogens, infecting very young cephalopods, have three (or two) axial cells. These stem nematogens give rise to ordinary nematogens.

**Phylogeny and evolution.** Studies of orthonectids in 1969 revealed them to be more complex than formerly supposed. In addition to reproductive cells, they contain specialized internal contractile and supportive cells. These studies emphasized the uniqueness of orthonectids rather than any relationship with another group and led to the possible conclusion that resemblances between dicyemids and orthonectids are superficial, and that, rather than grouping them together in one phylum, the Mesozoa, they should perhaps be considered separate groups of uncertain systematic position.

The unique structure, complex life cycle, wide distribution, and host specificity of dicyemids indicate that the cephalopod-dicyemid association has been a very long one. In addition, some zoologists feel that the basic features of mesozoan morphology are primitive rather than derived. If these hypotheses are true, the Mesozoa are of great phylogenetic significance.

## Mesozoic Era

The Mesozoic Era is the time period from about 225,000,000 years to 65,000,000 years ago, and it embraces the Triassic, Jurassic, and Cretaceous periods. The term Mesozoic was proposed in 1841 on the basis of the existing knowledge of fossils in Great Britain. The vast amount of data accumulated since that time has served to confirm the quality of this judgment, because the Mesozoic Era is characterized by many groups of organisms that are quite different from those in the Paleozoic and Cenozoic eras. It is now widely believed that continental drift (*q.v.*), the separation of the continents from a primordial landmass, was initiated during this era.

This article provides an overview of the rocks, life, and environments of Mesozoic time. For additional detail on these topics see TRIASSIC PERIOD; JURASSIC PERIOD; and CRETACEOUS PERIOD. See also EARTH, GEOLOGICAL HISTORY OF for the relation of Mesozoic events and those of other eras during earth history; and FOSSIL RECORD and STRATIGRAPHIC BOUNDARIES for relevant information on Mesozoic stratigraphy and paleontology.

### MESOZOIC ROCKS

Mesozoic rocks are widespread in every continent, and marine deposits occupy progressively greater areas with each successive period. There were initially two major continental shield areas, Laurasia, including most of North America and Asia, and Gondwanaland, in the Southern Hemisphere. These were separated by the Tethys, an ocean that extended from the present central Atlantic region, through the Mediterranean and Middle East, to Indonesia and New Zealand. Marine deposits also were laid down throughout the era in a geosynclinal belt around the margins of the Pacific Ocean. Subsequently, the world paleogeography was complicated by the opening of the Atlantic and Indian oceans by sea-floor spreading (*q.v.*). The shield areas were emergent as land or were covered by continental or shallow marine sediments, and deeper water marine sediments were laid down in the

Tethys and circum-Pacific zone intermittently. In both cases, there is a widespread tendency for Mesozoic rocks to rest unconformably upon Paleozoic rocks that were deformed by the Hercynian orogeny (major episode of mountain building, which occurred during Carboniferous-Permian time).

Triassic  
deposits

Triassic marine deposits are substantially confined to the Tethyan and circum-Pacific zones, but they also occur in parts of the Arctic coastlands. The best known marine rocks are those around the Mediterranean, where they consist usually of thick limestones and dolomites with subordinate red beds, mainly of older Triassic age. The carbonates include massive reef limestones that contain corals and calcareous algae, and bedded limestones containing stromatolites (distinctive fossil algae deposits). The circum-Pacific marine Triassic deposits consist dominantly of clastic and volcanic sediments. Continental Triassic deposits are much more widespread and consist mainly of red shales, marls, and sandstones with subordinate conglomerates, and salt deposits (gypsum, anhydrite, and halite). Gray beds with coals also are known, as in some localities of Central Asia, the southern Appalachian Mountains, and Australia. In areas of central and southern Europe, marine limestones and dolomites are interbedded with typical red continental beds.

Jurassic deposits were laid down conformably on the Triassic almost everywhere, and they occupy approximately the same areas, but marine deposits are more widespread. Within the Tethyan zone of southern Europe, limestones and dolomites are predominant, as in the Triassic. In the early Jurassic, shallow-water reefoid and stromatolitic limestones are common; but toward the end of the period, deeper water, fine-grained, pelagic limestones composed of calcareous microplankton were laid down over wide areas. Of special interest are certain red nodular limestones, often with black iron manganese oxide incrustations, and layers of bedded chert. In northern Europe, the marine beds commence with the Rhaetic shales, sandstones, and limestones, now considered to be uppermost Triassic. They are followed by variable thicknesses of marine deposits in which terrigenous clastic sediments, namely, shales, siltstones, and sandstones, predominate. Generally, the more northerly the occurrence of the deposits, the greater is the proportion of terrigenous clastic sediments to biogenic and chemically precipitated rocks such as limestones. Of considerable economic importance and academic interest are the minette-type oolitic ironstones, which occur mainly in the Lower and Middle Jurassic. In the course of time the pattern of sedimentation changed; the area of marine deposition spread somewhat, as did the area covered by limestones; but at the close of the period, lagoonal deposits, including calcium sulphate salts, were laid down and continental sedimentation occurred over wide areas.

Sedimentation

The pattern of sedimentation in North America during the Jurassic is similar to the European. Calcareous deposits are more abundant in the south, in areas such as Mexico, the Gulf Coast, and New Mexico. Marine deposits in the western interior region of the United States are Middle Jurassic in age. Jurassic sedimentation in this region began and ended with continental clastic deposits. The Western Cordillera received thick clastic deposits, consisting primarily of volcanic material, in what was clearly an unstable geosynclinal belt. This type of sedimentation is known from Alaska to the Andes, in Japan and New Zealand, and elsewhere around the Pacific. Thick salt deposits that are presumed to be of Early or Middle Jurassic age are known from subsurface drilling in Arkansas and Louisiana.

Continental clastic deposits, including coal, are widespread throughout Asia, where marine deposits are confined mainly to the oceanic margins or the Tethyan zone, excepting northeast Siberia. Upper Jurassic marine limestones are relatively widespread, and important salt deposits of this age occur in the southern U.S.S.R. and the Middle East. Jurassic sediments of the southern continents are largely continental, but marine limestones and clastics occur on the east coast of Africa, western Madagascar, and the west coast of Australia.

In Early Cretaceous time the same broad patterns of Jurassic sedimentation persisted. Shallow-water reefoid and deeper water pelagic limestones were laid down in the Mediterranean countries and Middle East. Elsewhere in Europe, nonmarine sandstones and shales of Lower Cretaceous (Neocomian) age are widespread in northern Spain, southern England, and northern France and Germany; but marine clays are found farther north, from England to the Moscow region. In North America, marine deposits of the Early Cretaceous are confined to the Western Cordilleran region and parts of the Arctic; nonmarine deposits are known on the Atlantic seaboard, where they lie unconformably on much older rocks. The areas of nonmarine sedimentation extended considerably from Jurassic times. Besides large areas in Central Asia, there are extensive nonmarine clastic deposits of Early Cretaceous and possibly Late Jurassic age in Africa, South America, and Australia that rest on Paleozoic or older rocks. Marine conditions persisted generally in the circum-Pacific belt, but there are notable stratigraphic gaps, as in New Zealand, that signify that uplift and orogeny occurred.

Cretaceous  
deposits

By Middle Cretaceous time (Aptian/Albian), a notable transgression of the sea began, and this is reflected by the fact that in many parts of the world marine deposits of this age overlie continental deposits. This is the case, for example, in northern Europe, the western interior of North America, and the coastlands of West Africa, Brazil, and southern Australia. In Europe, the characteristic deposits of this age are greensands (rich in the green iron silicate mineral, glauconite), clay, and sandy rocks with a silica cement (gaize). The dominant deposits of the western Tethys region are still carbonates, and those of the circum-Pacific geosynclinal zone are clastic rocks.

Marine deposits of Late Cretaceous age cover a vastly greater area than do older Mesozoic rocks; they occur extensively, for example, over the old shield areas of northern Africa and the western interior of North America. Hardly anywhere are marine deposits of the earlier Cretaceous overlain by continental Upper Cretaceous. Chalk is an interesting variety of limestone that occurs widely in northern Europe and parts of southern and central United States. In its pure state chalk is composed largely of coccoliths, the minute calcareous plates of a group of planktonic algae, and it is uncemented and therefore soft and friable. The widespread ironstones and manganese beds of the Jurassic substantially gave way to extensive phosphorites (*q.v.*), deposits that are of great commercial importance in some of the Mediterranean countries. With respect to clay minerals, montmorillonite first becomes dominant in Mesozoic time, at least in the Northern Hemisphere. Within the Alpine fold belts of southern Europe, Upper Cretaceous deposits are marked by the sudden appearance of flysch sediments—alternations of sandstones and shales that are thought to signify deposition in rather deep troughs into which the sand was carried by density currents.

Toward the close of the Cretaceous, a return to continental conditions is indicated in many areas, either by a break in deposition, as in England, or by the presence of nonmarine, clastic sediments, as in the Rocky Mountain region. Continuous sequences of marine deposits from the Cretaceous to the Paleocene, the oldest unit of the Cenozoic Era, do occur in Denmark, the Pyrenees and a few other continental areas, and in many deep-sea cores.

#### MESOZOIC LIFE

The vertebrate terrestrial life of the Mesozoic Era was dominated by reptiles. Faunas changed considerably during the course of the era, however. In Triassic times, a common and widely distributed animal group was the labyrinthodonts, large clumsy amphibians with an aquatic mode of life. They suddenly became extinct at the end of the period. The more advanced toads and frogs, Order Anura, arose in Late Triassic times and continued to flourish. The oldest known salamander is Cretaceous in age. Amphibians had declined, as early cotylosaurs, "stem reptiles," developed during Late Carboniferous through Permian time. The cotylosaurs are considered to be the

Vertebrate  
groups

group from which major reptile lines became differentiated. In Permian time, forms leading to turtles, marine groups such as plesiosaurs and ichthyosaurs, mammal-like therapsids, and thecodonts could be defined. The thecodonts are limited to the Triassic and include small bipedal forms (e.g., *Pseudosuchia*) and the crocodile-like, 20-foot-long phytosaurs. Thecodonts gave rise to such disparate groups as pterosaurs, birds, and dinosaurs. The dinosaurs first appeared in the Late Triassic, and they clearly are derived from thecodont ancestors. From small bipedal animals such as *Coelophysis* evolved the huge and spectacular creatures of the Jurassic. These include the herbivorous *Brontosaurus* and *Diplodocus* (Saurischia), and *Stegosaurus* and the carnivorous, bipedal *Allosaurus* (Saurischia). The best known carnivore of the Cretaceous was the huge saurischian *Tyrannosaurus*. Cretaceous dinosaurs were even more abundant and diversified than those of the Jurassic. They include large herbivores like *Iguanodon*, the armoured *Ankylosaurus*, and the horned *Triceratops*, together with the duckbill hadrosaurs and small, lightly built, bipedal forms such as *Ornithomimus*. The sudden extinction of the flourishing Late Cretaceous dinosaur fauna is one of the major mysteries of paleontology.

The Mesozoic is also characterized by the existence of other interesting groups of reptiles that became extinct at or near the close of the era. The pterosaurs, capable of limited gliding flight, might have become extinct through competition with birds. These had evolved from reptiles by Cretaceous times as evidenced by *Archaeopteryx*, a primitive Jurassic bird with major reptilian characters. Even more characteristic of the Mesozoic are those reptiles that became well adapted to swimming in the sea, such as the nothosaurs (Triassic), placodonts (Triassic), ichthyosaurs (Triassic to Cretaceous), plesiosaurs (Jurassic to Cretaceous), and mosasaurs (Cretaceous), the last being huge marine lizards.

Therapsid reptiles are of especial interest and are best known from abundant fossil remains in the Permian/Triassic Karroo deposits of South Africa. In the Triassic they consist of diversified forms including dicynodonts, tritylodonts, and ictiosaurs. The last group shows an impressive evolutionary series culminating in animals that are virtually indistinguishable in bone structure from mammals; hence, they give a clear indication of the origin of modern mammals.

Mesozoic mammals belong to several extinct orders; all were of small size. Late Triassic groups were triconodonts (to Middle Cretaceous), docodonts (to latest Jurassic), and symmetrodonts (to Middle Cretaceous). To these were added pantotheres and multituberculates by Late Jurassic. The latter became extinct in Early Cenozoic time, but the pantotheres gave rise to marsupials, known from the Cretaceous of North America, and to small, primitive placentals that are found in the Cretaceous of North America and Mongolia.

Mesozoic marine vertebrates also include several important groups of fish. The most primitive of the bony fish, the chondrost fishes, represented today by the sturgeon, were dominant in Triassic times but declined in importance at the end of that period. They were replaced by the holost fishes, characterized by heavy rhombic scales. This group of fish ranged throughout the Mesozoic but declined in Late Cretaceous times; they are represented today by only a few species, such as the garpike of the Mississippi River. Their decline probably resulted from competition by the most advanced group, the teleost (bony) fishes, which arose from the holosteans in the Jurassic and became dominant in Late Cretaceous times. Other Mesozoic fish include crossopterygian fishes and sharks.

Invertebrate groups

The marine invertebrate faunas of the Mesozoic are of greater importance to stratigraphers than the vertebrate faunas. A progressive increase in diversity of invertebrates occurred throughout the era. Perhaps the best known, and certainly the most useful for stratigraphic correlation because of their rapid evolution, are the cephalopod mollusca with (usually) plane spiral, chambered shells known as ammonites. These are as characteristic of

Mesozoic faunas as the dinosaurs and, like them, the ammonites became extinct at the end of the Cretaceous. From a solitary family that survived the widespread extinction of invertebrates at the close of the Paleozoic Era, there evolved a highly diversified series of ammonites in Triassic time. The group barely survived a further period of extinction at the close of the Triassic and underwent another major phase of radiation in the Jurassic. Cretaceous ammonites include a variety of interesting forms with shells showing varying degrees of deviation from the plane spiral pattern (e.g., *Scaphites*, *Baculites*, *Turrilites*). The total extinction of ammonites at the end of the Mesozoic Era is as great an enigma as the extinction of the Mesozoic reptile groups. The belemnites are another group of cephalopods that are quite characteristic of the Mesozoic; they also disappeared at the end of the Cretaceous.

Other important groups of mollusca are the bivalves (lamellibranchs) and gastropods. The bivalves became one of the dominant invertebrate groups from Triassic time onward. This is partly the result of the evolution of siphons, which allowed them to colonize a new ecological niche, namely, the muddy sediments of the sea floor. Among the numerous genera, *Gryphaea*, *Inoceramus*, *Spondylus*, *Trigonia*, *Pholadomya*, and the peculiar, coral-like rudists are especially characteristic of the era. The principal change among gastropods in the course of the Mesozoic was the rise in Late Cretaceous time of the siphonate order, Neogastropoda, many of which are carnivores.

Echinoderms are best represented by crinoids and echinoids. The former were abundant in shallow waters, and free-living, stalkless forms evolved later in the era. The early echinoids were of the more primitive, regular type; but Jurassic faunas included irregular, modern echinoids such as *Clypeus*. The heart urchins (e.g., *Micraster*) are very characteristic of the Cretaceous. Brachiopods, though less dominant than in the Paleozoic, were much more abundant and varied than today; the most abundant are members of the Rhynchonellida and Terebratulida, two of the three surviving groups. Among the larger Arthropoda, abundant crustaceans left their record preserved both as exoskeletons and fossil tracks and burrows. Corals are represented by the still thriving Scleractinia, which originated in the Triassic. These reef builders occurred most abundantly in the Tethyan zone. The so-called ahermatypic forms, which can live in the deep sea, appear to have evolved by Late Jurassic time. Calcareous and siliceous sponges are also well represented in the fossil record.

The invertebrate microfaunas are represented by abundant foraminifera, radiolaria, and ostracods, all of which are of great value to oil companies in correlation studies. The nodosarid family of benthonic foraminifera was dominant throughout most of the era, together with the more complex Lituolacea in the Tethys. Appearing first in the Late Jurassic and expanding rapidly in the Cretaceous, planktonic foraminifera such as *Globigerina* are a notable component of Late Mesozoic pelagic deposits.

Although far less diverse than the marine faunas, Mesozoic invertebrates lived also in continental environments such as lakes and rivers. They include a few genera of bivalves, gastropods, and ostracods. The Triassic insect fauna seems modern in aspect because few now extinct orders survived the Permian. Grasshoppers, earwigs, flies, ants, bees, and wasps appeared before the Cretaceous. With regard to the plant kingdom, the Mesozoic may be called the age of Pteridophytes. This group comprises the ferns, the gymnosperm orders of cycads, ginkgos and conifers, and the angiosperms, which became well established by the end of the era. Cycadean plants, which were rare in Late Paleozoic and Early Triassic time, became common at the end of the Triassic, and the true Cycadales survived in reduced numbers to the present day. Conifers were widespread, and they provide most of the fossil logs that have been preserved as "petrified forests." Ginkgos, first abundant in Late Triassic, became particularly common in Arctic floras and are represented today by a solitary survivor, the maidenhair tree. A rich Paleozoic holdover

Major plant groups

flora of ferns and horsetails is also known in the Mesozoic fossil record. The most striking evolutionary event in the era was the sudden rise to dominance of the angiosperms, or flowering plants, in the Late Cretaceous. Their ancestry is obscure; the first undisputed record is in the Lower Cretaceous, but they must have evolved somewhat earlier in the era. With the rise of the angiosperms, land flora took on a modern aspect before the close of the Mesozoic.

For more primitive plants, the best record is preserved in marine deposits. The most primitive algae, the Cyanophyta, or blue greens, are represented by the wavy banding in limestones known as stromatolites. Lime-secreting red and green algae form an important component of many limestones in the Tethyan zone. Planktonic algae (diatoms and coccolithophorids) and dinoflagellates are also known. Many Late Jurassic and Cretaceous limestones are composed largely of coccoliths. Solution of siliceous diatoms, which appeared in the Jurassic, radiolarian skeletons, and the spicules of siliceous sponges, must have provided the major source for the bedded and nodular cherts that occur frequently in many younger Mesozoic rocks.

#### STRATIGRAPHIC CORRELATION OF MESOZOIC UNITS

The world standard for the correlation of Mesozoic strata is provided in the Table. The stages are based upon fossils found in marine deposits in classical European sections.

Stratigraphic Correlation of Mesozoic Units	
Maestrichtian Campanian Santonian Coniacian Turonian Cenomanian Albian Aptian Barremian Hauterivian Valanginian Berriasian	Cretaceous
Tithonian/Volgian Kimmeridgian Oxfordian Callovian Bathonian Bajocian Aalenian Toarcian Pliensbachian Sinemurian Hettangian	Jurassic
Rhaetian Norian Carnian Ladinian Anisian Scythian	Triassic

Though this is the generally accepted scheme, agreement on the stratigraphic boundaries (*q.v.*) is not universal. Some stratigraphers would include the Danian stage, here accepted as part of the Paleocene, in the Cretaceous. Precise correlation of the Tithonian and Volgian, which contain very different ammonite faunas, has not yet been achieved, and Berriasian ammonite faunas seem to show closer affinities to the Tithonian than to the Valanginian. A third topmost Jurassic stage, the Portlandian, has been widely used; but its lower boundary is somewhat higher in the ammonite sequence, and thus it affects the local definition of the Kimmeridgian. The Aalenian stage generally has not been recognized by British stratigraphers. There has been considerable difficulty in applying the scheme of stages for the Triassic in areas other than Europe.

The scheme given in the Table is based essentially on ammonite faunas, which provide by far the best means of correlation when they are available. Where ammonites are sparse or absent, recourse must be had to other groups. As far as marine deposits are concerned, Triassic pteriomorph bivalves, such as *Halobia*, *Daonella*, *Mono-*

*tis*, and *Rhaetavicula*, and the Jurassic and Cretaceous *Buchia* and *Inoceramus*, have proved useful. Belemnites, echinoids, and crinoids also have been used in the Cretaceous. In recent years much success has been obtained by correlating planktonic foraminifera of Cretaceous age, and oil companies in particular have used a variety of microfossils. Nonmarine deposits are much harder to correlate. A series of reptile zones has been established in the South African Karroo deposits, but vertebrates generally are much too scarce to be helpful. Pollen stratigraphy (*q.v.*) has been utilized with some success in recent years, but it does not always allow precise correlation. The same is true of attempting to correlate nonmarine bivalves.

#### MESOZOIC ENVIRONMENTS

At the beginning of the Mesozoic Era, the seas were at their most restricted; and more or less continuous marine transitions from the Permian were confined to very few areas, such as East Greenland, the Caucasus, the Salt Range of Pakistan, and parts of the circum-Pacific region. Subsequently, in later Triassic time, the seas spread widely over the Tethyan and circum-Pacific zones; but, except for a limited incursion of the Muschelkalk Sea in northern Europe and marginal marine incursions along the Arctic coastlands, the main continental-shield areas remained emergent. Thus, the shield areas were dry land or, perhaps, were covered by nonmarine or lagoonal sediments in some instances.

The marine transgression extended further in the Jurassic. In the early part of the period (and even in the latest Triassic) a shallow sea spread widely in northern and western Europe, and a marine gulf was established along the eastern side of Africa to Tanzania and Madagascar. There was also an extensive transgression in northeastern Siberia. In Middle Jurassic times, extensive parts of the western interior of North America were flooded, and shallow gulfs became established in western Australia. The Jurassic seas reached their maximum extent toward the close of the period; marine conditions prevailed continuously from the British Isles to European Russia and into the lands around the Gulf of Mexico. At the end of the Jurassic, however, a widespread regression set in. The sea retreated from much of northern and western Europe, from the western interior of North America, and also from most of northeastern Siberia.

The paleogeographic conditions of the Early Cretaceous resembled closely those of the latest Jurassic, but the seas began to transgress once more. By the middle of the period the seas reached for the first time coastlands of the South Atlantic, southern Australia, eastern India, and the eastern United States. In Late Cretaceous times the seas attained their maximum extent in the era, and the proportion of shield areas covered compares with that of the Early Paleozoic. The most spectacular changes took place in North America, where a wide seaway extending from the Arctic to the Gulf of Mexico split the subcontinent into two major landmasses, and in northern Africa, where the sea crossed the Sahara to establish a marine link between the Gulf of Guinea and the Mediterranean. Regression set in over large areas at the close of the period.

Although there is not an exact synchronism of major transgressions and regressions in all cases, the movements of sea level relative to the continents on a worldwide basis during the Mesozoic cannot be doubted.

If one accepts the abundant evidence favouring continental drift, then such drift must be taken into account in reconstructions of Mesozoic paleontology. Opinions differ as to when the major continental dispersal began. The evidence from the distribution of terrestrial animals, marine sediments along the margins of the southern continents, rock magnetism, and oceanography appears to favour a relatively late breakup, initiated no earlier than the Middle Jurassic. This would imply that in Early Mesozoic time the Atlantic and Indian oceans did not exist.

The evidence of orogeny and volcanism is consistent with this picture because both were more widespread and intense in the later Mesozoic. Volcanic activity was persistent throughout the era only in the circum-Pacific geosynclinal zone, where many basaltic and andesitic lavas

Continental drift

and tuffs are intercalated with clastic sediments, which themselves often have a significant volcanic component. During the Triassic, important eruptions of basalts took place in central Siberia, North Africa, and the northern Appalachians. In the Jurassic, the most important centres of volcanic activity in the shield areas were southern Africa, East Antarctica, and eastern Australia; Jurassic granites are known in West Africa, New England, and in parts of the circum-Pacific region. The vast flood basalts of southern Brazil and peninsular India are largely Cretaceous in age, as are widespread ultrabasic rocks in the western Tethys. Also belonging to the Cretaceous are the vast granite batholiths of the Andes, the western Cordillera of North America, and eastern Asia.

The Triassic and Early Jurassic generally are time periods of orogenic quiescence, but tectonic movements in geosynclinal and shield areas occurred in the Middle Jurassic. The most important orogenic phase in the Jurassic occurred at the close of the period, with events recorded in several continents. This heralded more intense disturbances, involving strong folding, thrusting, metamorphism, and intrusion in the Cretaceous Period throughout the circum-Pacific and Tethyan geosynclines.

Mesozoic  
climates

With respect to the evidence for climatic change, both rocks and fossils clearly indicate more equable conditions than exist today; polar ice caps were almost certainly absent. In consequence, Mesozoic floras and faunas tend to be cosmopolitan, with many of the same genera and species ranging from Greenland and Spitsbergen to Antarctica. In particular, the existence of large reptiles and reef corals in high latitudes of both hemispheres suggests relatively mild minimum temperatures. Major faunal realms existed, but it is by no means clear that they always relate to climate rather than to paleogeographic configurations and sedimentary facies. Research on oxygen isotopes in fossil shells has suggested the possibility of widespread temperature fluctuations in the Late Cretaceous, but this has yet to be confirmed by other evidence. Geochemical methods have added little to other evidence for the earlier Mesozoic.

Widespread aridity over the continents in Triassic time is suggested by extensive salt deposits and by fossil sand dunes (in South Africa). Ancient desert deposits also are known in the Jurassic of the western United States, and salt deposits in various parts of the Tethyan and adjacent regions indicate some aridity during this period. The northern continents at this time must have been more humid, as evidenced by coals and ironstones. There is no indication of extensive aridity during the Cretaceous.

**BIBLIOGRAPHY.** B. KUMMEL, *History of the Earth*, 2nd ed. (1970), a general, well-illustrated account of changing paleogeography and animal life on the whole globe; W.J. ARKELL, *Jurassic Geology of the World* (1956), a standard scholarly text on the Jurassic, indispensable for serious students of the subject; H. and G. TERMIER, *Atlas de paléogéographie* (1960), a series of paleogeographic maps for Phanerozoic time, with the Mesozoic well represented; W.B. HARLAND *et al.* (eds.), *The Fossil Record* (1967), essentially a piece of massive documentation by many specialists of the stratigraphical ranges of all important fossil groups; E.H. COLBERT, *Evolution of the Vertebrates*, 2nd ed. (1969), a general account of fossil vertebrates, easily assimilable by the non-specialist; BRITISH MUSEUM (NATURAL HISTORY), *British Mesozoic Fossils*, 3rd ed. (1967).

## Messiah and Messianic Movements

The term messianism, derived from the Hebrew word *mashiah* ("anointed") and denoting the Jewish religious concept of a person with a special mission from God, is used in a broad and at times very loose sense to refer to beliefs or theories regarding an eschatological (concerning the last times) improvement of the state of man or the world, and a final consummation of history.

### NATURE AND SIGNIFICANCE

**Origins.** The term messiah has been applied to a variety of redeemer figures, and many movements with a markedly eschatological or utopian-revolutionary character or message have been termed messianic. Though

messianic movements have occurred throughout the world, they seem to be especially characteristic of the Jewish and Christian traditions. Hence, not only the word messiah but also other terms relating to the messianic type of phenomena are derived from biblical religion and from the history of Jewish and Christian beliefs—*e.g.*, "prophetic," "millenarian," and "chilastic" movements—the last two terms referring to a 1,000-year reign of Christ and his saints before the final end of history. Moreover, the scientific study of messianic beliefs and movements—originating, as it did, in the Western theological and academic tradition—was directed mainly to phenomena occurring either in Christian history or in cultures exposed to Western colonial, missionary, and modernizing influences. These Western origins of messianic terms and concepts give discussions of the subject an almost unavoidable Judeo-Christian slant. Hence, many present-day sociologists and anthropologists have attempted to develop a more neutral terminology—*e.g.*, nativistic movements, religious movements of liberty and salvation, renewal movements, revitalization movements, crisis cults—but many of these terms emphasize incidental and adventitious aspects of the phenomenon and miss its essential features.

**Relationship of messianism to concepts of time.** Basic to messianism is a certain relationship to the time dimension; the time process is expected to lead to a major change—or even to a final consummation—as a result of which a happier, better, or perfect state of things will take the place of the imperfect present. Intrinsic to messianism is the negative evaluation of the present. If the present is satisfactory and right, it need not be "fulfilled" and transcended, but rather perpetuated or renewed and rejuvenated in accordance with a pattern set by myth and ritual. Because, however, the present is viewed as unsatisfactory and blighted by suffering, death, sin, and other evils, it has to be changed and superseded by a new age. Such a new age may be conceived either as something utterly new or as a return to a past golden age. Messianism thus tends to develop in situations of stress, suffering, and frustration. It is also most conspicuous in cultures whose time concept permits an historic orientation; *i.e.*, instead of a constant pattern of cyclical returns, a repetition as in natural processes, there is a linear time process leading to a fulfillment and end that is possibly predestined. A certain historical dimension is thus an essential feature of the fully developed messianic complex.

**Messianism as ideology and as movement.** A distinction must be made between messianism as a complex of ideas, doctrines, hopes, and expectations on the one hand, and messianic movements on the other. Messianism is the potentiality of messianic movements; messianic movements are messianism in action. Even the "facts" of suffering and frustration require ideas and social symbolism before they can assume cultural shape and historical reality (*i.e.*, before they can appear, be expressed, or function as such in a particular time and culture). Conversely, beliefs and doctrines require a specific constellation of facts in order to pass from potentiality to actuality. The student of the subject is therefore faced with two distinct problems: (1) how do messianic ideas arise and how do they function in the culture and history of specific societies? and (2) what situations or events precipitate messianic movements—that is, turn a messianic ideology into an active social and historical movement? Related to these problems is the question of the relationship of the social and religious context to the role of the charismatic personality (one having spiritual power and influence) and messianic leader.

Messianic ideologies and movements are not necessarily centred on a messianic figure, though there is a tendency for such movements to personify the messianic ideal and to have a personal messiah play the central role in its realization. Very often messianic movements, envisaging a decisive improvement in the spiritual and practical affairs of man, are initiated by strong charismatic personalities. Messianic movements being, by definition, movements concerned with radical changes for the better (*e.g.*, salvation, redemption, liberation), they have

Develop-  
ment of  
neutral  
terminology

played a significant role in the history of mankind. Before the modern secular age and in premodern societies (in which most cultural values have a religious sanction of one kind or another), messianism was one of the chief ideological and practical vehicles for radical cultural, social, political, or religious change.

**MESSIAH AND MESSIANIC MOVEMENTS  
IN JUDAISM AND CHRISTIANITY**

**Judaism.** *Biblical messianism and messianic movements.* In biblical Hebrew the adjective or noun *mashiah* is used of material objects (e.g., the shield of Saul in II Sam. 1:21) as well as of consecrated persons, such as anointed priests (e.g., Lev. 4:3) and kings (e.g., Saul, in I Sam. 10:1; David, in I Sam. 16:13 and II Sam. 5:3; and Solomon, in I Kings 1:39). The latter are also called the Lord's anointed (e.g. II Sam. 1:14; Lam. 4:20), the title expressing the charismatic character and divine sanction of their office as well as the unique inviolability of their status (e.g., I Sam. 26:8–11 and II Sam. 1:14). In usage during and after the Babylonian Exile (6th century BC) the term "anointed" could denote anyone with a special mission from God: prophets (cf. Isa. 61:1), the patriarchs (Abraham, Isaac, and Jacob), and even Gentile kings (e.g., the 6th-century-BC founder of the Persian Empire, Cyrus II the Great, in Isa. 45:1). The Old Testament never speaks of an eschatological messiah—one inaugurating the last times—and even the "messianic" passages containing prophecies of a future golden age under an ideal king never use this term. Nevertheless, many modern scholars hold that Israelite messianism grew out of beliefs connected with kingship. Comparisons with the forms of divine or sacral kingship current among Near Eastern peoples (Egypt in particular) suggests that in Israel, too, kingship had a definitely sacral character. Though not in any sense divine, the anointed king of Israel would be called the "son of God," and messianic hopes and functions would be ascribed to him. Many prophecies and psalms (e.g., Ps. 2) have been interpreted in this sense, and this alleged kingship ideology has been connected with the messianic doctrines of early Christianity. When the vicissitudes of actual reality and the careers of particular historic kings proved more and more disappointing, the messianic kingship ideology was projected onto the future. With the declining national fortunes of Israel, whose political kingdoms were conquered or even abolished by the great empires (Assyria, Babylonia, etc.), the notion developed of the eschatological messiah-king.

After the Babylonian Exile, and under the influence of apocalyptic literature—a type of literature that flourished from c. 2nd century BC–c. 2nd century AD and was concerned with the dramatic intervention of God into history in behalf of the elect—the prophetic vision of a future restoration and of the universal establishment of God's Kingdom became firmly associated with the ingathering of Israel under a scion of David's (king of United Israel, beginning his reign c. 1000 BC) house, one who would be the Lord's anointed. Hence the Hebrew word *mashiah* (*messias* in Greek, and *messiah* in English) came to mean the anointed one *par excellence*; i.e., the ultimate redeemer and expected king of the Davidic line who would deliver Israel from foreign bondage and restore the glories of its golden age.

*In Hellenistic Judaism.* In the period of Seleucid (Syrian Greek dynasty ruling Palestine c. 200–165 BC) and later Roman and Byzantine (63 BC–AD 638) rule and oppression, the expectation of a personal messiah acquired increasing prominence and became the centre of a number of other eschatological concepts held by different groups in different combinations and with varying emphases. The Qumrān sect, a Jewish monastic group known in modern times for its preservation of the Dead Sea Scrolls, held a doctrine—found also in later Jewish sects—of a messianic pair: a priestly messiah of the House of Aaron (the brother of Moses) and a royal messiah of the House of David. This messianic detail, incidentally, shows that these "anointed ones" were not thought of as saviours—as in later Christian thought—but rather as ideal lead-

ers presiding over an ideal, divinely-willed, and "messianic" socioreligious order. The "son of David" messianism, with its political implications, was overshadowed by apocalyptic notions of a more mystical and mythological character. Thus it was believed that a heavenly being called the "son of man" (the term is derived from Daniel 7:13) would descend to save his people (e.g., as in the apocryphal books of Enoch). The messianic ferment of the period, attested by contemporary Jewish-Hellenistic literature, is also vividly reflected in the New Testament.

The destruction of the Temple at Jerusalem by the Romans (AD 70), exile, persecution, and suffering only intensified Jewish messianism, which continued to develop theoretically in theological and semimythological speculations and to express itself practically in messianic movements. In popular apocalyptic literature another messianic figure gained some prominence: the warrior-messiah of the House of Joseph (or Ephraim) who would precede the triumphant messiah of the House of David—but would himself fall in the battle against Gog and Magog, two legendary powers under Satan and opposed to the people of God (Ezek. 38:2; Rev. 20:8). The notion seems to have developed toward the end of the 2nd century, after the failure of the last revolt against the Romans (AD 132–135), led by Bar Kokhba, who was hailed as the messiah, but it is connected with a more basic notion of apocalyptic messianism; that is, the belief that the messianic advent is preceded by suffering and catastrophe. In some versions of apocalyptic messianism, the notion of a messianic age merges with that of an end of days and last judgment: the "new heaven and new earth" are ushered in amid destruction and catastrophe.

*In medieval and modern Judaism.* Messianic faith tended to develop into mass enthusiasm, frequently fed by calculations based on the Book of Daniel and other biblical passages. Almost every generation had its messianic precursors and pretenders; e.g., Abū 'Isā al-Isfahānī and his disciple Yudghan in 8th-century and David Alroy in 12th-century Persia; the propagandists of the messianic agitation in the Jewries of western Europe in the 11th and 12th centuries; and—perhaps the most notorious of all—the 17th-century pseudomessiah Shabbetai Tzevi (Sabbatai Zevi) of Smyrna. Belief in, and fervent expectation of, the messiah became firmly established tenets of Judaism and are included among the great Jewish medieval philosopher Maimonides' Thirteen Articles of Faith. There was much variety in the elaboration of the doctrine—from the early apocalyptic visionaries and later Kabbalistic (Jewish esoteric) mystics at one end of the scale to the rationalist theologians on the other. The latter (including Maimonides) emphasized the unmiraculous nature of the messianic age.

Modernist movements in Judaism tended to maintain the traditional faith in an ultimately redeemed world and a messianic future for mankind, without insisting on a personal messiah figure. Judaism undoubtedly owes its survival, to a considerable extent, to its steadfast faith in the messianic promise and future. Jewish messianism, in spite of its spiritual and mystical connotations, never relinquished its basically this-worldly orientation and its understanding of the messianic order in historical, social, and political terms. Hence, many writers consider the participation of Jews in so many secular reform, liberation, and revolutionary movements (both political and social) as a secularized version of traditional Jewish messianism. Similarly, the ideology of Zionism, as a movement for Jewish national emancipation and liberation, is not devoid of messianic features.

**Christianity.** *Messianism and messianic movements in the New Testament period.* The preaching and ministry of Jesus of Nazareth and the activities of his followers in the 1st century AD can be properly understood only in the context of contemporaneous Jewish messianic and eschatological beliefs. Though the precise nature of Jesus' beliefs about himself and about the nature of the "messianic" task that he attributed to himself are still a matter of scholarly controversy, there is little doubt that already at an early date his followers saw in him the promised "anointed one" (Greek *christos*, whence the English

Christ) of the Lord, the son of David. This view is evident in the Gospel accounts that attempt to trace the ancestry of Jesus back to David, evidently for the purpose of legitimizing his messianic status. According to Luke 2:11 his messiahship was also proclaimed by angels at his birth. Jesus himself seems to have rejected the term—possibly because of its political implications—in favour of other eschatological titles (*e.g.*, the “Son of Man”), but the early community of his followers, believing, as they did, in his Resurrection after the crucifixion, evidently held this term to be expressive more than any other of the role and function that they attributed to their master and “Lord” (Greek *kyrios*). In due course the title (“Jesus, the Christ”) became synonymous with the proper name, and the word Christ was used by believers as the name of the risen Jesus (*cf.* Gal. 1:6; Heb. 9:11).

With the adoption of the Greek word “Christ” by the church of the Gentiles (non-Jewish believers), the nationalist and political implications of the term “messiah” vanished altogether in Christianity, and the “Son of David” and the “Son of Man” motifs, to which subsequently was added that of the “suffering Servant” (Isa. 52–53), could merge in a politically neutral and religiously original messianic conception. Subsequently, the doctrine of the messiahship of Jesus (*i.e.*, Christology) also had to take into account other features of evolving Christian dogma (the Messiah as the Son of God; the Trinity, of God the Father, Son, and Holy Spirit; the incarnation of the Word), and thus came to assert that Jesus as the Messiah, Saviour, and Redeemer was essentially divine. In due course the concept of salvation was radically spiritualized, and the Messiah, through his sacrificial death, was viewed as having delivered man from his bondage to sin and having restored him to communion with God. Meanwhile, Christians asserted that the present world order would provisionally continue until the Second Coming (the Parousia) of Christ in power and glory to judge the living and the dead.

The early Christians held this Second Coming to be imminent, but as time went on this particular expectation shifted to the eschatological horizon. Some early Christian circles also believed that, after his return, Christ would reign on earth for 1,000 years (*cf.* Rev. 20:1–5). This belief easily combined with that in a fifth kingdom (*cf.* Dan. 2:44)—*i.e.*, the Kingdom of Christ following the four empires (Assyrian, Persian, Greek, and Roman) of this world. (It was from this belief that the Fifth Monarchy Men, an extreme English Puritan sect of the middle of the 17th century, derived their name.) Emphasis on the expected Second Coming introduced an element of messianic unrest in addition to questioning the validity of the present order; it was soon repudiated by the church as “unspiritual,” since it envisaged a messianic kingdom upon earth—rather in the manner of the Jews—instead of a heavenly kingdom.

*In early Christianity.* Belief in the Second Coming of Christ and the establishment of his reign upon earth continued to exist as an undercurrent known as millenarianism or chiliasm (from Latin *millenarias* and Greek *chilioi*, “a thousand”), and occasionally came to the surface in sectarian, revolutionary, or heretical movements. The heretical element, though not inherent in millenarianism as such, resided in the tendency of radical religious or social criticism to use chiliast-messianic terminology when such criticism propagated the notion that the present rulers—and even the very forms—of church and state would be superseded by a perfect order.

It is necessary, therefore, to distinguish between early Christian and later, post-4th-century, messianism. Original Christianity was a messianic movement from its very beginning, and the millenarianism of the early Christians was an extension of their belief in the imminent Parousia, or Second Coming. Later medieval chiliasm by definition implied disappointment with what was supposed to be an already redeemed world, and the eager expectation of the passing away of the present order. The difference is due to an inner, theologico-religious development on the one hand, and an outer, politico-religious event on the other. The fact that the Second Coming had not taken place

caused the gradual liquidation of imminent messianism. The emphasis was placed on the Saviour who had come and redeemed the world from sin, rather than on his final Parousia. The granting of toleration to Christianity by the Roman emperor Constantine the Great (died 337), and its becoming subsequently the religion of the Roman Empire, heralded a development in which the church became an ally of the present order rather than the har-binger of its passing away.

*In medieval and modern Christianity.* The speculations of the 12th-century Italian theologian Joachim of Fiore, which envisaged the imminent supersession of the present age (the second age of the world, the dispensation of the Son, which had replaced the first age, of the Father) and church by the age of the Holy Spirit and by a “spiritual church,” exerted considerable influence on subsequent messianic movements. These increased in the 15th century and in the Reformation and post-Reformation periods. The extreme wing of the Bohemian Hussite movement, known as the Taborites, sought to establish the Kingdom of God by force of arms. The left-wing Protestant Anabaptists as well as the Bohemian and Moravian Brethren were millenarians. The great Peasants’ War in Germany (1524–25), in which the radical reformer Thomas Müntzer and the radical Zwickau prophets took a leading part, and the Anabaptist “Kingdom of God” in the German city of Munster (1534–35)—ruled over by the fanatical John of Leiden—are examples of millenarian-apocalyptic movements or of social movements with a messianic dimension.

In England, the Independents (those who separated themselves from the Church of England) thought of ushering in the Kingdom of God, and groups such as the Fifth Monarchy Men believed that revolution was necessary to prepare the way for the reign of Christ and his saints. The revolutionary Puritan leader Oliver Cromwell’s (1599–1658) sober common sense and his dissolution of the so-called Parliament of Saints prevented apocalyptic enthusiasm from dominating the Commonwealth. The millenarian element also was strong in 17th- and 18th-century German Pietism, and it played a major role in the doctrines of many sects that arose in the 19th century in the United States and Great Britain (*e.g.*, Irvingites, Mormons, Adventists, Jehovah’s Witnesses, Christadelphians, and others). Many of these sects, however, are more correctly described as entertaining messianic expectations than as actual messianic movements.

*Secular movements.* Western civilization, even in its modern secularized forms, is heir to a long tradition of Christian patterns of thought and sensibility. Thus, it is not surprising that many movements of social reform as well as ideologies regarding an ideal future should bear traces—conscious or unconscious—of Christian influence. Both the 18th- and 19th-century Enlightenment and the Romantic versions of the idea of the progress of humanity to an ideal state of peace and harmony betray their descent from messianic-millenarian beliefs. The 18th-century German philosopher Immanuel Kant, when speaking of the ideal state of eternal peace, describes this concept as a “philosophical chiliasm.” The indebtedness of presocialist, utopian thinkers—such as the French social reformer Henri de Saint-Simon, the English reformer Robert Owen, and the French reformer Charles Fourier—to Christian millenarianism was recognized by Karl Marx and Friedrich Engels, who, in their *Communist Manifesto* (1848), contemptuously referred to the utopias of these writers as “duodecimo editions of the New Jerusalem.” Some early socialist movements, including Christian socialism, exhibited messianic features. Marxist Communism, in spite of its explicit atheism and dogmatic materialism, has a markedly messianic structure and message. Some of the analogies with traditional Christian eschatology have been described, in a slightly ironical vein, by the English philosopher Bertrand Russell, who contends that Marx adapted the Jewish messianic pattern of history to socialism in the same way that the philosopher-theologian St. Augustine (AD 354–430) adapted it to Christianity. According to Russell, the materialistic dialectic that governs historical development

corresponds—in the Marxist scheme—to the biblical God, the proletariat to the elect, the Communist Party to the church, the revolution to the Second Coming, and the Communist commonwealth to the millennium.

Whether or not Socialism and Communism, as well as certain national liberation movements, are described as secularized messianism, pseudomessianism, “substitute” messianism, and the like, is partly a matter of semantics, partly an attempt to use evaluative instead of descriptive language. The differences between secular ideologies and traditional messianic expectations are obvious. The similarities are founded on actual historic contacts and derivation (as in the history of reform and revolutionary movements in the West as well as of liberation movements in countries colonized by the West), and also on the fact that they are variations of the same social dynamics and of a basic myth, expressing in powerful imagery certain elemental human experiences and aspirations.

#### MESSIANIC MOVEMENTS IN OTHER RELIGIONS

**Primitive religions.** Messianic movements have occurred in many primitive societies all over the world. Most of the movements studied and described in scholarly literature arose in societies that had been exposed to contact with the white, or Western, man. This presence frequently had traumatizing and disintegrating effects on many levels of primitive society (economic, cultural, religious), creating new tensions, pressures, deprivations, and frustrations. The factors contributing to this situation were not only the political and economic aspects of Western colonization but also the disintegration of traditional cultural values and religious symbols by the Christian missionaries who formed, as it were, part of the colonial “establishment.” Hence, many primitive messianic movements—even when antiwhite and anticolonialist—exhibit markedly Christian features both in the details of their symbolism as well as in their overall messianic ideology. Some messianic movements (e.g., that of Simon Kimbangu in the former Belgian Congo from 1921, or that of Isaiah Shembe from 1911, among the South African Bantu, as also several movements in Brazil), in fact, appeared outwardly as Christian revivalist sects with an eschatological character. The movement of Simon Kimbangu has been admitted to the World Council of Churches as a member.

A variety of names has been applied to these movements that emphasize various messianic characteristics. “Nativistic” movements expect salvation from a revival of native values and customs and a rejection of everything alien; e.g., many of the North American Indian movements from the 17th century on, including the Pueblo Indian Revolt led by Popé in 1680; the anonymous Delaware prophet (1762) and Pontiac; the religious revival and politico-military revolt led by Tenskwatawa and Tecumseh in 1807; the Ghost Dance outbreaks of 1870 and subsequent years among Southwestern and Plains Indians. The many messianic movements in Melanesia focussing on the arrival—in ships or airplanes—of “cargo” (i.e., the coveted wealth and riches that symbolize power, well-being, and salvation) are generally referred to as cargo cults. Some anthropologists speak of “revitalization movements,” whereas others emphasize the connection between acculturation and primitive messianic movements. Since it is not acculturation as such that produces messianism but the crises and dislocations caused by certain forms of culture contact, many scholars now prefer the more neutral and objective term “crisis cults.” Since many movements are started or propagated by the activity and preaching of prophet-like leaders, they are also spoken of as “prophetic movements.”

There is a tendency among modern anthropologists to consider primitive messianisms as forms of protonationalism in non-European and premodern societies. Though Christian influence and Christian symbols often play a major role in the crystallization of messianic ideologies, they are by no means their only source. The ideological starting point of a messianic movement can be supplied by native traditions and mythologies, by Christian ideas, or by motives that are born under the pressure or circum-

stance. (For a fuller discussion of these various movements, see TRIBAL RELIGIOUS MOVEMENTS, NEW.)

**Islām and Zoroastrianism.** Islām is not a messianic religion and has no room for a saviour-messiah. Nevertheless, there gradually developed—and probably under Christian influence—the notion of an eschatological restorer of the faith, identified as a descendant of the Prophet or as the returning ‘Isā (i.e., Jesus). He is usually referred to as the *mahdī*; i.e., the “[divinely] guided one.” In Sunnī (traditional) Islām the whole subject is one of folklore rather than of dogmatic theology, though all orthodox Muslims believe in the coming of a final restorer of the faith. In times of crisis and of political or religious ferment, mahdistic expectations have increased and have given rise to many self-styled *mahdīs*, the best known of all being Muḥammad Aḥmad, the Mahdī of Sudan, who raised a revolt against the Egyptian administration in 1881 and after several spectacular victories established the mahdist state that existed until defeated by the English military leader Kitchener at Omdurman (Sudan) in 1898. In the Islāmīc Shī‘ah sect (which holds a belief in the transference of spiritual leadership through the family of ‘Ali, Muḥammad’s cousin and son-in-law), the doctrine of the *mahdī* is an essential part of the creed. Among the Twelvers, the main Shī‘ah group, the expected *mahdī* is believed to be the hidden 12th *imām*, or religious leader, who will reappear from his place of occultation. The notion of a *mahdī* also played a role in the foundation of new religions or Shī‘ah sects—e.g., the belief of the Druzes that the Egyptian caliph of the Fātimid dynasty al-Ḥākim (reigned 996–1021), who is thought to be the last prophet and divine incarnation, would return at the end of days (1,000 years after his appearance at the end of the 9th century AD) to establish his rule over the world. Other Islāmīc-based messianic figures include the founder of the Indian Ahmadiya sect, Mirza Ghulam Ahmad, who in the late 19th century declared himself to be the Christ and the Mahdī; and the founder of the religion that subsequently became known as Bahā’ism, the Iranian Mirzā ‘Alī Moḥammad of Shīrāz, who proclaimed himself in 1844 to be the Bāb (“gate”) on the 1,000th anniversary of the disappearance of the 12th *imām*.

Zoroastrianism is a religion with a thoroughly eschatological orientation: for it world history is a battlefield on which the forces of light and good fight the powers of darkness and evil. Though the notion of a personal saviour figure is not essential to the Zoroastrian system, it did nevertheless arise. The Iranian prophet Zoroaster’s ministry (6th century BC) is said to have opened the last of the history of the world’s four periods of 3,000 years each. He is followed, at intervals of 1,000 years, by three “saviours,” considered to be posthumous sons of Zoroaster. The last of these, the *soshyans* (or *saoshyant*), will appear at the end of days, and God will entrust to him the task of the final rehabilitation of the world and the resurrection of the dead.

**Religions of the East.** Hinduism and Buddhism, unlike Zoroastrianism, lack historical and eschatological orientation. Certain “messianic” elements, however, are recognizable. The Hindu belief in a progressive deterioration of the world cycles and in the saving manifestations of the divine at the critical moments is a case in point. Yet it would be a misrepresentation of the facts to describe the expected return of the god Viṣṇu (Vishnu) at the end of the present cycle in his tenth *avatāra* (“incarnation”), Kalkin, as a messianic hope. In Mahāyāna (the Greater Vehicle) Buddhism the figure of the *bodhisattva* (future Buddha) Maitreya has a certain messianic quality: Maitreya will ultimately descend from his present abode in one of the heavens and bring the faithful to paradise. Some scholars believe that Zoroastrian eschatology may have influenced Buddhist Maitreya beliefs. A great many insurrections and peasant revolts in China had religious-sectarian and eschatological overtones. In the best known of these politico-religious movements, the Taiping (Great Peace) Rebellion of 1851–64, which was led by Hung Hsiu-ch’üan, Christian influence and messianic elements are obvious.

The role of the *mahdī*

movements

## TYPES AND FUNCTIONS OF MESSIANISM

The preceding survey of messianic beliefs and movements indicates that they are not amenable to hard-and-fast classifications. Nevertheless, it should be possible to point out several major features and types. There is a distinction—as noted before—between eschatological beliefs and doctrines, and messianic movements. The latter need not arise even where the former exists of old.

The  
messianic  
ideal as  
restorative

*Restorative and future oriented.* The messianic ideal, on the one hand, may be the return to an original state of bliss that has been forfeited for one reason or another and the restoration to a pristine perfection (the Paradise Lost-Paradise Regained theme). Connected with this notion is the idea of the messiah as a *returning* saviour: the Second Coming of Christ; the reappearing *imām*; the awakening and return of the sleeping monarch or hidden emperor of many legends (*e.g.*, King Arthur or Frederick Barbarossa in medieval Europe and King David in some Jewish legends); the returning culture hero or the returning ancestor spirits, as in the North American Ghost Dance movements. On the other hand, there is the idea of the messianic future as a radically new state of being, the like of which has never been before. This viewpoint is that of the utopian-revolutionary form of messianism (“a new heaven and a new earth”), and it tends to be present, at least to some extent, even in essentially restorative ideologies and movements. The expectation of a radically new state of being often expresses itself in antitraditional and antinomian (against divine or moral law) behaviour: the destruction of traditional symbols or cult objects and the transgression of traditional laws and taboos signify that the old things have passed away and that a new era of freedom has dawned. Thus, in Christianity the old (Mosaic) Law, according to St. Paul, is fulfilled in Christ; in Judaism the 17th-century messiah Shabbetai Tzevi solemnly broke the prohibitions of the Judaic law in his mystical rituals; in many Melanesian cargo cults there was destruction of cult objects; and the North American Ojibwa threw away their sacred medicine bundles on the shores of Lake Superior. Conversely, many movements are extremely conservative and hold the messianic advent to be conditional on strict traditional observance, ascetic rigour, and penitential discipline: they are hypernomian (excessively legalistic) rather than antinomian. There is, very often, a conflict between conservative and revolutionary tendencies in many messianic movements.

*Eschatological and reformative.* The role and function of the messianic leader depends on a variety of socio-cultural and individual factors. Many messianic movements have no messiahs at all, only prophets and precursors who announce the impending salvation and give instructions how to prepare for it. These prophets may be of the eschatological type, predicting a cosmic catastrophe and subsequent mighty deeds of salvation, or they may be of the moral and reforming type, exhorting their followers to qualify for salvation by adhering to strict codes of belief and behaviour. The 16th-century radical reformers Thomas Müntzer and the Zwickau prophets considered themselves prophets and apostles only; the leader of the Münster prophets, John of Leiden, however, considered himself a messianic king; the English Quaker James Nayler entered Bristol in 1656 to the shouts of “Hosannah to the Son of David” from a crowd of enthusiastic followers. Similarly, leaders of many primitive messianic cults have claimed to be divine.

Millenarian  
approaches

Not all millenarian sects are founded by prophetic, visionary, inspired, or illuminate enthusiasts. Some groups are extremely “rationalist” in their approach; their messianic expectations are based not on mystical experiences but on their interpretation of Holy Scripture. Many adventist and millenarian sects (*e.g.*, the Christadelphians, Jehovah’s Witnesses) are of this kind. A very literalist and “rational” exegesis (interpretation) of prophecies (*e.g.*, the statements in the books of Daniel and Revelation) provides the leader of such groups and sects with the date and details of the expected messianic advent. The understanding of prophecy in the literalistic sense also implies that the course of history is strictly predeter-

mined and that the messianic hour is fixed and can therefore be computed.

*Active and passive messianisms.* Closely related to the above distinction is that between active and passive messianism. Passive messianism holds the end to be preordained. The believers do not make the revolution but prepare for its advent. On the active end of the scale are the aggressive and militant movements that believe themselves called to be instrumental in ushering in the new order. In many cases the activity is not of the military-revolutionary but rather of the ritual-magical type. The believers engage in cultic or other preparatory (*e.g.*, penitential) activities in order to hasten the advent or to prove that they are worthy of it—*e.g.*, the Jewish movement that centred on Shabbetai Tzevi, the North American Ghost Dance, and the Melanesian cargo cults. Some millenarian groups are very outspoken in their rejection of the present order and refuse to cooperate with it, but they desist from active steps to establish the Kingdom, as the latter will be established by God himself in his own time.

*Immediate and distant messianisms.* Messianic movements imply the imminent occurrence of some decisive event. They have therefore been called short-range messianisms. Long-range messianism, on the other hand, is a matter of beliefs and doctrines rather than of ferment and agitation; the expected advent is a dim and often colourless dogma on a far-away horizon rather than the life-giving power of a dynamic movement. Short-range messianisms may turn into long-range beliefs as a result of initial failure and disappointment. When the expected event has failed to materialize at the appointed time or the messianic promises have not been fulfilled, then the messianic date may be postponed or the present time declared to be an interim period pending the final consummation.

*Other messianic types.* Messianisms can also be distinguished according to the contents of their expectations. Mention has already been made of the distinction between restorative and innovative messianisms, as well as of the dialectical relationship between catastrophic and messianic redemption. In Jewish eschatology, for example, the advent of the messiah is preceded by a period of terrible suffering and tribulation, the so-called “birth pangs of the messianic age”; and in Christian eschatology the final consummation of history is preceded by the rule of the Antichrist. Messianism may be particular or universal, or exhibit different combinations of these two characteristics. Most messianisms tend to be particularistic and exclusive, at least in the sense of distinguishing between the elect who accept the messianic message or who otherwise qualify, and who hence will be saved, and the others who do not, and who will be lost. The community of the saved may be identical with a particular and ascriptively defined group (people, race) or part thereof, or with an electively defined part of mankind.

Exclusive  
and  
inclusive  
messianisms

Messianism also can broaden its scope beyond a particular group and even mankind so as to embrace the whole cosmos. The messianic era is then described as one of cosmic rejuvenation and perfection. Very often this element is so strong that the new reality can no longer be described in ordinary language and in categories taken from historical experience. The new reality is of a mythological and symbolic order, and its inauguration presupposes the passing away or even cataclysmic annihilation of the old order. The transition from historical to mythological symbolism can be made in many different ways, and messianic movements exhibit great variety in the forms of interrelationship between history and myth. Particular historical and geographical symbols can become “mythologized” and universalized (*e.g.*, the “New Jerusalem” or the heavenly Jerusalem in Christian symbolism) and, conversely, universal symbols—such as those exhibited in Christianity—can be reinterpreted in a particularistic fashion (*e.g.*, “Jesus” or “Christ” in some African movements and sects).

Related to, though not identical with, the myth-history differentiation (see above *Relationship of messianism to concepts of time*) is that between politico-social and spiritual messianism. Predominantly historical messianisms

tend to focus on social and political hopes; these, in their turn, may become partly or wholly spiritualized. The issue played a prominent role in medieval Christian-Jewish polemics. Christian authors accused the Jews of a gross, carnal, and materialistic understanding of the messianic prophecies. The Jews considered the accusation as a compliment, believing that whatever the spiritual, cosmic, or inner aspects of salvation, it had to be vindicated primarily on the concrete historical level of national, social, and political realities. Where spiritual deliverance becomes altogether detached from social and political utopianism, it is doubtful whether the term messianism can still be legitimately applied, as the phenomena concerned belong to a different type of doctrine of salvation.

**Interpretation.** Although messianic movements are, almost by definition, as it were, doomed to failure, not all of them dissolve completely. Reinterpretation or spiritualization of the original message often enables a movement to survive apparent failure. The study of messianic movements, therefore, has to pay attention not only to the causal character of their origins and the dynamics of their development but also to their capacity for transformation and survival. From a sociological point of view it has been argued that messianic movements, even where they appear to have failed, have had an integrative function in situations of social stress and cultural change. Thus, many primitive messianisms have been interpreted as connecting links between prepolitical and political activity; *i.e.*, from premodern religious revolt to modern revolutionary movement. Whether messianic movements play an integrative or, to the contrary, an impairing or nonadaptive role in society depends on a variety of factors as well as on a variety of criteria of interpretation, and not necessarily on the nature of the messianic message as such. The fact that messianic doctrines and beliefs exist, that messianic movements arise, and that the messianic hope is projected on individual messiah figures, seems to testify to some basic human predispositions, among which are orientation to the time process, capacity to negate the present but not to be crushed by this negation, ability to "hope" (*i.e.*, to envisage a future that is congruous with the ideals and values that the human mind can project), and the faculty of projecting these orientations, hopes, and values in mythical symbols.

## Metabolism

Metabolism is a term that embraces all of the chemical changes that occur in the cells of living organisms, enabling them to grow, to maintain their identity, and to reproduce. Each chemical change is catalyzed by a specific protein called an enzyme. Cellular metabolism is a highly integrated, purposeful activity for which, even in a single cell, many hundreds of enzymes are needed; me-

tabolism effects the exchange of matter and energy between the cell and its environment. Metabolism is so finely controlled that there is neither extensive overutilization nor underutilization of food materials nor overproduction nor underproduction of energy derived from them. This article concentrates on the nature of the cellular processes involved in metabolism and the manner in which they are regulated.

The first section of the article, *A summary of metabolism*, presents an overview of the entire subject. Its purpose is to provide the reader with a brief discussion of the salient features of metabolism. The succeeding sections of the article deal in detail with the individual metabolic pathways, reactions, and regulatory mechanisms involved in metabolism. The physical and chemical properties of the components of living things dealt with in this article are found in various other articles: CARBOHYDRATE; LIPID; NUCLEIC ACID; VITAMIN; NUCLEOTIDES; and PROTEIN. For details of enzymatic action, see ENZYME.

This article is divided into the following major sections:

- I. A summary of metabolism
  - Biological energy exchanges
  - Integration of catabolism and anabolism
  - The study of metabolic pathways
- II. The fragmentation of complex molecules
  - The catabolism of glucose
  - The catabolism of sugars other than glucose
  - The catabolism of lipids (fats)
  - The catabolism of proteins
- III. The combustion of food materials
  - The oxidation of molecular fragments
  - Biological energy transduction
- IV. The biosynthesis of cell components
  - The nature of biosynthesis
  - The supply of biosynthetic precursors
  - The synthesis of building blocks
  - The synthesis of macromolecules
- V. Regulation of metabolism
  - Fine control
  - Coarse control

### I. A summary of metabolism

All living organisms ultimately derive their energy from sunlight; however, only green plants and photosynthetic micro-organisms can directly utilize light energy to synthesize cellular components from simple sources such as carbon dioxide (CO<sub>2</sub>), water (H<sub>2</sub>O), and ammonia (NH<sub>3</sub>). Most other organisms must use the products of photosynthesis as food, either directly (by consuming plant material) or indirectly (by consuming organisms that have consumed plant material). The chemical reactions undergone by the components of the food—mostly proteins, carbohydrates, and lipids (fats)—serve two main purposes: they provide, from complex starting materials, the simpler fragments from which cell constituents are synthesized; and they yield the energy needed for such chemical syntheses and for the many other energy-requiring life processes. An understanding of metabolism thus requires knowledge not only of the manner in which the fragmentation of food materials yields energy and of the manner in which that energy is conserved for the performance of useful work but also of the manner in which these events are integrated.

#### BIOLOGICAL ENERGY EXCHANGES

The energy changes associated with physico-chemical processes are the province of a subdiscipline of physics termed thermodynamics. The first two laws of thermodynamics state, in essence, that energy can neither be created nor destroyed and that the effect of physical and chemical changes is to increase the disorder, or randomness (*i.e.*, entropy), of the universe. Although it might be supposed that biological processes—through which organisms grow in a highly ordered and complex manner, maintain order and complexity throughout their life, and pass on the instructions for order to succeeding generations—are in contravention of these laws, this is not so. Living organisms neither consume nor create energy: they can only transform it from one form to another. From the environment they absorb energy in a form useful to them; to the environment they return an equiva-

Free energy and heat

lent amount of energy in a biologically less useful form. The useful energy, or free energy, may be defined as energy capable of doing work under isothermal conditions (conditions in which no temperature differential exists); free energy is associated with any chemical change. Energy less useful than free energy is returned to the environment, usually as heat. Heat cannot perform work in biological systems because all parts of cells have essentially the same temperature and pressure.

**The carrier of chemical energy.** Although energy can be made available to cells in a variety of forms, it is usable by them largely in only one form. The situation is analogous to lighting an electric lamp: the energy for illumination may be derived from the burning of coal, from the disintegration of radioactive nuclei, or from the kinetic energy of a waterfall, but the lamp cannot be lighted unless the various forms of energy—heat, nuclear, or kinetic—are transformed into an electric current, the only form of energy usable by the lamp. Similarly, although photosynthetic organisms harness the radiant energy of sunlight directly, by converting it to chemical energy in the pigment chlorophyll, and non-photosynthetic organisms tap the chemical energy stored in the food materials synthesized through photosynthesis, both types of organism use one specific chemical compound for energy exchange: adenosine triphosphate (ATP; Figure 1). Adenosine triphosphate functions as the major carrier of chemical energy in all forms of living matter. As it transfers its energy to other molecules, ATP loses its terminal phosphate group as inorganic phosphate ( $P_i$ ), or two of its phosphate groups as inorganic pyrophosphate ( $PP_i$ ), becoming adenosine diphosphate (ADP) or adenosine monophosphate (AMP), respectively. These

products can, directly or indirectly, be reconverted to ATP by regaining phosphate groups in reactions coupled to the utilization of either light energy (in photosynthetic cells) or chemical energy (in nonphotosynthetic organisms).

Metabolism may thus be viewed as a network of cellular processes in which reactions called catabolic reactions—the occurrence of which is accompanied by a decrease in free energy—are coupled to the synthesis of ATP from ADP and inorganic phosphate, whereas energy-requiring reactions, called anabolic reactions, are coupled to the energy-yielding reactions by which ATP is split to ADP and inorganic phosphate or to AMP and pyrophosphate (see below, *Biological energy transduction*, for a discussion of the mechanisms by which ATP is synthesized from ADP and inorganic phosphate).

**Catabolism. Formation of small molecules.** The release of chemical energy from food materials essentially occurs in three phases. In the first phase (phase I), the large molecules that make up the bulk of food materials are broken down into small constituent units: proteins are converted to the 20 or so different amino acids of which they are composed; carbohydrates (polysaccharides such as starch in plants and glycogen in animals) are degraded to sugars such as glucose; and fats (lipids) are broken down into fatty acids and glycerol. The amounts of energy liberated in phase I are relatively small: only about 0.6 percent of the free, or useful, energy of proteins and carbohydrates, and about 0.1 percent of that of fats, is released during this phase. Because this energy is liberated largely as heat, it cannot be utilized by the cell. The purpose of the reactions of phase I, which, in animals, occur mainly in the intestinal tract and in tissues in which reserve materials are prepared, or mobilized, for energy production, is to prepare the foodstuffs for the energy-releasing processes.

**Incomplete oxidation.** In the second phase of the release of energy from food (phase II), the small molecules produced in the first phase—sugars, glycerol, a number of fatty acids, and about 20 varieties of amino acids—are incompletely oxidized (in this sense, oxidation means the removal of electrons or hydrogen atoms), the end product being (apart from carbon dioxide and water) one of only three possible substances: the two-carbon compound acetate, in the form of a compound called acetyl coenzyme A (Figure 1); the four-carbon compound oxaloacetate; and the five-carbon compound  $\alpha$ -oxoglutarate. The first, acetate in the form of acetyl coenzyme A, constitutes by far the most common product—it is the product of two-thirds of the carbon incorporated into carbohydrates and glycerol; all of the carbon in most fatty acids; and approximately half of the carbon in amino acids. The end product of several amino acids is  $\alpha$ -oxoglutarate; that of a few others is oxaloacetate, which is formed either directly or indirectly (from fumarate). These processes, represented diagrammatically in Figure 2, show what happens in the bacterium *Escherichia coli*, but remarkably similar processes occur in animals, plants, fungi, and other organisms capable of oxidizing their food materials wholly to carbon dioxide and water.

**Complete oxidation.** Total oxidation of the relatively few products of phase II occurs in a cyclic sequence of chemical reactions known as the tricarboxylic acid (TCA) cycle, or the Krebs cycle, after its discoverer, Sir Hans Krebs; it represents phase III of energy release from foods. Each turn of this cycle (see below *The tricarboxylic acid [TCA] cycle*) is initiated by the formation of citrate, with six carbon atoms, from oxaloacetate (with four carbons) and acetyl coenzyme A; subsequent reactions result in the reformation of oxaloacetate and the formation of two molecules of carbon dioxide. The carbon atoms that go into the formation of carbon dioxide are no longer available to the cell. The concomitant stepwise oxidations—in which hydrogen atoms or electrons are removed from intermediate compounds formed during the cycle and, via a system of carriers, are transferred ultimately to oxygen to form water—are quantitatively the most important means of generating ATP from ADP and inorganic phosphate. These events are known as

The three possible end products of incomplete oxidation

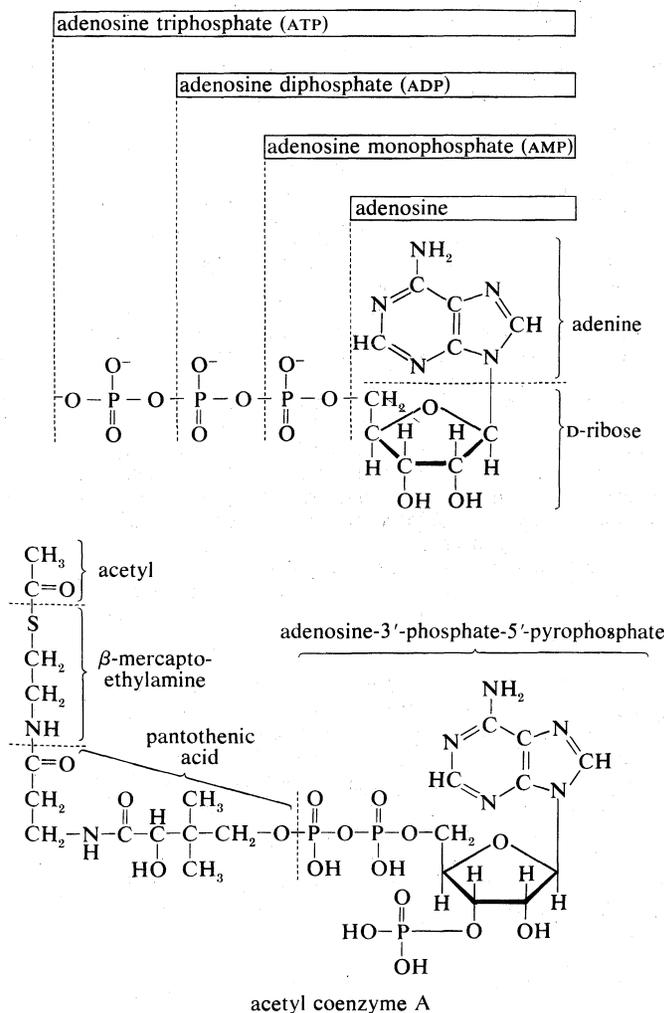

Figure 1: *Biological energy carriers.* (Top) ATP, ADP, and AMP. (Bottom) Acetyl coenzyme A (acetyl CoA).

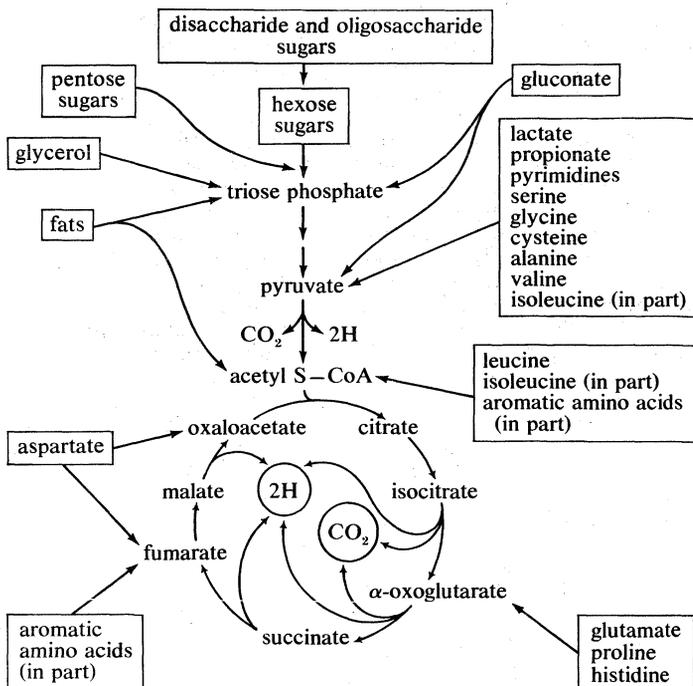

Figure 2: Pathways for the catabolism of nutrients by *Escherichia coli*.

terminal respiration and oxidative phosphorylation (for details of this process, see below *Biological energy transduction*).

Some micro-organisms, incapable of completely converting their carbon compounds to carbon dioxide, release energy by fermentation reactions, in which the intermediate compounds of catabolic routes either directly or indirectly accept or donate hydrogen atoms. Such secondary changes in intermediate compounds result in considerably less energy being made available to the cell than occurs with the pathways that are linked to oxidative phosphorylation; however, fermentation reactions yield a large variety of commercially important products. Thus, for example, if the oxidation (removal of electrons or hydrogen atoms) of some catabolic intermediate is coupled to the reduction of a substance called pyruvate or of acetaldehyde derived from pyruvate, the products formed are lactic acid and ethyl alcohol, respectively.

**Anabolism.** Catabolic pathways effect the transformation of food materials into the interconvertible intermediates of the pathways shown in Figure 2. Anabolic pathways, on the other hand, are sequences of enzyme-catalyzed reactions in which the component building blocks of large molecules, or macromolecules (*e.g.*, proteins, carbohydrates, and fats), are constructed from the same intermediates. Thus, catabolic routes have clearly defined beginnings but no unambiguously identifiable end products; anabolic routes, on the other hand, lead to clearly distinguishable end products from diffuse beginnings. The two types of pathway are linked through reactions of phosphate transfer, involving ADP, AMP, and ATP as described above, and also through electron transfers, which enable reducing equivalents (*i.e.*, hydrogen atoms or electrons), which have been released during catabolic reactions, to be utilized for biosynthesis. But, although catabolic and anabolic pathways are closely linked, and although the overall effect of one type of route is obviously the opposite of the other, they have few steps in common. The anabolic pathway for the synthesis of a particular molecule generally starts from intermediate compounds quite different from those produced as a result of catabolism of that molecule; for example, micro-organisms catabolize aromatic (*i.e.*, containing a ring, or cyclic, structure) amino acids to acetyl coenzyme A and an intermediate compound of the TCA cycle. The biosynthesis of these amino acids, however, starts with a compound derived from pyruvate and an

intermediate compound of pentose (a general name for sugars with five carbon atoms) metabolism. Similarly, histidine is synthesized from a pentose sugar but is catabolized to  $\alpha$ -oxoglutarate.

Even in cases in which a product of catabolism is used in an anabolic pathway, differences emerge; thus, fatty acids, which are catabolized to acetyl coenzyme A, are synthesized not from acetyl coenzyme A directly but from a derivative of it, malonyl coenzyme A (see below *The biosynthesis of cell components: Lipid components*). Furthermore, even enzymes that catalyze apparently identical steps in catabolic and anabolic routes may exhibit different properties. In general, therefore, the way down (catabolism) is different from the way up (anabolism). These differences are important because they allow for the regulation of catabolic and anabolic processes in the cell.

In eucaryotic cells (*i.e.*, those with a well-defined nucleus, characteristic of organisms higher than bacteria) the enzymes of catabolic and anabolic pathways are often located in different cellular compartments. This also contributes to the manner of their cellular control; for example, the formation of acetyl coenzyme A from fatty acids, referred to above, occurs in animal cells in small sausage-shaped components, or organelles, called mitochondria, which also contain the enzymes for terminal respiration and for oxidative phosphorylation. The biosynthesis of fatty acids from acetyl coenzyme A, on the other hand, occurs in the cytoplasm.

#### INTEGRATION OF CATABOLISM AND ANABOLISM

**Fine control.** Possibly the most important means for controlling the flux of metabolites through catabolic and anabolic pathways, and for integrating the numerous different pathways in the cell, is through the regulation of either the activity or the synthesis of key (pacemaker) enzymes. It was recognized in the 1950s, largely from work with micro-organisms, that pacemaker enzymes can interact with small molecules at more than one site on the surface of the enzyme molecule. The reaction between an enzyme and its substrate—defined as the compound with which the enzyme acts to form a product—occurs at a specific site on the enzyme known as the catalytic, or active, site; the proper fit between the substrate and the active site is an essential prerequisite for the occurrence of a reaction catalyzed by an enzyme (see ENZYME). Interactions at other, so-called regulatory sites on the enzyme, however, do not result in a chemical reaction, but cause changes in the shape of the protein; the changes profoundly affect the catalytic properties of the enzyme, either inhibiting or stimulating the rate of the reaction. Modulation of the activity of pacemaker enzymes may be effected by metabolites of the pathway in which the enzyme acts or those of another pathway; the process may be described as a fine control of metabolism. Very small changes in the chemical environment thus produce important and immediate effects on the rates at which individual metabolic processes occur.

Most catabolic pathways are regulated by the relative proportions of ATP, ADP, and AMP in the cell. It is reasonable to suppose that a pathway that serves to make ATP available for energy-requiring reactions would be less active if sufficient ATP were already present, than if ADP or AMP were to accumulate. The relative amounts of the adenine nucleotides (*i.e.*, ATP, ADP, and AMP) thus modulate the overall rate of catabolic pathways. They do so by reacting with specific regulatory sites on pacemaker enzymes necessary for the catabolic pathways and non-participants in the anabolic routes that effect the opposite reactions. Similarly, it is reasonable to suppose that many anabolic processes, which require energy, are inhibited by ADP or AMP; the presence of these nucleotides may be regarded therefore as cellular distress signals indicating a lack of energy.

Since one way in which anabolic pathways differ from catabolic routes is that the former result in identifiable end products, it is not unexpected that the pacemaker enzymes of many anabolic pathways—particularly those effecting the biosynthesis of amino acids and nucleotides

The differences between catabolic and anabolic pathways

—are modulated by the end products of these pathways or, in cases in which branching of pathways occurs, by end products of each branch. Such pacemaker enzymes usually act at the first step unique to a particular anabolic route. If branching occurs, the first step of each branch is controlled. By this so-called negative feedback system, the cellular concentrations of products determine the rates of their formation, thus ensuring that the cell synthesizes only as much of the products as it needs.

**Coarse control.** A second and less immediately responsive, or “coarse,” control is exerted over the synthesis of pacemaker enzymes. The rate of protein synthesis reflects the activity of appropriate genes, which contain the information that directs all cellular processes. Coarse control is therefore exerted on genetic material rather than on enzymes. Preferential synthesis of a pacemaker enzyme is particularly required to accommodate a cell to major changes in its chemical milieu. Such changes occur in multicellular organisms only to a minor extent, so that this type of control mechanism is less important in animals than in micro-organisms (see HOMEOSTASIS). In the latter, however, it may determine the ease with which a cell previously growing in one nutrient medium can grow after transfer to another. In cases in which several types of organism compete in the same medium for available carbon sources, the operation of coarse controls may well be decisive in ensuring survival.

Alterations in the differential rates of synthesis of pacemaker enzymes in micro-organisms responding to changes in the composition of their growth medium also manifest the properties of negative feedback systems. Depending on the nature of the metabolic pathway of which a pacemaker enzyme is a constituent, the manner in which the alterations are elicited may be distinguished. Thus, an increase in the rates at which enzymes of catabolic routes are synthesized results from the addition of inducers—usually compounds that exhibit some structural similarity to the substrates on which the enzymes act. A classic example of an inducible enzyme of this type is  $\beta$ -galactosidase. *Escherichia coli* growing in nutrient medium of a certain composition do not utilize the milk sugar, lactose (glucose-4- $\beta$ -D-galactoside); however, if the bacteria are placed in a growth medium containing lactose as the sole source for carbon, they synthesize  $\beta$ -galactosidase in very large amounts. The reaction catalyzed by the enzyme is the hydrolysis (*i.e.*, breakdown involving water) of lactose to its two constituent sugars, glucose and galactose; the preferential synthesis of the enzyme thus allows the bacteria to utilize lactose for growth. Another characteristic of the process of enzyme induction is that it continues only as long as the inducer (in this case, lactose) is present; if cells synthesizing  $\beta$ -galactosidase are transferred to a medium containing no lactose, synthesis of  $\beta$ -galactosidase ceases, and the amount of the enzyme in the cells is diluted as they divide, until the original low level of the enzyme is re-established.

In contrast, the differential rates of synthesis of pacemaker enzymes of anabolic routes are usually not increased by the presence of inducers. Instead, the absence of small molecules, which act to repress enzyme synthesis, accelerates enzyme formation. Similar to the fine control processes described above is the regulation by coarse control of many pacemaker enzymes of amino acid biosynthesis. Like the end product inhibitors, the repressors in these cases also appear to be the amino acid end products themselves.

It is useful to regard the acceleration of the enzyme-forming machinery as the consequence, metaphorically, of either placing a foot on the accelerator or removing it from the brake. Analysis of the mechanisms by which gene activity is controlled suggest, however, that the distinction between inducible and repressible enzymes may be more apparent than real (see below *Regulation of metabolism*).

#### THE STUDY OF METABOLIC PATHWAYS

There are two main reasons for studying a metabolic pathway: (1) to describe, in quantitative terms, the

chemical changes catalyzed by the component enzymes of the route; and (2) to describe the various biological controls that govern the rate at which the pathway functions.

Studies with whole organisms or organs can provide information that one substance is converted to another and that this process is localized in a certain tissue; for example, experiments can show that urea, the chief nitrogen-containing end product of protein metabolism in mammals, is formed exclusively in the liver. They cannot reveal, however, the details of the enzymatic steps involved. Clues to the identity of the products involved, and to the possible chemical changes effected by component enzymes, can be provided in any of four ways involving studies with either whole organisms or tissues.

First, under stress or the imbalances associated with diseases, certain metabolites (*i.e.*, products of metabolism) may accumulate to a much greater extent than normal. Thus, during the stress of violent exercise, lactic acid appears in the blood, while glycogen, the form in which carbohydrate is stored in muscle, disappears. Such observations do not, however, prove that lactic acid is a normal intermediate of glycogen catabolism; rather, they show only that compounds capable of yielding lactic acid are likely to be normal intermediates. Indeed, in the example, lactic acid is formed in response to abnormal circumstances, and is not directly formed in the pathways of carbohydrate catabolism. On the other hand, the abnormal accumulation of pyruvic acid in the blood of vitamin B<sub>1</sub>-deficient pigeons was a valuable clue to the role of this vitamin in the oxidation of pyruvate.

Second, the administration of metabolic poisons may lead to the accumulation of specific metabolites. If fluoroacetic acid or fluorocitric acid is ingested by animals, for example, citric acid accumulates in the liver. This correctly suggests that fluorocitric acid administered as such, or formed from fluoroacetic acid via the tricarboxylic acid (TCA) cycle, inhibits an enzyme of citrate oxidation.

Third, the fate of any nutrient—indeed, often the fate of a particular chemical group or atom in a nutrient—can be followed with relative ease by administering the nutrient labelled with an isotope. Isotopes are forms of an element that are chemically indistinguishable from each other but differ in physical properties.

The use of a non-radioactive isotope of nitrogen in the 1930s first revealed the dynamic state of body constituents. It had previously been believed that the proteins of tissues are stable once formed, disappearing only with the death of the cell. By feeding amino acids labelled with isotopic nitrogen to rats, it was discovered that the isotope was incorporated into many of the amino acids found in proteins of the liver and the gut, even though the total protein content of these tissues did not change. This suggested that the proteins of these tissues exist in a dynamic steady state, in which relatively high rates of synthesis are counterbalanced by equal rates of degradation. Thus, although the average liver cell has a life-span of several months, half of its proteins are synthesized and degraded every five to six days. On the other hand, the proteins of the muscle or the brain, tissues that (unlike the gut or liver) need not adjust to changes in the chemical composition of their milieu, do not turn over as rapidly. The high rates of turnover observed in liver and gut tissues indicate that the coarse controls, exerted through the onset and cessation of synthesis of pacemaker enzymes, do occur in animal cells.

Finally, genetically altered organisms (mutants) fail to synthesize certain enzymes in an active form. Such defects, if not lethal, result in the accumulation and excretion of the substrate of the defective enzyme; in normal animals, the substrate would not accumulate, because it would be acted upon by the enzyme. The significance of this observation was first realized in the early 20th century when the phrase “inborn errors of metabolism” was used to describe hereditary conditions in which a variety of amino acids and other metabolites are excreted in the urine (see METABOLISM, DISEASES OF). In micro-organisms, in which it is relatively easy to cause genetic muta-

Identifica-  
tion of metab-  
olites

Inducers  
in  
microbial  
systems

tions and to select specific mutants, this technique has been very useful. In addition to their utility in the unravelling of metabolic pathways, the use of mutants in the early 1940s led to the postulation of the one gene-one enzyme hypothesis by the Nobel Prize winners G.W. Beadle and E.L. Tatum; their discoveries opened the field of biochemical genetics and first revealed the nature of the fine controls of metabolism.

Because detailed information about the mechanisms of component enzymatic steps in any metabolic pathway cannot be obtained from studies with whole organisms or tissues, various techniques have been developed for studying these processes—*e.g.*, sliced tissues, and homogenates and cell-free extracts, which are produced by physical disruption of the cells and the removal of cell walls and other debris. The sliced-tissue technique was successfully used by the Nobel Prize winner Sir Hans Krebs in his pioneer studies in the early 1930s on the mechanism of urea formation in the liver. Measurements were made of the stimulating effects of small quantities of amino acids on both the rate of oxygen uptake and the amount of oxygen taken up; the amino acids were added to liver slices bathed in a nutrient medium. Such measurements revealed the cyclic nature of the process; specific amino acids acted as catalysts, stimulating respiration to an extent greater than expected from the quantities added. This was because the added material had been re-formed in the course of the cycle (see below *The catabolism of proteins: Disposal of nitrogen*).

The use of homogenates

Homogenates of tissue are useful in studying metabolic processes because permeability barriers that may prevent ready access of external materials to cell components are destroyed. The tissue is usually minced, blended, or otherwise disrupted in a medium that is suitably buffered to maintain the normal acid-base balance of the tissue, and contains the ions required for many life processes, chiefly sodium, potassium, and magnesium. The tissue is either used directly—as was done by Krebs in elucidating, in 1937, the TCA cycle from studies of the respiration of minced pigeon breast muscle—or fractionated (*i.e.*, broken down) further. If the latter procedure is followed, homogenization is often carried out in a medium containing a high concentration of the sugar sucrose, which provides a milieu favourable for maintaining the integrity of cellular components. The components are recovered by careful spinning in a centrifuge, at a series of increasing speeds. It is thus possible to obtain fractions containing predominantly one type of organelle: nuclei (and some unbroken cells); mitochondria, lysosomes, and microbodies; microsomes (*i.e.*, ribosomes and endoplasmic reticulum fragments); and—after prolonged centrifugation at forces in excess of 100,000 times gravity—a clear liquid that represents the soluble fraction of the cytoplasm. The fractions thus obtained can be further purified and tested for their capacity to carry out a given metabolic step or steps. This procedure was used to show that isolated mitochondria catalyze the oxidation reactions of the TCA cycle and that these organelles also contain the enzymes of fatty acid oxidation. Similarly, isolated ribosomes are used to study the pathway and mechanism of protein synthesis.

The final procedure in the elucidation of a reaction in a metabolic pathway usually involves isolation of the appropriate enzyme. The reaction catalyzed by that enzyme and the factors that control the rate of catalysis are then measured.

It should be emphasized that biochemists realize that studies on isolated and highly purified systems, such as those briefly described above, can do no more than approximate biological reality. The identification of the fine and coarse controls of a metabolic pathway, and (when appropriate) other influences on that pathway, must ultimately involve the study of the pathway in the whole cell or organism. Although some techniques have proved adequate for relating findings in the test tube to the situation in living organisms, study of the more complex metabolic processes, such as those involved in differentiation and development, may require the elaboration of new experimental approaches.

## II. The fragmentation of complex molecules

Food materials must undergo oxidation in order to yield biologically useful energy. Oxidation does not necessarily involve oxygen, although it must involve the transfer of electrons from a donor molecule to a suitable acceptor molecule; the donor is thus oxidized and the recipient reduced. Many micro-organisms either must live in the absence of oxygen (*i.e.*, are obligate anaerobes) or can live in its presence or its absence (*i.e.*, are facultative anaerobes).

If no oxygen is available, the catabolism of food materials is effected via fermentations, in which the final acceptor of the electrons removed from the nutrient is some organic molecule, usually generated during the fermentation process. There is no net oxidation of the food molecule in this type of catabolism; that is, the overall oxidation state of the fermentation products is the same as that of the starting material.

Organisms that can use oxygen as a final electron acceptor also use many of the steps in the fermentation pathways of food catabolism to fragment molecules; the fragments, instead of serving as electron acceptors, are fed into the TCA cycle, the pathway of terminal respiration.

In this cycle all of the hydrogen atoms (H) or electrons ( $e^-$ ) are removed from the fragment and are channelled through a series of electron carriers, ultimately to react with oxygen (O; see below *Energy conservation*). All carbon atoms are eliminated as carbon dioxide ( $\text{CO}_2$ ) in this process. The sequence of reactions involved in the catabolism of food materials may thus be conveniently considered in terms of an initial fragmentation (fermentation), followed by a combustion (respiration) process.

### THE CATABOLISM OF GLUCOSE

**Glycolysis.** *The transformation of glucose.* Quantitatively, the most important source of energy for cellular processes is the six-carbon sugar, glucose ( $\text{C}_6\text{H}_{12}\text{O}_6$ ). The structure of glucose is shown in Figure 3, in which the carbon atoms are numbered consecutively. (See CARBOHYDRATE for a discussion of the chemical nature of glucose and other carbohydrates.) Glucose is made available to animals through the hydrolysis of polysaccharides, such as glycogen and starch, the process being catalyzed by digestive enzymes. In animals, the sugar thus set free passes from the gut into the bloodstream and from there into the cells of the liver and other tissues. In micro-organisms, of course, no such specialized tissues are involved.

The fermentative phase of glucose catabolism (glycolysis) involves several enzymes; the action of each is summarized below. In living cells, many of the compounds that take part in metabolism exist as negatively charged moieties, or anions, and are named as such in most of this article; *e.g.*, pyruvate, oxaloacetate.

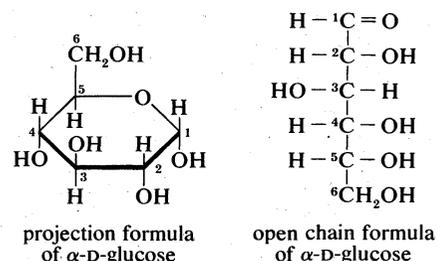

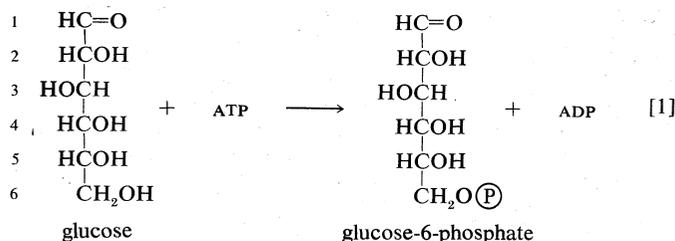

Figure 3: The structure of  $\alpha$ -D-glucose.

In order to obtain a net yield of ATP from the catabolism of glucose, it is first necessary to invest ATP. During step [1] the alcohol group ( $\text{CH}_2\text{OH}$  at position 6 of the glucose molecule) readily reacts with the terminal phosphate group of ATP, forming glucose-6-phosphate and ADP. For convenience, the phosphoryl group ( $\text{PO}_3^{2-}$ ) is represented by  $\text{P}$ . Because the decrease in free energy is so large during this reaction, it is virtually irreversible under physiological conditions.

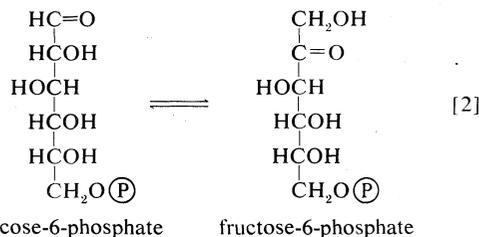

The formation of glucose-6-phosphate

In animals, this phosphorylation of glucose, which yields glucose-6-phosphate, is catalyzed by two different enzymes. In most cells, a hexokinase with a high affinity for glucose—*i.e.*, only small amounts of glucose are necessary for enzymatic activity—effects the reaction. In addition, the liver contains a glucokinase, which requires a much greater concentration of glucose before it reacts. Glucokinase functions only in emergencies, when the concentration of glucose in the blood rises to abnormally high levels.

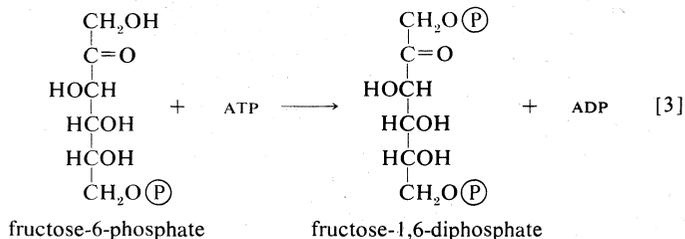

Certain facultative anaerobic bacteria also contain hexokinases but apparently do not use them to phosphorylate glucose. In such cells, external glucose can be utilized only if it is first phosphorylated to glucose-6-phosphate via a system linked to the cell membrane that involves a compound called phosphoenolpyruvate (formed in step [9] of glycolysis), which serves as an obligatory donor of the phosphate group; *i.e.*, ATP cannot serve as the phosphate donor in the reaction.

The reaction in which glucose-6-phosphate is changed to fructose-6-phosphate is catalyzed by phosphoglucose isomerase [2]. In the reaction, a secondary alcohol group

( $-\text{CHOH}$ ) at the second carbon atom is oxidized to a keto-group (*i.e.*,  $-\text{C}=\text{O}$ ), and the aldehyde group ( $-\text{CHO}$ ) at the first carbon atom is reduced to a primary alcohol group ( $-\text{CH}_2\text{OH}$ ). Reaction [2] is readily reversible, as is indicated by the double arrows.

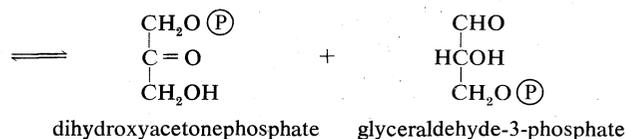

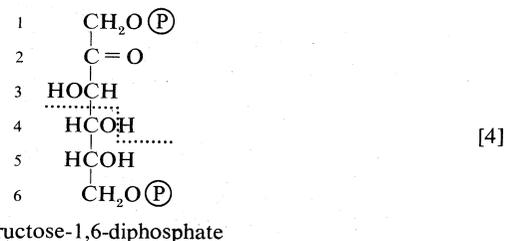

The formation of the alcohol group at the first carbon atom permits the repetition of the reaction effected in step [1]; that is, a second molecule of ATP is invested. The product is fructose-1,6-diphosphate [3]. Again, as in

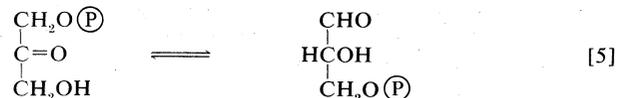

the hexokinase reaction, the decrease in free energy of the reaction, which is catalyzed by phosphofructokinase, is sufficiently large to make this reaction virtually irreversible under physiological conditions; ADP is also a product.

The first three steps of glycolysis have thus transformed an asymmetrical sugar molecule, glucose, into a symmetrical form, fructose-1,6-diphosphate, containing a phosphoryl group at each end; the molecule next is split into two smaller fragments that are interconvertible. This elegant simplification is achieved via steps [4] and [5], which are described in the next section.

**The aldolase reaction.** In [4], the enzyme catalyzes the breaking apart of the six-carbon sugar fructose-1,6-diphosphate into two three-carbon fragments. The

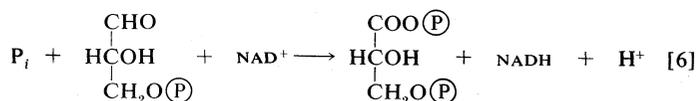

molecule is split between carbons 3 and 4. Reversal of this cleavage—*i.e.*, the formation of a six-carbon compound from two three-carbon compounds—is possible. Because the reverse reaction is an aldol condensation—*i.e.*, an aldehyde (glyceraldehyde-3-phosphate) combines with an alcohol (dihydroxyacetonephosphate)—the enzyme is commonly called aldolase. The two three-carbon fragments produced in step [4], dihydroxyacetonephosphate and glyceraldehyde-3-phosphate, are also called triose phosphates. They are readily converted to each other by a process [5] analogous to that in step [2].

The enzyme that catalyzes the interconversion [5] is triose phosphate isomerase, a different enzyme than that catalyzing step [2].

**The formation of ATP.** The second stage of glucose catabolism comprises reactions [6] through [10], in which a net gain of ATP is achieved through the oxidation of one of the triose phosphate compounds formed in step [5]. One molecule of glucose forms two molecules of the triose phosphate; both three-carbon fragments follow the same pathway, and steps [6] through [10] must occur to complete the glucose breakdown.

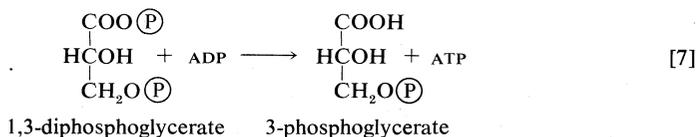

Step [6], in which glyceraldehyde-3-phosphate is oxidized, is one of the most important reactions in gly-

glyceraldehyde-3-phosphate 1,3-diphosphoglycerate

colysis; it is during this step that the energy liberated during oxidation of the aldehyde group ( $-\text{CHO}$ ) is conserved in the form of a high-energy phosphate compound; namely, as an anhydride of a carboxylic acid and phosphoric acid, 1,3-diphosphoglycerate. The hydrogen atoms or electrons removed from the aldehyde group during its oxidation are accepted by a coenzyme (so called because it functions in conjunction with an enzyme) involved in hydrogen or electron transfer; the coenzyme, nicotinamide adenine dinucleotide ( $\text{NAD}^+$ ), is reduced to form  $\text{NADH} + \text{H}^+$  in the process. The  $\text{NAD}^+$  thus reduced is bound to the enzyme glyceraldehyde-3-phosphate dehydrogenase, catalyzing the overall reaction, step [6].

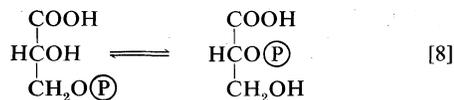

The 1,3-diphosphoglycerate produced in step [6] reacts with ADP in a reaction catalyzed by phosphoglycerate kinase, with the result that one of the two phosphoryl groups is transferred to ADP to form ATP and 3-phosphoglycerate. This reaction [7] is highly exergonic (*i.e.*, it

Conversion of energy of oxidation into ATP

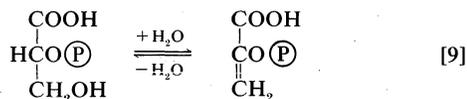

proceeds with a loss of free energy); as a result, the oxidation of glyceraldehyde-3-phosphate, step [6], is irreversible. In summary, the energy liberated during oxidation of an aldehyde group ( $-\text{CHO}$  in glyceraldehyde-3-phosphate) to a carboxylic acid group ( $-\text{COOH}$  in 3-phosphoglycerate) is conserved as the phosphate bond energy in ATP during steps [6] and [7]. This step occurs twice for each molecule of glucose; thus the initial investment of ATP in steps [1] and [3] is recovered.

The 3-phosphoglycerate in step [7] now forms 2-phosphoglycerate, in a reaction catalyzed by phospho-

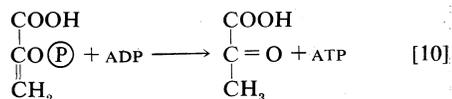

3-phosphoglycerate 2-phosphoglycerate

glyceromutase [8]. During step [9] the enzyme enolase reacts with 2-phosphoglycerate to form phosphoenolpyruvate (PEP), water being lost from 2-phosphoglycerate in the process. Phosphoenolpyruvate acts as the second

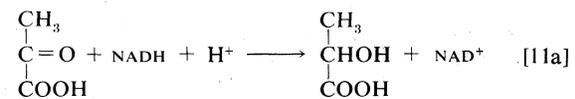

2-phosphoglycerate phosphoenolpyruvate

source of ATP in glycolysis. The transfer of the phosphate group from PEP to ADP, catalyzed by pyruvate kinase [10], is also highly exergonic and is thus virtually irreversible under physiological conditions.

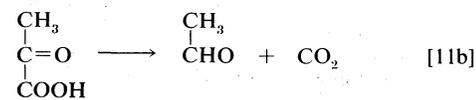

phosphoenolpyruvate pyruvate

Reaction [10] occurs twice for each molecule of glucose entering the glycolytic sequence; thus the net yield is two molecules of ATP for each six-carbon sugar. No further molecules of glucose can enter the glycolytic pathway, however, until the  $\text{NADH} + \text{H}^+$  produced in step [6] is reoxidized to  $\text{NAD}^+$ . In anaerobic systems, this means that electrons must be transferred from ( $\text{NADH} + \text{H}^+$ ) to some organic acceptor molecule, which thus is reduced in the process. Such an acceptor molecule could be the pyruvate formed in reaction [10]. In certain bacteria (e.g., so-called lactic acid bacteria) or in muscle cells functioning vigorously in the absence of adequate supplies of oxygen, pyruvate is reduced to lactate via a reaction catalyzed by lactate dehydrogenase (reaction [11a]); i.e., reduced  $\text{NAD}^+$  gives up its hydrogen

pyruvate lactate

atoms or electrons to pyruvate, and lactate and  $\text{NAD}^+$  are formed. Alternatively, in organisms such as brewers' yeast, pyruvate is first decarboxylated to form acetaldehyde and carbon dioxide in a reaction catalyzed by pyruvate decarboxylase [11b]; acetaldehyde then is reduced

pyruvate acetaldehyde

by ( $\text{NADH} + \text{H}^+$ ) in a reaction catalyzed by alcohol dehydrogenase [11c], yielding ethanol and oxidized coenzyme ( $\text{NAD}^+$ ).

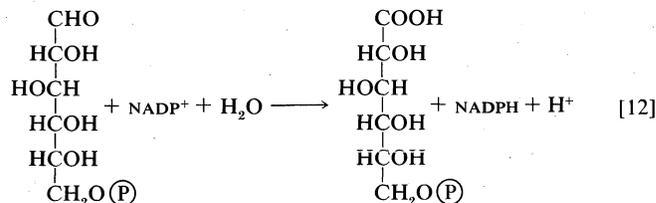

acetaldehyde ethanol

Many variations of reaction [11] occur in nature. In the heterolactic (mixed lactic acid) fermentations carried out by some micro-organisms, a mixture of reactions [11 a, b, and c] regenerates  $\text{NAD}^+$  and results in the production, for each molecule of glucose fermented, of a molecule each of lactate, ethanol, and carbon dioxide. In other types of fermentation, the end products may be derivatives of acids such as propionic, butyric, acetic, and succinic; decarboxylated materials derived from them (e.g., acetone); or compounds such as glycerol.

**The phosphogluconate pathway.** Many cells possess, in addition to all or part of the glycolytic pathway that comprises reactions [1] through [11], other pathways of glucose catabolism that involve, as the first unique step, the oxidation of fructose-6-phosphate [12] instead of the formation of fructose-6-phosphate [2]. This is the phosphogluconate pathway, or pentose-phosphate cycle. During reaction [12], hydrogen atoms or electrons are re-

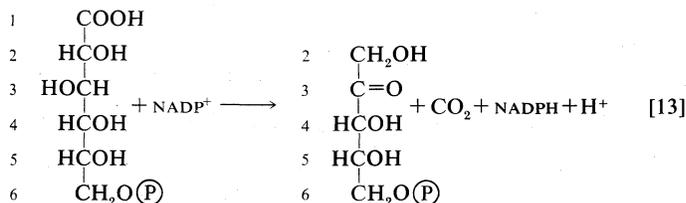

The oxidation of glucose-6-phosphate

glucose-6-phosphate

6-phosphogluconate

moved from the carbon atom at position 1 of glucose-6-phosphate in a reaction catalyzed by glucose-6-phosphate dehydrogenase. The product of the reaction is 6-phosphogluconate. The reducing equivalents (hydrogen atoms or electrons) are accepted by nicotine adenine dinucleotide phosphate ( $\text{NADP}^+$ ), a coenzyme similar to but not identical with  $\text{NAD}^+$ . A second molecule of  $\text{NADP}^+$  is reduced as 6-phosphogluconate is further oxidized; the reaction is catalyzed by 6-phosphogluconate dehydrogenase [13]. The products of the reaction also include ribu-

6-phosphogluconate

ribulose-5-phosphate

lose-5-phosphate and carbon dioxide. (The numbers at the carbon atoms in step [13] indicate that carbon 1 of 6-phosphogluconate forms carbon dioxide.)

Ribulose-5-phosphate can undergo a series of reactions in which two-carbon and three-carbon fragments are interchanged between a number of sugar phosphates; this sequence of events can lead to the formation of two molecules of fructose-6-phosphate and one of glyceraldehyde-3-phosphate from three molecules of ribulose-5-phosphate (i.e., the conversion of three molecules with five carbons to two with six and one with three). Although the cycle, which is outlined in Figure 4, is the main pathway in micro-organisms for fragmentation of pentose sugars, it is not of major importance as a route for the oxidation of glucose. Its primary purpose in most cells is to generate reducing power in the cytoplasm, in the form of reduced  $\text{NADP}^+$ . This function is especially prominent in tissues—such as the liver, mammary gland, fat tissue, and the cortex (outer region) of the adrenal gland—that actively carry out the biosynthesis of fatty acids and other fatty substances (e.g., steroids). A second function of reactions [12] and [13] is to generate from glucose-6-phosphate the pentoses that are used in the synthesis of nucleic acids (see below *The biosynthesis of cell components*).

In photosynthetic organisms, some of the reactions of the phosphogluconate pathway are part of the major route for the formation of sugars from carbon dioxide; in this case, the reactions occur in a direction opposite

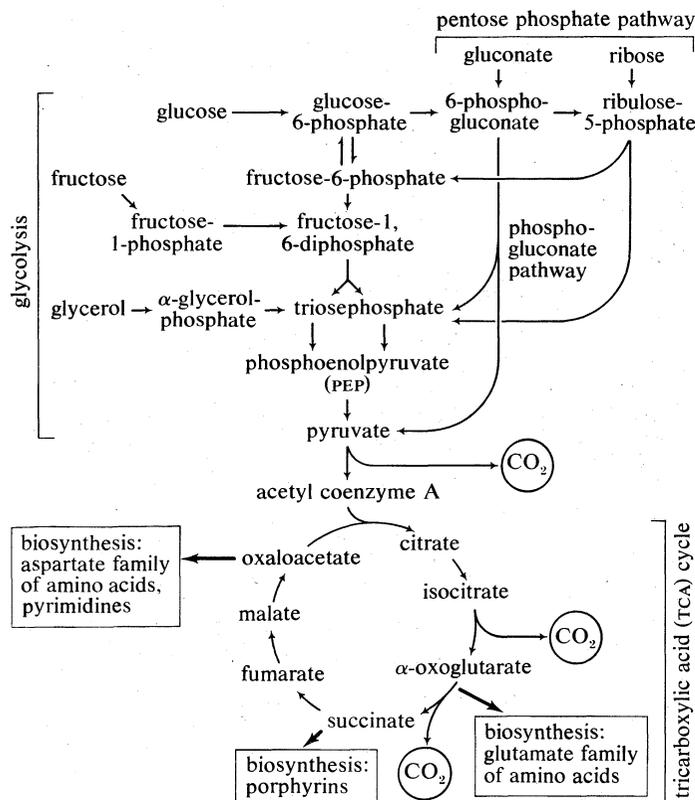

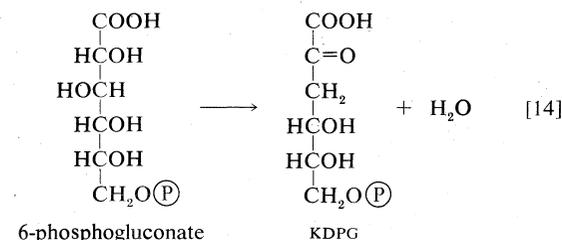

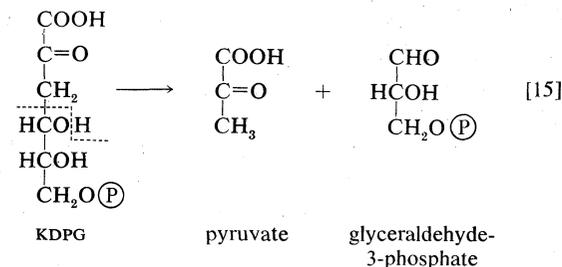

Figure 4: Pathways for the utilization of carbohydrates.

to that in which they occur in non-photosynthetic tissues (see PHOTOSYNTHESIS).

A different route for the catabolism of glucose also involves 6-phosphogluconate; it is of considerable importance in micro-organisms lacking some of the enzymes necessary for glycolysis. In this route, 6-phosphogluconate (derived from glucose via steps [1] and [12]) is not oxidized to ribulose-5-phosphate via reaction [13] but, in an enzyme-catalyzed reaction [14], loses water, forming the compound 2-keto-3-deoxy-6-phosphogluconate (KDPG).

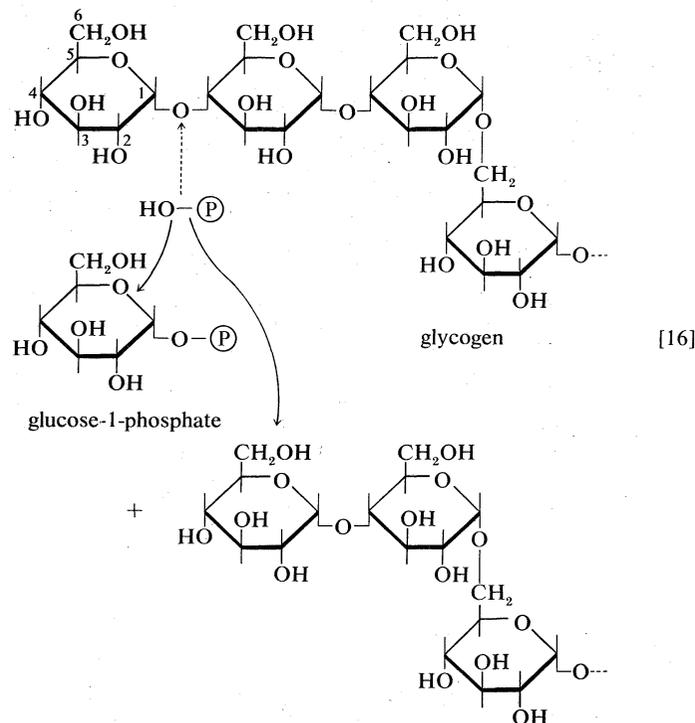

This is then split into pyruvate and glyceraldehyde-3-phosphate [15] both of which are intermediates of the glycolytic pathway.

#### THE CATABOLISM OF SUGARS OTHER THAN GLUCOSE

The main storage carbohydrate of animal cells is glycogen, in which chains of glucose molecules—linked end to end, the C1 position of one glucose being linked to the C4 position of the adjacent one—are joined to each other by occasional linkages between a carbon at posi-

tion 1 on one glucose and a carbon at position 6 on another. Two enzymes cooperate in releasing glucose molecules from glycogen. Glycogen phosphorylase catalyzes the splitting of the 1,4-bonds by adding the elements of phosphoric acid at the point shown by the broken arrow in [16], rather than water, as in the digestive hydrolysis of polysaccharides such as glycogen and starch. The products of [16] are glucose-1-phosphate and chains of sugar molecules shortened by one unit; the chains are degraded further by repetition of step [16]. When a bridge linking two chains, at C1 and C6 carbon atoms of adjacent glucose units, is reached, it is hydro-

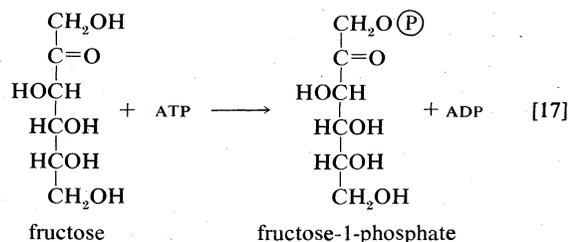

lyzed in a reaction involving the enzyme  $\alpha$  (1  $\rightarrow$  6) glucosidase. After the two chains are separated, reaction [16] can occur again. The glucose-1-phosphate thus formed from glycogen or, in plants, from starch, is converted to glucose-6-phosphate by phosphoglucomutase [78], which catalyzes a reaction very similar to that effected in step [8] of glycolysis; glucose-6-phosphate can then undergo further catabolism via glycolysis [2–10] or via either of the routes involving formation of 6-phosphogluconate [12].

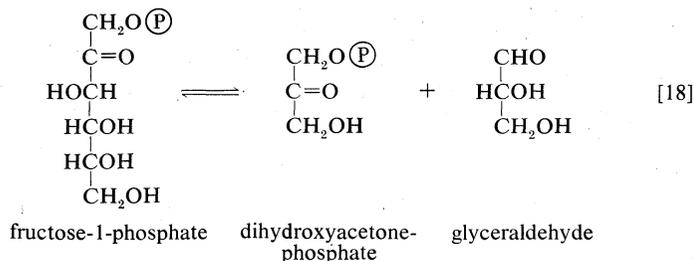

Other sugars encountered in the diet are likewise transformed to products that are intermediates of central metabolic pathways. Lactose, or milk sugar, is composed of one molecule of galactose linked to one molecule of glucose. Sucrose, the common sugar of cane or beet, is made up of glucose linked to fructose. Both sucrose and lactose are hydrolyzed to glucose and fructose or galactose, respectively. Glucose is utilized as already described, but special reactions must occur before the other sugars can enter the catabolic routes. Galactose, for example, is phosphorylated in a manner analogous to step [1] of glycolysis. The reaction, catalyzed by a galactokinase, results in the formation of galactose-1-phosphate; this product is transformed to glucose-1-phosphate by a sequence of reactions requiring as a coenzyme uridine-triphosphate (UTP). Fructose may also be phosphorylated in animal cells either via hexokinase [1], in which case fructose-6-phosphate is the product, or in liver tissue via a fructokinase that gives rise to fructose-1-phosphate [17]. Adenosine triphosphate supplies the phosphate group for the phosphorylation of fructose in both cases.

Fructose-1-phosphate is also formed when facultative anaerobic micro-organisms use fructose as a carbon source for growth; in this case, however, the source of the phosphate is phosphoenolpyruvate rather than ATP. Fruc-

Fragmentation of lactose and sucrose

fructose-1-phosphate can be catabolized by one of two routes. In the liver, it is split by an aldolase enzyme [18] abundantly in that tissue (but lacking in muscle); the products are dihydroxyacetonephosphate and glyceraldehyde. It will be recalled that dihydroxyacetonephosphate is an intermediate compound of glycolysis. Although glyceraldehyde is not an intermediate of glycolysis, it can be converted to one in a reaction involving the conversion of ATP to ADP; the product, glyceraldehyde-3-phosphate, is an intermediate of glycolysis.

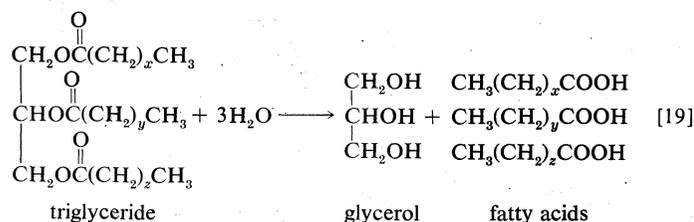

In many organisms other than mammals, fructose-1-phosphate does not have to undergo reaction [18] in order to enter central metabolic routes. Instead, a fructose-1-phosphate kinase, distinct from the phosphofructokinase that catalyzes step [3] of glycolysis, effects the direct conversion of fructose-1-phosphate and ATP to fructose-1,6-diphosphate and ADP.

#### THE CATABOLISM OF LIPIDS (FATS)

Although carbohydrates are the major fuel for most organisms, fatty acids are also a very important energy source. In vertebrates, at least half of the oxidative energy used by the liver, kidneys, heart muscle, and resting skeletal muscle is derived from the oxidation of fatty acids; in fasting or hibernating animals or in migrating birds, fat is virtually the sole source of energy.

Neutral fats or triglycerides, the major components of storage fats in plant and animal cells, consist of the alcohol glycerol linked to three molecules of fatty acids (see LIPID). Before a molecule of neutral fat can be metabolized, it must be hydrolyzed to its component parts. Hydrolysis [19] is effected by intracellular enzymes

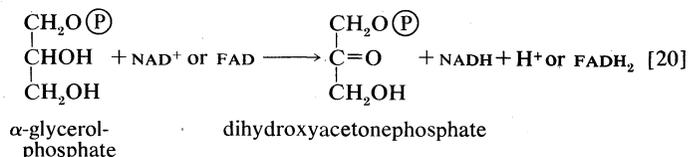

or gut enzymes, and forms phase I of fat catabolism. Letters  $x$ ,  $y$ , and  $z$  represent the number of  $-\text{CH}_2-$  groups in the fatty acid molecules.

As is apparent from [19], the three molecules of fatty acid released from the triglyceride need not be identical; a fatty acid usually contains 16 or 18 carbon atoms but may also be unsaturated; that is, containing one or more double bonds ( $-\text{CH}=\text{CH}-$ ). Only the fate of saturated fatty acids, of the type  $\text{CH}_3(\text{CH}_2)_n\text{COOH}$  ( $n$  can be an even or an odd number), is dealt with here.

**Fate of glycerol.** It requires but two reactions to channel glycerol into a catabolic pathway (see Figure 2). In a reaction catalyzed by glycerolkinase, ATP is utilized to phosphorylate glycerol; the products are  $\alpha$ -glycerolphosphate and ADP. Alpha-glycerolphosphate then is oxidized

to dihydroxyacetonephosphate [20], an intermediate of glycolysis. The reaction is catalyzed by either a soluble (cytoplasmic) enzyme, glycerolphosphate dehydroge-

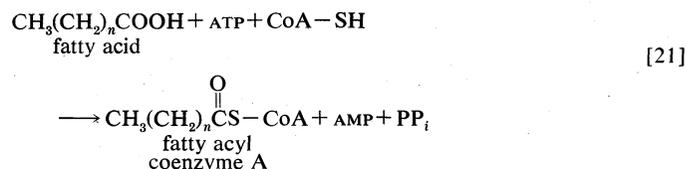

nase, or a similar enzyme present in the mitochondria. In addition to their different locations, the two dehydrogenase enzymes differ in that a different coenzyme accepts the electrons removed from  $\alpha$ -glycerolphosphate. In the case of the cytoplasmic enzyme,  $\text{NAD}^+$  accepts the electrons (and is reduced to  $\text{NADH} + \text{H}^+$ ); in the case of the mitochondrial enzyme, flavin adenine dinucleotide (FAD) accepts the electrons (and is reduced to  $\text{FADH}_2$ ).

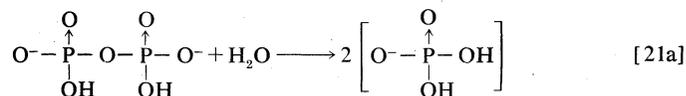

**Fate of fatty acids.** As with sugars, the release of energy from fatty acids necessitates an initial investment of ATP. A problem unique to fats is a consequence of the relative insolubility in water of most fatty acids. Their catabolism thus requires mechanisms that fragment them in a controlled and stepwise manner. The mechanism

involves a coenzyme for acyl group (e.g.,  $\text{CH}_3\text{C}=\text{O}$ ) transfer, namely, coenzyme A. The functional portion of this complex molecule is the sulfhydryl ( $-\text{SH}$ ) group at one end. The coenzyme is often identified as  $\text{CoA-SH}$  (see step [21]). The organized and stepwise degradation of fatty acids linked to coenzyme A is ensured because the necessary enzymes are sequestered in particulate structures. In micro-organisms, these enzymes are associated with cell membranes, and in higher organisms with mitochondria.

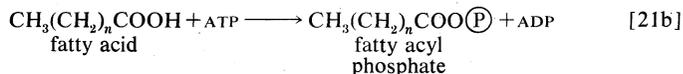

Fatty acids are linked to coenzyme A ( $\text{CoA-SH}$ ) in one of two main ways. In higher organisms, enzymes in the cytoplasm called thiokinases catalyze the linkage of fatty acids with  $\text{CoA-SH}$  to form a compound that can be called a fatty acyl coenzyme A [21]. This step requires

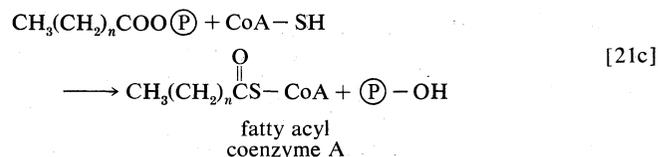

ATP, which is split to AMP and inorganic pyrophosphate ( $\text{PP}_i$ ) in the process. In this series of reactions,  $n$  indicates the number of hydrocarbon units ( $-\text{CH}_2-$ ) in the molecule. Because most tissues contain highly active pyrophosphatase enzymes [21a], which catalyze the vir-

tually irreversible hydrolysis of inorganic pyrophosphate ( $\text{PP}_i$ ) to two molecules of inorganic phosphate ( $\text{P}_i$ ), reaction [21] proceeds overwhelmingly to completion; i.e., from left to right. In obligate anaerobic bacteria, the linkage of fatty acids to coenzyme A may require the formation of a fatty acyl phosphate; i.e., the phosphorylation of the fatty acid using ATP. ADP is also a product [21b]. The fatty acyl moiety  $[\text{CH}_3(\text{CH}_2)_n\text{COO}]$  is then

transferred to coenzyme A [21c], forming a fatty acyl coenzyme A compound and  $\text{P}_i$ .

The role of coenzyme A in the fragmentation of fats

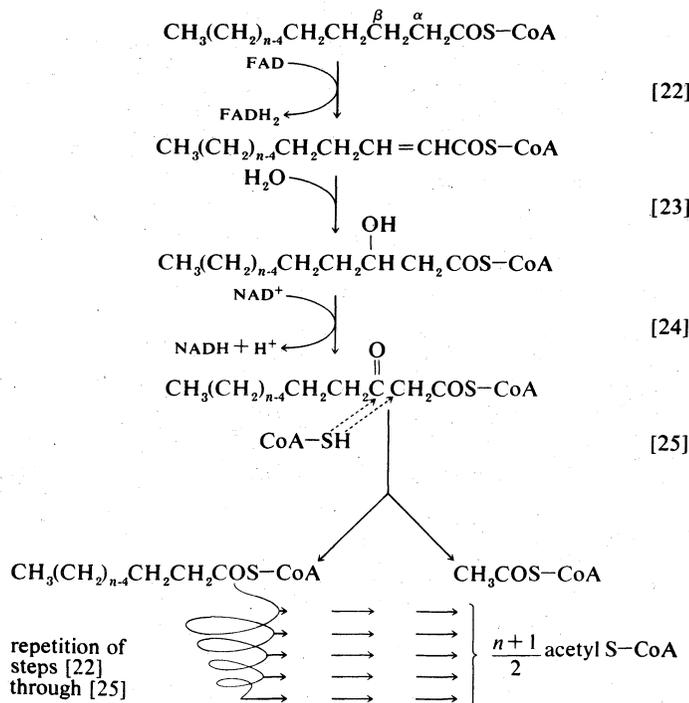

Figure 5: Fragmentation of acyl coenzyme A with an even number of carbon atoms (see text).

In either case, it is the fatty acyl coenzyme A molecules that are fragmented in the sequence of events summarized in Figure 5.

Initially (step [22], Figure 5) two hydrogen atoms are lost from the fatty acyl coenzyme A, resulting in the formation of an unsaturated fatty acyl coenzyme A (*i.e.*, with a double bond,  $-\text{CH}=\text{CH}-$ ) between the  $\alpha$ - and  $\beta$ -carbons of the acyl moiety—the  $\alpha$ -carbon is the one closest to the carboxyl ( $-\text{COOH}$ ) group of a fatty acid; the next closest is the  $\beta$ -, and so on to the end of the hydrocarbon chain). The hydrogen atoms are accepted by the coenzyme FAD (flavin adenine dinucleotide), which is reduced to  $\text{FADH}_2$ . The product of step [22],  $\alpha,\beta$ -unsaturated fatty acyl coenzyme A, is enzymatically hydrated [23]; *i.e.*, water is added across the double bond. The product, called a  $\beta$ -hydroxyacyl coenzyme A, can again be oxidized in an enzyme-catalyzed reaction [24]; the electrons removed are accepted by  $\text{NAD}^+$ . The product is called a  $\beta$ -ketoacyl coenzyme A.

The next enzymatic step [25] enables the energy invested in step [21] to be conserved. The  $\beta$ -ketoacyl coenzyme A that is the product of reaction [24] is split, not by water, but by coenzyme A. The process, called thiolysis (as distinct from hydrolysis), yields the two-carbon fragment acetyl coenzyme A and a fatty acyl coenzyme A having two fewer carbon atoms than the molecule that underwent reaction [22]; otherwise the two are similar.

The shortened fatty acyl coenzyme A molecule now undergoes the sequence of reactions again, beginning with the dehydrogenation step [22], and another two-carbon fragment is removed as acetyl coenzyme A. With each passage through the process of fatty acid oxidation, the fatty acid loses a two-carbon fragment as acetyl coenzyme A and two pairs of hydrogen atoms to specific acceptors. The 16-carbon fatty acid, palmitic acid, for example, undergoes a total of seven such cycles, yielding eight molecules of acetyl coenzyme A and 14 pairs of hydrogen atoms, seven of which appear in the form of  $\text{FADH}_2$  and seven in the form of  $\text{NADH} + \text{H}^+$ . The reduced coenzymes,  $\text{FADH}_2$  and reduced  $\text{NAD}^+$ , are reoxidized when the electrons pass through the electron transport chain, with concomitant formation of ATP (see below *Biological energy transduction*). In anaerobes, organic molecules other than FAD and  $\text{NAD}^+$  are electron acceptors; thus the yield of ATP is reduced. In all organisms, however, the acetyl coenzyme A formed from the breakdown of fatty acids joins that arising from the catabolism

of carbohydrates (see below *The oxidation of pyruvate*) and many amino acids (see below *The catabolism of proteins*); Figure 2 shows the interrelationships.

Fatty acids with an odd number of carbon atoms are relatively rare in nature but may arise during microbial fermentations or through the oxidation of amino acids such as valine and isoleucine. They may be fragmented through repeated cycles of steps [22] to [25] until the final five-carbon acyl coenzyme A is split into acetyl coenzyme A and propionyl coenzyme A, which has three carbon atoms. In many bacteria, this propionyl coenzyme A can be transformed either to acetyl coenzyme A and carbon dioxide or to pyruvate. In other micro-organisms and in animals, propionyl coenzyme A has a different fate: carbon dioxide is added to propionyl coenzyme A in a reaction requiring ATP. The product, methyl malonyl coenzyme A, has four carbon atoms; the molecule undergoes a rearrangement, forming succinyl coenzyme A, which is an intermediate of the TCA cycle.

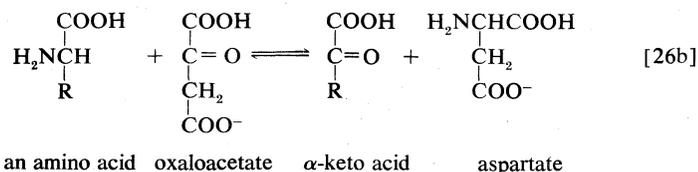

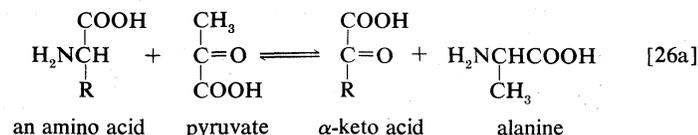

#### THE CATABOLISM OF PROTEINS

The amino acids derived from proteins function primarily as the precursors, or building blocks, for the cell's own proteins and (unlike lipids and carbohydrates) are not primarily a source of energy (see PROTEIN for a discussion of amino acids and classes of proteins). Many micro-organisms, however, can grow on amino acids as the sole carbon and nitrogen source; under these conditions, they derive from them all of their energy and all of the precursors of the macromolecules that comprise cell components. Moreover, it has been calculated that a man of average weight (70 kilograms, or 150 pounds) turns over about 0.4 kilogram of protein per day. About 0.1 kilogram is degraded and replaced by dietary amino acids; the remainder is recycled as part of the dynamic state of cell constituents. Plants contain and metabolize many amino acids in addition to the 20 or so normally found in proteins; discussion of these special pathways is outside the scope of this article, however.

Before proteins can enter cells, the bonds linking adjacent amino acids (peptide bonds) must be hydrolyzed; this process releases the amino acids constituting the protein. The utilization of dietary proteins thus requires the operation of extracellular digestive enzymes; *i.e.*, enzymes outside the cell. Many micro-organisms secrete such enzymes into the nutrient mediums in which they are growing; animals secrete them into the gut. The turnover of proteins within cells, on the other hand, requires the functioning of intracellular enzymes that catalyze the splitting of the peptide bonds linking adjacent amino acids; little is known about the mechanism involved.

Amino acids may be described by the general formula  $\text{RCH}(\text{NH}_2)\text{COOH}$ , in which R represents a specific chemical moiety. The catabolic fate of amino acids involves (1) removal of nitrogen, (2) disposal of nitrogen, and (3) oxidation of the remaining carbon skeleton.

**Removal of nitrogen.** The removal of the amino group ( $-\text{NH}_2$ ) generally constitutes the first stage in amino acid catabolism. The amino group usually is initially transferred to one of three different  $\alpha$ -keto compounds (*i.e.*, of the general structure  $\text{RCO}\text{COOH}$ ): pyruvate, which is an intermediate of carbohydrate fragmentation; or oxaloacetate or  $\alpha$ -oxoglutarate, both intermediates of the TCA cycle. The products are alanine, aspartate, and glutamate (reactions [26a, b, and c]).

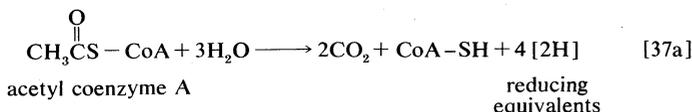

The products of fatty acid oxidation

in which pyruvate reacts with coenzyme A in the presence of TPP and lipS<sub>2</sub> to form acetyl coenzyme A and carbon dioxide. The lipS<sub>2</sub> reduced during this process is reoxidized in the presence of the enzyme lipoyl dehydrogenase, with the concomitant reduction of NAD<sup>+</sup>.

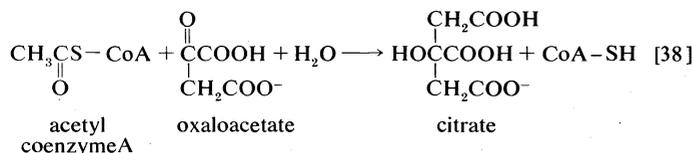

**The tricarboxylic acid (TCA) cycle.** Acetyl coenzyme A arises not only from the oxidation of pyruvate but also from that of fats (Figure 5) and many of the amino acids comprising proteins (Figure 2); the sequence of enzyme-catalyzed steps that effects the total combustion of the acetyl moiety of the coenzyme represents the terminal oxidative pathway for virtually all food materials. The balance of the overall reaction of the TCA cycle [37a] is that three molecules of water react with acetyl

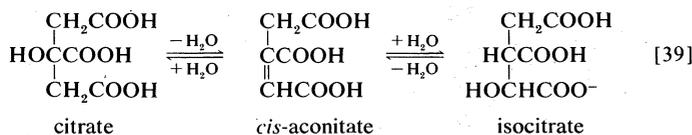

coenzyme A to form carbon dioxide, coenzyme A, and reducing equivalents. The oxidation by oxygen of the reducing equivalents is accompanied by the conservation (as ATP) of most of the energy of the food ingested by aerobic organisms.

The relative complexity and number of chemical events that comprise the TCA cycle, and their location as components of spatially determined structures such as cell membranes in micro-organisms and mitochondria in plants and higher animals, reflect the problems involved chemically in "dismembering" a compound having only two carbon atoms and releasing in a controlled and stepwise manner the reducing equivalents ultimately to be passed to oxygen. These problems have been overcome by the simple but effective device of initially combining the two-carbon compound with a four-carbon acceptor; it is much less difficult chemically to dismember and oxidize a compound having six carbon atoms.

In the TCA cycle, acetyl coenzyme A initially reacts with oxaloacetate to yield citrate and to liberate coenzyme A.

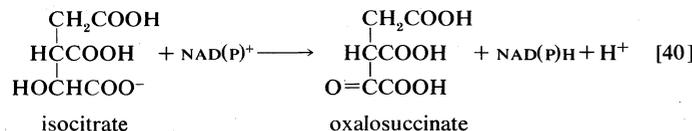

This reaction [38] is catalyzed by citrate synthase. (As mentioned above, many of the compounds in living cells that take part in metabolic pathways exist as charged moieties, or anions, and are named as such. Citrate undergoes isomerization (*i.e.*, a rearrangement of certain atoms comprising the molecule) to form isocitrate [39]. The reaction involves first the removal of the

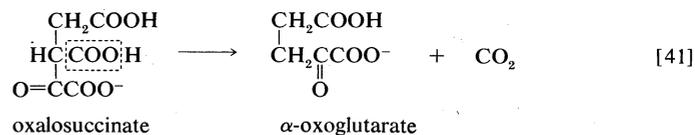

elements of water from citrate to form *cis*-aconitate, and then the re-addition of water to *cis*-aconitate in such a way that isocitrate is formed. It is probable that all three reactants—citrate, *cis*-aconitate, and isocitrate—remain closely associated with aconitase, the enzyme that catalyzes the isomerization process, and that most of the *cis*-aconitate is not released from the enzyme surface but is immediately converted to isocitrate.

Isocitrate is oxidized—*i.e.*, hydrogen is removed—to form oxalosuccinate; the two hydrogen atoms are usually transferred to NAD<sup>+</sup>, thus forming reduced NAD<sup>+</sup> [40]; in some micro-organisms, and during the biosynthesis of

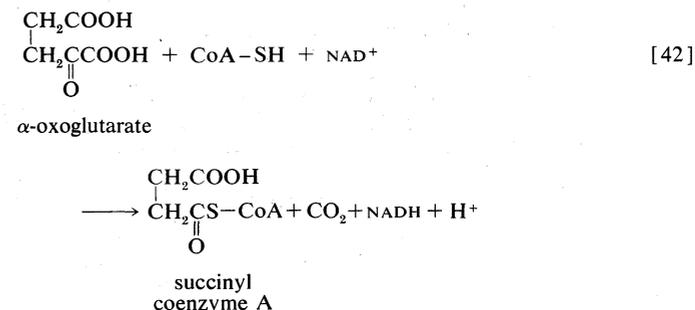

glutamate in the cytoplasm of animal cells, however, the hydrogen atoms may also be accepted by NADP<sup>+</sup>. Thus the enzyme controlling this reaction, isocitrate dehydrogenase, differs in specificity for the coenzymes; various forms occur not only in different organisms but even within the same cell. In [40] NAD(P)<sup>+</sup> indicates that either NAD<sup>+</sup> or NADP<sup>+</sup> can act as a hydrogen acceptor.

The position of the carboxyl group (—COOH) that is "sandwiched" in the middle of the oxalosuccinate molecule renders it very unstable; as a result, the carboxyl group is lost as carbon dioxide (note the dotted rectangle)

in a reaction [41] that can occur spontaneously but may be further accelerated by an enzyme.

The five-carbon product of reaction [41],  $\alpha$ -oxoglutarate, has chemical properties similar to pyruvate (free acid forms of both are so-called  $\alpha$ -oxoacids), and the chemical events involved in the oxidation of  $\alpha$ -oxoglutarate are analogous to those already described for the oxidation of pyruvate (see reaction [37]). Reaction [42] is

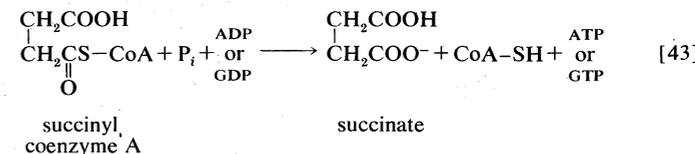

effected by a multi-enzyme complex; TPP, lipS<sub>2</sub> (6,8-dithio-*n*-octanoate), and coenzyme A are required as coenzymes. The products are carbon dioxide and succinyl coenzyme A. As was noted with reaction [37], this oxidation of  $\alpha$ -oxoglutarate results in the reduction of lipS<sub>2</sub>, which must be reoxidized. This is done by transfer of reducing equivalents to FAD and thence to NAD<sup>+</sup>. The resultant NADH + H<sup>+</sup> is reoxidized by the passage of the electrons, ultimately, to oxygen, via the electron transport chain.

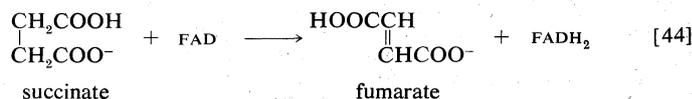

Unlike the acetyl coenzyme A produced from pyruvate in reaction [37], succinyl coenzyme A undergoes a phosphorylation reaction—*i.e.*, transfer of the succinyl moiety from coenzyme A to inorganic phosphate. The succinyl phosphate thus formed is not released from the enzyme surface; an unstable, high-energy compound called an acid anhydride, it transfers a high-energy phosphate to ADP, directly or via guanosine diphosphate (GDP). If guanosine triphosphate (GTP) forms, ATP can readily arise from it in an exchange involving ADP [43a].

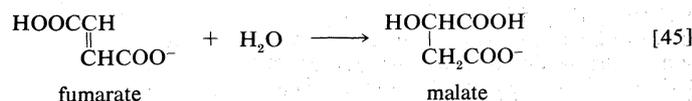

The remainder of the reactions of the TCA cycle serve to regenerate the initial four-carbon acceptor of acetyl coenzyme A (oxaloacetate) from succinate, the process requiring in effect the oxidation of a hydrocarbon group (—CH<sub>2</sub>—) to a carbonyl group (—CO—), with concomitant release of reducing equivalents (2[2H]). It is therefore similar to, and is effected in like manner to, the oxidation of fatty acids (steps [22–24]; see Figure 5). As is the case with fatty acids, hydrogen atoms or electrons are initially removed from the succinate formed in [43] and are accepted by FAD; the reaction, catalyzed by

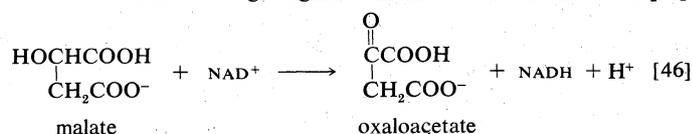

succinate dehydrogenase [44], results in the formation of fumarate and reduced FAD.

The elements of water are added across the double bond ( $-\text{CH}=\text{CH}-$ ) of fumarate in a reaction catalyzed by fumarase [45]; this type of reaction also occurred in step [39] of the cycle. The product of reaction [45] is malate.

Malate can be oxidized to oxaloacetate by removal of two hydrogen atoms, which are accepted by  $\text{NAD}^+$ . This type of reaction, catalyzed by malate dehydrogenase in reaction [46], also occurred in step [40] of the cycle. The formation of oxaloacetate completes the TCA cycle, which can now begin again with the formation of citrate [38].

A summary of the energy conserved during the TCA cycle

The loss of the two molecules of carbon dioxide in steps [41] and [42] does not yield biologically useful energy. The formation of ATP accompanies step [43], in which one molecule of ATP is formed during each turn of the cycle. The hydrogen ions and electrons that result from steps [40], [42], [44], and [46] are passed down the chain of respiratory carriers to oxygen, with the concomitant formation of ATP (see below). The oxidation of each molecule of reduced  $\text{NAD}^+$  is coupled to the formation of three molecules of ATP. Similarly, the oxidation of reduced FAD results in the formation of two ATP. Each turn of the cycle can thus lead to the production of 11 ATP in this way, and a total of 12 ATP are produced, including that in [43]. It will be recalled that the fragmentation of glucose to two molecules of pyruvate yielded two ATP; the aerobic oxidation via the TCA cycle of two molecules of pyruvate thus makes available to the cell at least 15 times more ATP per molecule of glucose catabolized than is produced anaerobically.

#### BIOLOGICAL ENERGY TRANSDUCTION

**Adenosine triphosphate as the currency of energy exchange.** At the normal pH of the cell (pH is a measure of the acidity or alkalinity of a solution; the normal pH of a cell is about 7 on a scale of 1 to 14) the three phosphate (or, more precisely, phosphoryl) groups of ATP (see Figure 1) are almost completely negatively charged (*i.e.*, ionized) because of the four negatively charged oxygen atoms ( $\text{O}^-$ ). The negative charges are very close together and strongly repel each other. The hydrolysis of ATP to ADP, with the formation of a phosphoryl group and a hydrogen ion [47] relieves some of the electrostatic repulsion. The negatively charged products (ADP and the phosphoryl group), which are electrically more stable than the parent molecule, do not readily recombine.

The total free energy ( $G$ ) of the products is much less than that of ATP; hence the reaction proceeds with the liberation of energy (*i.e.*, it is exergonic). The amount of energy liberated under strictly defined conditions is called the standard free energy change ( $\Delta G^\circ$ ); this value for the hydrolysis of ATP is relatively high, at  $-8$  kilocalories per mole. (One kilocalorie is the amount of heat required to raise the temperature of 1,000 grams of water one degree centigrade.) Conversely, the formation of ATP from ADP and inorganic phosphate ( $\text{P}_i$ ) is an energy-requiring (*i.e.*, endergonic) reaction with a standard free energy change of  $+8$  kilocalories per mole.

The hydrolysis of the terminal phosphate of ADP is also

accompanied by a considerable liberation of free energy (the standard free energy change is  $-6.5$  kilocalories per mole); AMP hydrolysis liberates less energy (the standard free energy change is  $-2.2$  kilocalories per mole).

The free energy of hydrolysis of a compound thus is a measure of the difference in energy content between the starting substances (reactants) and the final substances (products). Adenosine triphosphate does not have the highest standard free energy of hydrolysis of all the naturally occurring phosphates but instead occupies a position at approximately the halfway point in a series of phosphate compounds with a wide range of standard free energies of hydrolysis. Compounds such as 1,3-diphosphoglycerate or phosphoenolpyruvate (PEP), which are above ATP (see Figure 6), are often called high-energy

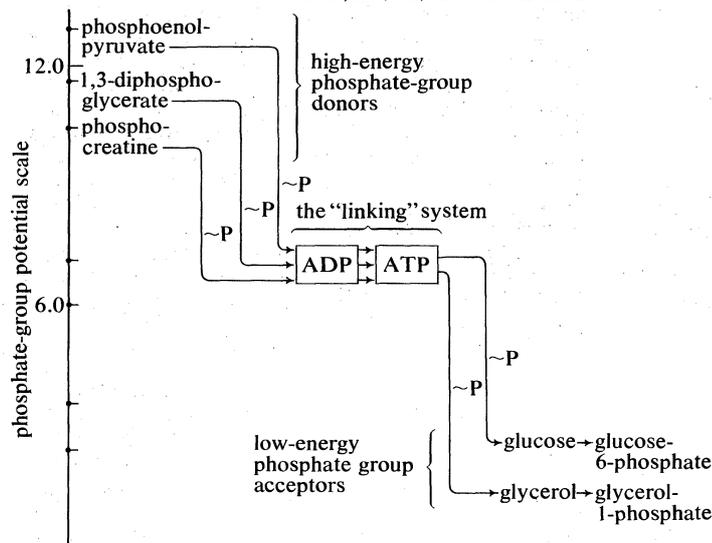

Figure 6: The transfer of phosphate groups from high-energy donors to low-energy acceptors by way of the ATP-ADP system (see text).

phosphates; they are said to exhibit a high phosphate group transfer potential because they have a tendency to lose their phosphate groups. Compounds such as glucose-6-phosphate or fructose-6-phosphate, which are below ATP, have a tendency to hold on to their phosphate groups and thus act as low-energy phosphate acceptors. Both ATP and ADP act as intermediate carriers for the transfer of phosphate groups (more precisely, phosphoryl groups) and hence of energy, from compounds lying above ATP to those lying beneath it. Thus, in glycolysis, ADP acts as an acceptor during the synthesis of ATP from PEP (see reaction [10]), and ATP acts as a donor during the formation of fructose-1,6-diphosphate from fructose-6-phosphate (see reaction [3]).

The function of ATP as a common intermediate of energy transfer during anabolism is further dealt with below (see *The biosynthesis of cell components*). In certain specialized cells or tissues the chemical energy of ATP is used to perform work other than the chemical work of anabolism; for example, mechanical work—such as muscular contraction, or the movement of contractile structures called cilia and flagella, which are responsible for the motility of many small organisms. The performance of osmotic work also requires ATP; *e.g.*, the transport of ions or metabolites through membranes against a concentration gradient, a process that is basically responsible for many physiological functions, including the secretion of hydrochloric acid in the stomach and the removal of water from the kidneys.

**Energy conservation.** The synthesis of ATP affords a means by which energy liberated during the oxidative stages of catabolism can be conserved in a stable, utilizable form until such time as the cell needs energy to drive various energy-requiring processes. The catabolism-linked synthesis of ATP occurs by two quite distinct mech-

The utilization of ATP to perform work

anisms: one is called substrate level phosphorylation; the other, oxidative, or respiratory chain, phosphorylation. Oxidative phosphorylation is the major method of energy conservation under aerobic conditions in all non-photosynthetic cells.

**Substrate level phosphorylation.** In substrate level phosphorylation a phosphoryl group is transferred from an energy-rich donor (*e.g.*, 1,3-diphosphoglycerate) to ADP to yield a molecule of ATP. This type of ATP synthesis (see reactions [7], [10], and [43]) does not require molecular oxygen ( $O_2$ ), although it is frequently, but not always, preceded by an oxidation (*i.e.*, dehydrogenation) reaction. Substrate level phosphorylation is the major method of energy conservation in oxygen-depleted tissues and during fermentative growth of micro-organisms.

**Oxidative, or respiratory chain, phosphorylation.** In oxidative phosphorylation, the oxidation of catabolic intermediates by molecular oxygen occurs via a highly ordered series of substances that act as hydrogen and electron carriers. They constitute the electron transfer system, or respiratory chain. In most organisms, the electron transfer system is fixed in the membranes of mitochondria. Sufficient free energy is released over certain segments of the respiratory chain to allow the synthesis of ATP by a complex and, as yet, poorly understood process.

Four types of hydrogen or electron carriers are known to participate in the respiratory chain, in which they serve to transfer two reducing equivalents (2H) from reduced substrate ( $AH_2$ ) to molecular oxygen (see reaction [48]); the products are the oxidized substrate ( $A$ ) and water ( $H_2O$ ).

The carriers are  $NAD^+$  and, less frequently,  $NADP^+$ ; the flavoproteins FAD and FMN (flavin mononucleotide); ubiquinone (or coenzyme Q); and several types of cytochromes. Each carrier has an oxidized and reduced form (*e.g.*, FAD and  $FADH_2$ , respectively), the two forms constituting an oxidation-reduction, or redox, couple. Within the respiratory chain each redox couple undergoes cyclic oxidation-reduction—*i.e.*, the oxidized component of the couple accepts reducing equivalents from either a substrate or a reduced carrier preceding it in the series, and in turn donates these reducing equivalents to the next oxidized carrier in the sequence. Reducing equivalents are thus transferred from substrates to molecular oxygen by a number of sequential redox reactions.

Most oxidizable catabolic intermediates initially undergo a dehydrogenation reaction, during which a dehydrogenase enzyme transfers the equivalent of a hydride ion ( $H^+ + 2e^-$ ,  $e^-$  representing an electron) to its coenzyme, either  $NAD^+$  or  $NADP^+$  (as examples, see [40] and [46]). The reduced  $NAD^+$  (or  $NADP^+$ ) thus produced diffuses to the membrane-bound respiratory chain to be ox-

idized by an enzyme known as NADH dehydrogenase; the enzyme has as its coenzyme FMN. There is no corresponding NADPH dehydrogenase in mammalian mitochondria; instead, the reducing equivalents of reduced  $NAD^+$  are transferred to  $NAD^+$  in a reaction catalyzed by a transhydrogenase enzyme, with the products being reduced  $NAD^+$  and  $NADP^+$ . A few substrates (*e.g.*, acyl coenzyme A and succinate; see reactions [22] and [44]) bypass this reaction and instead undergo immediate dehydrogenation by specific membrane-bound dehydrogenase enzymes. During the reaction, the coenzyme FAD accepts two hydrogen atoms and two electrons ( $2H + 2e^-$ ). The reduced flavo-proteins (*i.e.*, reduced FMN and reduced FAD) donate their two hydrogen atoms to the lipid carrier ubiquinone, which is thus reduced. The fourth type of carrier, the cytochromes, consists of hemoproteins—*i.e.*, proteins with a nonprotein component, or prosthetic group, called heme (or a derivative of heme), which is an iron-containing pigment molecule. The iron atom in the prosthetic group is able to carry one electron and oscillates between the oxidized, or ferric ( $Fe^{3+}$ ), and the reduced, or ferrous ( $Fe^{2+}$ ), forms. The five cytochromes present in the mammalian respiratory chain, designated cytochromes  $b$ ,  $c$ ,  $c_1$ ,  $a$ , and  $a_3$ , act in sequence between ubiquinone and molecular oxygen. The terminal cytochrome of this sequence ( $a_3$ , also known as cytochrome oxidase) is able to donate electrons to oxygen rather than to another electron carrier;  $a_3$  is also the site of action of two substances that inhibit the respiratory chain, potassium cyanide and carbon monoxide.

It is suspected that other iron-containing proteins also act as electron carriers at several points in the respiratory chain, but, because their exact sites of action have not yet been clarified, they have been omitted from the schematic diagram of the respiratory chain shown in Figure 7.

In each redox couple the reduced form has a tendency to lose reducing equivalents (*i.e.*, to act as an electron or hydrogen donor); similarly, the oxidized form has a tendency to gain reducing equivalents (*i.e.*, to act as an electron or hydrogen acceptor). The oxidation-reduction characteristics of each couple can be determined experimentally under well-defined, standard conditions. The value thus obtained is the standard oxidation-reduction (redox) potential ( $E_0$ ). Values for respiratory chain carriers range from  $E_0 = -320$  millivolts (one millivolt = 0.001 volt) for  $NAD^+$ /reduced  $NAD^+$  to  $E_0 = +820$  millivolts for  $\frac{1}{2}O_2/H_2O$ ; the values for intermediate carriers lie between. Reduced  $NAD^+$  is the most electro-negative carrier, oxygen the most electropositive acceptor. During respiration reducing equivalents undergo stepwise transfer from the reduced form of the most electronegative carrier (reduced  $NAD^+$ ) to the oxidized form of the most electropositive couple (oxygen). Each step is accompanied by a decline in standard free energy

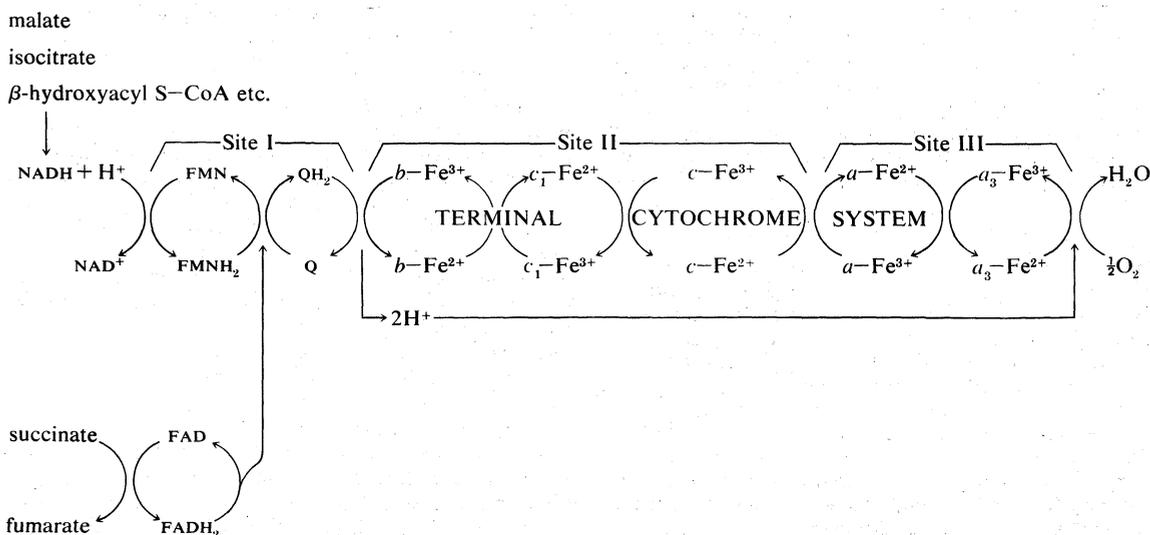

Figure 7: The respiratory chain (see text).

( $\Delta G'$ ) proportional to the difference in the standard redox potentials ( $\Delta E_0$ ) of the two carriers involved.

Overall oxidation of reduced  $\text{NAD}^+$  by oxygen ( $\Delta E_0 = +1,140$  millivolts) is accompanied by the liberation of free energy ( $\Delta G' = -52.4$  kilocalories per mole); in theory this energy is sufficient to allow the synthesis of six or seven molecules of ATP. In the cell, however, this synthesis of ATP, called oxidative phosphorylation, proceeds with an efficiency of about 46 percent; thus only three molecules of ATP are produced per atom of oxygen consumed—this being the so-called P/2e<sup>-</sup>, P/O, or ADP/O ratio. The energy that is not conserved as ATP is lost as heat. The oxidation of succinate by molecular oxygen ( $\Delta E_0 = +790$  millivolts), which is accompanied by a smaller liberation of free energy ( $\Delta G' = -36.5$  kilocalories per mole), yields only two molecules of ATP per atom of oxygen consumed (P/O = 2).

One phosphorylation site is located at the level at which NADH dehydrogenase acts—between reduced  $\text{NAD}^+$  and ubiquinone (site I in Figure 7). A second phosphorylation site is located between ubiquinone and cytochrome *c* (site II), and a third between cytochrome *c* and oxygen (site III).

The  
"energized  
state"

The mechanism by which the energy released during respiration is conserved as ATP is far from clear. Some form of nonphosphorylated "energized state" is produced in the mitochondrial membrane prior to the formation of ATP, but its exact identity is the subject of considerable controversy.

A respiratory control mechanism allows the cell to consume oxygen only when it needs to synthesize ATP. In the absence of ADP the "energized state" is quite stable and is capable of driving a number of energy-requiring, or endergonic, membrane phenomena. When, under certain experimental conditions in the absence of ADP, these phenomena cannot occur, respiratory control can be demonstrated. The "energized state" accumulates and oxygen consumption slows because there is no ADP present to allow the formation of ATP. If ADP is then added, the "energized state" is dissipated as ATP is synthesized, and the rate of oxygen consumption increases until all of the ADP has been converted into ATP, at which point oxygen consumption again slows. A similar circumstance occurs in the cell; when sufficient ATP is present, the concentration of ADP is low, and the consumption of both the "energized state" and oxygen is low.

As mentioned above, the oxidative phosphorylation systems of animal cells, as well as those of green plants and yeast, are located within mitochondria. These are particularly numerous in tissues requiring large amounts of energy either for mechanical (heart and skeletal muscle of animals) or biosynthetic (pancreas of animals) purposes. In transverse section, mitochondria are seen to consist of an outer, limiting membrane and a highly folded inner membrane (crista). The latter, which contains the respiratory carriers and the enzymes responsible for ATP synthesis and fatty acid oxidation, encloses a highly viscous matrix, which contains the soluble enzymes of the TCA cycle (see also CELL AND CELL DIVISION). The multi-enzyme systems primarily responsible for the release and subsequent oxidation of reducing equivalents are thus spatially related such that the products of catabolism (reduced  $\text{NAD}^+$  and  $\text{FADH}_2$ ) are readily available as substrates for respiration. The oxidative phosphorylation systems of bacteria are located in the cell membrane and exhibit much greater diversity than do those of other cells with respect to composition of the respiratory carriers.

#### IV. The biosynthesis of cell components

##### THE NATURE OF BIOSYNTHESIS

**The stages of biosynthesis.** The biosynthesis of cell components (anabolism) may be regarded as occurring in two main stages. In the first, intermediate compounds of the central routes of metabolism are diverted from further catabolism and are channelled into pathways that usually lead to the formation of the relatively small molecules that serve as the building blocks, or precursors, of macromolecules.

In the second stage of biosynthesis, the building blocks

are combined to yield the macromolecules—proteins, nucleic acids, lipids, and polysaccharides—that make up the bulk of tissues and cellular components. In organisms with the appropriate genetic capability, for example, all of the amino acids can be synthesized from intermediates of the main routes of carbohydrate fragmentation and oxidation. Such intermediates act also as precursors for the purines, the pyrimidines, and the pentose sugars that comprise deoxyribonucleic acid (DNA) and for a number of types of ribonucleic acid (RNA). The assembly of proteins necessitates the precise combination of specific amino acids in a highly ordered and controlled manner; this in turn involves the copying, or transcription, into RNA of specific parts of DNA (see below *The synthesis of macromolecules*). The first stage of biosynthesis thus requires the specificity normally required for the efficient functioning of sequences of enzyme-catalyzed reactions. The second stage also involves—directly for protein and nucleic acid synthesis, less directly for the synthesis of other macromolecules—the maintenance and expression of the biological information that specifies the identity of the cell, the tissue, and the organism.

**Utilization of ATP.** The two stages of biosynthesis—the formation of building blocks and their specific assembly into macromolecules—are energy-consuming processes and thus require ATP. Although the ATP is derived from catabolism, catabolism does not "drive" biosynthesis. As explained in the first section of this article, the occurrence of chemical reactions in the living cell is accompanied by a net decrease in free energy. Although biological growth and development result in the creation of ordered systems from less ordered ones and of complex systems from simpler ones, these events must occur at the expense of energy-yielding reactions. The overall coupled reactions are, on balance, still accompanied by a decrease in free energy, and are thus essentially irreversible in the direction of biosynthesis. The total energy released from ATP, for example, is usually much greater than is needed for a particular biosynthetic step; thus, many of the reactions involved in biosynthesis release inorganic pyrophosphate ( $\text{PP}_i$ ) rather than phosphate ( $\text{P}_i$ ) from ATP, and hence yield AMP rather than ADP. Since inorganic pyrophosphate readily undergoes virtually irreversible hydrolysis to two equivalents of inorganic phosphate (see [21a]), the creation of a new bond in the product of synthesis may be accompanied by the breaking of two high-energy bonds of ATP—although, in theory, one might have sufficed.

The efficient utilization for anabolic processes of ATP and some intermediate compound formed during a catabolic reaction requires the cell to have simultaneously a milieu favourable for both ATP generation and consumption. Catabolism occurs readily only if sufficient ADP is available; hence, the concentration of ATP is low. On the other hand, biosynthesis requires a high level of ATP and consequently low levels of ADP and AMP. Suitable conditions for the simultaneous function of both processes are met in two ways. Biosynthetic reactions often take place in compartments within the cell different from those in which catabolism occurs; there is thus a physical separation of energy-requiring and energy-yielding processes. Furthermore, biosynthetic reactions are regulated independently of the mechanisms by which catabolism is controlled. Such independent control is made possible by the fact that catabolic and anabolic pathways are not identical; the pacemaker, or key, enzyme that controls the overall rate of a catabolic route usually does not play any role in the biosynthetic pathway of a compound. Similarly, the pacemaker enzymes of biosynthesis are not involved in catabolism. As discussed below (see *Regulation of metabolism: Fine control*), catabolic pathways are often regulated by the relative amounts of ATP, ADP, and AMP in the cellular compartment in which the pacemaker enzymes are located; in general, ATP inhibits and ADP (or AMP) stimulates such enzymes. In contrast, many biosynthetic routes are regulated by the concentration of the end products of particular anabolic processes, so that the cell synthesizes only as much of these building blocks as it needs.

## THE SUPPLY OF BIOSYNTHETIC PRECURSORS

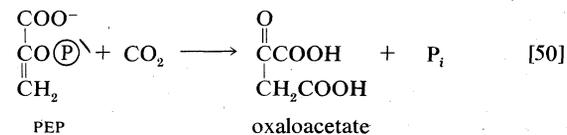

When higher animals consume a mixed diet, sufficient quantities of compounds for both biosynthesis and energy supply are available. Carbohydrates yield intermediates of glycolysis and of the phosphogluconate pathway, which in turn yield acetyl coenzyme A (see Figure 4); lipids yield glycolytic intermediates and acetyl coenzyme A (see Figure 2); and many amino acids form intermediates of both the TCA cycle and glycolysis. Any intermediate withdrawn for biosynthesis can thus be readily replenished by the catabolism of further nutrients. This situation does not always hold, however. Micro-organisms in particular can derive all of their carbon and energy requirements by utilizing a single carbon source. The sole carbon source may be a substance such as a carbohydrate or a fatty acid, or an intermediate of the TCA cycle (or readily converted to one). In both cases, reactions ancillary to those discussed thus far must occur before the carbon source can be utilized.

**Anaplerotic routes.** Although the catabolism of carbohydrates can occur via a variety of routes (see Figure 4), all give rise to pyruvate. During the catabolism of pyruvate, one carbon atom is utilized to form acetyl coenzyme A [37], and two are involved in the TCA cycle ([41] and [42]). Because the TCA cycle is initiated by the condensation of acetyl coenzyme A with oxaloacetate, which is regenerated in each turn of the cycle, the removal of any intermediate from the cycle would cause the cycle to stop. Yet, as also indicated in Figure 4, various essential cell components are derived from  $\alpha$ -oxoglutarate, succinyl coenzyme A, and oxaloacetate, so that these compounds are, in fact, removed from the cycle. Microbial growth with a carbohydrate as the sole carbon source is thus possible only if a cellular process occurs that effects the net formation of a TCA cycle intermediate from an intermediate of carbohydrate catabolism. Such a process, which replenishes the TCA cycle, has been described as an anaplerotic reaction.

The anaplerotic function may be carried out by either of two enzymes that catalyze the fixation of carbon dioxide onto a three-carbon compound, either pyruvate [49] or phosphoenolpyruvate (PEP, [50]) to form oxaloacetate, which has four carbon atoms. Both reactions require energy. In [49], it is supplied by the cleavage

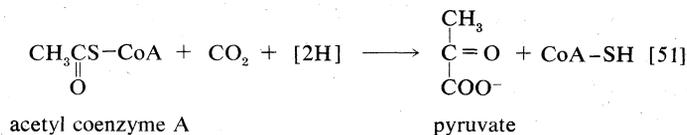

of ATP to ADP and inorganic phosphate ( $\text{P}_i$ ); in [50] it is supplied by the release of the high-energy phosphate of

PEP as inorganic phosphate. Pyruvate serves as a carbon dioxide acceptor not only in many bacteria and fungi but also in the livers of higher organisms, including man; PEP serves as the carbon dioxide acceptor in many bacteria, such as those that inhabit the gut.

Unlike higher organisms, many bacteria and fungi can grow on acetate or compounds such as ethanol or a fatty acid that can be catabolized to acetyl coenzyme A. Under these conditions, the net formation of TCA cycle intermediates proceeds in one of two ways. In obligate anaerobic bacteria, pyruvate can be formed from acetyl coenzyme A and carbon dioxide [51]; reducing equivalents [2H] are necessary for the reaction. The pyruvate so formed can then react via either step [49] or [50].

lents [2H] are necessary for the reaction. The pyruvate so formed can then react via either step [49] or [50].

Reaction [51] does not occur in many facultative anaerobic organisms or in strict aerobes, however. Instead, in these organisms two molecules of acetyl coenzyme A give rise to the net synthesis of a four-carbon intermediate of the TCA cycle via a route known as the glyoxylate cycle. In this route (Figure 8), the steps of the TCA

The glyoxylate cycle

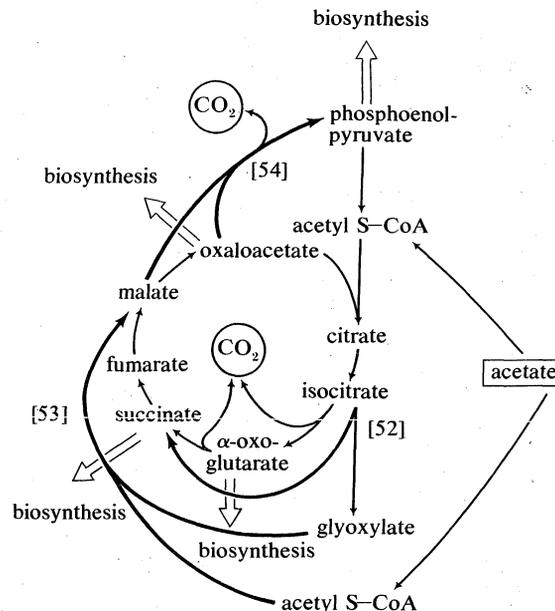

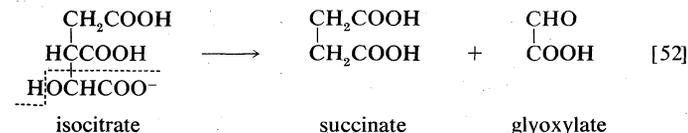

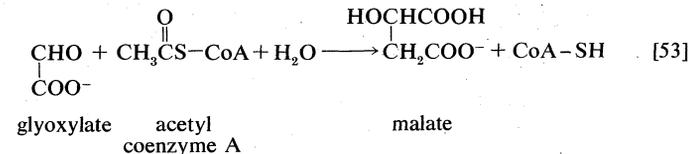

Figure 8: The glyoxylate cycle. Numbers refer to reactions described in text.

cycle that lead to the loss of carbon dioxide (see [40], [41], and [42]) are bypassed. Instead of being oxidized to oxalosuccinate, as occurs in [40], isocitrate is split by isocitrate lyase [52] in a reaction similar to that of

reactions [4] and [15] of carbohydrate fragmentation. The dotted line in [52] indicates the way in which isocitrate is split. The products are succinate and glyoxylate. Glyoxylate, like oxaloacetate, is an  $\alpha$ -oxoacid and thus can condense, in a reaction catalyzed by malate synthase, with acetyl coenzyme A; the products are coenzyme A and malate [53].

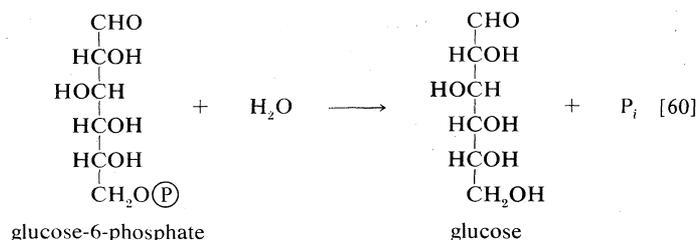

In conjunction with the reactions of the TCA cycle that effect the re-formation of isocitrate from malate (steps [46], [38], and [39]) steps [52] and [53] lead to the net production of a four-carbon compound (malate) from two two-carbon units (glyoxylate and acetyl coenzyme A). The sequence thus complements the TCA cycle, enabling the cycle to fulfill the dual roles of providing both energy and biosynthetic building blocks.

**Growth of micro-organisms on TCA cycle intermediates.** Most aerobic micro-organisms grow readily on substances such as succinate or malate as their sole source of carbon. Under these circumstances, the formation of the intermediates of carbohydrate catabolism requires an enzymatic step ancillary to the central pathways. In most cases, this step is catalyzed by phosphoenolpyruvate (PEP) carboxykinase [54]. Oxaloacetate is decarboxylated (*i.e.*, carbon dioxide is removed) during this energy-requiring reaction. The energy may be supplied by ATP or a similar substance (*e.g.*, GTP) that can

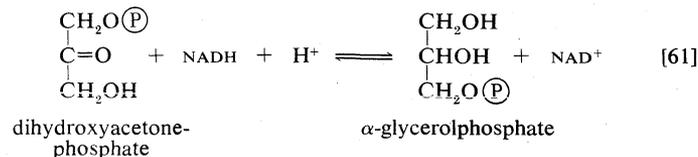

phate provides the starting material for the formation of storage polysaccharides such as starch and glycogen, of monosaccharides other than glucose, of disaccharides (carbohydrates with two sugar components), and of some structural polysaccharides (*e.g.*, cellulose). The maintenance of the glucose content of vertebrate blood requires some glucose-6-phosphate to be converted to glucose. This process occurs in the kidney, in the lining of the intestine, and most importantly in the liver. The reaction does not occur by reversal of the hexokinase or glucokinase reactions that effect the formation of glucose-6-phosphate from glucose and ATP [1]; rather, glucose-6-phosphate is hydrolyzed in a reaction catalyzed by glucose-6-phosphatase, and the phosphate is released as inorganic phosphate [60].

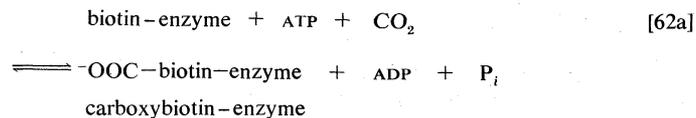

**Lipid components.** The component building blocks of the lipids found in storage fats, in lipoproteins (combinations of lipid and protein), and in the membranes of cells and organelles are glycerol, the fatty acids, and a number of other compounds (*e.g.*, serine, inositol).

**Glycerol.** Glycerol is readily derived from dihydroxyacetonephosphate, an intermediate of glycolysis (see [4]). In a reaction catalyzed by  $\alpha$ -glycerolphosphate dehydrogenase [61], dihydroxyacetonephosphate is reduced

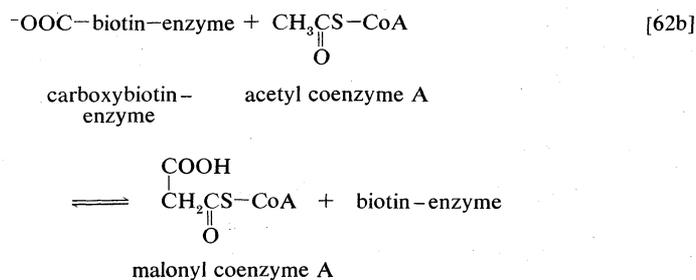

to  $\alpha$ -glycerolphosphate; reduced NAD<sup>+</sup> provides the reducing equivalents for the reaction and is oxidized. This compound reacts further (see below *Other components*).

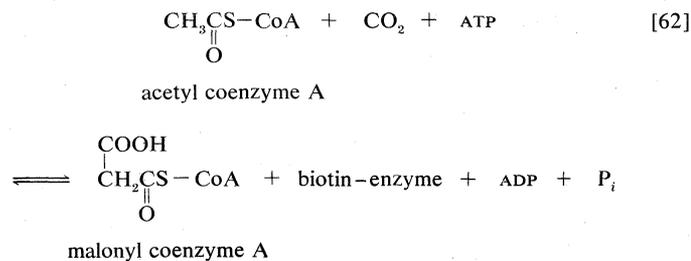

**Fatty acids.** Although all the carbon atoms of the fatty acids found in lipids are derived from the acetyl coenzyme A produced by the catabolism of carbohydrates and fatty acids (Figure 2), the molecule first undergoes a carboxylation, forming malonyl coenzyme A, before participating in fatty acid synthesis. The carboxylation reaction is catalyzed by acetyl CoA carboxylase, an enzyme whose prosthetic group is the vitamin biotin. The biotin-enzyme first undergoes a reaction that results in the attachment of carbon dioxide to biotin; ATP is required and forms ADP and inorganic phosphate [62a]. The complex product, called carboxybiotin-enzyme,

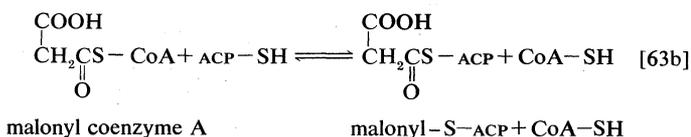

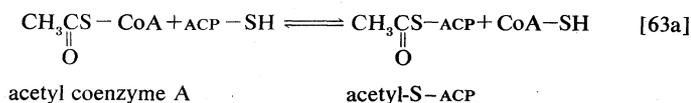

immediately releases the carboxy moiety to acetyl coenzyme A, forming malonyl coenzyme A and restoring the biotin-enzyme [62b].

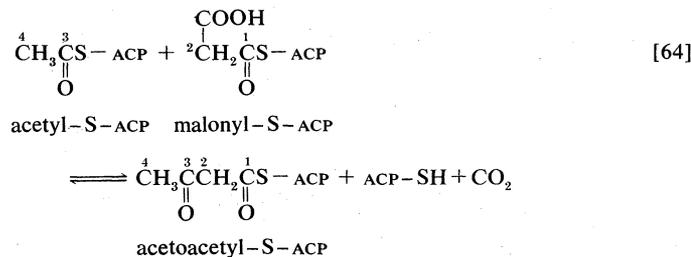

The overall reaction [62] catalyzed by acetyl coenzyme A carboxylase thus involves the expenditure of one molecule of ATP for the formation of each molecule of malonyl coenzyme A from acetyl coenzyme A and carbon dioxide.

Malonyl coenzyme A and a molecule of acetyl coenzyme A react with the sulfhydryl group of a relatively small molecule known as acyl-carrier protein (ACP-SH); in higher organisms ACP-SH is part of a multi-enzyme complex called fatty acid synthetase. ACP-SH is involved in all of the reactions leading to the synthesis of a fatty acid such as palmitic acid from acetyl coenzyme A and malonyl coenzyme A. The products of [63a]

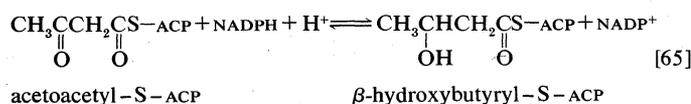

and [63b] are acetyl-S-ACP, malonyl-S-ACP, and coenzyme A. The enzymes catalyzing [63a] and [63b] are known as acetyl transacylase and malonyl transacylase, respectively. Acetyl-ACP and malonyl-ACP react in a reaction catalyzed by  $\beta$ -ketoacyl-ACP synthetase so that the acetyl moiety (CH<sub>3</sub>CO-) is transferred to the malonyl moiety (HOOCH<sub>2</sub>CO-). Simultaneously, the carbon dioxide fixed in step [62] is lost, leaving as a product a four-carbon moiety attached to ACP and called acetoacetyl-S-ACP [64].

It should be noted that the carbon atoms of acetyl-S-ACP occur at the end of acetoacetyl-S-ACP (see carbon atoms numbered 4 and 3 in [64]) and that carbon dioxide plays an essentially catalytic role; the decarboxylation of the malonyl-S-ACP [64] provides a strong thermodynamic pull toward fatty acid synthesis.

The analogy between reaction [64] of fatty acid synthesis and the cleavage reaction [25] of fatty acid catabolism is apparent in the other reactions of fatty acid synthesis. The acetoacetyl-S-ACP, for example, undergoes reduction to  $\beta$ -hydroxybutyryl-S-ACP [65]; the reaction is catalyzed by  $\beta$ -ketoacyl-ACP reductase. Reduced NADP<sup>+</sup> is the electron donor, however, and not reduced NAD<sup>+</sup> (which

would participate in the reversal of reaction [24]). NADP<sup>+</sup> is thus a product in [65]. In [66]  $\beta$ -hydroxybutyryl-S-ACP is dehydrated (*i.e.* one molecule of water is removed),

Analogies between fatty acid synthesis and breakdown

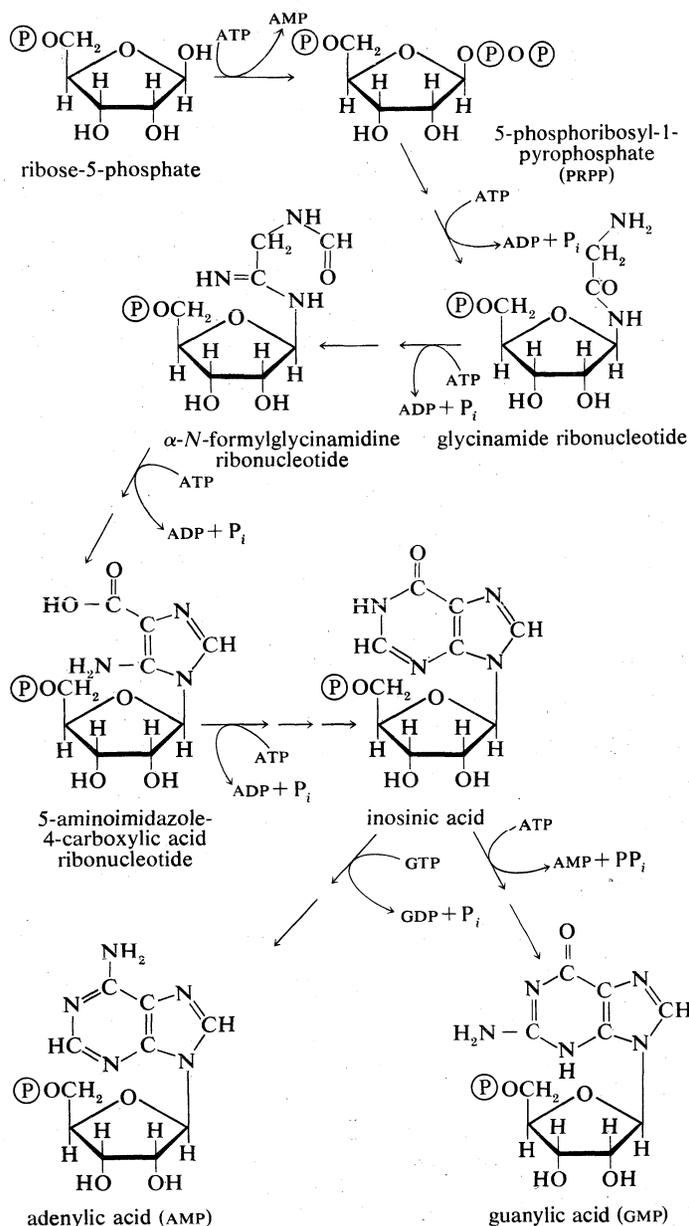

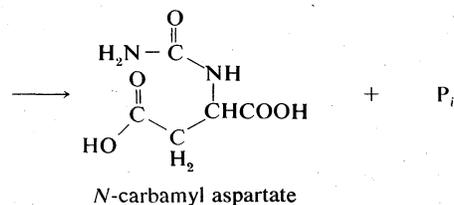

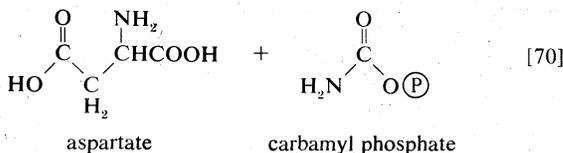

Figure 11: Biosynthesis of purine nucleotides. Not all of the intermediate compounds formed are shown.

The overall sequence that leads to the parent purine ribonucleotide, which is inosinic acid, involves 10 enzymatic steps.

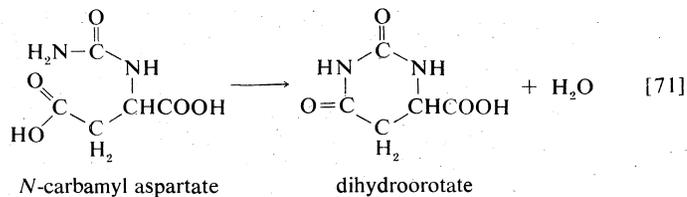

Figure 11 is an outline of the manner in which inosinic acid is synthesized. Inosinic acid can be converted to AMP and GMP; these in turn yield the triphosphates (*i.e.*, ATP and GTP) via reactions catalyzed by adenylate kinase [69] and nucleoside diphosphate kinase (see reaction [43a]).

**Pyrimidine ribonucleotides.** The biosynthetic pathway for the pyrimidine nucleotides is somewhat simpler than that for the purine nucleotides. Aspartate (derived from the TCA cycle intermediate, oxaloacetate) and carbamyl phosphate (derived from carbon dioxide, ATP, and ammonia via reaction [30]) condense to form *N*-carbamyl aspartate [70], which loses water [71] in a reaction

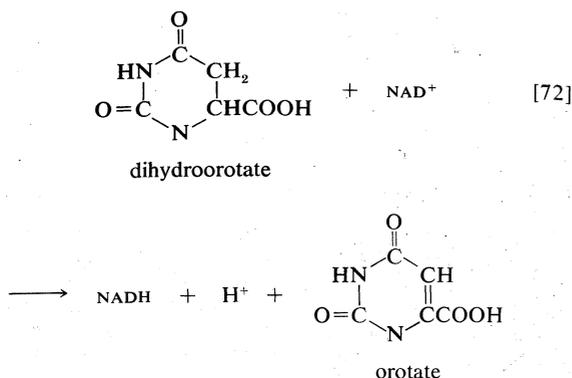

catalyzed by dihydroorotase; the product, dihydrooro-

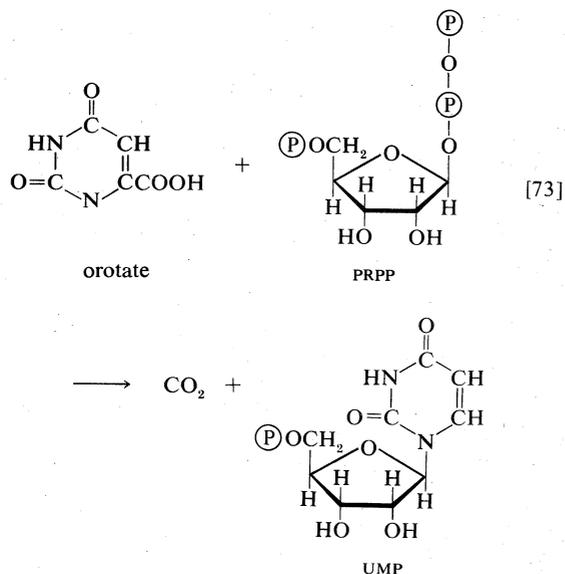

tate, is then oxidized to orotate in a reaction catalyzed by dihydroorotic acid dehydrogenase, in which  $\text{NAD}^+$  is reduced [72].

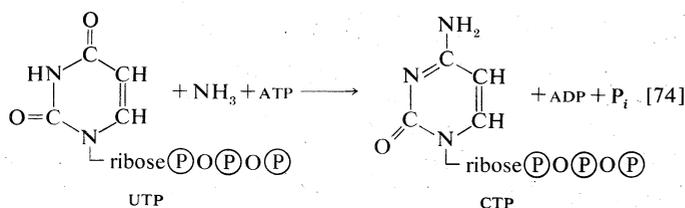

The orotate accepts a pentose-phosphate moiety [73] from 5-phosphoribosyl-1-pyrophosphate (PRPP); PRPP,

which is formed from ribose-5-phosphate and ATP, also initiates the pathways for biosynthesis of purine nucleotides (Figure 11) and of histidine (Figure 10). The product loses carbon dioxide to yield the parent pyrimidine nucleotide, uridylic acid (UMP; see [73]).

Analogous to the phosphorylation of purine nucleotides (steps [69] and [43a]) is the phosphorylation of UMP to UDP and thence to UTP by interaction with two molecules of ATP. Uridine triphosphate (UTP) can be converted to the other pyrimidine building block of RNA, cytidine triphosphate (CTP). In bacteria, the nitrogen for this reaction [74] is derived from ammonia; in higher animals, glutamine is the nitrogen donor.

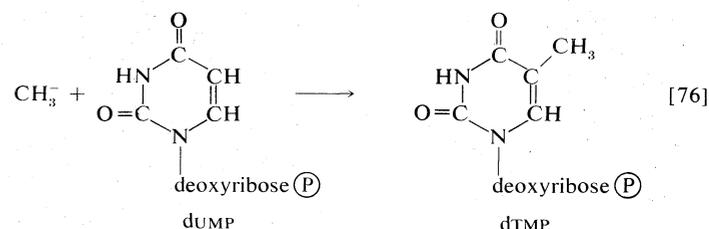

**Deoxyribonucleotides.** The building blocks for the synthesis of DNA differ from those for the synthesis of RNA in two respects. In DNA, the purine and pyrimidine nucleotides contain the pentose sugar 2-deoxyribose instead of ribose. In addition, the pyrimidine base uracil, found in RNA, is replaced in DNA by thymine. The deoxyribonucleoside diphosphate can be derived directly from the corresponding ribonucleoside diphosphate by a process involving the two sulfhydryl groups of the protein, thioredoxin, and a flavoprotein, thioredoxin reductase, that can in turn be reduced by reduced NADP<sup>+</sup>. Thus, for the reduction of XDP, in which X represents a purine base or cytosine, the reaction may be written as shown in [75a] and [75b]. In [75a] oxidized thioredoxin-

S<sub>2</sub> is reduced to thioredoxin-(SH<sub>2</sub>) by reduced NADP<sup>+</sup>, which is oxidized in the process. Thioredoxin-(SH<sub>2</sub>) then reduces XDP to deoxyXDP in a reaction [75b] in which thioredoxin is reformed.

Deoxythymidylic acid (dTMP) is derived from deoxyuridylic acid (dUMP). Deoxyuridine diphosphate (dUDP) is first converted to dUMP, by reaction [69] proceeding from right to left. Deoxyuridylic acid then accepts a methyl group (CH<sub>3</sub>-) in a reaction catalyzed by an enzyme (thymidylate synthetase) with the vitamin folic acid as a coenzyme; the product is dTMP [76].

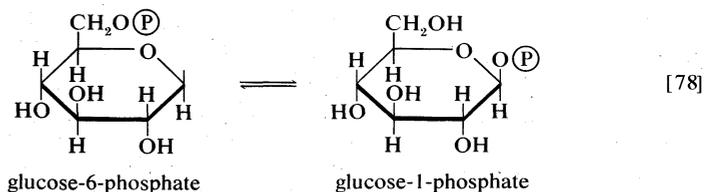

#### THE SYNTHESIS OF MACROMOLECULES

**Carbohydrates and lipids.** The formation of polysaccharides and of phospholipids from their component building blocks not only requires the investment of the energy of nucleoside triphosphates but uses these molecules in a novel manner. The biosynthetic reactions described thus far have mainly been accompanied by the formation of energy-rich intermediates (*e.g.*, PEP in [56]) with the formation of either AMP or ADP; however, nucleotides serve as intermediate carriers in the formation of glycogen, starch, and a variety of lipids. This unique process necessitates reactions by which ATP, or another nucleoside triphosphate, which can be readily derived from ATP via reactions of type [43a], combines with a phosphorylated reactant to form a nucleoside-diphosphate product. Although the change in standard free energy is small in this reaction, the subsequent hydrolysis of the inorganic pyrophosphate also released (reaction [21a]) effectively makes the reaction irreversible in the direction of synthesis. The nucleoside triphosphate is represented as NTP in [77], and the phosphorylated reactant as R-(P).

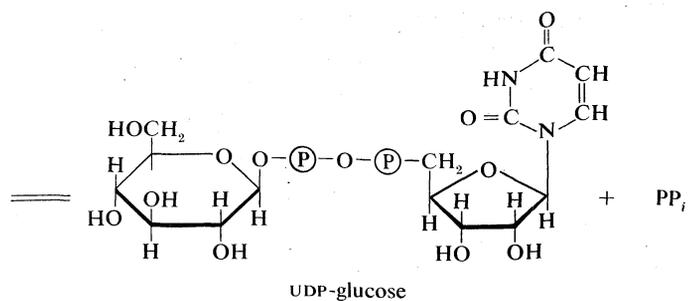

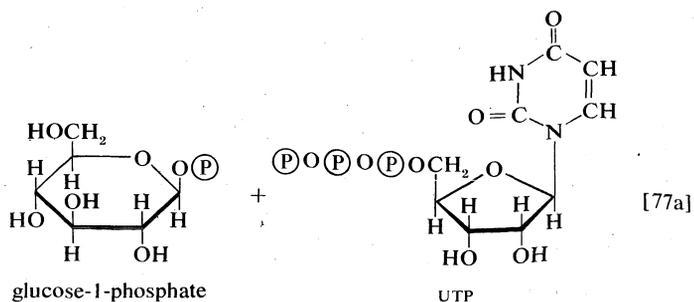

Reactions of type [77] are catalyzed by pyrophosphorylases, reaction [21a] by inorganic pyrophosphatase.

**Formation of storage polysaccharides.** In the formation of storage polysaccharides—*i.e.*, glycogen in animals, starch in plants—reaction [77] is preceded by the conversion of glucose-6-phosphate to glucose-1-phosphate, in a reaction catalyzed by phosphoglucomutase [78]. Glucose-1-phosphate functions as R-(P) in reaction

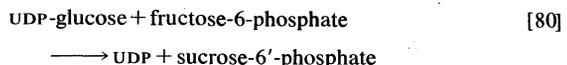

[77a]. UTP is the specific NTP for glycogen synthesis in animals [77a]; the products are UDP-glucose and pyrophosphate. In bacteria, fungi, and plants, ATP, CTP, or GTP serves instead of UTP. In all cases, the nucleoside diphosphate glucose (NDP-glucose) thus synthesized can donate glucose to the terminal glucose of a polysaccharide chain, thereby increasing the number (*n*) of glucose molecules by one to *n* + 1 [79]. UDP is released in this process, which is catalyzed by glycogen synthetase. Starch synthesis in plants occurs by an analogous pathway

catalyzed by amylose synthetase; ADP-glucose rather than UDP-glucose is the preferred glucose donor [79a]. Similarly, cellulose, the major structural polysaccharide in plant cell walls, is synthesized in some plants by reaction [79a]; other plants undergo analogous reactions in which GDP-glucose or CDP-glucose acts as the glucose donor.

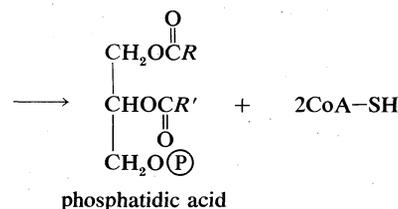

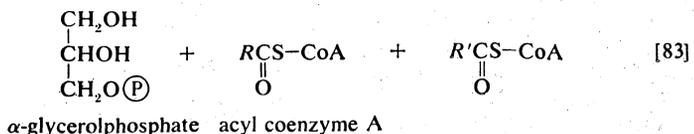

Nucleoside diphosphate sugars also participate in the synthesis of disaccharides; for example, common table sugar, sucrose (consisting of glucose and fructose), is formed in sugarcane by the reaction sequence shown in [80] and [81]; UDP-glucose and fructose-6-phosphate

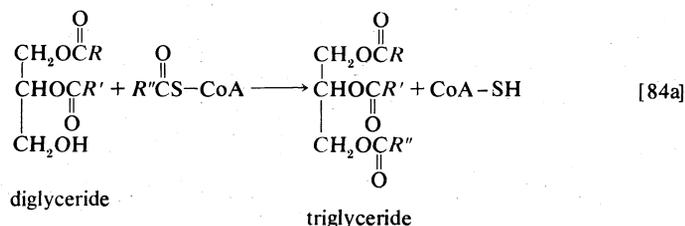

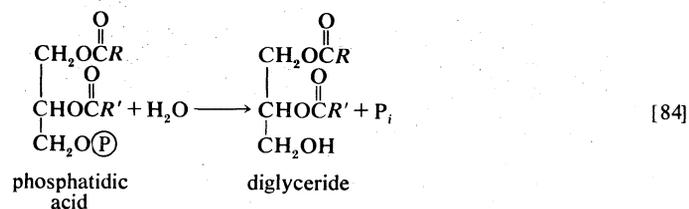

first form a phosphorylated derivative of sucrose, sucrose-6'-phosphate, which is hydrolyzed to sucrose and inorganic phosphate. Lactose, which consists of galactose and glucose, is the principal sugar of milk. It is synthesized in the mammary gland as shown in [82]; UDP-galactose and glucose react to form lactose; UDP is also a product.

**Formation of lipids.** The neutral fats, or triglycerides, that comprise storage lipids, and the phospholipid components of lipoproteins and membranes, are synthesized from their building blocks by a route that branches after the first biosynthetic reaction. Initially, one molecule of  $\alpha$ -glycerol phosphate, the intermediate derived from carbohydrate catabolism, and two molecules of the appropriate fatty acyl coenzyme A (formed as described above, under *Biosynthesis of lipid components*) combine, yielding phosphatidic acid [83]. This reaction occurs preferentially with acyl coenzyme A derivatives of fatty acids con-

taining 16 or 18 carbon atoms. In reaction [83], R and R' represent the hydrocarbon moieties ( $\text{CH}_2(\text{CH}_2)_n-$ ) of two fatty acid molecules. A triglyceride molecule (neutral fat) is formed from phosphatidic acid in a reaction catalyzed by a phosphatase that results in loss of the phosphate group [84]; the diglyceride thus formed can

then accept a third molecule of fatty acyl coenzyme A (represented as  $\text{R}''\text{CS-CoA}$  in [84a]).

In the biosynthesis of phospholipids, however, phosphatidic acid is not hydrolyzed; rather, it acts as the R-(P) in reaction [77], the NTP here being cytidine triphosphate (CTP). A CDP-diglyceride is produced, and inorganic pyrophosphate is released [77b]. CDP-diglyceride is the common precursor of a variety of phospholipids. In subsequent reactions, each catalyzed by a specific enzyme, CMP is displaced from CDP-diglyceride by one of three compounds—serine, inositol, or  $\alpha$ -glycerol phosphate—to form CMP and, respectively, phosphatidylserine [85a], phosphatidylinositol [85b], or, in [85c], 3-phosphatidylglycerol-1'-phosphate (PGP). These reactions differ from

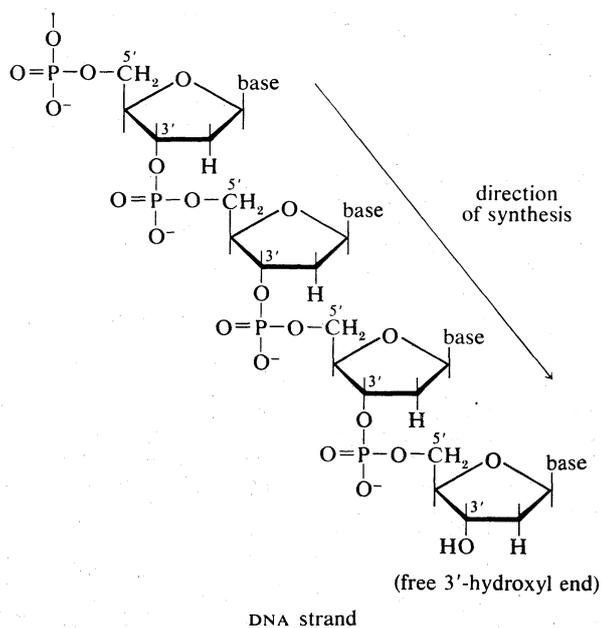

those of polysaccharide biosynthesis ([79], [82]) in that phosphate is retained in the phospholipid, and the nucleotide product (CMP) is therefore a nucleoside monophosphate rather than the diphosphate. These compounds can react further: phosphatidylserine to give, sequentially, phosphatidylethanolamine and phosphatidylcholine; phosphatidylinositol to yield mono- and diphosphate derivatives that are components of brain tissue and of mitochondrial membranes; and PGP to yield the phosphatidylglycerol abundant in many bacterial membranes and the diphosphatidylglycerol that is also a major component of mitochondrial and bacterial membranes.

**Nucleic acids and proteins.** As with the synthesis of polysaccharides and lipids, the formation of the nucleic acids and proteins from their building blocks requires the input of energy. Nucleic acids are formed from nucleoside triphosphates, with concomitant elimination of inorganic pyrophosphate, which is subsequently hydrolyzed via reaction [21a]. Amino acids also are activated, forming, at the expense of ATP, aminoacyl-complexes. This

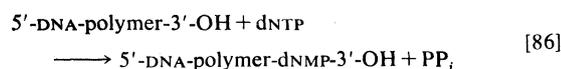

Biosynthesis of phospholipids

activation process is also accompanied by loss of inorganic pyrophosphate. But, although these biochemical processes are basically similar to those involved in the biosynthesis of other macromolecules, their occurrence is specifically subservient to the genetic information in DNA. DNA contains within its structure the blueprint both for its own exact duplication and for the synthesis of a number of types of RNA, among which is a class termed messenger RNA (mRNA). A complementary relationship exists between the sequence of purines (*i.e.*, adenine and guanine) and pyrimidines (cytosine and thymine) in the DNA comprising a gene and the sequence in mRNA into which this genetic information is transcribed. This information is then translated into the sequence of amino acids in a protein, a process that involves the functioning of a variety of other classes of ribonucleic acids (see GENE).

**Synthesis of DNA.** The maintenance of genetic integrity demands not only that enzymes exist for the synthesis of DNA but that they function so as to ensure the replication of the genetic information (encoded in the DNA to be copied) with absolute fidelity. This implies that the assembly of new regions of a DNA molecule must occur on a template of DNA already present in the cell. The synthetic processes must also be capable of repairing limited regions of DNA, which may have been damaged, for example, as a consequence of exposure to ultraviolet irradiation. The physical structure of DNA is ideally adapted to its biological roles. Two strands of nucleotides are wound around each other in the form of a double helix. The helix is stabilized by hydrogen bonds that occur between the purine and pyrimidine bases of the strands. Thus, the adenine of one strand pairs with the thymine of the other, and the guanine of one strand with the cytosine of the other. The base pairs may be visualized as the treads of a spiral staircase, in which the two chains of repeating units (*i.e.*, ribose-phosphate-ribose) form the sides.

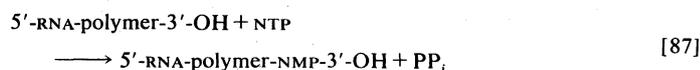

During the biosynthesis of DNA, the two strands unwind, and each serves as a template for the synthesis of a new, complementary strand, in which the bases pair in exactly the same manner as occurred in the parent double helix. The process is catalyzed by a DNA polymerase enzyme, which catalyzes the addition of the appropriate deoxyribonucleoside triphosphate (NTP in [86]) onto one end (specifically, the free 3'-hydroxyl end (—OH) of the growing DNA chain (see diagram of DNA strand). In [86] the addition of a deoxyribonucleoside monophosphate (dNMP) moiety onto a growing DNA chain (5'-DNA-poly-

mer-3'-OH) is shown; the other product is inorganic pyrophosphate. The specific nucleotide inserted in the growing chain is dictated by the base in the complementary (template) strand of DNA with which it pairs. The functioning of DNA polymerase thus requires the presence of all four deoxyribonucleoside triphosphates (*i.e.*, dATP, dTTP, dGTP, and dCTP) as well as preformed DNA to act as a template. Although a number of DNA polymerase enzymes have been purified from different organisms, it is not yet certain whether those that have been most extensively studied are necessarily involved in the formation of new DNA molecules, or whether they are primarily concerned with the repair of damaged regions of molecules. A polynucleotide ligase that effects the formation of the phosphate bond between adjacent sugar molecules is concerned with the repair function but may also have a role in synthesis.

**Synthesis of RNA.** Various types of RNA are found in living organisms: messenger RNA (mRNA) is involved in the immediate transcription of regions of DNA; transfer RNA (tRNA) is concerned with the incorporation of amino acids into proteins; and structural RNA is found in the ribosomes that form the protein-synthesizing machinery of the cell. In cells of organisms with well-defined nuclei (*i.e.*, eucaryotes), a heterogeneous RNA fraction of unknown function is constantly broken down and resynthesized in the nucleus of the cell but does not leave it. The different types of RNA are synthesized via RNA polymerases [87], the action of which is analogous to

that of the DNA polymerases that catalyze reaction [86]. In [87] the growing RNA chain is represented by 5'-RNA-polymer-3'-OH, and the ribonucleoside triphosphate by NTP. One product (5'-RNA-polymer-NMP-3'-OH) reflects the incorporation of ribonucleoside monophosphate; the other product is, as in [86], inorganic pyrophosphate. Synthesis of RNA requires DNA as a template, thus ensuring that the base composition of the RNA faithfully reflects that of the DNA; in addition, as in DNA synthesis, all four nucleoside triphosphates must be present. The major differences between reactions [86] and [87] are that, in the latter, the nucleotides contain ribose instead of deoxyribose, and that, in RNA, uracil replaces the thymine of DNA.

It appears that, although only one strand of the DNA double helix serves as template during the formation of RNA, some regions are transcribed from one strand, some from the other.

An important constraint on RNA synthesis is that the accurate copying of the appropriate DNA strand by RNA polymerase must start at the beginning of a gene—and not somewhere along it—and must stop as soon as the genetic information has been transcribed. The way in which this selectivity is achieved is not yet fully understood, although it has been established that *E. coli* contains a protein, the sigma factor, that is not required for the incorporation of the nucleoside triphosphates into the growing RNA chain but apparently is essential for binding RNA polymerase to the proper DNA sites to initiate RNA synthesis. After the initiation step, the sigma factor is released; the role of the sigma factor in transcription suggests that the DNA at the initiation sites must be unique in some way so as to ensure that the correct strand is used as the template. Evidence indicates further that other protein factors are involved in the termination of transcription.

**Synthesis of proteins.** Approximately 120 macromolecules are involved directly or indirectly in the process of the translation of the base sequence of a messenger RNA molecule into the amino acid sequence of a protein. The relationship between the base sequence and the amino acid sequence constitutes the genetic code. The basic properties of the code are: it is triplet—*i.e.*, a linear sequence of three bases in mRNA specifies one amino acid in a protein; it is non-overlapping—*i.e.*, each triplet is discrete and does not overlap either neighbour; it is de-

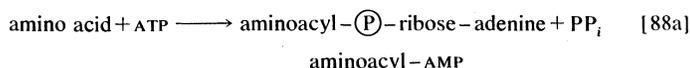

The varieties of RNA

generate—*i.e.*, many of the 20 amino acids are specified by more than one of the 64 possible triplets of bases; and it appears to apply universally to all living organisms.

The main sequence of events associated with the expression of this genetic code, as elucidated for *E. coli*, may be summarized as follows (see also GENE).

1. Messenger RNA binds to the smaller of two subunits of large particles termed ribosomes.

2. The amino acid that begins the assembly of the protein chain is activated and transferred to a specific transfer RNA (tRNA); the activation step, catalyzed by an aminoacyl-tRNA synthetase specific for a particular amino acid, effects the formation of an aminoacyl-AMP complex [88a] in a manner somewhat analogous to reaction [77]; ATP is required, and inorganic pyrophosphate is a product. The aminoacyl-AMP, which remains bound to the enzyme, is transferred to a specific molecule of tRNA in a reaction catalyzed by the same enzyme. AMP is released, and the other product is called aminoacyl-tRNA [88b]. In

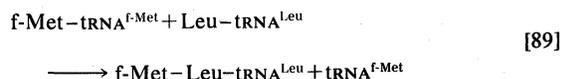

*E. coli*, the amino acid that begins the assembly of the protein is always a formylmethionine (f-Met). There is no evidence that f-Met is involved in protein synthesis in eucaryotic cells.

3. Aminoacyl-tRNA binds to the mRNA-ribosomal complex in a reaction in which energy is provided by the hydrolysis of GTP to GDP and inorganic phosphate. In this step and in 5 below, the genetic code is translated. All of the different tRNA's contain triplets of bases that pair specifically with the complementary base triplets in mRNA; the base triplets in mRNA specify the amino acids to be added to the protein chain. During or shortly after the pairing occurs the aminoacyl-tRNA moves from the aminoacyl-acceptor (A) site on the ribosome to another site, called a peptidyl-donor (P) site.

4. The larger subunit of the ribosome then joins the mRNA-f-Met-tRNA-smaller ribosomal subunit complex.

5. The second amino acid to be added to the protein chain is specified by the triplet of bases adjacent to the initiator triplet in mRNA. The amino acid is activated and transferred to its tRNA by a repetition of reactions [88a] and [88b]. This newly formed aminoacyl-tRNA now binds to the A site of the mRNA-ribosome complex, with concomitant hydrolysis of GTP.

6. The enzyme peptidyl transferase, which is part of the larger of the two ribosomal subunits, catalyzes the transfer of formylmethionine from the tRNA to which it is attached (designated tRNA<sup>f-Met</sup>) to the second amino acid; for example, if the second amino acid were leucine, step 5 would have achieved the binding of leucyl-tRNA (Leu-tRNA<sup>Leu</sup>) next to f-Met-tRNA<sup>f-Met</sup> on the ribosome-mRNA complex. Step 6 catalyzes the transfer reaction that is shown in [89], in which tRNA<sup>f-Met</sup> is released from formylmethionine (f-Met), and Leu-tRNA<sup>Leu</sup> is bound to formylmethionine.

7. In the next step three results are achieved. The dipeptide f-Met-Leu (a dipeptide consists of two amino acids) moves from the A (aminoacyl-acceptor) site to the P (peptidyl-donor) site on the ribosome; the tRNA<sup>f-Met</sup> is thereby displaced from the P site, and the ribosome moves the length of one triplet (three bases) along the mRNA molecule. The occurrence of these events is accompanied by the hydrolysis of a second molecule of GTP and leaves the system ready to receive the next aminoacyl-tRNA (by repetition of step 5). The cycle of events in 5, 6, and 7 is repeated until the ribosome moves to a triplet on the mRNA that does not specify an amino acid but provides the signal for termination of the amino acid chain. Triplets of this type are represented by one uracil (U)

preceding, and adjacent to, two adenines (UAA) or preceding one adenine and one guanosine in either order (UGA, or UAG).

8. At the termination of synthesis the completed protein is released from the tRNA to which it had remained linked. Two further events then occur in *E. coli*. First, the formyl constituent of the f-methionyl moiety is hydrolyzed by the catalytic action of a formylase, producing a protein with methionine at the end. If the required protein does not contain methionine in this position (and the majority of proteins in *E. coli* appear to), the methionine and possibly other amino acids that follow it are removed by enzymatic reactions. Second, the ribosome-mRNA complex dissociates, and the ribosomal subunits become available for a new round of translation by binding another mRNA molecule, step 1.

For the sake of brevity, other ancillary protein factors that participate in this sequence 1 to 8 have been omitted; the role of many of these factors is as yet poorly understood.

## V. Regulation of metabolism

### FINE CONTROL

As has been pointed out, the numerous metabolic pathways that function in a cell do not do so in a random and uncontrolled manner. The flux of nutrients along each pathway is governed chiefly by two factors: (1) the availability of substrates on which pacemaker, or key, enzymes of the pathway can act and (2) the intracellular levels of specific metabolites that affect the reaction rates of pacemaker enzymes. Key enzymes are usually rather complex proteins that, in addition to the site at which the catalytic process occurs (*i.e.*, the active site), contain sites to which the regulatory metabolites bind. Interactions with the appropriate molecules at these regulatory sites cause changes in the shape of the enzyme molecule. Such changes may either facilitate or hinder the changes that occur at the active site. The rate of the enzymatic reaction is thus speeded up or slowed down by the presence of a regulatory metabolite.

In many cases, the specific small molecules that bind to the regulatory sites have no obvious structural similarity to the substrates of the enzymes; these small molecules are therefore termed allosteric effectors, and the regulatory sites are termed allosteric sites (see ENZYME). Allosteric effectors may be formed by enzyme-catalyzed reactions in the same pathway in which the enzyme regulated by the effectors functions. In this case, a rise in the level of the allosteric effector would affect the flux of nutrients along that pathway in a manner analogous to the feedback phenomena of homeostatic processes. Such effectors may also be formed by enzymatic reactions in apparently unrelated pathways. In this instance, the rate at which one metabolic pathway operates would be profoundly affected by the rate of nutrient flux along another. It is this situation that, to a large extent, governs the sensitive and immediately responsive coordination of the many metabolic routes in the cell.

**End-product inhibition.** A biosynthetic pathway is usually controlled by an allosteric effector produced as the end product of that pathway, and the pacemaker enzyme on which the effector acts usually catalyzes the first step that uniquely leads to the end product. This phenomenon, called end-product inhibition, is illustrated by the multi-enzyme, branched pathway for the formation from oxaloacetate of the "aspartate family" of amino acids (Figure 10). The system of interlocking controls, described in greater detail in Figure 12, has been elucidated largely through studies with *E. coli*. As mentioned previously in this article, only plants and micro-organisms can synthesize many of these amino acids, many animals requiring such amino acids to be supplied preformed in their diet.

Figure 12 shows that there are a number of pacemaker enzymes in the biosynthetic route for the aspartate family of amino acids. Most of the pacemaker enzymes are uniquely involved in the formation of one product. Each of the enzymes functions after a branch point in the pathway, and all are inhibited specifically by the end

product that emerges from the branch point. It is not difficult to visualize from Figure 12 how the supplies of lysine, methionine, and isoleucine required by a cell can

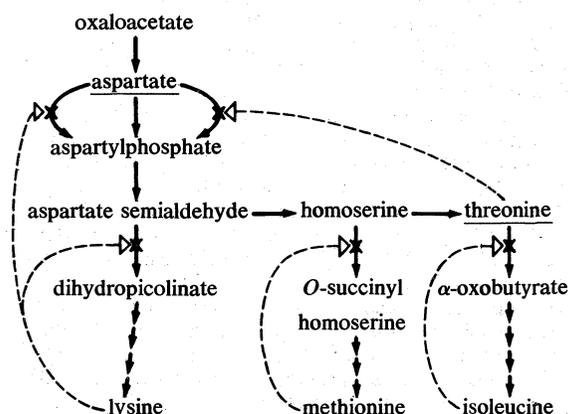

Figure 12: "Fine control" of the enzymes of the aspartate family in *E. coli* (see text).

be independently regulated. Threonine, however, is both an amino acid essential for protein synthesis and a precursor of isoleucine. If the rate of synthesis of threonine from aspartate were regulated as are the rates of lysine, methionine, and isoleucine, there would be a risk of imbalance in the supply of isoleucine. This risk is overcome in *E. coli* by the existence of three different aspartokinase enzymes, all of which catalyze the first step common to the production of all the products derived from aspartate. Each has a different regulatory effector molecule. Thus, one type of aspartokinase is inhibited by lysine, a second by threonine. The third kinase is not inhibited by any naturally occurring amino acid, but its rate of synthesis (see next section) is controlled by the concentration of methionine within the cell. The triple control mechanism resulting from the three different aspartokinases ensures that the accumulation of one amino acid does not shut off the supply of aspartyl phosphate necessary for the synthesis of the others.

Another example of control through end-product inhibition also illustrates the manner in which the operation of two biosynthetic pathways may be coordinated. It will be recalled (see above *Nucleic acids and proteins*) that both DNA and the various types of RNA are assembled from purine and pyrimidine nucleotides; these in turn are built up from intermediates of central metabolic pathways (see above *Mononucleotides*). The first step in the synthesis of pyrimidine nucleotides is that catalyzed by aspartate transcarbamylase [70a]. This step initiates a sequence of reactions that leads ultimately to the formation of pyrimidine nucleotides such as UTP and CTP [74]. Studies with highly purified preparations of aspartate transcarbamylase have revealed that the affinity of this enzyme for its substrate (aspartate) is markedly decreased by the presence of CTP. This effect can be overcome by the addition of ATP, a purine nucleotide. The enzyme can be dissociated into two subunits. One subunit contains the enzymatic activity and (in the dissociated form) does not bind CTP. The other binds CTP but has no catalytic activity. Apart from providing physical evidence that pacemaker enzymes contain distinct catalytic and regulatory sites, the interaction of aspartate transcarbamylase with the different nucleotides provides an explanation for the control of the supply of nucleic acid precursors. If a cell contains sufficient pyrimidine nucleotides (e.g., UTP), aspartate transcarbamylase, the first enzyme of pyrimidine biosynthesis, is inhibited. If, however, the cell contains high levels of purine nucleotides (e.g., ATP), as required for the formation of nucleic acids, the inhibition of aspartate transcarbamylase is relieved, and pyrimidines are formed.

**Positive modulation.** Not all pacemaker enzymes are controlled by inhibition of their activity. Instead, some are subject to positive modulation—i.e., the effector is required for the efficient functioning of the enzyme. Such

enzymes exhibit little activity in the absence of the appropriate allosteric effector. One instance of positive modulation is the anaplerotic fixation of carbon dioxide onto pyruvate and phosphoenolpyruvate (PEP); this example also illustrates how a metabolic product of one route controls the rate of nutrient flow of another (see Figure 9).

The carboxylation of pyruvate in higher organisms [49] and the carboxylation of phosphoenolpyruvate in gut bacteria [50] occurs at a significant rate only if acetyl coenzyme A is present. Acetyl coenzyme A acts as a positive allosteric effector and is not broken down in the course of the reaction. Moreover, some pyruvate carboxylases [49] and the PEP carboxylase of gut bacteria are inhibited by four-carbon compounds (e.g., aspartate). These substances inhibit because they interfere with the binding of the positive effector, acetyl coenzyme A. Such enzymatic controls are reasonable in a physiological sense: it will be recalled that anaplerotic formation of oxaloacetate from pyruvate or PEP is required to provide the acceptor for the entry of acetyl coenzyme A into the TCA cycle. The reaction need occur only if acetyl coenzyme A is present in sufficient amounts. On the other hand, an abundance of four-carbon intermediates obviates the necessity for forming more through carboxylation reactions such as [49] and [50].

Similar reasoning, though in the opposite sense, can be applied to the control of another anaplerotic sequence, the glyoxylate cycle (Figure 8). The biosynthesis of cell materials from the two-carbon compound acetate is, in principle, akin to biosynthesis from TCA cycle intermediates. In both processes, it is the availability of intermediates such as PEP and pyruvate that determines the rate at which a cell forms the many components produced through gluconeogenesis. Although in the strictest sense the glyoxylate cycle has no defined end product, PEP and pyruvate are, for these physiological reasons, best fitted to regulate the rate at which the glyoxylate cycle is required to operate. It is thus not unexpected that the pacemaker enzyme of the glyoxylate cycle, isocitrate lyase (reaction [52]), is allosterically inhibited by PEP and by pyruvate.

**Energy state of the cell.** It is characteristic of catabolic routes that they do not lead to uniquely identifiable end products. The major products of glycolysis and the TCA cycle, for example, are carbon dioxide and water. Within the cell, the concentrations of both are unlikely to vary sufficiently to allow them to serve as effective regulatory metabolites. The processes by which water is produced (Figure 7) initially involve, however, the reduction of coenzymes, the reoxidation of which is accompanied by the synthesis of ATP from ADP. Moreover, as described in previous sections, the utilization of ATP in energy-consuming reactions yields ADP and AMP. At any given moment, therefore, a living cell contains ATP, ADP, and AMP; the relative proportion of the three nucleotides provides an index of the energy state of the cell. It is thus reasonable that the flux of nutrients through catabolic routes is, in general, impeded by high intracellular levels of both reduced coenzymes (e.g., FADH<sub>2</sub>, reduced NAD<sup>+</sup>) and ATP, and that these inhibitory effects are often overcome by AMP.

The control exerted by the levels of ATP, ADP, and AMP within the cell is illustrated by the regulatory mechanisms of glycolysis and the TCA cycle (Figure 9); these nucleotides also serve to govern the occurrence of the opposite pathway, gluconeogenesis, and to avoid mutual interference of the catabolic and anabolic sequences. Although not all of the controls mentioned below have been found to operate in all living organisms examined, it has been observed that, in general:

1. Glucose-6-phosphate stimulates glycogen synthesis from glucose-1-phosphate [79] and inhibits both glycogen breakdown [16] and its own formation from glucose [1].
2. Phosphofructokinase, the most important pacemaker enzyme of glycolysis [3], is inhibited by high levels of its own substrates (fructose-6-phosphate and ATP); this inhibition is overcome by AMP. In tissues, such as heart muscle, which use fatty acids as a major fuel, inhibition of

Regulation of the activity of aspartate transcarbamylase

glycolysis by citrate may be physiologically the more important means of control. Control by citrate, the first intermediate of the TCA cycle, which produces the bulk of the cellular ATP, is thus the same, in principle, as control through ATP.

3. Fructose-1,6-diphosphatase [59], which catalyzes the reaction opposite to phosphofructokinase, is strongly inhibited by AMP.

4. Rapid catabolism of carbohydrate requires the efficient conversion of PEP to pyruvate. In liver and in some bacteria, the activity of the pyruvate kinase that catalyzes this process [10] is greatly stimulated by the presence of fructose-1,6-diphosphate, which thus acts as a potentiator of a reaction required for its ultimate catabolism.

5. The oxidation of pyruvate to acetyl coenzyme A [37] is inhibited by acetyl coenzyme A. Because acetyl coenzyme A also acts as a positive modulator of pyruvate carboxylation [49], this control reinforces the partition between pyruvate catabolism and its conversion to four-carbon intermediates for anaplerosis and gluconeogenesis.

6. Citrate synthase [38], the first enzyme of the TCA cycle, is inhibited by ATP in higher organisms and by reduced NAD<sup>+</sup> in many micro-organisms. In some strictly aerobic bacteria, the inhibition by reduced NAD<sup>+</sup> is overcome by AMP.

7. Citrate acts as a positive effector for the first enzyme of fatty acid biosynthesis [62]. A high level of citrate, which also indicates a sufficient energy supply, thus inhibits carbohydrate fragmentation (see [2]) and diverts the carbohydrate that has been fragmented from combustion to the formation of lipids.

8. Some forms of isocitrate dehydrogenase [40] are maximally active only in the presence of ADP or AMP and are inhibited by ATP. Again, the energy state of the cell serves as the signal regulating an enzyme involved in energy transduction.

#### COARSE CONTROL

Although fine control mechanisms allow the sensitive adjustment of the flux of nutrients along metabolic pathways relative to the needs of cells under relatively constant environmental conditions, these processes may not be adequate to cope with severe changes in the chemical milieu.

Such severe changes may arise in higher organisms with a change in diet or when, in response to other stimuli, the hormonal balance is altered (see HORMONE). In starvation, for example, the overriding need to maintain blood glucose levels may require the liver to synthesize glucose from noncarbohydrate products of tissue breakdown at rates greater than can be achieved by the enzymes normally present in the liver. Under such circumstances, cellular concentrations of key enzymes of gluconeogenesis, such as pyruvate carboxylase [49] and PEP-carboxykinase [54], may rise by as much as 10-fold, while the concentration of glucokinase [1] and of the enzymes of fatty acid synthesis decreases to a similar extent. Conversely, high carbohydrate diets and administration of the hormone insulin to diabetic animals elicit a preferential synthesis of glucokinase [1] and pyruvate kinase [10]. These changes in the relative proportions and absolute amounts of key enzymes are the net result of increases in the rate of their synthesis and decreases in the rate of their destruction. Although such changes reflect changes in the rates of either transcription, translation, or both of specific regions of the genome, the mechanisms by which the changes are effected have not yet been clarified.

Micro-organisms sometimes encounter changes in environment much more severe than those encountered by the cells of tissues and organs, and their responses are correspondingly greater. Mention has already been made of the ability of *E. coli* to form  $\beta$ -galactosidase when transferred to a medium containing lactose as the sole carbon source (see *Integration of catabolism and anabolism*); such a transfer may result in an increase of 1,000-fold or more in the cellular concentration of the enzyme.

Because this preferential enzyme synthesis is elicited by exposure of the cells to lactose, or to nonmetabolizable but chemically similar analogues, and because synthesis ceases as soon as the eliciting agents (inducers) are removed,  $\beta$ -galactosidase is termed an inducible enzyme. It has been established that a regulator gene exists that specifies the amino acid sequence of a so-called repressor protein, and that the repressor protein binds to a unique portion of the region of DNA concerned with  $\beta$ -galactosidase formation. Under these circumstances, the DNA is not transcribed to mRNA, and virtually no enzyme is made. The repressor, however, is an allosteric protein and readily combines with inducers. Such a combination prevents the repressor from binding to DNA and allows transcription and translation of  $\beta$ -galactosidase to proceed.

Although this mechanism for the specific control of gene activity may not apply to the regulation of all inducible enzymes—for example, those concerned with the utilization of the sugar arabinose—and is not universally applicable to all coarse control processes in all micro-organisms, it can explain the manner in which the presence in growth media of at least some cell components represses (*i.e.*, inhibits the synthesis of) enzymes normally involved in the formation of such components by gut bacteria such as *E. coli*. Although, for example, the bacteria must obviously make amino acids from ammonia if that is the sole source of nitrogen available to them, it would not be necessary for the bacteria to synthesize enzymes required for the formation of amino acids supplied preformed in the medium. Thus, of the three aspartokinases formed by *E. coli* (Figure 12), two are repressed by their end products, methionine and lysine. On the other hand, the third aspartokinase, which (as described above) is inhibited by threonine, is repressed by threonine only if isoleucine is also present. This example of so-called multivalent repression is of obvious physiological utility. It is likely that the amino acids that thus specifically inhibit the synthesis of aspartokinases do so by combining with specific protein repressor molecules; however, whereas the combination of the inducer with the repressor of  $\beta$ -galactosidase inactivates the repressor protein and hence permits synthesis of the enzyme, the repressor proteins for biosynthetic enzymes would not bind to DNA unless they were also combined with the appropriate amino acid. Aspartokinase synthesis would thus occur in the absence of the end-product effectors and not in their presence.

This explanation applies also to the coarse control of the anaplerotic glyoxylate cycle (Figure 8). The synthesis of both of the enzymes unique to that cycle, isocitrate lyase [52] and malate synthase [53], is controlled by a regulator gene that presumably specifies a repressor protein unable to bind to DNA unless combined with pyruvate or PEP. Cells growing on acetate do not contain high levels of these intermediates because they are continuously being removed for biosynthesis. The enzymes of the glyoxylate cycle are therefore formed at high rates. If pyruvate or substances catabolized to PEP or pyruvate are added to the medium, however, further synthesis of the two enzymes is speedily repressed.

## Metabolism, Diseases of

Metabolism may be viewed as the combined action of the various processes in the body that provide it with the necessary substances and energy to enable the individual organism to maintain, grow, and reproduce itself. Many disturbances of normal metabolism are caused by nutritional deficiencies, by endocrine disease, or by diseases of the liver and kidney. These types of disorders will be only touched upon in this article, since they are discussed extensively elsewhere; the present article will focus primarily on disorders caused by genetic factors that block or alter the normal pathways of metabolism; these disorders often have been called the "inborn errors of metabolism."

### THE CAUSES OF METABOLIC DISEASES

**Nutritional deficiencies.** The metabolic disturbances caused by nutritional deficiencies arise either from deficiencies of calories and protein or from deficiencies of essential vitamins, minerals, or fatty acids (see MALNUTRITION and NUTRITIONAL DISEASES AND DISORDERS). In underdeveloped countries there may be insufficient food to eat, and young children may suffer from malnutrition, particularly in the periods immediately after weaning from the mother and when growth is most rapid. Undernutrition may take one of two forms: (1) There may be inadequate intake of both calories and protein in roughly equal proportions. In such situations the infant develops marasmus, a disease in which there is lack of normal weight gain without any other clear evidence of disease. Such infants are highly susceptible to infections and may be subject to diarrhea and dehydration; many die in the first two or three years of life. (2) In other situations, there may be an adequate intake of calories but a markedly deficient intake of protein. Such children develop kwashiorkor, which is characterized by a low protein concentration in the blood, swelling of the face, hands, and feet, and a change of skin and hair colour so that normally dark-haired children often have hair that has a red or gray colour. In this much more serious form of protein malnutrition there is urgent need of treatment with amino acids (the "building blocks" of protein) to ensure survival and recovery. Malnutrition due to deficiencies of calories and protein is less often seen in the United States and western Europe than in countries less developed economically. When it occurs, it is usually caused by maternal deprivation or by congenital malformations within the infant's intestinal tract that prevent the nutrients from being properly absorbed.

Vitamins are organic compounds required in minute amounts to catalyze the cellular metabolism that is essential for growth of the organism, and if vitamins are lacking the body develops structural or functional defects. If the deficiency is of vitamin A, excessive sensitivity to light and a thickening of the mucous membranes result; if of vitamin B<sub>1</sub>, beriberi develops, a disease with many possible effects including degenerative changes in the nerves and the heart. A lack of vitamin B<sub>2</sub> brings visual disturbances. Vitamin B<sub>6</sub> deficiency causes irritability and convulsions. Vitamin B<sub>12</sub> deficiency in young infants causes megaloblastic anemia, so called because of the presence in the blood of megaloblasts, large red cells with nuclei. Lack of vitamin C causes scurvy; of D, rickets; and of K, bleeding in the newborn.

In the same way, certain minerals appear to be important for maintaining the proper balance in the body. A deficiency of sodium, for example, causes nausea, diarrhea, muscle cramps, and dehydration, and an excess of potassium causes heart block—a lack of coordination between the upper and the lower chambers of the heart. Although most disturbances of vitamin and mineral metabolism are caused by diet and environmental factors, several have been shown to be of genetic importance; these will be discussed in later sections.

**Diseases of the endocrine system, the liver, and the kidneys.** The metabolic disturbances caused by endocrine disease may generally be viewed as an excess or a deficiency of one of the hormones secreted by an endocrine (ductless) gland. The main endocrine organs that can

cause metabolic disturbances are the anterior and posterior portions of the pituitary, the thyroid, the adrenal cortex and adrenal medulla (the outer and inner substances, respectively, of the adrenal gland), the parathyroid, the testis, and the ovary. Genetically determined disturbances of the thyroid and the adrenal cortex are discussed in ENDOCRINE SYSTEM DISEASES AND DISORDERS.

The metabolic disturbances caused by liver disease are numerous. The disturbances most often seen are caused by (1) inflammations of the liver, most often caused by a virus; (2) cirrhosis or scarring of the liver, seen in persons poisoned by fumes of certain insecticides and other chlorinated hydrocarbons, and frequently seen in chronic alcoholics, who suffer not only from the toxic effects of alcohol upon the liver but also from inadequate food intake and the resultant protein malnutrition; and (3) gallbladder disease, which is usually caused by a slowing down of the flow of bile into the common bile duct and into the intestine, which permits formation of gallstones (see LIVER, HUMAN). One or two enzyme defects involving the liver have been described; these will be discussed later in this article.

The main metabolic disturbances caused by kidney diseases are due to (1) glomerulonephritis, which is an inflammation of the kidney tissues; (2) malformations of the kidney, ureters, and bladder, which may cause obstruction to the normal flow of urine and lead to severe destruction of kidney tissue; and (3) disturbances of transport mechanisms across the kidney tubular membranes. Many of the latter are genetically determined and run in families. These also will be discussed elsewhere in this article (see EXCRETORY SYSTEM DISEASES).

**Inborn errors of metabolism.** *Historical background.* During the early days of the present century, most scientists thought of genetics in purely mechanistic terms. Genes were thought to be small particles strung like beads on a chromosome, and each gene was considered to be responsible for determining a specific trait such as eye colour or skin pigment or whether one has an extra set of fingers or toes. At about the same time, however, physiologists and biochemists were beginning to show that atoms and molecules in living things appear to be identical in every way to the ones found in nonliving things and, furthermore, that these atoms and molecules obey the same physical and chemical laws and operate without the intervention of outside energy.

In 1908 the British physician Sir Archibald Garrod developed a hypothesis about metabolic diseases of a hereditary nature. He said that, in certain conditions, the biochemical abnormality is clearly visible. For example, in albinism, the affected person lacks pigment in the eyes and skin; in alkaptonuria, the urine turns dark upon standing; in cystinuria, the affected person passes cystine stones in the urine; and in pentosuria there is a reducing substance (a substance that removes oxygen from other substances) in the urine. That year, in lectures that he gave before the Royal College of Physicians, he pointed out the main features of these hereditary metabolic disorders: (1) the onset of the particular abnormality can be dated to the first days or weeks of life; (2) the condition tends to be familial and occurs more frequently among the offspring of cousin marriages; and (3) the disorders are relatively benign and compatible with a normal life expectancy. He proposed that the abnormalities are caused by genetically determined blocks in the normal pathway of metabolism. For example, if compound A is converted by a successive series of steps to compounds B, C, and D, and each step in the conversion requires a separate enzyme system, and if one of the enzymes proves to be inactive, there will be an accumulation of the compound immediately preceding and a deficiency of the compound immediately following the block. These abnormalities will be clearly visible and will call attention to the defect. Hence Garrod named the conditions "inborn errors of metabolism."

Much of this was, by necessity, supposition; but, in the meantime, work being carried on with lower forms of life gave substance to the concept that genes operate by chemical means. In the 1930s the geneticist George Bea-

Kidney diseases interfering with metabolism

Visible signs of inborn metabolic defects

Effects of sodium and potassium lack

dle and the biochemist Edward Tatum provided evidence that each enzymatic step is controlled by a single gene. For these studies, they used the mold *Neurospora crassa*, which normally will grow in simple media of inorganic salts, glucose, and biotin, a growth vitamin. Mutant forms of *Neurospora* cannot grow on the simple media and require supplementation with specific amino acids and vitamins before they will grow. Beadle and Tatum irradiated asexual spores and tested them on unsupplemented medium. In this experiment, the 299th spore tested gave a mutant strain that would grow only when vitamin B<sub>6</sub> was added to the medium, and the 1,090th spore gave a strain requiring vitamin B<sub>1</sub>. This meant that a specific gene was required to determine the requirement for vitamin B<sub>6</sub> and another one for vitamin B<sub>1</sub> and provided direct confirmation in a simple organism of Garrod's concept that enzymatic blocks are responsible for genetically determined metabolic diseases.

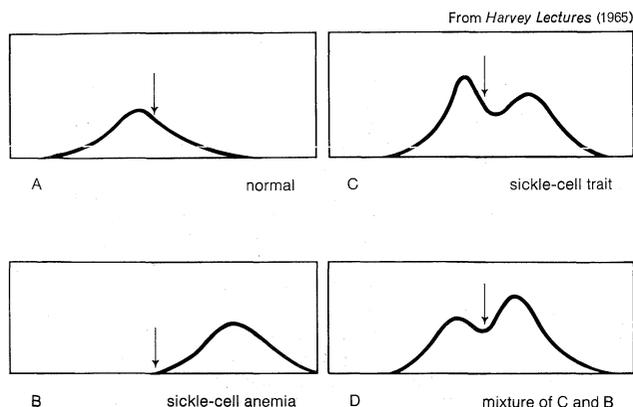

Figure 1: Electrophoretic patterns of normal and sickle-cell hemoglobins. The single peaks (A and B) correspond to an electrophoretically homogeneous material, whereas the heterozygote (C) carries a mixture of normal adult and sickle-cell hemoglobin.

Defective enzymes cause of metabolic disease

Perhaps the most important discovery was made in 1949, when the chemist Linus Pauling and his colleagues showed that the blood of a person with sickle-cell anemia has a speed of movement when separated by means of electrophoresis (see below) that is different from that of the blood of a normal individual. Sickle-cell anemia is a genetically determined disease in which the red blood cells assume a crescent shape when the oxygen pressure in the environment of the cells is lowered. The disease afflicts about one in every 350 American Negroes and is seen more frequently among the Bantus in Africa. As shown in Figure 1, if one takes a drop of blood and places it on either filter paper or starch gel and runs an electric current through the medium for several hours (a process called electrophoresis), the hemoglobin from a normal person runs to the left of the point of origin (Figure 1a), while that of a person with sickle-cell anemia runs to the right (Figure 1b). If one takes blood from a carrier of the trait who has both normal and sickle-cell hemoglobin, two peaks develop (Figure 1c), and the same effect would be achieved if the blood from a normal person were mixed in a test tube with that of a person with sickle-cell anemia (Figure 1d). A difference in the rate of migration with electrophoresis indicated that the hemoglobin molecule in the two instances has a different charge. This meant that there was a difference in the amino-acid composition of the hemoglobin molecule.

Subsequently the biochemist Vernon Ingram demonstrated, by breaking down the hemoglobin molecule and separating it into 28 peptides, each consisting, on the average, of 9 to 11 amino acids, that sickle-cell anemia differs from normal hemoglobin by the substitution of one amino acid, valine, for another, glutamic acid, in one particular position in one of the 28 peptides.

From this, and from a number of basic discoveries and theoretical developments that were occurring at this time, including the development of the double helix model for deoxyribonucleic acid (DNA), the description of the

mechanism for protein synthesis, and the breaking of the genetic code, came the current concepts of sickle-cell anemia: that it results ultimately from a miscoding of a single base pair of subunits in the DNA molecule; that the miscoding affects ribonucleic acid (RNA), which in turn calls for valine instead of glutamic acid at one point in one peptide of the hemoglobin molecule.

*Galactosemia as an example.* Nearly 200 human diseases can properly be classified as fitting Garrod's definition of an "inborn error of metabolism." In each condition, the physician must be able to describe: (1) the clinical signs and symptoms in the patient; (2) the nature of the biochemical defect; (3) the mode of inheritance of the abnormality, including the ability to detect the carriers of the trait within the family; (4) the proper laboratory tests to establish the correct diagnosis; and (5) the approaches and results of clinical treatment. This can be shown by a typical "inborn error of metabolism" such as galactosemia, which is a hereditary disease characterized by a congenital inability to convert galactose to glucose.

Infants with this condition appear to be normal at birth but, after a few days of milk feeding, they begin to vomit, become lethargic, fail to gain weight, and show enlargement of the liver. There may be swelling of the abdomen and of the face, hands, and feet because of the accumulation of fluid, and, in severe cases, death occurs from malnutrition and wasting. Infants who survive are usually malnourished and dwarfed at two or three months of age, and mental retardation and cataracts in the eyes may be noted. Others affected by the disorder may develop permanent liver damage months or years after the acute phase of the disease. The signs and symptoms regress after milk and milk products are omitted from the diet. If one tests the urine, there is constantly present a sugar that turns out to be galactose, not glucose.

The main steps in the breakdown of galactose to glucose in the body involve four separate steps as shown in Figure 2. Each step is catalyzed by a specific enzyme, which is given in capital letters. In galactosemia, the children lack galactose-1-phosphate uridylyl transferase, the enzyme involved in the second step of the reaction. When this oc-

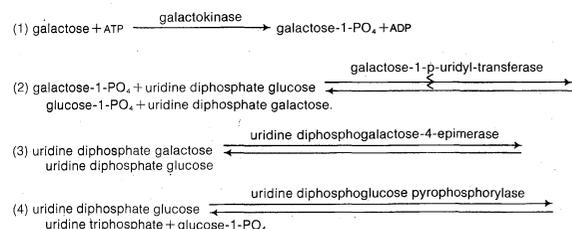

Figure 2: Main steps in the breakdown of galactose to glucose. The expansions of the abbreviations are as follows: ATP, adenosine triphosphate; PO<sub>4</sub>, phosphate; ADP, adenosine diphosphate.

curs, there is an accumulation of galactose-1-phosphate, the compound immediately preceding the site of the block; and this causes first the development of the cataracts in the eyes, the damage to the liver, and the presence of galactose in the urine. At the same time, there is a decreased formation of glucose in the blood, and this causes low blood-sugar levels and sometimes convulsions. The mental retardation sometimes seen in these children may be the result of the high galactose level, or the low glucose level, or both.

Galactosemia is transmitted as an autosomal recessive trait. In this situation, if two carriers of the trait (each one with one normal and one mutant gene) mated and had four children, by random chance one of the four children would be expected to have the disease, two of the four children to be carriers of the trait like their parents, and one to be entirely normal, as shown in Figure 3. The person with galactosemia does not show any enzyme activity; the parents of the children show about 50 percent of the normal range of enzyme activity.

The identification of galactosemia is suggested by the presence of the reducing substance, galactose, instead of glucose in the urine. It is also suggested by an excess of

Effects of galactosemia

galactose in the blood but must be confirmed by quantitatively testing for the enzyme galactose-1-phosphate uridyl transferase in the red blood cells. Recently, screening programs have been developed for testing for this enzyme defect among newborn infants in order that proper treatment can be instituted before the onset of clinical symptoms. The simplest screening test consists of pricking the baby's heel and collecting a drop of blood on a piece of filter paper. This blood is treated with a series of reagents and then viewed under a longwave ultraviolet light. Samples of normal blood will cause bright fluorescence; no fluorescence is observed with galactosemic blood.

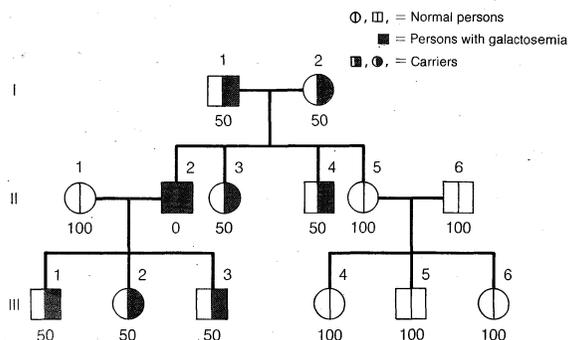

Figure 3: Transmittal of galactosemia. The numbers 50 and 100 in each generation (represented by roman numerals) indicate percentages of enzyme activity.

During the past few years, investigators have increasingly turned to the use of white blood cells and somatic (body) cell cultures for carrying out *in vitro* (test-tube) studies on many of the "inborn errors of metabolism." In the case of galactosemia, total white blood cells separated from red blood cells can be used to test for the enzyme among the affected children, their parents, and the normal population. Similarly, if one takes a specimen of skin from a patient with the disease and lets the fibroblast (connective-tissue cell) layer grow in tissue culture media, the cells will multiply and can be tested for the enzyme. It can be seen that fibroblasts from the affected children are unable to convert galactose to carbon dioxide, while their parents are intermediate when compared with normal controls. In contrast, all three groups can convert glucose to carbon dioxide in a normal manner. Finally, techniques have recently been developed by which it is possible to detect galactosemia before birth. As shown in Figure 4, if one puts a needle into the amniotic sac (the sac containing the fetus) in a pregnant woman of 10 to 12 weeks' gestation and removes 10 milliliters (about 0.04 fluid ounce) of amniotic fluid, it is possible to cultivate the fetal cells in the same manner as with skin cells from older people. These cells will grow

and can be tested for the presence of galactose-1-phosphate uridyl transferase to determine whether the fetus in the uterus will or will not have galactosemia.

Treatment of galactosemia consists of the rigid exclusion of lactose and galactose from the diet. During early infancy, this is relatively easy, since there are commercially available lactose-free milk and milk products. As the child gets older, processed foods that contain lactose must be avoided, and it is safer to give such children pure meat, vegetables, fruit, and lactose-free bread. The omission of lactose is highly effective in preventing liver disease and cataracts from developing.

Treatment of galactosemia

#### DISTURBANCES IN AMINO ACID METABOLISM

At least 35 disturbances of amino acid metabolism have been described in man. These may conveniently be divided into the 29 disorders that involve the whole body and the six disorders of transport involving only the surface membranes in the kidney tubules or the lining of the intestine. In many of the systemic disorders, the site of the metabolic block has been located, the mode of inheritance determined, the carriers of the trait identified, screening procedures for finding the condition in the newborn infant developed, the abnormality found in white blood cells, cultivated skin fibroblasts and amniotic fluid cells derived from abdominal taps.

A widespread screening for amino acid defects among normal newborn infants has led to the impression that not all disturbances of amino acid metabolism are necessarily associated with disease or mental retardation. It may well be that some of the defects were detected because studies were first carried out in populations for the mentally retarded. The occurrence of the amino acid disturbances may have been coincidental, and a similar survey of healthy normal people might uncover the same defects. A few conditions are discussed below in which the clinical syndrome has been reasonably accurately defined (see also Table 1).

**Phenylalanine and tyrosine disorders.** Recent studies in biochemistry have permitted a better understanding of the normal pathway for the degradation of the amino acids phenylalanine and tyrosine in man. This occurs in a series of separate steps as shown in Figure 5: (1) Phenylalanine is first converted to tyrosine in the presence of the enzyme system "phenylalanine hydroxylase." The absence of the enzyme is responsible for the clinical condition phenylketonuria (see below). (2) Tyrosine is next converted to *p*-hydroxyphenylpyruvic acid in the presence of the enzyme tyrosine transaminase. (3) The *p*-hydroxyphenylpyruvate is in turn converted to homogentisic acid in one step in the presence of the enzyme *p*-hydroxyphenylpyruvic acid oxidase. An absence of this enzyme causes tyrosinemia (see below). (4) Homogentisic acid is then converted to maleylacetoacetate in the presence of the enzyme homogentisic oxidase. An absence of this enzyme causes alkaptonuria. (5) As another pathway of metabolism, tyrosine is also converted to 3, 4-

dihydroxyphenylalanine (DOPA), and eventually to melanin by the action of the enzyme tyrosinase. The absence of this enzyme is responsible for the hereditary defect albinism.

**Phenylketonuria.** Phenylketonuria was described first in the early 1930s by the Norwegian physician and biochemist Ashbörn Fölling. In the course of examining two mentally retarded siblings who were brought to him because of a peculiar body odour, he found that their urine reacted with ferric chloride, resulting in an unusual green colour. This led him to undertake a survey of several hundred retarded children in a nearby institution; he found that eight additional children, including two more pairs of siblings, showed a similar green colour in the urine upon the addition of ferric chloride. Thus, he was able to show that this group of mental defectives differed chemically from all others, and this work opened up a whole new approach toward investigating the causation of mental deficiency. The green colour was shown later to be caused by phenylpyruvic acid in the urine, and the peculiar odour to be caused by phenylacetic acid, both products of the metabolism of phenylalanine.

If the parents are carefully questioned and the baby is given a thorough physical examination, phenylketonuria (often called PKU) frequently is discovered before the

mental defect becomes evident. During the first few weeks of life, affected infants show unusual irritability, have epileptic seizures, and vomit so severely that the parents seek medical advice. Half of the children with phenylketonuria have some type of skin inflammation. Although there are exceptions, phenylketonurics tend to have blue eyes, blonde hair, and fair skin.

The mental defect first becomes evident when the child is from four to six months of age. Prior to the screening program, which is now almost universal in the United States, the earliest that children were brought to a physician was when they were five months of age; at that time it was observed that they did not behave normally for their age. The principal nervous-system findings include agitated behaviour and finger posturing, overactive reflexes and a certain rigidity of the muscles, and severe mental retardation. Although roughly 80 percent of the children have abnormal brain waves, epileptic seizures occur in only about a third of them.

The intelligence tests of phenylketonuric children are subject to error. In the first place, test values are inaccurate when the majority of the subjects are in the imbecile or idiot range and cannot communicate satisfactorily. Furthermore, most of the published data are based on institutionalized children who might do better in a more

Intelligence of phenylketonurics

Discovery of phenylketonuria

stimulating environment. Hence the intelligence of phenylketonuric children may, in fact, be somewhat higher than is currently believed. Despite this, there seems little doubt that the overwhelming majority of untreated phenylketonuric children have an intelligence quotient of less than 50 (normal is 100, and quotients of less than 70 are usually considered to indicate mental deficiency).

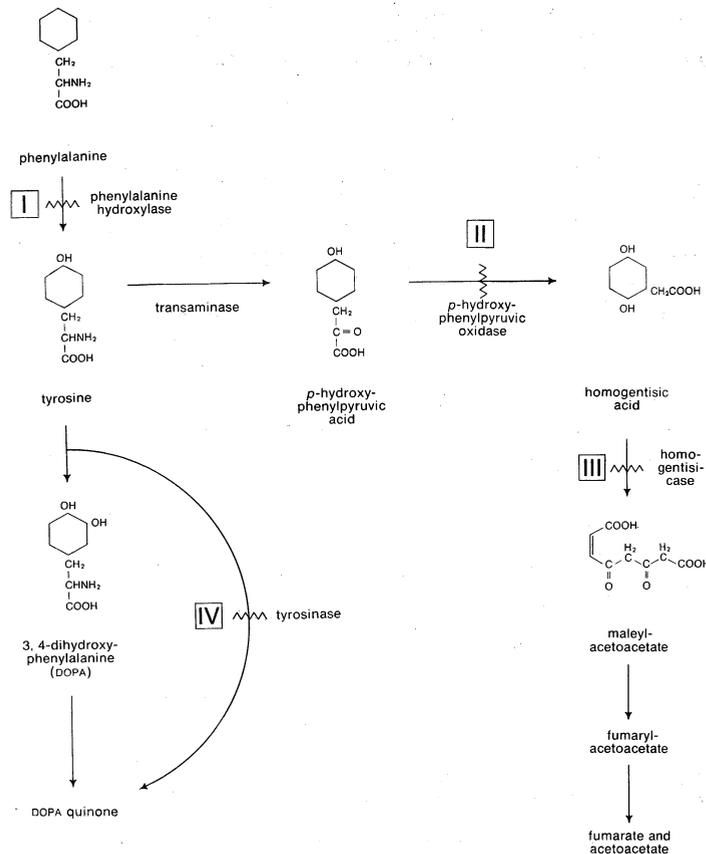

Figure 5: Normal pathway for the degradation of phenylalanine and tyrosine in man.

Phenylketonuria is caused by a deficiency of phenylalanine hydroxylase, which catalyzes the oxidation of phenylalanine to tyrosine as shown in Figure 5. The deficiency of phenylalanine hydroxylase causes an excessive accumulation of L-phenylalanine in the blood and spinal fluid. The excessive phenylalanine inhibits the normal pathway of tyrosine metabolism, which results in a decreased production of melanin, and this is responsible for the light pigment in the skin and hair of affected persons. The excessive phenylalanine (or one of its products) also probably causes some damage to the central nervous system; this is characterized by mental retardation, epileptic seizures, and abnormal brain wave patterns.

Phenylketonuria is transmitted by an autosomal recessive gene. As with galactosemia, described in the previous section, if two carriers of the trait for phenylketonuria mate, one would expect one out of four offspring to have phenylketonuria, two out of four offspring to be carriers like their parents, and one out of four offspring to be completely normal as shown in Figure 3. The carriers of the trait for phenylketonuria can be detected by means of a type of test called a loading test. If a person is heterozygous for a given trait (*i.e.*, if he is a carrier), he carries one "normal" and one "mutant" gene, and the molecules derived from the "mutant" gene may be expected to differ from those derived from the "normal" gene within the same person. On superficial examination, such persons might appear to be unaffected by the defect. More careful physical and biochemical studies may reveal departures from the norm, however, and these persons can frequently be identified from the population as a whole. In phenylketonuria, one would expect the carrier to have

about half the normal amount of phenylalanine hydroxylase in the liver. With less enzyme available, such individuals would not be able to make the normal response to a load of phenylalanine. In Figure 6, the effect is shown of giving 0.1 gram per kilogram of L-phenylalanine by mouth to a normal subject, a carrier for phenylketonuria, and a person who has phenylketonuria. It is apparent that the carrier shows a sharper rise of plasma phenylalanine levels than the normal person and the levels remain at a higher level for a longer time.

The widespread screening for phenylketonuria among newborn infants has led to the recognition that not all instances of high levels of phenylalanine in the blood are caused by the classic form of phenylketonuria and that a number of variants of the condition undoubtedly exist. Approximately one-third of all instances of elevated phenylalanine levels detected by screening are caused by variants of phenylketonuria. Children with these variants of the disorder appear to develop normally without the use of a low-phenylalanine diet.

During recent years, a number of reports have appeared describing the offspring of women who have phenylketonuria. As a general rule, these children show mental retardation, a decrease of head size and, frequently, multiple congenital abnormalities, even though they do not have phenylketonuria. These findings emphasize the toxic effect of phenylalanine or its metabolites (the products of its metabolism) upon the developing fetus, both in the uterus and after the birth of the infant.

Patients with classic phenylketonuria show a rapid and persistent increase of plasma phenylalanine levels during the first week of life. The concentrations level off at between 25 and 60 milligrams per 100 cubic centimetres of blood and remain elevated during childhood and adult life. Infants excrete p-hydroxyphenylacetic acid early in infancy and phenylpyruvic acid after one month of age.

In 1963 a semiquantitative method was described for the detection of elevated phenylalanine levels among newborn infants. By this technique, about one in 10,000 newborn infants will be found to have a plasma phenylalanine level of six milligrams or higher per 100 cubic centimetres; of the infants having these levels about two thirds have the classic form of phenylketonuria and one third are afflicted by one of the milder variants.

Elevation of plasma phenylalanine can be effectively controlled by reducing the content of this amino acid in the diet. It cannot be completely eliminated because phenylalanine is an essential amino acid and sufficient amounts must be supplied to ensure normal physical growth. Since natural protein contains about five percent of this compound, artificial replacement of dietary protein is necessary. Most fruits, vegetables, and cereals can be given the child when he reaches the normal age for such foods.

Although experiences vary, most infants with phenylketonuria treated with the low-phenylalanine diet have shown near-normal mentality, with intelligence quotients ranging from 85 to 100. While their intellectual development has not always been as good as that of their unaffected siblings, they show marked improvement as compared with their affected siblings who are not fed the low-phenylalanine diet.

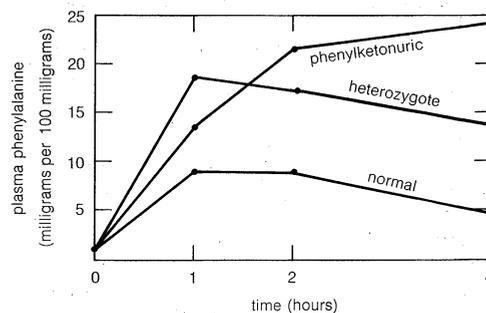

Figure 6: Effects of administration of L-phenylalanine on normal person, carrier (heterozygote), and person with fully developed phenylketonuria (see text).

of phenyl-  
ketonuria

**Tyrosinemia.** In 1962 four Swedish families were reported in which seven out of 13 children were afflicted with an inborn error of tyrosine metabolism characterized by a deficiency of liver *p*-hydroxyphenylpyruvate oxidase, the enzyme that converts *p*-hydroxyphenylpyruvic acid to homogentisic acid as shown in Figure 5. The condition appears to be transmitted by an autosomal recessive gene, and the carriers of the trait sometimes show an abnormal tolerance test after a tyrosine load.

Effects of tyrosinemia

The main clinical features are multiple defects in kidney function and replacement of the liver cells with fibrous tissue. There may be fewer circulating platelets than normal and increased pigmentation of the skin. There is little or no mental retardation and no particular nervous system abnormalities. With time the children develop rickets that does not improve when vitamin D is given.

The identity of the disorder is suggested when the urine shows a positive reaction to a specific test for proteins and nitrogen compounds and when tyrosine levels in both the blood and urine are elevated. Moderately successful results have been obtained by withholding both phenylalanine and tyrosine from the diet.

**Alkaptonuria.** The identification of alkaptonuria rests on the classical triad of arthritis, pigmentation of cartilages, and a darkening of the urine caused by the presence of homogentisic acid. The condition is caused by a deficiency of liver homogentisic oxidase, the enzyme that converts homogentisic acid to maleylacetoacetate as is shown in Figure 5.

Alkaptonuria is compatible with long life. Except for the discoloration of the urine, there are no clinical manifestations until the affected person is in his twenties or thirties, when ochronosis begins to appear. This consists of deposits of ochre-like pigments in various parts of the body. These are particularly prominent in the eyes, in the sclera just back of the juncture with the cornea; in the ear and nasal cartilages; and in the superficial tendons of the hands. By middle age, many alkaptonuric persons complain of pain and stiffness of the large joints because of deforming arthritis. The spine becomes rigid; there is an arching of the upper spine, and motion of the hip, knee, or shoulder joints becomes limited.

The disorder is identified by observing that the urine turns dark upon standing because of oxidation of homogentisic acid. The only treatment needed is to relieve the discomfort of the arthritis.

**Albinism.** Albinism is a general term that applies to a series of conditions in which there is little or no melanin, a dark pigment, in the skin and eyes. Albinism is caused by a failure in synthesis of the enzyme tyrosinase (Figure 5) within the melanocytes of the skin.

Effects of albinism

The defect may be generalized or localized. Patients with generalized albinism have white or extremely pale yellow hair that is silky in texture. The pupils of the eyes appear to be red, and the iris is pink or bluish from reflected light; the eyes appear to wander purposelessly and are unduly sensitive to light. Traces of pigment can be found in the uveal border of the eye, however, and albinos of the coloured races frequently have blue or light-brown eyes. The only treatment needed is prevention of exposure to sunlight and proper protection of the eyes by dark glasses. Some of the localized variants of albinism include: (1) piebald albinism; (2) presence of a white forelock and spotting of the skin, and (3) albinism of the eye alone.

**Branched-chain amino acid disorders.** The degradative pathways of the branched-chain amino acids, leucine, isoleucine, and valine, are shown in Figure 7. The clinical syndromes along this pathway are: maple syrup urine disease, isovaleric acidemia, and hypervalinemia.

**Maple syrup urine disease.** In 1954 a new disorder was described characterized by difficulty in feeding, an absence of the Moro reflex, the development of irregular jerky respirations, spasticity, and rigid arching of the back during the first few weeks of life. (The Moro reflex is the baby's stretching up both arms in an embracing motion when the table on which he is resting is slapped on either side of him.) The baby's urine has an odour strikingly similar to that of maple syrup. Biochemi-

cal abnormalities include an elevation of the three branched-chain amino acids leucine, isoleucine, and valine (first vertical column in Figure 7) in the plasma and the urine, and a marked increase of their corresponding alpha-keto acids (second vertical column in Figure 7), particularly ketoisocaproic acid, in the urine. Maple syrup urine disease represents a deficiency of alpha-keto decarboxylase enzymes in the white cells, fibroblasts, and liver. Persons having this defect do well on a diet low in leucine, isoleucine, and valine, and the nervous-system damage in the condition can be prevented by treatment.

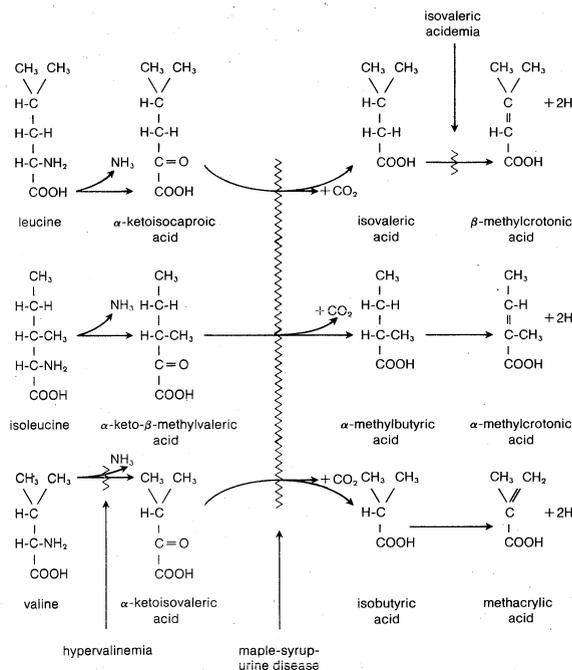

Figure 7: Normal breakdown of branched-chain amino acids. Zigzag lines represent absence of enzymes.

In 1967 a variant of maple syrup urine disease was described that differed strikingly from the classical picture of maple syrup urine disease in that there was a late onset of symptoms and the children appeared to be perfectly normal between attacks.

**Isovaleric acidemia.** In 1967 a group of investigators from Boston described a second inborn error of leucine metabolism characterized by a peculiar body odour, episodic acidosis (decreased alkalinity of the blood and tissues), and slight mental retardation. Biochemical investigations revealed striking elevations of isovaleric acid in the body fluids, but other short-chain keto acids were within normal limits, indicating, as is shown in Figure 7, that the genetic defect is at the level of the enzyme isovaleryl-CoA dehydrogenase and that the abnormality involves only leucine metabolism and not that of the two other branched-chain amino acids.

**Hypervalinemia.** A case was described in which a two-month-old Japanese infant started to vomit shortly after birth, failed to gain weight, appeared to be mentally retarded, had elevated levels of valine in the urine. This condition involves the deficiency of valine transaminase, but leucine and isoleucine appear to be normal, as shown in Figure 8.

**Glycine metabolism disorders.** In Figure 7, it is shown that in the normal individual valine is converted successively to alpha-ketoisovaleric acid, to isobutyric acid, to methylacrylic acid. If one continues with the breakdown of valine, one comes to a series of steps involving the breakdown of propionic acid. At least two of the defects involving glycine metabolism, ketotic hyperglycinemia, and methylmalonic aciduria, have been shown to be related to the metabolism of propionic acid.

**Ketotic hyperglycinemia.** A decade ago, a case was described of a child who had episodes of vomiting, became sleepy, dehydrated, and acidotic. It had infections, a de-

Signs of hyperglycinemia

crease of the gamma globulin in the plasma, and a low white-blood-cell count. The child also had bleeding into the skin, caused by low levels of platelets in the blood, and was retarded. Laboratory studies showed that the child had 10 to 20 times higher concentrations of glycine in the plasma and urine than normal children.

Since glycine is one of the important products of protein breakdown, it was decided to reduce the protein intake of the child by half. The frequency and intensity of the episodes of vomiting and acidosis decreased and there was general improvement. Recently, it has been shown that the disorder arises from a deficiency, early in the breakdown of propionic acid, of the enzyme biotin.

**Methylmalonic aciduria.** Recently some English workers described two children who failed to thrive and showed a persistent metabolic acidosis much like the children with ketotic hyperglycinemia. They found, however, that the children's plasma and urine were loaded not with glycine but with methylmalonic acid. Investigations revealed that a block occurred in the breakdown of propionic acid, but at a later stage than that for ketotic hyperglycinemia.

Two types of methylmalonic aciduria

It has been shown that persons with methylmalonic aciduria may be divided into at least two main groups. In some, the administration of vitamin B<sub>12</sub>, which is a coenzyme (nonprotein and active portion of an enzyme), to the reaction will correct the defect and reduce the plasma and urine methylmalonic acid to normal levels. In others, vitamin B<sub>12</sub> has no effect.

**Urea cycle disorders.** The normal pathway of citrulline in mammalian systems is shown in Figure 8. In this cycle, which is sometimes also called the Krebs-Henseleit cycle, citrulline serves as an intermediate substance in a cyclic mechanism resulting in the production of urea from ATP, ammonia (NH<sub>3</sub>), and carbon dioxide (CO<sub>2</sub>). Four metabolic blocks have been described within this cycle: (1) carbamyl phosphate synthetase deficiency, involving the synthesis of carbamyl phosphate; (2) ornithine transcarbamylase deficiency, involving the reaction of ornithine and carbamyl phosphate in the formation of citrulline; (3) citrullinemia, involving the conversion of citrulline and aspartic acid to argininosuccinic acid; and (4) argininosuccinic aciduria, with cleavage of argininosuccinic acid to arginine and fumaric acid (Figure 8).

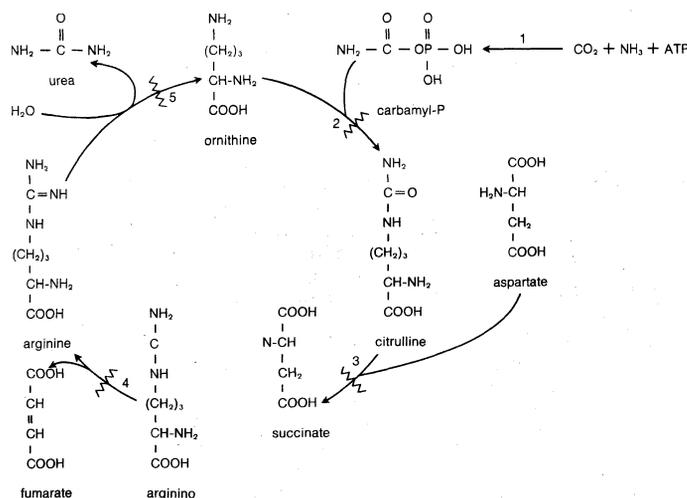

Figure 8: Krebs-Henseleit cycle.

**Citrullinuria.** In the early 1960s a group of Canadian workers described a mentally retarded child with a new amino acid disturbance characterized by the presence of citrulline in the urine, plasma, red blood cells, and spinal fluid. The child had chronic and persistent vomiting and showed severe alkalosis (increased alkalinity of the blood and tissues). Subsequently, it was shown that in this condition there is a decrease of argininosuccinate synthetase activity in fibroblasts. It appears likely that this decrease is caused not so much by an actual absence of the enzyme protein at step 3 in Figure 8, but rather by the inability of

the citrulline or aspartate to react with the enzyme protein in a proper manner.

**Argininosuccinic aciduria.** In 1958 a group of British investigators described a new clinical syndrome characterized by mental retardation and the presence in the urine of an amino acid not normally seen there. All three of the affected persons originally observed showed strikingly similar facial appearances, and all had brittle hair. One of the three persons also suffered from lesions of the skin and mucous membrane of the cheek, and had brittle nails. All were retarded mentally and had grossly abnormal electroencephalograms (brain wave tracings). Two had epileptic seizures. Argininosuccinic acid was present in large amounts in the urine, blood, and spinal fluid. Studies using red cells, white cells, and fibroblasts have shown that the condition is caused by a deficiency of argininosuccinase at step 4 in Figure 8.

**Sulfur amino acid disorders.** As shown in Figure 9, the normal pathway of methionine breakdown involves

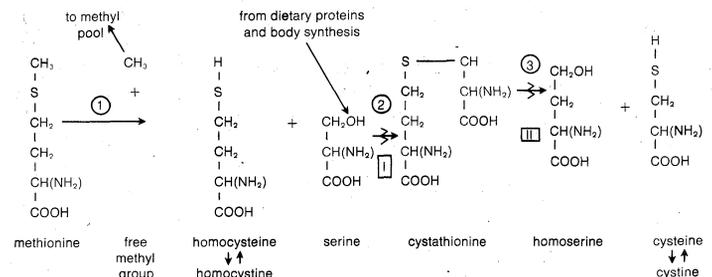

Figure 9: Normal pathway of methionine metabolism.

removal of methyl (CH<sub>3</sub>) to form homocysteine, which in turn combines with serine to form cystathionine, which then separates to form cysteine and homoserine.

**Homocystinuria.** Persons with homocystinuria (homocystine in the urine) show a consistent picture of mental retardation; ectopia lentis (displacement of the lenses of the eyes); fine, fair hair; shuffling gait; thromboembolic episodes (obstruction of blood vessels by blood clots); and skeletal changes. The condition is caused by a deficiency of cystathionine synthetase at step 2 in Figure 9. Infants with this condition can be treated with a diet that is low in methionine and is supplemented with cystine.

**Cystathioninuria.** Cystathioninuria—presence of cystathionine in the urine—is characterized by mental retardation and developmental abnormalities. The condition is caused by a deficiency of the cystathionine-cleaving enzyme, cystathionase, at step 3 in Figure 9. Some persons with this defect respond dramatically to the administration of vitamin B<sub>6</sub>, which results in a marked fall of cystathionine excretion.

**Cystinosis.** In cystinosis, the infant grows and develops normally during the first six to eight months of life. The parents then note his refusal of feedings other than liquids. This is followed by the infant's urinating excessively and ceasing to grow altogether. The infant may be brought into the hospital in a crisis with fever, dehydration, and acidosis. He usually is found to be severely affected by rickets despite taking adequate amounts of vitamin D; he has enlargement of the liver, is short, and has poor body tone. Bright reflective cystine crystals may be seen in the eyes, liver, and bone marrow.

For many years, cystinosis was confused with cystinuria, which is primarily a defect in the transport across the kidney tubules (*i.e.*, a passage back into the blood through the walls of the tubules) of the dibasic amino acids: lysine, arginine, cystine, and ornithine. Since cystine is relatively insoluble in acidic urine, cystine stones are sometimes seen in that condition. In contrast, cystinosis is a systemic disease, in which cystine deposits are seen in many of the systems in the body. It has recently been shown, for example, that the white blood cells and skin fibroblasts from such patients show at least a 100-fold increase in cystine content, and even the parents of such children show a five- to six-fold increase in cystine content compared with normal people. The cystine crys-

Effects of cystinosis

tals ultimately cause damage to the kidney tubules, and this causes a generalized defect in reabsorption of all of the amino acids as well as of sugar, phosphates, and water; the defect in reabsorption accounts for the clinical symptoms in the disease. Although the specific enzyme defect responsible for the accumulation of cystine is not known, the enzyme involved is probably one of those involved in the degradation of cystine or its products.

#### DISORDERS OF AMINO ACID TRANSPORT

One of the unique characteristics of living cells is their capacity to maintain an internal composition different from that of their external environment. For many years it was supposed that the composition of cells was established when they were formed and thereafter was maintained by the impermeability of the membranes. By means of radioactively labelled compounds, it soon became apparent, however, that salts, sugars, and amino acids could pass freely both into and out of the cell through the membrane. Furthermore, it was found that, in many of the cells in the body, there was an "active" transport across the gradient (*i.e.*, dissolved particles were moved from a weaker to a stronger solution) and this process required energy derived from the metabolic activity of the cell. Through the study of "inborn errors of metabolism," it has been possible to show that specific transport mechanisms are controlled by "structural" genes. Furthermore, the control mechanisms for amino acids seem to fall in groups, so that certain genes control the dibasic amino acids, others control imino acids and glycine, and so on. Study of transport mechanisms in different body organs have indicated that the genetic control of one group of amino acids extends to several different systems of cells, so that the same defect of membrane transport for the dibasic amino acids in cystinuria is observed in the kidney tubules and in the mucous membrane lining the intestine.

Five disorders of amino acid transport

The main hereditary disorders of amino acid transport are: (1) cystinuria, which represents an abnormality in the transport of dibasic amino acids; (2) Hartnup disease, which is caused by a defect in the transport of tryptophan; (3) imino-glycinuria, which represents a defect in the transport of glycine, proline, and hydroxyproline; (4) tryptophan malabsorption syndrome, or the "blue diaper syndrome," which represents a tryptophan malabsorption in the intestine alone; (5) methionine malabsorption syndrome, or the "oasthouse urine disease," which is an example of methionine malabsorption in the intestine alone; and (6) the Fanconi syndrome, which is a generalized kidney transport defect characterized by the failure of the renal tubules to reabsorb water, potassium, phosphates, glucose, and many amino acids. The latter is usually seen in association with cystinosis.

**Cystinuria.** Cystinuria is a hereditary metabolic disorder involving the transport of the four dibasic amino acids, cystine, lysine, arginine, and ornithine. Persons with this disorder excrete on the average 0.73 gram of cystine, 1.8 grams of lysine, 0.83 gram of arginine, and 0.37 gram of ornithine; these amounts persist through life relatively uninfluenced by dietary intake. Cystine stones form in the kidney because cystine is one of the least soluble of the amino acids. In urine of pH 5-7 (*i.e.*, ranging from slightly acid to neutral), cystine is only slightly soluble, to the extent of 300-400 milligrams per litre. When the urine volume decreases, particularly at night, this amino acid is likely to come out of solution and form stones. Since lysine, arginine, and ornithine are freely soluble, they do not become incorporated into stone. Kidney-stone formation may be reduced or eliminated by drinking large volumes of liquids, particularly at night, and by making the urine more alkaline with sodium bicarbonate. While the main symptoms of cystinuria are confined to the kidney, a similar transport defect has been described in the walls of the small intestine. When persons with this defect are given large doses of lysine or ornithine by mouth, these amino acids are less completely absorbed, and a considerable portion appears unchanged in the stools. The remainder is converted by bacteria in the colon to cadaverine and putrescine, sub-

stances that are then absorbed and can easily be detected in the urine.

Cystinuria is one of the most common "inborn errors of metabolism" in man. It is estimated that approximately one in 600 of the population excretes abnormally large quantities of cystine. The cystine crystals are identified in the sediment of the urine as transparent, shiny, hexagonal leaflets. The crystals are soluble in ammonia and insoluble in acetic acid. Cystine can also be identified by a simple test with sodium cyanide and sodium nitroprusside. Cystinuria is transmitted as an autosomal recessive trait. There appear to be two forms of the disease. Only carriers of one of the forms can be identified easily.

**Hartnup disease.** Most persons with Hartnup disease have a skin disorder consisting of scaly red rashes affecting the exposed areas of the body and identical in appearance with that of classic pellagra, which is caused by a deficiency of the vitamin nicotinamide. The pathway for the degradation of tryptophan is shown in Figure 10.

Cause and control of Hartnup disease

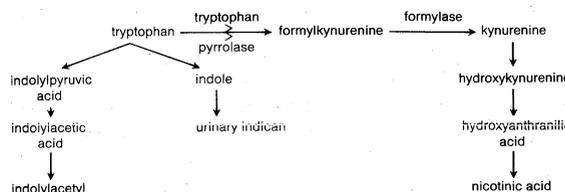

Figure 10: Pathway for the degradation of tryptophan, showing the site of the probable metabolic block in Hartnup disease.

Patients with Hartnup disease have a constant gross excess of amino-acid excretion in the urine. Since there is no other abnormality of kidney transport, it appears that the condition is caused by a defective transport of tryptophan across the cells of the kidney tubules. As a result, tryptophan cannot be converted to formylkynurenine and a nicotinamide (nicotinic acid) deficiency develops. There is also a delayed and incomplete absorption of tryptophan through the intestinal tract. When tryptophan is fed by mouth, these persons show an increase of tryptophan in the stools, decrease of formylkynurenine and kynurenine in the urine, increase of the indolylacetic acid and indolylacetyl glutamine in the urine, and increased amounts of indican in the urine. Persons with Hartnup disease improve, and the pellagra can be effectively managed if nicotinamide is administered.

#### DISTURBANCES IN CARBOHYDRATE METABOLISM

The principal "inborn errors of metabolism" in this area are the systemic disturbances that involve galactosemia (see above), pentosuria, fructosuria, fructosemia, the glycogen-storage diseases, the red blood cell enzyme defects (see BLOOD DISEASES), the intestinal disturbances of carbohydrate metabolism, and the bilirubin disturbances. Of these, pentosuria and fructosuria are entirely benign conditions compatible with normal life expectancies.

**Fructosemia.** When persons with fructosemia eat any fruits, the effects are nausea, vomiting, sweating, tremors, confusion, convulsions, and coma. If they continue to be given fruits, they ultimately show liver damage and mental retardation. The condition is caused by a deficiency of the liver enzyme fructoaldolase, which is responsible for splitting fructose-1-phosphate. When the enzyme is absent, fructose-1-phosphate accumulates in the liver, and this accumulation inhibits other enzymes involved in carbohydrate metabolism, particularly those concerned in glycogen breakdown; low blood glucose levels result. Many of the symptoms seen in fructosemia are related to the low blood-sugar concentration. The condition is managed by avoiding fruits and other fructose-containing foods and by taking glucose during an attack.

**Glycogen-storage diseases.** The glycogen-storage diseases are a group of congenital and familial disorders characterized by the deposition in the tissues of abnormally large quantities of glycogen. Glycogen is the chief form in which carbohydrates are stored in the body. It has a large molecule made up of chains of alpha-D-glu-

Synthesis of glycogen

cose arranged in a multibranched, treelike structure. Glycogen is synthesized and broken down by a series of enzymatic steps as shown in Figure 11: (1) glucose reacts with adenosine triphosphate (ATP) to form glucose-6-phosphate with the help of the enzyme hexokinase; (2) glucose-6-phosphate is then converted to glucose-1-phosphate with the help of glucose-1, 6-diphosphate and phosphoglucomutase; (3) the glucose-1-phosphate is then converted to uridine diphosphate glucose by means of uridine diphosphate glucose pyrophosphorylase; (4) the biosynthesis of glycogen from uridine diphosphate glucose by means of glycogen synthetase and glucose-1-phosphate is capable of adding glucosyl (alpha-D-glucose) units to the outer chains of the glycogen molecule, increasing its size. Numbers six to nine in the chart indicate the stages in the breakdown of glycogen into glucose. The glycogen is of normal structure in glycogen storage disease of Types I, II, V, and VI; abnormal in types III and IV. Persons with type II are weak and suffer heart failure; they usually die before they are two years old. Persons with types I, III, IV, and VI have enlarged livers. Those with type V are unable to exercise vigorously because glycogen is not released to provide energy.

type	name	enzyme defect	organs affected	mode of inheritance*
I	von Gierke	glucose-6-phosphatase	liver, kidney	AR
II	Pompe	alpha (1→4) glucosidase	muscle, heart	AR
III	Forbes	amylase-1, 6-glucosidase	liver	AR
IV	Andersen	amylase (1, 4→1, 6) transglucosylase	liver	AR
V	McArdle	phosphorylase	muscle	XR
VI	Hers	phosphorylase	liver	AR(?)

\*AR = autosomal recessive; XR = X-linked recessive.

Two types of intestinal disturbances

**Intestinal disturbances of carbohydrate metabolism.** As shown in Figure 12, the small intestine contains a number of specific enzymes, disaccharidases, whose function is to break a double sugar into its corresponding single sugars. When one of these enzymes is absent, a child develops chronic diarrhea and fails to gain weight in early infancy. These disturbances may be divided into two subgroups: hereditary lactose malabsorption and hereditary disaccharidase intolerance.

In hereditary lactose malabsorption (hereditary alactasia) there is a deficiency of intestinal lactase. Infants with this deficiency do not tolerate either breast or cow's milk but improve in condition when cereals are introduced and there is an associated reduction in the intake of sugar. In

hereditary disaccharidase intolerance there is an absence of sucrose (invertase) and isomaltase, and a subnormal amount of maltase in the intestinal lining. Infants show much the same clinical picture as with lactose malabsorption, but their malabsorption is of sucrose.

**Bilirubin disturbances.** Hereditary deficiency of the liver enzyme glucuronyl transferase is believed to be the cause of failure to convert the pigment bilirubin into a form that will be excreted, with the result that bilirubin levels are high and there is persistent jaundice.

In the more severe form, called congenital nonhemolytic jaundice with kernicterus (Crigler-Najjar syndrome),

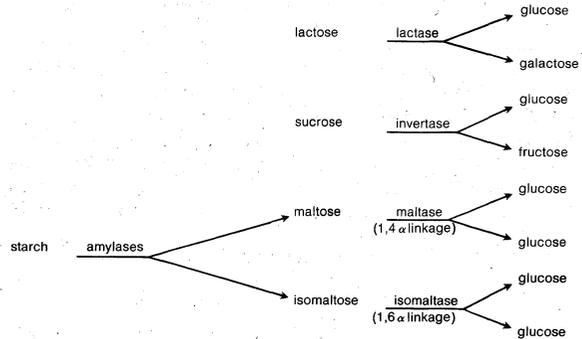

Figure 12: Breakdown of double sugars (e.g., lactose, sucrose) into single sugars (e.g., glucose, galactose) by means of enzymes (e.g., lactase).

affected infants develop severe jaundice in the first days of life and, in about two-thirds of the sufferers, arched back, spasticity, and rigidity soon become apparent; many of the infants die within the first year of life. The nerve cells of the thalamus (the basal ganglia) are characteristically stained, but the liver shows few, if any, changes. While infants with the Crigler-Najjar syndrome usually show no glucuronyl transferase activity, some show a marked lowering of bilirubin concentration in the blood when treated with phenobarbital. Others show no response to that form of treatment but will show a persistently lower serum bilirubin concentration after treatment with artificial blue light.

The milder form, which develops in young adults, is called familial nonhemolytic jaundice (Gilbert's disease). Most persons with this form of jaundice are not aware that they are abnormal. They frequently complain of weakness and lack of energy, but they attribute this state to overindulgence in alcohol, lack of sleep, overwork, excitement, or infection. The jaundice appears only

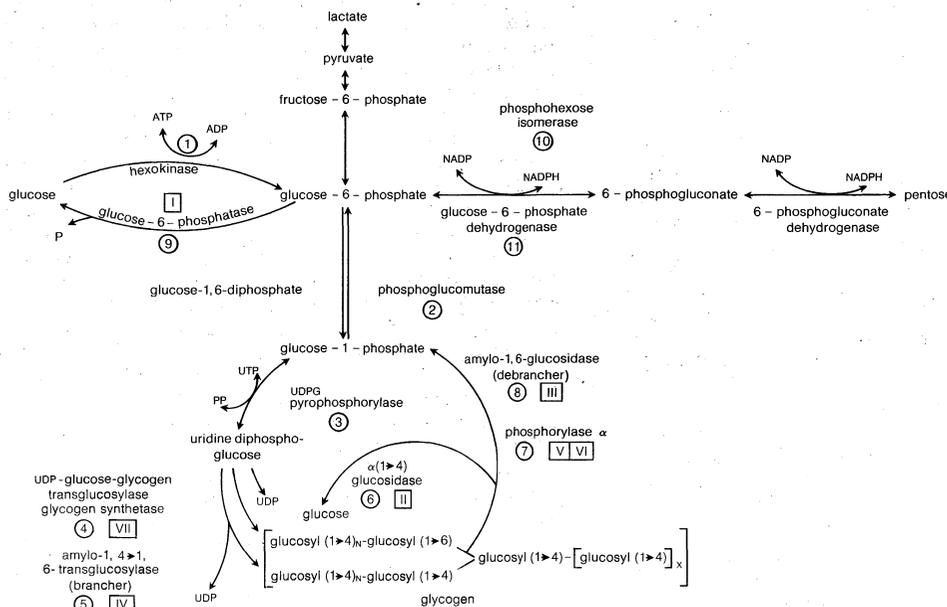

Figure 11: Synthesis and breakdown of glycogen.

intermittently, and even then is usually mild in nature. There is a partial absence of active glucuronyl transferase in these patients, and no treatment is needed.

#### DISTURBANCES IN LIPID METABOLISM

Disorders of fat (lipid) metabolism fall into two categories: those involving the lipids in the blood and those concerned with the storage of lipids in various body organs and tissues. Among the stored lipids there are characteristically excessive quantities of certain glycolipids and phospholipids with a common structure called ceramide. Ceramide, sphingosine, and the lipids stored in these disturbances are shown in Table 3.

**Gaucher's disease.** Gaucher's disease was first described in 1882. In the common adult form, affected persons have moderate to marked enlargement of the spleen, anemia, and patchy brown pigmentation of the skin, especially over the fronts of the legs and on the cheeks. The bones show characteristic changes in shape, and a decrease of calcification may occur in the backbone, the pelvis, and the tibiae and humeri, bones of the lower legs and upper arms. This loss in calcification may result in fractures and deformities.

In contrast, the infantile type of Gaucher's disease pursues a rapid and malignant course. The infant, who is usually normal at birth, soon becomes apathetic, with progressive physical and developmental retardation. The abdomen becomes enlarged, with an increase in size of the spleen and later of the liver. Subsequently, nervous-system symptoms begin to appear, with lack of body tone and with rigidity of the back. Difficulty in swallowing, choking spells, severe cough, and intermittent cyanosis

show both physical and mental retardation. He gradually becomes weaker and shows increasing nervous-system deterioration and wasting of the extremities; the abdomen becomes noticeably protuberant. The spleen and liver are both markedly enlarged, the liver enlargement being more prominent than in Gaucher's disease. The skin is usually clear, but occasionally it has been observed to have extensive brownish, molelike pigmented areas, or, rarely, eruptive xanthomas (yellow patches caused by lipid deposits). A cherry-red spot is present in the macula lutea (a small highly sensitive area near the centre of the retina) in somewhat less than half of the patients. There is marked anemia. The infant becomes apathetic and dull, and death usually occurs at about six months of age.

In this disease there is an extremely widespread distribution of characteristic cells, called Niemann-Pick cells, which are large and pale with foamy appearing cytoplasm, the cell substance outside the nucleus. The cytoplasm contains small cavities and exhibits a characteristic colour when stained. It has been shown recently that Niemann-Pick disease is caused by a deficiency of sphingomyelinase, a sphingomyelin-cleaving enzyme, which separates sphingomyelin into phosphorylcholine and ceramide (see Table 3). The condition is transmitted by an autosomal recessive gene.

**Tay-Sachs disease.** A familial disease of infants was described in 1881 in which, during the first years of life, the maculae of both retinas have a cherry-red spot surrounded by a fairly well-defined white area. Affected children appear to be essentially normal until the age of four months. The first noticeable signs of abnormality are increased sensitivity to noise, irritability, and levelling off of development. Early in the course of the disease the infant's muscles twitch, and he has convulsions. There is a progressive loss of muscle strength until the infant becomes completely helpless. The infant no longer notices or recognizes the mother; his eyes cease to fix on objects; gradually it becomes apparent that he sees badly, and later he becomes blind. Eventually deterioration of the nervous system leads to a state of idiocy. The infant becomes emaciated and has repeated respiratory infections. Most affected children die at about three years of age.

The ganglion cells (the nerve cells making up clumps of gray matter) throughout the central nervous system are swollen, and the cytoplasm appears finely granular and sometimes has empty spaces. The accumulated lipid in Tay-Sachs disease is a ganglioside (see Table 3). Most children with Tay-Sachs disease lack hexosaminidase component A, one of the enzymes that break down ganglioside, and this undoubtedly accounts for its massive accumulation in the central nervous system.

**Metachromatic leukodystrophy.** The predominant manifestations of metachromatic leukodystrophy are severe impairment of the central nervous system and a decrease in nerve conduction velocity in peripheral nerves. These lesions cause motor incoordination and mental retardation. In the infantile form, there is weakness, loss of balance, poor body tone, paralysis, and difficulties in speech and swallowing within the first two to three years of life. In the juvenile form, there are initially symptoms that are predominantly psychological, followed by progressive dementia. Metachromatic leukodystrophy is identified by the presence of metachromatic granules (granules that stain irregularly) in the urine and the accumulation of excessive amounts of sulfatide in various tissues in the body (see Table 3). Biochemical studies have shown that the defective enzyme is arylsulfatase A, which shows decreased activity in brain, white cells, and fibroblasts. The condition is transmitted as an autosomal recessive.

**Fabry's disease.** Fabry's disease shows its effects primarily in males. It is characterized by the appearance of many purplish papules (small, solid elevations) in the body, especially in the scrotal region and along the side of the hipbone (the ilium). Affected males generally die of kidney failure in middle age. This is caused by a loss of kidney function associated with the accumulation of a glycolipid, a lipid containing sugar radicals, in the glo-

\*Point of attachment of various components.

Gaucher  
cells

(blue colour in the spleen) are frequently present. Characteristic cells, called Gaucher cells, move in increasing numbers into the lungs, liver, spleen, lymph nodes, and bone marrow. Affected infants become emaciated and usually die before they are one year old.

The lipid that accumulates in the Gaucher cells has been shown to be glucocerebroside (See Table 3), and the disease is caused by a deficiency of glucocerebrosidase, a glucocerebroside-cleaving enzyme that separates glucocerebroside into glucose and ceramide. Both the adult and infantile forms of Gaucher's disease are generally transmitted as an autosomal recessive.

Most persons with the adult form of Gaucher's disease do not require treatment, but in some cases removal of the spleen and orthopedic measures are indicated. No definitive treatment is available for the infantile form.

**Niemann-Pick disease.** In 1914 a German physician described a new clinical syndrome that has many clinical features in common with Gaucher's disease but appears to spread more diffusely through all the organs. The clinical changes usually begin early in life. Although the infant may appear to be normal at birth, he soon begins to

meruli, the clusters of the microscopic blood vessels in the nephrons—the functional units of the kidneys.

The abnormal glycolipid has been identified as ceramide trihexoside (Table 3), and the condition is caused by a deficiency of the enzyme ceramide trihexosidase. The disease is usually identified by determining the level of this enzyme in a specimen of the lining of the small intestine. The condition is linked to the X chromosome. (X and Y are the sex chromosomes; males have a combination of XY; females, XX. Since a man contributes the Y chromosome to a son's XY combination, a son cannot inherit the defect from his father.) Female carriers of the condition have intermediate levels of ceramide trihexosidase.

#### DISTURBANCES OF MUCOPOLYSACCHARIDE METABOLISM

Some inherited disorders involve the metabolism of the mucopolysaccharides, as shown in Table 4. In the Hurler and Hunter syndromes, there is excessive excretion of the mucopolysaccharides chondroitin sulfate B and heparitin sulfate and excessive storage of some gangliosides.

In these syndromes—both are also called gargoylism—changes are present in every part of the body. The head is enlarged and tends to be abnormally long and narrow. The lips are thick, and the teeth appear to be poorly formed and wide apart. The eye sockets are widely separated. The skin is dry and coarse. The neck is short and the shoulders tend to be hunched, so that the head appears to be sitting directly on the chest. The back is hunched, and the abdomen is large and protuberant. Frequently the liver and spleen are enlarged. By X-ray examination of an infant's skull one can see that the seams—the suture lines—are widened, and that the soft spot in front—the anterior fontanelle—is enlarged; one also sees occasional bony ridges. The long bones, fingers and toes, and rib cage appear to be shorter and broader than usual; and sometimes there is a delay in the development of centres of bone fusion.

Hurler's syndrome is transmitted by an autosomal recessive gene. Affected individuals show corneal clouding and dwarfism but seldom develop deafness. On the other hand, in Hunter's syndrome, transmitted by an X-linked gene, corneal clouding is never seen and only about one-third of the affected persons are dwarfed, but over 40 percent of the patients are deaf.

#### DISTURBANCES OF PURINE AND PYRIMIDINE METABOLISM

The principal disturbances of purine and pyrimidine metabolism are the Lesch-Nyhan syndrome, gout, hereditary xanthinuria, and hereditary orotic aciduria.

**Lesch-Nyhan syndrome.** In 1964 a group of physicians described a sex-linked familial nervous-system disease consisting of incoordination, spasticity, mental retardation, aggressive behaviour, compulsive biting resulting in mutilation of the lips and fingers, and excessive uric acid in the blood.

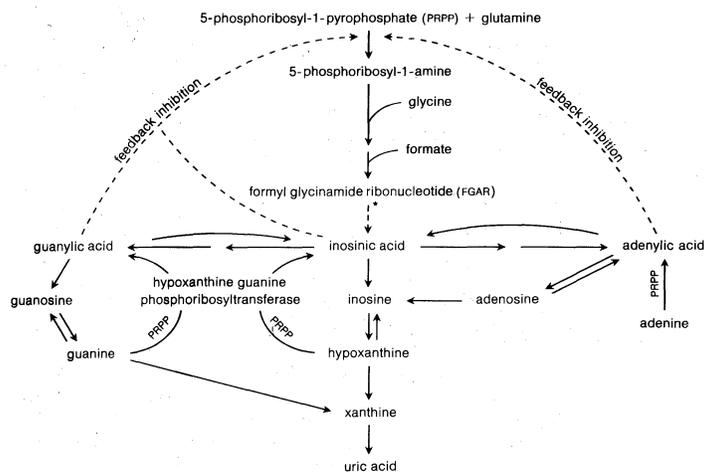

The affected children excreted three to six times the normal amount of uric acid in the urine. The condition is caused by a deficiency of the enzyme hypoxanthine guanine phosphoribosyl transferase (HGPRT); the lack of this

enzyme makes it impossible for such affected persons to form inosinic acid and guanylic acid (see Figure 13).

The Lesch-Nyhan syndrome is transmitted by an X-linked gene, and the skin cells (fibroblasts) of the female carriers of the trait have been separated into two groups, one with normal enzyme activity and one with a virtual absence of HGPRT activity. Since this enzyme is present in cultivated fetal cells, it has been possible to detect the Lesch-Nyhan syndrome prenatally.

**Gout.** Gout is a form of joint disease characterized clinically by recurrent, paroxysmal, acute attacks of severe inflammation, usually of a single peripheral joint, followed by complete remission. It more commonly affects men and results from the deposition in and about the joints of the sodium salt of the uric acid present in marked excess throughout the body. As a result of the urate deposits, knobby deformities develop on the knuckles and the finger joints. The deposits may also be found

Characteristics of gout

\*azaserine block  
Figure 13: Major pathways for breakdown of purine to form uric acid.

in cartilages unconnected with joints, such as in the rim of the outer ear. The attacks of gouty arthritis tend to come and go unpredictably, but attacks can sometimes be precipitated by injury, food, and alcohol.

Various theories have been advanced to explain the complex features of gout, but none is compatible with all of the known facts of the disease. At present it is believed that the disease is caused by a combination of overproduction of uric acid and an impaired capacity to excrete uric acid through the kidneys. Attacks of acute gouty arthritis can be reduced by a diet low in purines and by restraint of alcohol consumption. Colchicine, phenylbutazone, and adrenocorticotrophic hormone are effective during an acute attack, and uric acid deposits can be prevented by the prolonged use of such agents as probenecid. The elevation of uric acid appears to be transmitted by an autosomal dominant gene.

**Xanthinuria.** Persons affected by xanthinuria need to urinate frequently and have traces of blood in the urine. Examination of the urine reveals the presence of xanthine stones. The condition is caused by a deficiency of xanthine oxidase, the enzyme required to convert xanthine to uric acid (see Figure 13) and is transmitted as an autosomal recessive abnormality. The majority of affected persons do not need treatment. Xanthine is not easily soluble in urine, a high fluid intake, alkali therapy, and restriction of purines in the diet often are of benefit.

**Hereditary oroticaciduria.** Hereditary oroticaciduria is a rare disorder of pyrimidine metabolism manifested by an anemia with many megaloblasts (large nucleated red cells) among the blood cells, low white-blood-cell count, retarded growth, and the urinary excretion of large quantities of orotic acid. This disease is thought to represent defects involving the enzymes orotidylic pyrophosphorylase and orotidylic decarboxylase.

#### MISCELLANEOUS DISTURBANCES

**Disturbances of porphyrin metabolism.** At least five disturbances of porphyrin metabolism are known: (1) In congenital erythropoietic porphyria there is continuous moderate breakdown of the red blood cells, and sensitivity of the skin to light—photosensitivity—results in ulceration and scarring. Abnormally high levels of uroporphyrin and coproporphyrin are found in the red blood cells, urine, and feces. (2) In erythropoietic protoporphyria the skin is sensitive to light and there are increased levels of protoporphyrin in the red blood cells. (3) Persons with intermittent porphyria have attacks of severe pain in the abdomen, of weakness and paralysis of the limbs, and of psychic changes resembling hysteria. During the attacks, and to a lesser extent at other times, there are abnormally high levels of  $\delta$ -aminolevulinic acid, porphobilinogen, and uroporphyrin in the urine. Alcohol and barbiturates can precipitate attacks. (4) Variegated porphyria causes either photosensitivity of the skin, or neurologic changes, or both. There are high levels of  $\delta$ -aminolevulinic acid, porphobilinogen, uroporphyrinogen, and coproporphyrinogen in both the urine and the feces. (5) Cutanea tarda porphyria causes skin lesions, liver disease, and diabetes. The urine contains uroporphyrinogen and coproporphyrinogen. Removal of 300 to 500 millilitres (about 0.3–0.5 quart) of blood every two to three weeks results in a decrease of the urinary excretion of porphyrins and improvement of the symptoms.

**Disturbances of mineral metabolism.** The disturbances of mineral metabolism include Wilson's disease, hemochromatosis, and familial periodic paralysis.

Wilson's disease is a familial disorder characterized by a progressive degeneration of the basal ganglia of the brain, development of a brownish or grayish ring in the limbus—outer ring—of the cornea, and replacement of the liver cells with fibrous tissue. In young adult life, affected persons start to have involuntary, purposeless movements of the hands and feet; a tremor develops, and eventually there are difficulties in swallowing. A change in personality becomes evident. Not infrequently, persons with the disease die at an early age.

The disease has been shown to be caused by a deficiency in the circulation of the copper-binding protein ceruloplasmin. This causes an excess of free copper in the body; the copper is deposited in the liver, eyes, and brain, and is responsible for the clinical symptoms. Treatment with a substance such as penicillamine removes copper from the tissues and increases its excretion in the urine.

Hemochromatosis is an inborn error of metabolism characterized clinically by enlargement of the liver and pigmentation of the skin. Affected persons frequently develop diabetes mellitus and heart failure. These symptoms are caused by a toxic accumulation of iron in the body tissues. In males, the symptoms begin after 35 years of age, when sufficient amounts of iron have been accumulated. In females, the natural loss of iron through menstruation causes fewer symptoms, and these usually do not occur until after menopause. Treatment consists of removal of blood at regular intervals to reduce the iron levels in the body.

Familial periodic paralysis is a rare disease of obscure causation. The attacks of paralysis are frequently preceded by a "warning" period when the affected persons feel tired and irritable or have a sense of apprehension. In the typical case, paralysis begins in the legs and progresses toward the centre of the body until the sufferer becomes completely helpless and unable to move. The deep reflexes (involuntary contractions of muscles when their tendons are tapped) are lost, but there is no loss of sensation to pain or touch, and the mind is clear. After a few hours, there is gradual recovery, beginning with the central muscles and ending with the leg muscles. Episodes of paralysis may occur as often as several times weekly, and can sometimes be induced by strenuous exercise, a high carbohydrate meal, or the injection of epinephrine.

The condition is transmitted as an autosomal dominant trait and most attacks start at between 7 and 21 years of age. There appear to be at least three forms of the disease. Most are associated with low levels of potassium in the blood, but a few are associated with high levels, and some have been reported with normal levels.

**Cystic fibrosis of the pancreas.** Cystic fibrosis of the pancreas is probably one of the most important inborn errors of metabolism among Caucasians. It is estimated that about one out of every 25 individuals in the white population in North America and Europe is a carrier of the trait.

The clinical features of cystic fibrosis may be divided into three main groups: (1) The earliest and most severe manifestation is a blockage of the intestinal tract at birth because of a thickening of the meconium (the mass of material that accumulates in the bowel of the fetus) caused by a deficiency of the pancreatic enzymes. In older infants, there are symptoms from poor intestinal digestion, bulky, foul-smelling stools, and weight loss and an enlargement of the abdomen; these effects are much like those in a child suffering from starvation. (2) After the first few months of life, the infant develops a series of respiratory infections, sometimes resembling whooping cough. The child coughs a great deal but is unable to get rid of the thick secretions in the lungs and air passages. The lung tissue becomes replaced by scar tissue and the child dies. (3) All infants with cystic fibrosis show a marked increase in the salt concentration of their sweat. During a heat wave, they may suffer heat prostration.

Although the ultimate cause of cystic fibrosis remains unknown, there is general agreement that there is a disturbance of all of the secretory glands in the body. Their secretions become thickened and reduced, and it is this lack of lubrication that is responsible for the clinical symptoms. Many persons with the disorder die in early childhood from lung disease, but a few survive into adulthood and are relatively free of symptoms. Treatment consists of giving pancreatic enzymes by mouth, giving extra salt during the hot weather, and the use of aerosol and mist combined with drainage and antibiotics to reduce the degree of lung damage.

**Hypophosphatasia.** Persons with hypophosphatasia show severe decalcification and poor mineralization of the long bones, ribs, jaws, and teeth. In the most severe state, the fetus dies in the uterus. Infants that are born alive show marked bony deformities and die at an early age from infections, particularly of the chest. The condition is caused by a deficiency or absence of alkaline phosphatase in the serum, white blood cells, and the kidneys; this results in deficient calcification of the bones.

## Metallurgy

Metallurgy is the science of extracting metals from their ores, refining, purifying, and working them, mechanically or otherwise, to adapt them to use. It is also concerned with the chemical and physical properties of metals, their atomic and crystalline structure, the principles of combining them to form alloys, the means for improving or enhancing their properties for particular applications, and the relations between properties, structures, and uses. Further, it includes the thermal and mechanical processing of metals as materials of manufacture.

Metals are any of a class of substances that typically show a peculiar lustre, are good conductors of electricity and heat, are opaque, and may be fused.

Metallurgy as a science is relatively new, metals having been subjected to scientific study for less than a century. Since the 19th century, more and more attention has been devoted to a scientific understanding of the properties and structure of metals.

Metallurgy is a particularly broad subject, its scope overlapping many other sciences and technologies, such as physics, chemistry, mining, mechanical and chemical engineering, economics, and manufacturing.

This article deals primarily with technology. Articles on subjects of a scientific nature that are related to aspects of metallurgy include THERMODYNAMICS, PRINCIPLES OF; ELECTROCHEMICAL REACTIONS; CRYSTALLOGRAPHY; METALS, THEORY OF; and PHASE CHANGES AND EQUILIBRIA. This article covers the following major areas: history of metallurgy; mineral dressing; process metallurgy; metal processing; and physical metallurgy.

### History

The present-day use of metals is the culmination of a long path of development extending over approximately 6,000 years. It is generally agreed that the first metals known to man were gold, silver, and copper, which occurred in the native or metallic state, of which the earliest were in all probability nuggets of gold found in the sands and gravels of riverbeds. Such native metals became known and were appreciated for their ornamental and utilitarian values during the latter part of the Stone Age.

Gold, even when combined with silver in the alloy form, is too soft to be used in tools or weapons. It is, however, very resistant to corrosion, has a pleasing appearance, and was employed at an early date for jewelry and other decorative purposes. The rarity and softness of native silver similarly precluded its wide application for armament, tools, and weapons.

Copper occurs in the native state in many parts of the world, sometimes in huge masses and often in a state of high purity. It is soft but will harden when beaten and hammered, making it possible to produce blades, sickles, and daggers that could be sharpened to cut food, vegetation, and flesh. Native copper in all probability was the first metal to receive wide application for utilitarian purposes.

Copper was also the first metal to be extracted from its ores. Copper workings dating from 3000 to 4000 BC have been discovered in parts of the Middle East, notably in the area of Sumer in Mesopotamia at the northern tip of the Persian Gulf. Ornaments and weapons found in this area suggest that casting of metals also began about 3500 BC and that there was an interval of about 2,000 years between the making of crudely wrought metal articles and the earliest castings.

An essential step toward the Metal Age was the discovery that metals could be melted and cast to shape in molds; another was the discovery that metals could be recovered from metal-bearing minerals. There was a close relationship between these metallurgical developments and the growth of civilization. Man needed a stronger metal than native copper. Possibly more by accident than intent, he discovered that certain copper ores containing the tin-bearing mineral cassiterite could be treated in a charcoal fire at a red heat to produce an alloy of copper and tin known as bronze. This discovery occurred between 4000 and 1400 BC. Bronze is harder than copper, has a lower melting temperature, and casts more

readily, producing sounder castings. There is definite evidence that the advantages of these bronzes were soon appreciated. The earliest copper ores used in smelting (extraction of a metal from its ores by heat) were surface outcrops that had been weathered until many of their impurities were removed.

### EMERGENCE OF BRONZE, IRON, AND BRASS

As the depth of ore bodies below the surface increased, the ore not only tended to become harder, it tended to change radically in composition. A fundamental step was taken when an early genius realized that copper also occurred in unweathered ores; processes that involved quite advanced metallurgical knowledge were gradually devised for working these ores. As they were less pure than the weathered surface material, the copper produced was correspondingly impure. By the latter half of the 3rd millennium BC, copper was being produced with its impurity content rising to 2 to 3 percent. The alloys containing several percent of arsenic, antimony, iron, or lead, forerunners of the true Bronze Age, at least in central Europe, possessed marked advantages when compared with copper itself; but they tended to be brittle, and the superiority of tin as an alloying material was soon appreciated. Starting with a tin content of 5 percent or less, these bronzes quickly settled down to tin contents of about 10 to 12 percent. The Bronze Age was heralded by these discoveries.

Although bronze was known in Sumer as early as 3000 BC, tin ores were scarce and not as widely distributed as copper ores; hence sources of tin ores were sought outside the Middle East. At about 2000 BC the people of Hissarlik, the site of the city of Troy, learned the art of bronze making using ores obtained from central Europe. Migration of peoples from the Middle East to Egypt, Europe, India, and, possibly, China, brought on by wars and drought, was largely responsible for the spread of the bronze culture into these areas.

During the Bronze Age the Egyptians introduced the lost-wax process, a method known today as the investment method of casting. In this method an exact model or pattern of the article to be cast is made in wax, then covered with a claylike material to form the mold. The composite is heated to harden the mold and to melt the wax, which drains off, leaving an exact negative impression, which is then filled with molten metal and allowed to solidify. The statue of the pharaoh Pepi I and his son, dating from about 2600 BC, is one of the earliest examples known of the lost-wax art.

By 1400 BC iron was assuming increasing importance, and was smelted and worked simultaneously with copper and bronze, as indicated in the Table.

Iron does not occur on earth except in ores, but meteoric iron, while rare, has been known from a very early date. A characteristic of meteoric iron is a high nickel content, and iron of this type has been found in ancient iron articles. By about 1200 BC, iron had attained sufficient importance for this date to be used as marking the beginning of the Iron Age.

Smelting of iron from ore involves a much more elaborate technique than does smelting of copper, and iron smelting was correspondingly slow in coming. The earliest record of iron smelting dates from about 1300 BC. Evidence from excavations indicates that the art of iron making originated in the mountainous country to the south of the Black Sea, an area dominated by the Hittites. Later the art apparently spread to the Palestinians, for crude furnaces dating from 1200 BC have been unearthed at Gerar, together with a number of iron objects.

Smelting of iron oxide with charcoal demanded a high temperature, and the product even then was merely a spongy mass of pasty globules of metal intermingled with a semiliquid slag. Repeated reheating and hammering eliminated much of the slag, creating wrought iron, a much better product than the iron sponge. This wrought iron was low in carbon content, hence soft, and its use for weapons and tools was limited. It was discovered that continued heating to a red heat in a mass of glowing charcoal (during which carbon was absorbed) made the

soft metal much harder. As early as 1200 BC iron with 1.5 percent carbon at the surface, corresponding somewhat to modern case-hardened iron, was being processed. The carbon-containing iron had the further great advantage that, unlike carbon-free iron, it could be made still harder by quenching—*i.e.*, rapid cooling by immersion in water.

By 1000 BC iron was beginning to be known in central Europe. Its use spread slowly westward; iron making was fairly widespread in Great Britain at the time of the Roman invasion in 55 BC. In Asia iron was also known in ancient times, in China by about 700 BC.

Brass, an alloy of copper and zinc, made its appearance during the period from 1600 BC to 600 BC. In the beginning the alloy probably was obtained when mixtures of copper and zinc ores were unintentionally smelted. In any event, its value was not appreciated, and the metal was employed sparingly until it was used by the Roman Empire in the form of currency. The general establishment of a brass industry was one of the important metallurgical contributions made by the Romans. Bronze, iron, and brass were, then, the metallic materials on which successive peoples built their civilizations and of which they made their implements both for war and peace.

#### DEVELOPMENTS FROM 500 BC TO AD 1500

By 500 BC considerable technical progress had been made in the mining and recovery of ores, progress that was definitely linked with the beginning of scientific thought in metallurgy. By this time rich lead-bearing silver mines had opened in Greece and had reached depths of several hundred feet. These mines were vented by drafts provided by fires lit at the bottom of the shafts. Ores were hand-sorted, crushed, and washed with streams of water to separate valuable minerals from the barren, lighter materials. Because these minerals were principally sulfides,

they were roasted (heated in air without fusion) to form oxides that were then smelted to recover a lead–silver alloy.

Lead was removed from the silver by cupellation, a process of great antiquity in which the alloy was melted in a shallow porous clay or bone-ash receptacle called a cupel. A stream of air over the molten mass preferentially oxidized the lead. Its oxide was removed partially by skimming the molten surface; the remainder was absorbed into the porous cupel. Silver metal was retained in the cupel. The lead from the skimmings and discarded cupels was recovered as metal upon heating with charcoal.

Native gold itself often contained quite considerable quantities of silver. These silver–gold alloys, known as electrum, may be separated in a number of ways, but presumably the earliest was by heating in a crucible with common salt. In time and with repetitive treatments, the silver was converted into silver chloride, which passed into the molten slag, leaving a purified gold. Cupellation was also employed to remove from the gold such contaminants as copper, tin, and lead. Gold, silver, and lead were used for artistic and religious purposes, personal adornment, household utensils, and equipment for the chase.

In the thousand years between 500 BC and AD 500 man made a vast number of discoveries that were significant in the growth of metallurgy. The Greek mathematician and inventor Archimedes, for example, demonstrated that the purity of gold could be measured by determining its weight and the quantity of water displaced upon immersion—that is, by determining its density. In the pre-Christian portion of the period, the first important steel production was started in India, using a process already known to ancient Egyptians. Wootz steel, as it was called, was prepared as sponge (porous) iron in a unit not unlike a miniature blast furnace. The product, an unmelted sponge iron, was hammered while hot to expel slag, broken up, then sealed with wood chips in clay containers and heated until the pieces of iron absorbed carbon, converting it to steel. Steel is defined as iron that contains carbon as an essential constituent in any amount up to about 1.7 percent. The steel pieces could then be heated and forged to bars for later use in fashioning articles, such as the famous Damascus swords made by medieval Arab armourers.

Arsenic, zinc, antimony, and nickel may well have been known from an early date but only in the alloy state. By 100 BC mercury was known and was produced by heating the sulfide mineral cinnabar and condensing the vapours. Its property of amalgamating (mixing or alloying) with various metals was employed for their recovery and refining. Lead was beaten into sheets and pipes, the pipes being used in early water systems. The metal tin was available and Romans had learned to use it to line food containers. Although the Romans made no extraordinary metallurgical discoveries, they were responsible, in addition to the establishment of the brass industry, for contributing toward improved organization and efficient administration in mining.

During the early centuries of the Christian Era, many scientific philosophers, known as alchemists, believed that it was possible to transmute one element into another. Although this was not achieved, the discoveries of the alchemists contributed to a better understanding of metals and their compounds and laid the foundations of modern chemistry.

Beginning about the 6th century, and for the next thousand years, the most meaningful developments in metallurgy centred around iron making. Great Britain, where iron ore was plentiful, was an important iron making region. Iron weapons, agricultural implements, domestic articles, and even personal adornments were made. Fine quality cutlery was made near Sheffield. Monasteries were often centres of learning of the arts of metalworking. Monks became well known for their iron making and bell founding, the products made being utilized either in the monasteries, disposed of locally, or sold to merchants for shipment to more distant markets.

In Spain, another iron-making region, the Catalan forge was invented, and its use later spread to other areas. A

Native gold–silver alloys

Fine Sheffield cutlery

hearth type of furnace, it was built of stone and was charged with iron ore, flux (substance added to help fusion), and charcoal. The charcoal was kept ignited with air from a bellows blown through a bottom nozzle (tuyere). The sponge iron that slowly collected at the bottom was removed and upon frequent reheating and forging was hammered into useful shapes.

By the 14th century the furnace was greatly enlarged in height and capacity. Because the iron was in contact with hot charcoal for longer periods of time, it absorbed more and more carbon, which lowered its melting temperature sufficiently for it to exist in the molten state.

The first purposeful use of the iron from medieval furnaces was not for steelmaking but for producing cast-iron castings. Cast iron is a variety of iron containing about 2 to 4.5 percent carbon, poured molten into a mold to solidify in a desired shape. Chemically it is the same as pig iron, the crude iron from a furnace; normally it is brittle and cannot be hammer welded, forged, or rolled and is more easily fused than steel.

#### DEVELOPMENTS AFTER 1500

Metallurgical writings

During the 16th century, metallurgical knowledge was recorded and made available. Two books were especially influential. One, by the Italian Vannoccio Biringuccio, was entitled *De la pirotechnia* (Eng. trans., *The Pirotechnia of Vannoccio Biringuccio*, 1943). The other, by the German Georgius Agricola, was entitled *De re metallica*. Biringuccio was essentially a metalworker and reported methodically and with unusual completeness the knowledge he had acquired. His book dealt with smelting, refining, and assay methods (methods for determining the metal content of ores) and covered metal casting, molding, coremaking, and the production of such commodities as cannon and cast-iron cannonballs. His was the first methodical description of foundry practice.

Agricola, on the other hand, was a miner and an extractive metallurgist; his book considered prospecting and surveying in addition to smelting, refining, and assay methods. He also described the processes used for crushing and concentrating the ore and then, in some detail, the methods of assaying to determine whether ores were worth mining and extracting. Some of the metallurgical practices he described are retained in principle today.

Introduction of coke

From 1500 to the middle of the 19th century, metallurgical development was largely concerned with improved technology in the manufacture of iron and steel. In England, the gradual exhaustion of timber led first to prohibitions on cutting of wood for charcoal and eventually to the introduction of coke, derived from coal, as a more efficient fuel. Thereafter the iron industry expanded rapidly in Great Britain, which became the greatest iron producer in the world. The crucible process for making steel, introduced in England in 1740, by which the materials were placed in clay crucibles heated by coke fires, resulted in the first reliable steel made by a melting process.

Closely associated with steelmaking was the making of tinsplate, an industry that began to flourish early in the 17th century. The process was said to have originated in the metal-rich region of Bohemia (Czechoslovakia). The canned food industry that developed late in the 18th century stimulated a large expansion in consumption of tinsplate.

The earliest methods of steelmaking suffered the serious inherent disadvantage that the iron, normally in the form of pig iron, remained in intimate contact with charcoal, which made it difficult to reduce the carbon content to a point at which the metal became ductile. This difficulty was overcome by the puddling process invented in England in 1784. In it, melting was accomplished by drawing hot gases over a charge of pig iron and iron ore held on the furnace hearth. During its manufacture the product was stirred with iron rables (rakes), and, as it became pasty with loss of carbon, it was worked into balls, which were subsequently forged or rolled to a useful shape. The product, which came to be known as wrought iron, was low in elements that contributed to the brittleness of pig iron and contained enmeshed slag particles

that became elongated fibres when the metal was forged. Later, the use of a rolling mill equipped with grooved rolls to make wrought-iron bars was introduced.

These developments in metal recovery and metallurgical technology in the early 17th century and thereafter ran parallel with and played an important part in the Industrial Revolution sweeping England and the Continent. In England, especially, metallurgical skills were well developed in extractive metallurgy, exploitation of mineral wealth, manufacture of iron and steel, and in the growth of industries that depended upon basic metal-making processes.

Metallurgy developed from an art dependent on trial, experience, and rule of thumb into a combination of art and science involving knowledge of the principles underlying the behaviour of metals—principles grounded largely in chemistry and physics. It would be unprofitable, therefore, to continue the history of metallurgy, especially during the 19th and 20th centuries, along purely chronological lines. The reader will often find, however, that historical facts pertaining to certain significant processes and events in metallurgical technology will be given in the account of processes and events.

#### Mineral dressing

Before the Metal Age began, man had to discover that metals could be extracted from mineral-bearing rocks. Through ingenuity and, doubtless, accident, this came about; thus, metallurgy, from its beginning, was concerned with the problem of treating crude ore to segregate valuable minerals and to extract metals from them. This activity is now embraced in extractive metallurgy, which consists of two phases: mineral dressing and process metallurgy.

Minerals are any chemical elements or compounds occurring naturally in the earth's crust. When a deposit of minerals is of sufficient abundance to be profitably mined and treated to extract its metallic components, it is called an ore. The worthless material expelled during the extraction is known as gangue, or tailings.

The beneficiation (concentration) of ore has undoubtedly been practiced in one way or another since man first produced copper as far back as 3,000–4,000 BC. Treatments of ore involve first, a separation of particles of different minerals with little or no change in their chemical composition, and second, a breaking down of the valuable minerals to isolate the desired metallic elements. The mechanical operations necessary to separate mineral from gangue are called mineral dressing. Modern processes in mineral dressing have become increasingly directed toward using fundamental principles governed by laws of physics, chemistry, and electricity. The practice of mineral dressing constitutes only a part of the total effort involved in the recovery of metals from ores. Because most ores as mined contain more than one species of mineral, the first step in the general scheme of ore treatment is to free them from an interlocked state physically by comminution—a process that includes the breaking down of the ore to fine powders, their ultimate fineness depending upon the fineness of dissemination of the desired mineral particles to permit their separation from waste. As a rule, comminution begins by dry crushing the ore to below a certain size and finishes by wet or dry grinding to liberate the minerals from the unwanted gangue.

Types of treatments

#### CRUSHING AND GRINDING

In primitive times, crushers were either small hand-operated pestles and mortars or millstones that could be turned by men or horses or operated by waterpower. Today, crushing and grinding for liberation before beneficiation is generally done in stages, with the possibility of some beneficiation between stages. Generalization is difficult because each ore has individual characteristics that influence the crushing and grinding procedures.

Some ores in nature occur as mixtures of discrete mineral particles, such as gold in gravel beds in streams and diamonds in mines. These mixtures require little or no crushing, as the valuables are recoverable using other

techniques. Most ores, however, are made up of hard, tough rock masses that must be crushed before the valuable minerals can be released. Coarse, or primary, crushing today is most often done by squeezing until fracture occurs using large crushers capable of taking crude ore in sizes up to 7 feet (over 2 metres) in its largest dimensions and reducing it to lumps of from 1 to 6 inches (25 to 150 millimetres) in size. The product from primary crushing may then pass to one of several types of secondary crushers, where it is further reduced in size to a fraction of an inch. The main task of primary-, secondary-, and, sometimes, tertiary-stage crushing is to prepare the ore for fine grinding by either wet or dry methods. The minimum size of crushing consistent with economic considerations is in the order of one-fourth to one-half inch (6 to 13 millimetres).

Tumbling mills, horizontal cylinders containing grinding media of various kinds, such as rods, pebbles, or steel balls, are almost universally used for fine grinding to secure further comminution. Screens woven of wire to a given mesh size customarily are used to determine and to control particle size. Mesh is defined as the number of openings per linear unit; in the widely used Tyler Series of screens, it ranges from 3 to 325 per inch.

#### CONCENTRATION OR MINERAL PREPARATION

Hand sorting is the simplest form of concentration. The Chinese in 500 BC are reported to have processed marginal ores by hand sorting. Occasionally, hand sorting is still used to remove contaminating and waste products as well as to single out especially rich materials as ore passes along moving tables or conveyor belts. Minerals to be sorted in this fashion must have sufficiently distinctive colour, lustre, texture, or general appearance for the picker to distinguish the wanted from the unwanted materials. Another simple form of concentration is the art of panning, sometimes used in gold recovery; it concentrates heavy particles at the bottom of the pan while the lighter waste material is washed off on top. Still another simple concentrating device is an ordinary screen where the valuable mineral is either finer or coarser than the bulk of the ore. Washing coarse ore with a stream of water to remove fine sand and clay is often used.

In large-scale operations, where crushed and ground ores are to be concentrated, advantage is taken of the more common physical, chemical, magnetic, and electrical characteristics of the minerals. The basis of an economically practical process is that the particles of concentrate and gangue must not respond alike in any important degree to the specific separating force employed.

*Gravity concentration.* Gravity methods used to beneficiate ores are dependent on the combined effect of mass and shape of the particles in determining their movement relative to flowing water. In one method the water flows vertically upward either continuously, as in hydraulic classification or with an oscillating motion. To achieve separation by hydraulic classification, the rate of settling between the heavy and light mineral particles in the continuously flowing current of water must be reasonably different. By adjusting the rate of upward flow of a continuous stream of water, a classification between coarse and fine or between heavy and light particles is possible.

In using oscillating motion of water, a process known as jigging, the size variable is first reduced by screening, after which the differential settling rate of the particles is exploited. Jigging is one of the oldest methods for concentrating ores and is still widely used in some areas. In jigging, water is pulsed strongly upward and downward through a bed of particles. After sufficient pulsation, the top portion of the bed becomes an accumulation of the lighter gangue, which can be rejected, while the lower part is the heavier enriched concentrate.

Another method makes use of relatively undisturbed water that has been mixed with slow-settling heavy minerals (finely ground ferrosilicon, for example) to provide a liquid that can be maintained at a high density. When ore is fed into the liquid, particles of lower density than the

liquid float while particles of higher density sink. This is called sink-and-float, or heavy media, concentration.

In a third method of gravity concentration, the ground ore is carried either horizontally or down an inclined plane in a flowing stream of water. Separation depends on forces acting upon the particles as they move in a layer of water, on the rate of fall of the particles, and on their resistance to lateral displacement once they contact the floor of the concentrator. Spirals, a type of gravity separator using this principle, have been found especially satisfactory for treating ores of the finer sizes. The device is a spiral channel with a modified semicircular cross section into which the pulp (ground ore and water) is fed from the top. As the pulp flows down, the heavier particles concentrate on the inner side of the stream and are removed at conveniently located ports.

For these gravity methods to provide satisfactory separation, a marked difference in density of the wanted minerals and gangue must exist. Even when such a difference exists, these methods can become cumbersome and inefficient if the average particle is so small that its surface friction becomes the controlling property determining its movement through the surrounding fluid.

*Separation by flotation.* The process of concentrating ores by flotation was developed on a commercial scale early in the 20th century to remove very fine mineral particles that formerly had gone to waste in gravity concentration plants. Flotation has now become the most widely used process for extracting many minerals from their ores. It is based on the fact that the wettability of the different minerals, upon treatment, may be altered so that certain mineral particles remain unwetted and adhere to air bubbles. Through the use of relatively small amounts of chemicals or oils, particle surfaces may be altered to an air-avid or water-avid condition—that is, the surfaces prefer either water or air.

Thus, in a pulp of mineral particles and water through which air bubbles are passing, the air-avid particles attach themselves to the bubbles and are carried to the upper surface of the pulp, where they enter the froth; the froth containing these particles can then be removed. The water-avid particles remain in the pulp.

It is possible not only to float various minerals from gangue but also to separate certain valuable minerals from others selectively. Many complex ore mixtures formerly of little value have come to be among the principal sources of certain metals by proper application of the flotation process.

*Magnetic separation.* Magnetic separation is the most used and probably the most efficient method of beneficiating iron ores, the principal mineral of which is the iron oxide known as magnetite ( $\text{Fe}_3\text{O}_4$ ). The technique is based largely on the differing degrees of attraction exerted on various minerals when influenced by magnetic fields. It is applicable to the treatment of both coarse and fine particles, either wet or dry. In concentrating magnetic iron ore, low-intensity wet magnetic separators are most commonly used.

When ores are conveyed through a magnetic field of the proper strength, the magnetic portion is separated from the nonmagnetic. High-intensity magnetic separators have been developed for the separation of weakly iron magnetic minerals, permitting magnetic beneficiation of hematite ( $\text{Fe}_2\text{O}_3$ ), limonite ( $2\text{Fe}_2\text{O}_3 \cdot 3\text{H}_2\text{O}$ ), siderite ( $\text{FeCO}_3$ ), franklinite ( $\text{ZnFe}_2\text{O}_4$ ), ilmenite ( $\text{FeTiO}_3$ ), and wolframite ( $\text{Fe, Mn}$ )  $\text{WO}_4$ .

*Electrostatic separation.* This is a concentration method utilizing the force of an electric field to effect separation between minerals of different electrical properties. It is based on the phenomenon of attraction between unlike electrical charges and repulsion between like charges.

The process has proved quite successful in the treatment of heavy beach sands from which the valuable minerals ilmenite ( $\text{FeTiO}_3$ ), rutile ( $\text{TiO}_2$ ), or zircon ( $\text{ZrSiO}_4$ ) may be recovered. Its application to iron-ore beneficiation has also been considerable.

*Amalgamation.* Amalgamation is an ancient process still used to recover free gold. The process depends on the

Use of spiral separators

Gold recovery by panning

fact that when clean surfaces of gold or silver come in contact with mercury they readily form an alloy called an amalgam. The gold (or silver) is recovered by heating the amalgam in retorts until the mercury is distilled off.

**Fluidized-bed technique.** The fluidized-bed technique has been adopted in a number of processes to increase the economic recovery of metals from ores and concentrates. In this process, the material to be treated is kept in motion in a chamber by an upward current of gas that maintains the individual particles in suspension. Through precise adjustment of the velocity of the gas to conform with the grain size and specific gravity of the materials to be treated, a floating mixture of gas and solids is generated that behaves almost like a liquid. Increasing attention has been given to studies of high-temperature reactions in fluidized-bed systems, "high-temperature" implying the region of 2,500°–2,800° F (1,370°–1,540° C), the practical limit of fuel-combustion heating.

**Agglomeration.** For some time, the metallurgical industry has been confronted with the task of agglomerating ore fines (fine particles) and concentrates. Although a number of processes have been studied intensively, they have been unable to compete economically, except in special instances, with sintering and pelletizing.

In sintering, a mixture of fine material, fuel, and water is fed onto a grate where its surface is ignited. Air is drawn through the bed to promote combustion. The passage of a high-temperature flame front through the bed causes incipient fusion with the formation of a porous, coherent mass called sinter. Although sinter is too friable (subject to crumbling) to resist excessive breakage during shipping and must, therefore, be made near the site of its use, its performance in metallurgical processes related to control of the size of the lumps has been excellent, creating an increasing demand for it throughout the world.

In pelletizing, moistened, finely divided materials, which often contain binders to enhance balling and limestone to promote high-temperature strength and to serve as flux in subsequent use, are fed into balling pans that deliver roughly spherical aggregates or pellets that must be dried and fired at a suitable temperature to harden. Pellets are usually less than one-half inch (13 millimetres) in size and sufficiently strong after firing to resist breakage; hence they have no serious limitation from the standpoint of shipping. The pelletizing process is particularly suitable in agglomerating very fine concentrates and ores.

**Sampling and analysis.** Routine sampling is undertaken to provide information needed for technical control and economic appraisal of ores and concentrates. By sampling, it is possible to direct attention to adjustments that may be needed during the process of mineral dressing. Sampling and sample-preparation methods frequently are major factors in determining the speed, reproducibility, and accuracy of analyses obtained with the use of modern instruments.

Even before the 16th century, comprehensive schemes of assaying (measuring the value of) gold, silver, lead, copper, tin, mercury, and bismuth ores were known, using procedures that do not differ materially from those used in modern times. Although conventional methods of chemical analysis are used today to detect and estimate quantities of elements in ores and minerals, they are slow and not sufficiently accurate, particularly at low concentrations, to be entirely suitable for industrial control. As a consequence, to achieve greater efficiency, sophisticated analytical instrumentation is being used to an increasing extent as an integral part of overall process-control schemes in mineral dressing.

Emission spectroscopy and X-ray fluorescence spectroscopy, for example, are widely used for metallurgical and ore analysis. In emission spectroscopy, an electric discharge is established between a pair of electrodes, one of which is made of the material being analyzed. The electric discharge, which may be a spark or a sustained arc, vaporizes a portion of the sample and excites the elements in the sample to emit characteristic spectra. Detection and measurement of the wavelengths and intensities of the emission spectra reveal the identities and concentrations of the elements in the sample.

In the X-ray-fluorescence spectroscopy method of analysis, a sample is bombarded with X-rays, whereupon elements in the sample give off fluorescent X-radiation of wavelengths characteristic of these elements. The amount of emitted X-radiation, measured with a detector, is related to the concentration of individual elements in the sample. The sensitivity and precision of this method are poor for elements of low atomic number (*i.e.*, few protons in the nucleus, such as boron and beryllium) but for slags, ores, sinters, and pellets where the majority of the elements are in the higher atomic number range, as in the case of gold and lead the method has been generally suitable.

The trend toward achieving automatic control in metallurgical operations demands development of new and improved methods and devices to gain a better understanding of the complex physical and chemical nature of the materials being handled. Great strides in this direction are being made through the use of instrumentation, more sophisticated control systems, and the electronic digital computer for processing of data and process control.

### Process metallurgy

Process metallurgy comprises a series of steps or processes by which the impure minerals that have been isolated either by mining or mineral dressing are reduced to metal, refined, alloyed, and made available according to specifications. An old art involving chemical changes that break down, or decompose, the impure minerals into their metallic and nonmetallic components, it has become, with the aid of chemical science, the chief element in modern metallurgy. The steps followed to recover metals from their minerals are normally selected on the basis of several considerations, among them the chemical nature of the mineral itself, which may be a sulfide, oxide, carbonate, silicate, or other species. There are three classes of methods: (1) pyrometallurgy, the use of heat; (2) electrometallurgy, the use of electricity; and (3) hydrometallurgy, the use of water.

Classes of recovery methods

### PYROMETALLURGY

Pyrometallurgy is any metallurgical extractive process involving high temperatures that depends on heat action. Normally, the heat is supplied either by combustion of such fuels as coke, oil, or gas, or by electric power.

**Gas-solid reactions.** Ores in the form of oxides may be treated directly, but sulfide ores first must be roasted. Roasting is heating in air without fusion, its chief purpose being to transform sulfide minerals into an oxide. The sulfur escapes as a gas in the form of sulfur dioxide. Roasting is often employed to yield a product that is chemically and physically more amenable to some later process. It is commonly applied to such minerals as galena (PbS), sphalerite (ZnS), and chalcocite (Cu<sub>2</sub>FeS<sub>2</sub>) to render them in suitable state for conversion to the metal (reduction) by carbon.

Many roasting reactions are exothermic—that is, once the reaction has started on contact with an air blast, the heat liberated enables it to continue spontaneously. Careful control during the roasting is required because overheating may ensue, producing fusion and the cessation of oxidation. The product of roasting, often purposely brought to an agglomerated state, is known as calcine.

A development for processing ore using gas-solid reactions to extract metals is chlorination, in which the oxides of some metals are converted to chlorides by the reaction of chlorine only, and the oxides of other metals are converted by the additional help of carbon. Chlorination is especially applicable in the processing of complex ores where the conventional metallurgical methods are inadequate. Low-working temperatures, high yield, and sharp separation are the essential characteristics of chlorination. The chlorinating agents have a high reactivity, enabling the whole reaction to be carried out at much lower temperatures than those employed in usual smelting techniques. The advantages of chlorination are illustrated in the processing of titanium, for its oxide is technically impossible to reduce because of the high temperatures involved. Chlorine in the presence of carbon decomposes

Chlorination in titanium processing

Use of instrumentation

titanium dioxide at a relatively moderate temperature, forming titanium tetrachloride, from which the metal can be obtained by reduction with magnesium.

In the processes so far described, the products obtained are in a fairly divided condition. Although this result is suitable for some later smelting processes, in the production of lead and iron in the blast furnace a coarse product is essential. In the preliminary preparation of these finely divided materials for smelting, agglomeration is frequently important and may be achieved by sintering or pelletizing as described earlier.

**Distillation.** Metals obtained during the initial stages of processing usually contain impurities derived from the raw materials. To get a higher order of purity, further treatments and refining procedures, such as distillation, are used. Such volatile metals as zinc, mercury, and cadmium may be readily purified by distillation.

**Zinc production.** In zinc production, carbon reduction of the oxide in retorts is the major industrial method employed. The ore is mixed with pulverized coal, and the mixture is subjected to temperatures sufficiently high to reduce the oxide, generating a gas of zinc vapour, which is then liquefied in a condenser without contact with oxidizing gases.

Efforts to develop a blast-furnace process for zinc reduction have been successful. The furnace follows the standard blast-furnace design (see below *Blast-furnace smelting*) except that volatilization of zinc prevents it from being tapped from the furnace bottom as other metals are. Instead, the zinc vapours pass upward and are rapidly condensed with a shower of molten lead in an adjoining condenser. Impurities are rejected from the furnace as slag composed primarily of the oxides of iron, calcium, silicon, and aluminum. Subsequently, the metal is refined by redistillation to remove the chief impurities, consisting of lead, iron, and cadmium. Because lead and iron are less volatile than zinc and cadmium is more volatile, the operation is divided into two stages. In the first, zinc and cadmium are distilled from the lead and iron; in the second, cadmium is separated from zinc by fractional distillation, known as refluxing, followed by condensation (see ZINC PRODUCTS AND PRODUCTION).

**Carbonyls.** High volatility is a characteristic common to some of the unique compounds of carbon monoxide with the heavy metals. In general, these compounds, called carbonyls, are produced by direct action of carbon monoxide on the finely divided metal. The first to be discovered, late in the 19th century, was nickel carbonyl,  $\text{Ni}(\text{CO})_4$ ; since then, carbonyls of iron, cobalt, chromium, molybdenum, tungsten, and manganese, as well as of some of the less common metals, have been produced. One of the important uses of metal carbonyls is in the preparation of metal of exceptionally high purity.

The carbonyls of nickel, iron, cobalt, and molybdenum can be prepared by direct synthesis; *i.e.*, by treatment of the finely divided metal with carbon monoxide. The carbonyls of the other transition elements, such as silver and copper, are prepared from the halides, compounds formed with one of the halogen elements—fluorine, chlorine, bromine, and iodine.

At one time, nickel carbonyl,  $\text{Ni}(\text{CO})_4$ , was employed in a commercial process for the recovery of nickel from its ore. The gaseous carbonyl was heated and passed into vertical columns filled with pure nickel shot (small spheres), whereupon the carbonyl gas decomposed and deposited metallic nickel on the surface of the shot.

Iron pentacarbonyl,  $\text{Fe}(\text{CO})_5$ , is commercially available and is used in industry in the preparation of iron powder (carbonyl iron) obtained by thermal decomposition of the carbonyl. Because of its high purity and desirable magnetic properties, carbonyl iron is used by the electronics industry for the production of magnetic devices. Carbonyl iron also finds application in powder metallurgy (see below).

**Ferrous metallurgical processes.** Iron- and steel-manufacturing techniques are described in detail in the articles IRON MINING AND PROCESSING; STEEL PRODUCTION. The following represents a brief summary of these important metallurgical processes.

**Blast-furnace smelting.** The development of iron making has largely centred on the evolution of a suitable type of furnace in which to conduct the ore reduction operations. From the small stone structures used in the Middle Ages capable of producing relatively few pounds of iron a day, the blast furnace has evolved into a tall, massive, vertical structure, up to 100 feet (30 metres) in height, with production capacities in excess of 4,000 tons of pig iron per day. It derives its name from the air blast injected through tuyeres (nozzles) near the bottom of the furnace to attain high temperatures necessary for the reduction of ore to metal.

In the blast-furnace process, the raw materials, consisting of iron-bearing materials (iron ore, sinter, pellets, slags from steelmaking furnaces, iron or steel scrap), coke, and flux (principally limestone) are fed in at the top. Preheated air, frequently accompanied by natural gas, oil, or finely pulverized carbonaceous material to substitute for part of the fuel, is injected into the furnace at the bottom. The products, pig iron and slag, are removed from the hearth through tapholes, while the hot gases are discharged at the top into equipment for cleaning. There the gases are prepared for combustion in stoves that preheat the blast.

A considerable amount of effort is being devoted to better raw material (burden) preparation. The major iron-bearing materials are ore, sinter, and pellets. Ores are usually in the form of oxides, such as hematite, magnetite, limonite, or goethite. Hematite represents by far the largest proportion of ore used. Burden preparation is important because, as the particle size of the burden becomes smaller, the resistance to gas flow increases. Removing fine material improves gas flow, resulting in a smoother operating blast furnace.

Proper control of the size distribution of the burden has come to be recognized as very effective in improving the productivity of the blast furnace. Size control consists of two factors: (1) control of the size range, and (2) removal of dust just before charging. Control of size distribution of the burden is accomplished by maintaining a narrow size range for each charge layer in the blast furnace. It is not uncommon for the size range of iron ore to be kept at 0.2 to 1.2 inches (5 to 30 millimetres). The elimination of very fine materials and intensive burden preparation have resulted in phenomenal increases, as much as 100 percent, in productivity of some modern blast furnaces.

In connection with burden preparation, much has been done to beneficiate the lower grade iron ores and to agglomerate the concentrate to a useful size by sintering or pelletizing. The practice of using a high percentage of iron ore in the form of sinter or pellets has yielded further improvements in furnace productivity while lowering significantly the consumption of coke. Increasing demands for greater productivity from blast furnaces has led to the use of self-fluxing sinter and pellets and to consideration of using partially prerduced iron ore in the form of pellets as burden material. The latter is still in the experimental stage.

Progress in blast-furnace output, achieved by changes in operations and in burden preparation realized since 1950, has been outstanding.

**Electric-furnace smelting.** Electric smelting furnaces are used in several parts of the world to produce pig iron, the intermediate form through which almost all iron must pass in the manufacture of steel. Such furnaces are well suited to locations having an abundance of cheap electric power along with access to raw materials. The physical requirements for the reducing agent are less stringent in the electric furnace than in a blast furnace; coke breeze (fine screenings from coke) or mixtures of coke breeze with coal may be used.

**Direct-reduction processes.** Methods for reducing iron ore by means other than the blast furnace or the electric-smelting furnace have led to a group of techniques generally referred to as direct-reduction processes. A number of such processes have been developed to make use of raw materials not fully suited for use in modern blast furnaces; for example, high-titania iron ores that cannot

Burden preparation

Direct synthesis (of carbonyls)

Use of coke breeze

be smelted in a blast furnace, because of slag problems, can be smelted in electric pig-iron furnaces. Many authorities have argued for the potential economic advantages of direct reduction followed by electric-furnace steelmaking, as against the combination of a large blast furnace followed by basic oxygen steelmaking (see below), but in the early 1970s the question remained unresolved.

Among the more popular direct-reduction processes are those using rotary kilns for the reduction of the iron ore. Iron ore and carbon are mixed with limestone (as flux) and passed through a revolving kiln operating in the region of 1,830° F (1,000° C). Under favourable conditions, the reduction is essentially complete.

Total world needs for iron ore in the manufacture of pig iron and other forms of reduced iron are expected to reach more than 1,000,000,000 tons by 1980. Of the amount consumed in the 1970s, more than 92 percent was used in the form of crude ore, sinter, or pellets as burden for the blast furnace.

*Steelmaking.* In the middle of the 19th century all of the previous steelmaking processes were largely supplanted by new techniques, the first of which was the pneumatic, or Bessemer, process, developed independently by William Kelly in the United States and Sir Henry Bessemer in England. It occurred to the inventors that the oxygen for refining could be taken directly from air blown upward through a bath of molten pig iron held in a refractory-lined vessel. The air not only purified the iron, but the metal became hot enough to remain molten even when all of the silicon, manganese, and carbon were gone and hitherto infusible pure iron remained. The whole reaction required only a few minutes; at the end, an ingot of mild steel could be cast, ready for the forge or rolling mill. The vessel used is called a converter, and, depending on the nature of its lining, it is either an acid or a basic converter.

The lining material in the acid Bessemer converter is a highly siliceous rock, ground with a little fireclay, moistened and tamped in place. Reactions within the vessel leave untouched the sulfur and phosphorus in the pig iron; hence in the acid Bessemer process the pig iron must be low in these elements. Silicon in the pig iron is the chief heat-producing element.

When the acid Bessemer process, however, was applied to pig irons high in phosphorus content and low in silicon and manganese, the process did not produce satisfactory steel. In Europe, low-phosphorus pig iron is relatively scarce and costly, and early efforts to remove the phosphorus from high-phosphorus pig iron in the acid converter failed. In the United States, pig iron of low phosphorus content was available and was used for the manufacture of satisfactory steel by the acid Bessemer process.

In 1879 it was discovered that when the converter was lined with a basic material, such as burnt limestone, dolomite, or magnesite, and when burnt lime was charged with the molten pig iron, basic slag would form and be maintained in such condition that it would absorb and hold the phosphorus oxide produced during the blow. This discovery was the beginning of the so-called basic Bessemer process widely used on the Continent for refining pig irons smelted from high-phosphorus iron ores so common to many areas of Europe. The product, called Thomas steel, is satisfactory for all classes of tonnage steels, such as bars, boiler plate, pipe, structural steel, and rails.

In the basic Bessemer process, phosphorus is removed as calcium phosphate after silicon, manganese, and carbon have been oxidized from the liquid bath. To furnish heat during the phosphorus removal stage (the afterblow) a pig iron containing typically 1.4 to 2.5 percent phosphorus is required because it is the principal heat-producing element.

Unfortunately, the product of the Bessemer process has serious disadvantages in important applications such as sheet metal for deep-drawing. The lack of ductility and workability in very low-carbon steel was finally traced to nitrogen, which averaged 0.015 percent in Bessemer steel,

as compared with 0.005 percent in more ductile open-hearth and electric steel (see below). Belgian steelmakers found that if, after the carbon in the bath had dropped to about 0.50 percent, the blow was continued with oxygen in a two-to-one oxygen-steam mixture instead of air, low-carbon steels equalling open-hearth steel in nitrogen and phosphorus content, hardness, and drawability could be regularly produced.

The substitution of oxygen for air in steelmaking is now a practical matter, and several basic oxygen processes are in use. Plants utilizing top blowing with a stream of pure oxygen were first placed in operation in 1952 at Linz and Donawitz in Austria. The plants employed pig iron produced from local ores that are high in manganese and low in phosphorus. Phosphorus, sulfur, and carbon are eliminated, and steels very low in nitrogen are produced. The vessel for steelmaking has no tuyeres, the pure oxygen gas being fed through a tubular, water-cooled, retractable lance held in a vertical position above the bath. The action of the oxygen under pressure, normally held between 140 and 180 pounds per square inch, is partly chemical and partly physical. On striking the liquid-metal surface it immediately reacts with iron and the oxidizable constituents, causing the evolution of carbon monoxide gas within the bath, giving rise to a vigorous boiling action that assists in accelerating the refining reactions.

A major advantage of the basic oxygen process is its flexibility in handling raw materials of many types and compositions. The product has shown itself to be at least equivalent in quality to basic open-hearth steel of similar carbon content. Several modifications of the process have been developed for refining the high-phosphorus blast-furnace metal commonly encountered in Luxembourg, Belgium, and France.

The very rapid rates of reaction attained and the low cost of oxygen produced in large quantities have made the basic oxygen converter more economical as an instrument for steel production than the open hearth. As a consequence, growth in crude steel production by the oxygen converter has outstripped and overshadowed the open hearth. The advantages of the basic oxygen furnace compared with the open hearth are: higher production rates; lower investment costs; lower labour requirements; lower operating cost under most conditions; and equivalent steel quality.

Before about 1870, the world's steel industry grew mainly by the installation of Bessemer converters. As large quantities of scrap began to accumulate, the open-hearth process, which could consume such scrap, grew more popular. The principal features of the open-hearth process were developed around 1864 to 1868 through the combined inventions of Sir William Siemens and Pierre Émile Martin. Siemens, who conceived the process first, incorporated the principle of regeneration to preheat the combustion air in order to intensify the melting flame over a shallow bath. Preheating the combustion air made it possible to reach sufficient flame temperature to melt large quantities of scrap in a reasonable length of time. Martin's additional idea was to dilute the molten hot metal with solid scrap. The steel produced was, in many respects, superior to Bessemer steel.

The growth of the open-hearth process was such that by 1910 it had reached a position of predominance over the Bessemer process. By 1950 the open hearth's share of global crude steel production reached 79 percent, its maximum percentage. Since then its percentage has been decreasing because of the accelerated steel production in basic oxygen furnaces.

Although the advantages of the use of oxygen in steelmaking were first demonstrated on a large scale in basic oxygen converters, it was not long before large-scale use of oxygen was applied also to existing open-hearth furnaces. Oxygen steelmaking improved the economy and technology of most of the open hearths to which it was applied, but this improvement was not enough to stop the growth of the oxygen converter process at the expense of the open-hearth operation.

In the early 1900s small electric-arc furnaces were introduced to produce alloy steels in a melting process in

Basic  
oxygen  
process

Bessemer  
process

Open-  
hearth  
process

Electric-furnace process

which the energy input is primarily electrical. Charges of 100 percent scrap may be melted and refined with precise control. After World War II, the size of electric-arc furnaces increased considerably, and now furnaces with capacities up to 200 tons are not uncommon. Improvements in mechanical and electrical equipment along with oxygen injection have lowered operating costs to the point at which electric furnaces may be competitive with small basic oxygen converters where scrap prices are favourable.

The electric furnace as known today is primarily a unit for melting and refining steel scrap. Techniques have not yet been generally accepted for refining large batches of molten pig iron in electric furnaces. In electric-arc furnaces, the electrodes of carbon or graphite pierce the roof and are of proper size to carry the electricity without undue resistance. Electric currents of large amperage arc across the gap between the lower ends of the electrodes and the slag. Heat is generated principally by the resistance offered by the air gap and the slag layer to the flow of the current.

Another type of furnace is the high-frequency induction furnace, which has a cylindrical spiral coil of water-cooled copper tubing that carries an alternating current at about 2,500 hertz (cycles per second). A crucible rammed inside the coil is electrically and thermally insulated and contains the charge of selected steel scrap and ferroalloys for simple melting and mixing without refining. The intense alternating magnetic field set up inside the coil induces sufficient eddy currents in the metal charge to heat and melt it.

The flexibility of electric furnaces and their capability of being designed for melting in vacuum as well as in air make them attractive, particularly where costs of electric energy and scrap are low. By 1965, in the U.S., ingot tonnage produced by electric-furnace melting had grown to 10.3 percent of the total tonnage.

**Nonferrous metallurgical processes.** Detailed descriptions of the manufacturing techniques for copper, lead, zinc, and other important metals will be found in such articles as COPPER PRODUCTS AND PRODUCTION; LEAD PRODUCTS AND PRODUCTION; and ZINC PRODUCTS AND PRODUCTION. The following discussion of nonferrous metallurgy therefore includes only brief summaries of these processes.

**Copper.** The commercial production of copper is mainly by pyrometallurgical (smelting) methods or by hydrometallurgical (leaching) methods, usually followed by electrolytic refining or recovery. In general, the sulfide ores (chalcopyrite, chalcocite, covellite, and bornite) are treated pyrometallurgically after flotation; and the oxide ores (cuprite, malachite, and azurite) are treated hydrometallurgically. Most of the new copper produced since the latter 1950s was from the sulfide ores. By the 1950s selective flotation was almost universally used on sulfide minerals for concentration, although gravity methods had been popular in the past. Perfect separation between wanted mineral and gangue is not possible, but with constant supervision, repeated treatment, and exacting controls, it is possible to concentrate 95 percent or more of the copper into 10 to 20 percent of the original weight and to eliminate most of the gangue and much of the worthless sulfide. The enriched ore forms the raw material for smelting, which has as its object the rejection of the worthless material as slag and the concentration of copper.

The procedure for smelting is to concentrate the copper into matte (copper-iron sulfide) with the elimination of gangue as slag. This end is accomplished by smelting in a furnace in a reducing or neutral atmosphere with suitable fluxes to form two liquid layers—the upper layer containing the gangue minerals and the fluxes, the lower layer a mixture of molten sulfides known as matte. The amount of sulfur present in the feed largely determines the matte grade, the usual grades containing from 24 to 45 percent copper and the desired amount of iron in the form of iron sulfide. Any precious metals present in the ore are collected in the matte.

The partial elimination of sulfur from the concentrate

to control the composition of the matte can be done by roasting; but in new plants the concentrate is being charged directly to the smelting furnace because it is considered preferable to accept a lower grade of matte to avoid the cost and inconvenience of roasting. The matte contains virtually all of the copper.

Copper has a lower affinity for oxygen than has iron or sulfur. This fact and the fact that the oxidation of iron and sulfur liberates large quantities of heat are the basis for matte conversion. The removal of the iron and sulfur in the matte is effected by oxidation, using air injected into the converters. When this metal is cast and allowed to solidify, the surface takes on a rough, blistered appearance as a result of the evolution of absorbed (occluded) gases, mostly sulfur dioxide. For this reason the material is known as blister copper. It is subsequently refined by fire refining or electrolytic refining.

Blister copper, in addition to copper oxide, contains small amounts of other impurities. These impurities are best removed by fire refining, in which air is forced through the molten material to ensure complete oxidation of all oxidizable impurities, which are then skimmed from the metal. The oxidizing treatment is followed by a reducing treatment, known as poling, during which ends of green logs are forced into the molten pool. When the proper stage in deoxidation has been reached the metal is cast. The metal, which had a distinctive metallic rose colour, is called tough pitch and may readily be cast into dense slabs. It contains, however, any gold and silver recoverable from the original ore as well as traces of other impurities, some of which can be detrimental. The amounts of gold and silver often make their recovery economically attractive.

The final state of purification will be described under *Electrorefining*, included in the section on *Electrometallurgy* below; and the commercial production of copper by hydrometallurgical (leaching) methods, which is widespread, will be covered in the section on *Hydrometallurgy* below.

**Lead.** The most important source of lead is galena, the sulfide of lead (PbS). Galena, in its pure form, contains 86.5 percent lead; it almost invariably also contains silver and is in fact one of the main sources for that metal. Many deposits of galena are intimately mixed with other minerals, such as sphalerite (ZnS); hence, methods for treating the ores to separate the minerals from one another were developed. The advent of flotation at the start of the 20th century permitted this separation as well as the concentration of lead from low-grade and highly disseminated galena ores.

The usual blast-furnace smelting of lead permits not only the smelting of ores and concentrates in which lead is the metal of principal value but also of lead ores in which other metals, particularly gold and silver, are of greater value than the lead itself. The smelting and refining operations must be designed to produce, eventually, a refined lead acceptably free of impurities, while permitting the recovery of silver, gold, copper, zinc, antimony, bismuth, nickel, arsenic, cadmium, indium, tin, selenium, tellurium, the platinum metals, and possibly others. There is, however, no single operation designed to recover all of them.

The first basic operation in the extracting of lead from its sulfide ores and concentrates is to remove the sulfur by roasting in air. This operation converts the sulfide to lead monoxide, and the sulfur is removed as sulfur dioxide gas. The sulfide charge is burned with enough heat to convert it to a porous, not too friable cake that breaks into lumps as it discharges from the roaster grate. These lumps, called sinter, are mixed with coarse coke, and the mixture is charged to the top of a vertical shaft or blast furnace. The modern lead blast furnace, normally rectangular in plan, varies from 17 to 18 feet (5.2 to 5.5 metres) in height from the tuyeres, where the air is introduced near the bottom of the furnace, to the charge floor at the top. The walls of the furnace comprise water-cooled steel jackets sloping upwards and resting on a crucible of refractory brick. Feed to the furnace consists chiefly of lead oxide in the form of sinter, fluxes to form a

Tough pitch

Valuable by-products

Formation of liquid layers

proper slag, and coke to act as fuel and the reducing agent. The lead serves as an excellent collector of the silver, gold, copper, zinc, antimony, bismuth, and other metals. The nonreduced elements in the charge form the liquid slag that is easily separated from the liquid metal. The operation seems simple and, indeed, it is when correctly carried out, but it can be accomplished successfully only by the exercise of great skill in preparing the charge and operating the furnace.

The metal from the blast furnace for subsequent refining is transferred either in liquid form or as a solid to a refinery where it is purified either by kettle refining or by electrolytic refining. In kettle refining the liquid metal is oxidized with air or a reagent to form a liquid slag containing essentially all of the more oxidizable metals; *i.e.*, arsenic, antimony, and zinc. The oxidation, known as the softening step, can be quite selective and results in separate slags for each of the metals if desired. After softening, the lead can be desilverized by zinc and debismuthized by adding calcium or magnesium, and the drosses (scum of waste matters) formed are removed by skimming.

**Zinc.** Although zinc sulfide (zinc blende) is the most plentiful zinc mineral, in most deposits it is so intimately mixed with other sulfides, particularly galena, that the classical methods of mechanical separation fail to separate the zinc blende. The problem was solved by the technique of flotation, a process requiring that the ore be crushed to very fine particles. Most commercial zinc concentrates are now produced by this process.

In ordinary hearth roasting, to convert zinc sulfide to zinc oxide, these flotation concentrates produce a very fine calcine, which is difficult to treat in horizontal retorts. It is therefore necessary to agglomerate the roasted product by a sintering process. An alternate procedure sometimes used is to roast the concentrates on a moving grate, directly producing a sintered product.

A large fraction of the world's zinc is still produced from hand-charged horizontal retorts, in which the sintered zinc oxide mixed with pulverized coal is exposed to a temperature of 2,550° F (1,400° C). This process has a number of disadvantages, including the batch method of operation, but improvements have been made in furnace construction and methods of firing, and mechanical charging has been introduced.

To overcome the deficiencies of the horizontal retort process, a continuous method, known as the vertical retort process, was developed in the late 1920s. Continuity of operation is secured by providing a discharge mechanism at the bottom of the retort, enabling the spent material to be continuously ejected. The zinc vapour, together with carbon monoxide and hydrogen, passes upwards through the retorts and then to a condenser where the zinc metal is collected.

Vertical  
retort  
process

A powerful competitor to thermal reduction methods is the electrolytic process by which zinc is deposited from highly purified zinc sulfate solutions. This process has been widely adopted where power is cheap and plentiful, conditions that are essential since considerable power is needed. Another advance in zinc metallurgy, the zinc blast furnace, was described earlier.

**Tin.** The only important ore of tin is the mineral cassiterite ( $\text{SnO}_2$ ). Usually the raw ores contain less than 8 percent tin, but upon concentration the tin content can be raised to between 70 and 77 percent.

Tin oxide is reduced readily by carbonaceous material when heated at a fairly low temperature. Metallic tin, obtained by reducing the ore concentrate with coal in blast or reverberatory (horizontal flame) furnaces, is purified by a number of processes. Because much of the metal is either entrapped in the slag or reacts with the fluxes during smelting, the recovery of tin from slags, furnace linings, and drosses is an important phase in the metallurgy of tin.

**Nickel.** The most important sources of nickel are the mixed sulfide ores containing pentlandite [(FeNi)S]; nickel-bearing pyrrhotite ( $\text{Fe}_9\text{S}_8$ ); and nickel-bearing chalcopyrite ( $\text{CuFeS}_2$ ).

The extractive metallurgy of nickel is fairly complex

and costly and underwent rapid changes during and immediately following World War II. The nickel-bearing sulfide ores are initially ground and carried through a series of flotation and magnetic separation processes, yielding several distinct concentrates for separate processing.

**By-products.** Many minor metals, including arsenic, bismuth, cadmium, germanium, selenium, tellurium, antimony, cobalt, silver, gold, and platinum occur in association with the major nonferrous ores and are recoverable as by-products during metallurgical treatments. They represent a substantial part of the total value of the production derived from the treatments, which often are a major or even the sole sources for the production of these metals. For economic recovery, specific processes have been developed for individual metals.

**Melting.** The preparation of metal in the liquid state is a distinct stage in most metallurgical processes. Melting is only the beginning of a series of operations by which the metal is brought into its finished form. Although the procedures by which the more common ferrous and nonferrous metals are brought to the molten state do not differ greatly among the metals, there are reactive metals, such as titanium, that, because of their affinity for the gases nitrogen, oxygen, and hydrogen, must be melted and cast under vacuum or in the presence of an inert gas. To satisfy the conditions for melting some of the newer metals as well as the more common ones, new methods of melting based on new principles are being designed. In all of these, major efforts are being exerted to obtain in the process substantial improvements in metal quality.

Several processes of melting, described below, promise to become increasingly significant in upgrading the quality of metals, particularly of steels. These processes are limited in production capacity, about 30 tons per charge being maximum, but they are valuable because of the high grade of metal they produce by melting or remelting.

In vacuum-induction melting, the charge, which can be either solid or molten metal, is induction-heated (*i.e.*, heated by a current produced in the material by an external coil) under vacuum. In the consumable-electrode vacuum-arc process, by contrast, the charge serves also as the electrode. As the electrode melts, the vacuum removes the gases; water cooling limits contamination of the melt by the furnace walls (usually copper). The process is useful especially for consolidating reactive and refractory metals and for producing high-temperature, high-strength alloys. When metal of particularly high quality is needed, the electrodes are prepared from ingots that previously were vacuum-induction melted.

Electroslag refining was developed and is applied widely in the U.S.S.R. In this process also, the electrode (sometimes two) is the charge. Using no vacuum, the furnace is charged with a slag that covers the melt and eventually the ingot. The process is said to produce metal equal in quality to vacuum-arc remelted steel.

**Alloying.** A basic condition of metallurgical technology is that it must constantly meet increasingly exacting demands from the metal-using industries. Exact types of metal are specified, including the precise components they should contain so that specific mechanical and other critical properties can be forecast. The deliberate addition of various chemical elements to the molten metal, a process known as alloying, has gone far to make it possible to attain consistently good performance of finished parts in the enormously varied conditions of modern metal use.

The chemical elements to be incorporated by alloying to liquid steel were often added as ferroalloys rich in the desired element. They include alloys of iron with boron, calcium, chromium, niobium, manganese, molybdenum, nitrogen, phosphorus, selenium, silicon, tantalum, titanium, tungsten, vanadium, and zirconium. With the production of alloys for steelmaking purposes now being carried out in electric-reduction and other types of furnaces, however, a number of the alloy additions contain relatively little iron. Elements such as nickel, copper, lead, cobalt, and aluminum are usually added as virgin

Special  
melting  
conditions

metal or scrap. The term addition agent, instead of ferroalloy, is now preferred to describe any of the materials added to molten steel for altering composition and properties. In preparing nonferrous alloys, the elements added in any quantity are usually in the form of virgin metal.

Alloying additions may be added at various times in the melting process, such as with the charge, in the molten batch near the end of the melting period, in the ladle or in the mold. Timing of such additions is determined by their effect on the temperature of the molten metal, the ease with which the addition goes into solution, the susceptibility of an addition to oxidation, and the formation and elimination of reaction products. The principal purposes of alloying are to create materials from base metals that have increased strength and toughness, improved response to heat treatment, less susceptibility to embrittlement at low temperatures, or increased resistance to heat, corrosion, or wear, or a host of other properties. Alloys composed of a complex group of elements are continually being tailored to satisfy specific needs.

**Casting.** The operations of casting metals in the liquid state vary widely according to the form in which the metal is finally to be used. Broadly speaking, metallic objects tend to be divided according to their mode of production into two types: cast and wrought. So far as metallurgical operations are concerned, cast materials are brought to final form by permitting molten metal to fill and solidify in molds of desired shape. On the other hand, wrought materials generally begin their career by solidifying in a metal mold of simple shape and being brought to desired form by working, either cold or at elevated temperature, using practices such as rolling, pressing, forging, stamping, drawing, and extrusion. (For descriptions of these practices see below *Metal processing*.) Casting is a process practiced by foundries all over the world as a basic method for the production of shapes, using in one form or another almost all of the metals known to man.

Most castings are made by pouring metal into sand molds prepared from mixtures of moistened sand and clay packed over the faces of the pattern. Recently, however, specialized processes have been developed to produce castings having greater dimensional accuracy, smoother surfaces, and more finely reproduced detail than is obtainable in sand molds. Important processes among these are plastic-mold, composite-mold, investment, permanent-mold, and die casting.

**Plastic-mold casting.** The principal mold ingredient in plastic-mold casting is calcium sulfate, to which small amounts of two or more other substances are added to attain specific properties. The molds are used to produce nonferrous castings of superior surface and dimensional accuracy. Composite molds are assembled from several components, among which at least one varies from the others in the molding materials used. The goal is to derive the specific advantages of each molding material without being penalized by its disadvantages. Composite molds are mainly for alloyed aluminum castings classified as premium-quality castings or engineered castings.

**Investment casting.** This process (also known as the lost-wax and precision-casting process) employs molds that are produced by surrounding an expendable pattern of wax or plastic with a refractory slurry that sets at room temperature. The wax or plastic is then melted out and the metal poured into the hot cavity that remains. In one variation, the patterns are of frozen mercury, which is melted out, leaving the impression to be cast. The investment-casting process is used particularly on alloys that cannot be softened or made plastic for working by heat but must be shaped to exact dimensions.

**Permanent-mold casting.** These castings are produced in metal molds that can be used over and over again. The molds consist of two or more parts so that they can be readily disassembled to eject the casting and then reassembled to be ready for the next casting. The process is particularly suitable for high-volume production of simple castings, such as gray iron pipe having a fairly uniform wall thickness and no undercuts or intricate internal coring. Permanent mold casting is used successful-

ly for casting gray iron and alloys of aluminum, magnesium, copper, or zinc.

**Die casting.** This process has found extensive application for the lower melting nonferrous metals because of the accuracy of dimensions attainable and especially because of the speed with which castings are made. The process consists generally of forcing molten metal into metal dies or molds under pressure; the die is then opened by a machine and the casting ejected. It is widely used in making castings of low-melting alloys of zinc, tin, aluminum, magnesium, and, to a limited extent, for certain types of brass and bronze. The difficulties of the process increase rapidly as the melting temperatures of the metal rise. The process in Europe is termed pressure die casting.

**Ingot solidification.** By far the largest proportion of liquid metal produced throughout the world is cast in molds for ingots, which are then used for future mechanical working such as in rolling and forging. Steel ingots can range in size from small blocks weighing a few pounds to huge, tapered, octagonal masses weighing more than 100 tons.

In pure metal free from gas, the solidification process is comparatively simple, but it is by no means simple in complex alloys such as steel and the many nonferrous alloys that often contain dissolved gases as well as suspended oxides, sulfides, hydrides, nitrides, and silicates. The principal factors that play a part in ingot solidification are: contraction, which comes about because the metal after solidification generally occupies a smaller volume than in the liquid state; gas liberation, which comes about because most liquid metals dissolve large volumes of gas, especially oxygen and hydrogen, that are driven off during solidification as a result of their lower solubility in the solid state; segregation, resulting from impurities and various constituents that may undergo nonuniform separation upon solidification; and contraction stresses, resulting from the fact that the outer portions of an ingot necessarily solidify while the inner portions are still liquid.

The amount of gas, chiefly oxygen, dissolved in liquid steel and the amount of gases released during solidification determine the type of ingots; these are termed killed, semikilled, capped, or rimmed in ascending order of amount of gas retained.

Nonferrous metal and alloy ingots and slabs, although subject to the same general laws and phenomena as steel ingots and slabs, are rarely as large, so that many of the problems arising from large size, very slow cooling, and extensive segregation common to large steel ingots are not encountered in the nonferrous industries. On the other hand, blowholes (captured gas bubbles) lying just under the ingot skin, which often are regarded as normal in steel and weld during subsequent working, are not tolerable in nonferrous metals. They do not weld but tend to open out during the annealing process following cold rolling, causing defects.

Today, the casting in simple shapes of both ferrous and nonferrous metals is being done by continuous casting processes. Many continuous casting techniques had been used for years to cast shapes of nonferrous metals, particularly wire rod. Adapting these techniques to ferrous products has been difficult, largely because of the much higher casting temperature. The advantages promised by continuous casting, however, have led to persistent experimentation and to step-by-step improvements that have resolved most of the problems for steel in the period since 1950. The big economic gain from continuous casting is the high yield of sound steel, some 94 percent in contrast to about 80 percent for conventional ingot practices.

#### ELECTROMETALLURGY

Electrometallurgy is the science and technology of metallurgical operations conducted by electrochemical means—specifically, the use of electrolytic processes in the extraction and refining of metals and in electroplating. It is concerned with two branches: the conversion of electrical energy into chemical energy (as in electrowinning, electrorefining, and electroplating, described below); and the utilization of thermal energy derived from electrical

Frozen  
mercury  
patterns

Continuous  
casting  
processes

energy, which is mainly concerned with the electric furnace and its applications. The scope of both branches is very broad.

Fuller treatments of the metals discussed below will be found under ALUMINUM PRODUCTS AND PRODUCTION; MAGNESIUM PRODUCTS AND PRODUCTION; and under similar titles.

**Electrowinning.** Electrowinning (winning or recovering the metal by an electrolytic process) can be carried out on the molten metal or compound, or on a solution of a compound of the metal. In the first process a raw ore is fused (melted) or converted into an easily fusible compound, and the resulting current-conducting solution (electrolyte) is electrolyzed (decomposed by an electric current), producing a relatively pure metallic deposit on one electrode. The second process involves leaching the raw ore (see below *Hydrometallurgy*) with an aqueous solution; the resulting solution, or electrolyte, rich in the metal, then is recovered and electrolyzed, again producing a relatively pure metal deposit on one electrode.

**Aluminum.** The production of aluminum and magnesium are typical electrowinning operations. Unlike the other common industrial metals, pure aluminum is not produced by the direct smelting of its ores. It is produced electrolytically by a process that was discovered almost simultaneously in the United States and France in 1886 and is the basis of the modern aluminum industry. Purified alumina ( $Al_2O_3$ ) is dissolved in molten cryolite ( $Na_3AlF_6$ ) and electrolyzed with direct current. The mixture is contained in a carbon-lined steel box that serves as one electrode while carbon rods or blocks dipping into the molten bath form the other electrode. Under the influence of the current, the oxygen of the  $Al_2O_3$  is deposited on the carbon, which is thereby slowly burned, while the molten aluminum is deposited on the carbon lining of the cell, collecting in the bottom. Additional alumina is stirred into the electrolyte from time to time and the molten metal is removed. The alumina required is somewhat more than 1.9 pounds per pound of metal.

**Magnesium.** The English scientist Michael Faraday was the first to succeed (1833) in producing metallic magnesium by electrolysis of molten magnesium chloride. The electrolytic process was further developed and was used exclusively until about 1941, when other techniques, employing a thermal process, came into use for a small proportion of magnesium production. In the U.S., magnesium is produced by electrolysis of fused magnesium chloride, the pure chloride coming largely from seawater. The electrolytic cells are steel shells or pots containing suspended carbon rods for one electrode and iron or carbon for the other electrode.

Electrowinning is also employed in producing an important percentage of zinc and cadmium. In the extraction of both metals by electrolysis, the solution is the sulfate of the metal, which is electrolyzed in cells using aluminum for one electrode and lead for the other.

**Electrorefining.** In electrorefining, the crude metal to be refined forms one electrode and is suspended in a suitable aqueous electrolyte. Under electric current action this electrode dissolves, and pure metal is deposited on another electrode, usually composed of the same metal as that deposited. Electrorefining processes are employed commercially in the extraction of such metals as copper, nickel, and lead and the precious metals gold and silver. The production of electrolytic copper and nickel are typical electrorefining processes.

**Copper.** More than 90 percent of the copper produced in the U.S. is electrolytically refined. Slab electrodes of fire-refined copper are further refined by immersing them in a solution of copper sulfate in an electrolytic cell with the other electrode being of copper. In the multiple system, separate anodes (positive electrodes) and cathodes (negative electrodes) are used, the cathodes consisting of thin sheets of high-purity copper, known as starting sheets. In an individual cell all the anodes are connected in one parallel group and all the cathodes in another. In the series system no starting sheets are used, the electrodes of impure copper being in series in a single cell and

serving as both anode and cathode. This arrangement allows the impure copper to be corroded from the face of an electrode while pure copper is deposited on the back. Of the two systems, the multiple system is most widely used. Its advantages lie chiefly in the ability to treat copper of lesser purity and to operate at a lower voltage. Gold, silver, and other valuable insoluble impurities are recovered as by-products of electrorefining of copper.

**Nickel.** In the electrorefining process for nickel, the impure nickel is pressed into anode plates. The electrolyte used is composed of a nickel sulfate-chloride solution containing some boric acid, sodium sulfate, and about 40 grams of nickel per litre (2.5 pounds per cubic foot). Nickel starting sheets are used as cathodes. Elaborate precautions, such as the use of canvas diaphragms, are taken to separate the anodes and cathodes, to prevent the deposition of copper and iron, as well as nickel.

**Electroplating.** Electroplating is the production of a thin coating of one metal on another by electrodeposition. Practically any metal can be electroplated under properly controlled conditions. The process is used extensively for coating various base metals with zinc, cadmium, nickel, chromium, tin, aluminum, and many other metals. The deposited metal is obtained from a solution of its salts by the passage of an electric current through the solution. It is a complex process, and careful control of the current and of the chemical composition, temperature, and cleanliness of the bath are required for good deposits (see ELECTROPLATING).

#### HYDROMETALLURGY

Hydrometallurgy is the science and technology of extracting and recovering metals chemically from ores by the use of aqueous solutions. The principles involved in hydrometallurgy are those of physical chemistry, inorganic chemistry, electrochemistry, and analytical chemistry. The production of metals by hydrometallurgy can be broadly described as extensions of these principles on an industrial scale.

The operations usually involved are: dissolving a metal or metal compound by a suitable aqueous solvent (water alone or with added reagents), usually termed leaching; the separation of waste and purification of the leach solution; and the precipitation of metal from the leach solution by chemical or electrolytic means. Although the technology of hydrometallurgy was developed at the turn of the 20th century for recovering gold from low-grade ores, its features were practiced as early as the 16th century.

An important historical prerequisite to the development of hydrometallurgical procedures was the advent of commercial direct-current generators to provide an efficient low-cost technique for precipitating metals by electrolysis from aqueous solutions. After the beginning of the 20th century methods were improved and were augmented by the addition of still other techniques. Consequently, there evolved the great copper leaching plants in South America, the U.S., and Africa; vast aluminum extraction plants throughout the world; the electrolytic zinc industry; plants producing nickel and cobalt from sulfide ores and from the lateritic deposits in Cuba and other tropical areas; the gold-producing plants of South Africa, Canada, Australia, and the U.S.; and the gigantic plants in many parts of the world that employ hydrometallurgical techniques to extract uranium from ores that contain from a fraction of a pound to a few pounds of uranium in a ton of ore.

The feasibility and successful conduct of a hydrometallurgical operation depend on a variety of factors, any or all of which may be critical. An adequate supply of water is, of course, indispensable and, because metals are present as ions in aqueous solutions, a source of energy is required to convert the ions to metallic form. Beyond these essential features, several practical physical and chemical factors must be considered. The metals or minerals must be soluble in the leaching solution; the solvent must usually be such that it will dissolve selectively the desired metals or minerals; the solution, when it contains valuable metals, should be such that the metals present

Leaching  
operation

Physical  
and  
chemical  
factors

can be readily separated from one another; and the solution must also be such that the desired metals can be precipitated from it by one means or another, producing either pure metal, a mixture of metals, or a metal salt. For economic reasons, it is usually necessary that the leach solution either be capable of being regenerated and used again or that it be susceptible of treatment to recover by-products.

The various aspects of hydrometallurgical processes include the preparation of the ores, concentrates, and other materials that are to be leached; the leaching itself, which generally applies to the selective dissolution of metal compounds and minerals from ore mixtures; the solution purification, which depends largely on the chemistry of the positive and negative ions in the solution; the precipitation of the metal to be extracted by electrolysis with direct current or by treating the solution with a reducing gas such as hydrogen; and the regeneration of the solution for its reuse.

### Metal processing

The principal areas of metal processing covered below are cold and hot working, foundry processes, surface treatments, powder metallurgy, nuclear metallurgy, and heat treatment. Metal joining is treated in WELDING, BRAZING, AND SOLDERING.

#### COLD AND HOT WORKING

A great part of the world's metal production is cast into ingots that must be shaped to finished products by mechanical forces. Mechanical working not only brings the metal to desired shape but also changes its structure and properties.

When metal solidifies from a melt, especially if it does so in large masses and therefore slowly, it has a crystalline structure that is always relatively coarse and sometimes very coarse. Mechanical working breaks down this original cast structure and replaces it with a much finer and more satisfactory structure from the standpoint of physical properties. It is possible to produce a refined structure, comparable in scale with that of worked metal, by heat treatment alone; but this method is practical only with pieces of moderate size because larger masses cannot be cooled rapidly enough. Mechanical working also causes the redistribution of the nonmetallic constituents (inclusions), making them less harmful and, particularly for steel, serves to close up and even bring about welding of cavities.

Cold working consists in the plastic deformation (working) of a metal at such temperatures and at such rates that no recrystallization occurs during the process. Under such conditions, the metal is strain hardened, that is, increased in hardness and strength as a result of plastic deformation at temperatures lower than the recrystallization range. In general, these limiting temperatures are high in metals that melt at high temperatures and low in metals that melt at low temperatures. Cold deformation of metal thus produces fundamental structural changes accompanied by an increase in properties related to strength and a decrease in properties related to ductility.

Only when the working temperatures are above the recrystallization temperature, hence when softening occurs during the working process, can the term hot working be applied. During hot working, metal is deformed by mechanical working above the recrystallization temperature so that the coarse crystallinity of the cast state becomes progressively fragmented and rearranged to bring about the reconstruction and refinement of the crystalline structure. By proper selection of temperature and by mechanical working with dies or rolls, for example, various properties of the metal can be improved.

**Forging.** In forging, articles of metal are shaped by hammering or pressing metal blanks between pairs of forging dies. Hammering was the first method employed by man in shaping metal. In most forging processes, an upper die is attached to the ram of the forging hammer or press, so that it may be raised and dropped or forced under pressure against the rigidly supported, stationary lower die. Forgings are made in many metals and alloys,

including copper, brass, bronze, nickel, aluminum, magnesium, steel, titanium, and various high-temperature alloys.

As the metal is processed from the ingot stage to various shapes (blooms, billets, slabs, and bars) for forging, its crystals are elongated, producing fibre-like flow lines of grain structure. In closed-die forging, these flow lines of grain structure are worked in such positions as to impart maximum strength relative to the stresses expected in the forged article. For maximum strength, care must be taken that the grain runs parallel to the axis of greatest bending stress.

Drop forging employs a drop hammer, so designed that the falling weight of the ram and upper die, often augmented with force from a steam or air piston, forces the heated metal into cavities cut into the face of each die. The metal being worked in a forging hammer is commonly at a sufficient heat to bring it to a plastic state.

Much progress has been made in forging metals cold, that is, at temperatures below the point at which the grain structure begins to recrystallize. Cold forming of heads has been used for many years in the manufacture of bolts and similar parts. More recently, however, cold forming has been replacing conventional hot forging, especially in forming of larger parts.

The formation of parts by forging, called chipless machining, is popular, for example, in the forge rolling of gears from solid blanks. Many other parts that can be made this way will become candidates for the process because of the savings in materials and labour.

**Metal rolling.** Of the many methods of shaping metals, rolling is most widely used. The rolling mill has passed through a succession of developments, not only in size, power, and productive capacity but also in design and in ability to produce varieties of shapes of sections with grooved rolls. The process of shaping metal by rolling consists essentially of passing the material between rolls revolving at the same peripheral speed and in opposite directions and spaced so that the opening between them is somewhat less than the depth of the material entering. Metals are rolled both hot and cold.

**Hot rolling.** Except in the few instances when ingots are forged, hot working by hot rolling is almost universally used to reduce ingots of metals by mechanical force from their original cross section through the intermediate stages to bar, structural shape, plate, sheet, and strip, the more common hot-finished forms that are produced. Hot rolling is done by passing the heated metal through pairs of heavy rollers, which are either flat or grooved, so that each successive pass lessens the cross section and brings that material more nearly to the required final shape. The hot-working temperatures are different for the different metals, but the highest are always those at which the lowest melting constituent in the structure starts to melt. The temperature range of hot working is limited by this temperature and by the temperature at which the metal remains sufficiently plastic at the lower end of the range, so that it will not rupture on working. The temperature at which the mechanical working is finished, known as the hot-working finishing temperature, is important in governing the final treatments necessary and the structural and other properties obtained.

Hot rolling accomplishes three main purposes: (1) reduction of cross-sectional area, (2) refinement of structure, and (3) shaping of the metal into desired form. Although the products of a rolling mill vary widely in weight and shape, a common characteristic is that each piece is of uniform cross section from end to end and is of a length limited only by the weight of the mass of metal being rolled. All the shaping is done in the intermediate passes of the mill. The flow of metal in the rolling operation is continuous and almost entirely in the longitudinal direction. With steel, nearly all hot rolling is done at full red heat, at which it is quite plastic.

The details of rolling practice vary widely according to the metal being rolled and the purpose for which the product is required. Heavy plates and extremely thin sheets naturally demand entirely different treatment and procedures. The rolling of broad hot strip or sheet in coils

Chipless  
machining

Hot strip mills

has been in continuous development since 1926, when the first mill capable of rolling strip more than 24 inches (61 centimetres) wide was built. In these mills, which are continuous and used mainly for steel, the hot metal is fed into the first set of rolls rotating at a moderate speed. The material emerging from the first rolls is fed directly into a second set, which, since the length is increased by the passage through the first rolls, must run at considerably higher speed. A number of sets of rolls is used in series in this way, the finished product leaving the last rolls at a very high speed. Other types of rolling result in the production of sections having the form, for example, of H and I beams, channels, angles, railway rails, and other products. These are made by the action of suitably shaped grooves cut in the rolls. Successive passes in such rolls must provide for the easy flow of the metal from one shape to the next.

**Cold rolling.** Although steel is hot when it is reduced in size from its ingot and billet form, some of the softer nonferrous metals and alloys can be treated cold. The essential nature of cold rolling does not differ from hot rolling. The effect of cold rolling, however, is to produce hardening so that, after a time, the metal has to be annealed (heated and then cooled slowly) to soften it before further cold rolling. Cold rolling is used to reduce the thickness of section, produce a smoother, more dense surface, develop controlled mechanical properties, or obtain any one or combination of these three effects.

**Drawing.** Drawing is a process for forming sheet metal, tubing, and wire to obtain certain shapes and dimensions. Flat sheet metal is drawn to produce both shallow and deep shells or cups with straight walls. The distinction between shallow-drawing and deep-drawing is somewhat arbitrary. Shallow-drawing generally refers to the forming of a cup no deeper than half its diameter.

Wiredrawing is one of the oldest industrial arts and is employed to provide a slender rod or bar of metal of uniform cross-sectional shape. The shape can be round, square, hexagonal, octagonal, oval, half oval, half round, rectangular, or flat. The limits for drawn wire range from 0.001 inch (0.025 millimetre) to approximately 1 inch (25.4 millimetres) in maximum dimension. The rod or bar of metal is pulled through a series of dies of decreasing diameter until the final shape is obtained.

Tubes are sometimes drawn through a die to reduce the inside and outside diameters, to make various shapes, and to increase the strength and hardness of the metal.

**Extrusion.** Extrusion is a process of shaping metal into a continuous form by forcing it through a die of appropriate shape. In forward extrusion the metal is held in a container having an opening (die) of the desired finished section at one end. The metal is forced through the die under great pressure by a ram. In backward extrusion the ram is hollow and contains the die. The container has a closed end and pressure of the ram forces the metal in the opposite direction. The peak pressures exerted by the ram may be as low as 5,000 pounds per square inch (351 kilograms per square centimetre) for soft metals such as lead, or as high as 450,000 pounds per square inch (31,640 kilograms per square centimetre) for alloy steels. Collapsible container tubes are formed by striking a cold slug of metal, held in a container and die, a high speed impact blow from a punch. The impact causes the metal to fill the die cavity and to flow or squirt upward out of the die around the punch. The process is called impact extrusion.

Impact extrusion of tubes

**Spinning.** Spinning is another process for forming sheet metal or tubes into hollow cylinders, cones, and other circular shapes by a combination of rotation and force. Tools, usually consisting of rollers mounted in a lathe, are pressed against the spinning metal with just sufficient pressure to deform the sheet into and against a mandrel (a metal bar serving as a core), made to the shape of the completed workpiece. Normally, spinning is done without applying heat.

#### FOUNDRY PROCESSES

Earlier, under *Casting* it was noted that foundries throughout the world practice the art of casting metals in

molds with cavities made to conform to the object wanted. The process is known as founding. Molds are generally prepared in two halves, each formed by firmly packing a mixture of sand and clay moistened with water against a wood or metal pattern that conforms in shape to the object to be cast. Although many castings are solid, there is likely to be a hollow space within the casting. To form the hollow, a core, generally of sand held to shape with a binder, is set in the lower portion, or drag, of the mold. The upper portion of the mold is known as the cope.

**Cast iron.** The general term cast iron includes a number of different irons, known as gray irons, pig irons (the product of the blast furnace), white cast irons, chilled cast irons, malleable cast irons, and ductile cast irons. Cast irons cover a wide range of iron-carbon-silicon alloys usually containing more than 1.7 percent and less than 4.5 percent of carbon along with varying amounts of silicon, manganese, sulfur, and phosphorus. They may have an alloy content of less than one percent and up to several percent. Special types of corrosion-resistant iron are made with greater alloy content; for example, with 11 percent to 17 percent silicon, 25 percent to 30 percent chromium, or 4 percent to 30 percent nickel.

Gray iron is by far the most widely used of the cast metals (see also IRON MINING AND PROCESSING). The essential characteristic of gray iron is that much of the carbon is present as flake graphite, which gives it a gray-coloured fracture when broken. Its attributes have led to its widespread use for many industrial purposes, including automobile engine blocks, agricultural and machinery parts, stove and furnace parts, hollow ware, and ingot molds.

Flake graphite in gray iron

**Cast steel.** When steel is cast into suitable molds having cavities conforming to the shape of desired objects, it is known as cast steel and the objects as steel castings. Steel for steel castings is produced commercially by almost all the melting processes used commercially for making steel.

Five classes of commercial steel castings are produced; namely, low-carbon steels with carbon content less than 0.20 percent, medium-carbon steels with carbon content between 0.20 percent and 0.50 percent, high-carbon steels with carbon content above 0.50 percent, low-alloy steels with total alloy content less than 8 percent, and high-alloy steels with total alloy content above 8 percent. Steel castings are most often heat-treated, using the various methods that apply to wrought steel, to develop the necessary characteristics.

**Nonferrous castings.** The sand-casting process for production of nonferrous castings differs in no essential way from that used for production of castings made from ferrous metals. It permits the use of a large number of nonferrous alloys, providing a variety of physical and mechanical properties in both the as-cast and heat-treated conditions. In addition to casting in sand, many nonferrous castings are produced in permanent metal and in plastic molds, by die casting and by investment casting, processes described earlier.

#### SURFACE TREATMENTS

Metals are frequently given surface treatments to produce a protective layer that has corrosion resistance and other important properties differing from those of the base material. Such surface layers, applied to metals of all types, often also serve to change or improve appearance. These surface layers may be applied by hot dipping, electroplating, cementation, and several other ways.

**Hot dipping.** Hot-dipped coatings are generally of the lower melting point metals, such as zinc, tin, lead, tin-lead alloys (called *terne*), and aluminum. To apply the hot-dipped coatings, careful attention must be given to preparation of the metal surface to be coated and to the duration and temperature of immersion. The molten metal must wet the base metal and must alloy with it. Zinc coating by hot dip (one method of galvanizing) provides an adherent, protective coating on the surfaces of iron and steel products that is effective against corrosion from exposure to the atmosphere. Zinc is more active than

Galvanizing of iron and steel

iron, hence tends to corrode instead of the iron; by this "sacrificial" protection, it prevents iron from corroding at minor discontinuities in the zinc coating.

Tin coatings produced by hot dipping are excellent in appearance, resist corrosion, give a surface that assists in soldering, and provide a nontoxic, protective coating that is particularly useful where the metal comes in contact with foods and beverages. Hot-dipped tin coatings are applied mainly to steel, cast iron, copper, and copper alloys.

Lead coatings, which are applied to ferrous articles by hot dipping, contain from 2 percent to 10 percent tin to assist in bonding.

Hot dipping is one of the various methods used for applying aluminum coatings to ferrous articles. Close control of liquid-metal temperature and time of immersion is important as these factors influence the thickness of the unwanted brittle intermetallic layer between the base metal and the pure aluminum overlay.

**Cementation.** Another process for introducing elements into, as well as onto, the outer surface of metal objects is called cementation. Essentially, the part to be cemented is heated to an elevated temperature in contact with a solid, liquid, or gaseous medium containing the cementing material. The cemented material penetrates inward from the exposed surface, forming an alloy on the surface decreasing in concentration as the distance inward increases. Among the various cementation processes used by industry are: the carburizing (impregnating with carbon) of steel; calorizing (heating the part in contact with aluminum powder) of both ferrous and non-ferrous metals; and ceramic coating to protect nickel-base, cobalt-base, and vanadium-base alloys and refractory metals against oxidation at very high temperatures.

**Other processes for coating metals.** Metal spraying, metal cladding (covering by bonding), protective film formations, painting, and vitreous enamelling are among the other processes used in coating metals. Sprayed metal coatings are produced by use of an air blast to spray heated metal particles against the object to be coated. Such coatings are often used to resist corrosion, reclaim undersized and worn parts, and to provide hard, wear-resistant surfaces. In metal cladding, surfaces of slabs of two metals are brought carefully together for the purpose of developing a bond, sometimes by heat and pressure alone.

The formation of surface films on metals is accomplished by various methods, including oxide coating of aluminum and its alloys (the so-called anodizing treatment) in a bath of sulfuric acid, or forming a phosphate protective coating on iron, steel, zinc, cadmium, aluminum, and their alloys by treating them in a dilute acid phosphate solution to convert the metal surface to an insoluble crystalline phosphate film. Vitreous (glassy) or porcelain enamels on metals are used widely in the chemical, pharmaceutical, and food industries because of their excellent resistance to chemical attack.

#### POWDER METALLURGY

The methods of powder metallurgy afford a unique way of producing and shaping metals and alloys. In its simplest form, powder metallurgy consists of: (1) pressing metal powder in a die to produce a compressed shape called a green compact, and (2) sintering (diffusion bonding by heating) the compact at an elevated temperature in a protective atmosphere. During sintering, the compact becomes consolidated and strengthened. Powder-metallurgy methods are competitive under certain conditions with other metal-forming techniques.

Powder metallurgy is usually employed for two reasons: first, because it may be the only known means of producing certain metals, alloys, or mixtures of two or more metals having certain desirable physical or mechanical properties; and second, because powder metallurgy may be the cheapest way to manufacture certain small parts, often a result of the fact that parts can be formed directly to shape, with little or no machining.

**Powder manufacture.** Metal powder may be manufactured by mechanical or chemical methods. The most widely used mechanical method, starting with solids, is

milling by power-driven hammers (hammer milling) or by balls in a rotating container (ball milling). In starting with liquid metals, various mechanical processes that break up the metal into tiny droplets before they solidify can be employed. This method is called atomization.

Chemical methods for producing metal powders provide either for the reduction of compounds of the desired metals to powder using various agents or for the electrolysis of a liquid solution (aqueous or molten) that contains the desired metal. The latter process is similar to electroplating, but the conditions of current and temperature are adjusted to produce a porous, flaky, or brittle deposit of metal that is scraped off the cathode and broken up to obtain the powder. Nickel, copper, and iron powders are often made by this process from aqueous solutions.

To obtain specific properties in the finished product, powders are often mixed and blended before use. Excessive blending, however, especially in an overloaded blender, may work harden the powder, making it less compressible and thus more difficult to compact. To bond the powder particles into a mass solid enough to withstand the stresses in service, the powder must be heated or sintered after compressing. Sintering is done in protective atmospheres or in vacuum at temperatures below the melting points of the metals. Sometimes a liquid phase forms and assists in consolidation. In all sintering processes the dimensions of the mass of powder being sintered decrease, the amount of shrinkage depending on the composition of the powder, the amount of compression to which the powder has been subjected before sintering, and the time and temperature of sintering. This shrinkage must be allowed for in the design of parts that are to be made directly to shape. When the highest possible density is required, the compacts (parts) may be repressed and then resintered.

**Processes and products.** Three general classes of processes are used in powder metallurgy, depending on the type of metal used in each. One class involves metals of relatively low melting point that are ductile, such as silver, copper, and iron. Another class involves the refractory metals; *e.g.*, metals with melting points usually above 2,912° F (1,600° C), which normally are brittle, such as tungsten, molybdenum, tantalum, and titanium. The third class concerns the production of materials known as cemented carbides, which contain tungsten carbide.

In preparing compacts from ductile metal powders, the pressing operation forms the metal part to the desired shape at room temperature. Pressures range from 10 to 50 tons per square inch (14,000 to 70,000 kilograms per square millimetre) compacting the powder to a density of about 60 percent to 80 percent of that of a similar mass of solid metal. The ductile metal compacts show shrinkages of about 1 percent to 5 percent in dimensions during sintering.

Powder-metallurgy procedures of the refractory metals are used chiefly to produce a bar or ingot of the refractory metal, which is then further processed by mechanical working to make wire, rod, tube, or sheet. Because most refractory metals are either too brittle or too hard to be compacted in the same manner as the ductile metals, they are compacted at room temperature with a binder, such as paraffin wax, that holds the compressed particles together until they can be presintered to drive off volatile matter and establish a weak bond. Sintering in a satisfactory atmosphere at a proper temperature then follows to develop the needed strength.

The cemented-carbide materials made by powder metallurgy are cemented together by a metal, usually cobalt, forming a product of great hardness and high compressive strength. The principal constituent is tungsten carbide powder, although carbides of other refractory metals, notably titanium and tantalum, are often used along with the tungsten carbide. The carbide powders, blended with cobalt powder ranging in amounts of from 3 percent to 25 percent, are mixed with a binder such as paraffin wax and pressed to shape followed by presintering at about 1,652° F (900° C) to evaporate the binder. The presintered material can then be machined or ground

carbide  
powder

to provide the shape needed for the finished part before it is finally sintered. Certain advantages of cemented carbide as a cutting-tool material stem from its ability to cut while red-hot.

Powder metallurgy is applied to iron-base compacts to produce an essentially pore-free part having increased strength and density and improved machinability. This result is accomplished by infiltrating molten metals, commonly copper and copper-base alloys, into the pores of the compact by capillary action.

#### NUCLEAR METALLURGY

Nuclear metallurgy includes the production, fabrication, and application of metals of interest in nuclear engineering and the study of their properties. The study of atomic fission in 1939 led to the emergence of several relatively unknown metals and paved the way for the practical use of atomic energy. The phenomenon of fission concerns the splitting of an atomic nucleus into two or more parts by the addition of a neutron to that nucleus. Fissionable materials include plutonium and an isotope of uranium, uranium-235; thorium can be converted into another fissionable isotope of uranium, uranium-233 (see NUCLEAR FISSION).

These materials are referred to as nuclear fuels. Because of their affinity for neutrons, the metals boron, hafnium, cadmium, or gadolinium are used to control the number of neutrons striking the nuclear fuel and thus shut down a reactor or control its power level of operation.

Because uranium metal is highly reactive toward water or air at elevated temperatures, protective cladding of the fuel elements is necessary. Aluminum and zirconium are commonly used for this purpose. Beryllium is desirable for use as a moderator—that is, to slow down high-energy neutrons produced by the fission process so that they become more effective in producing additional fission reactions.

Low-melting sodium and sodium-potassium alloys are used as coolants in several reactors. The liquid metal is circulated over the hot fuel elements and then to a steam generator where the heat in the liquid metal is recovered.

In addition to the usual problems associated with metals at high temperatures, there are some unique problems in nuclear metallurgy. One such is radiation damage, the failure of a material due to the intense radiation in a reactor. Uranium undergoes embrittlement and drastic changes in dimensions as a result of irradiation. Another serious problem that eventually results in a shutdown of the reactor is accumulation of fission products in the nuclear fuel. Direct removal of the fission products and economic reprocessing of the fuel constitute a major challenge to the nuclear metallurgist (see also NUCLEAR REACTOR).

#### HEAT TREATMENT

Many articles of iron, steel, aluminum, copper, magnesium, titanium, nickel, and their alloys intended for important engineering uses are subjected to some form of heat treatment for the purpose of obtaining certain desirable conditions or properties. Heat treatments are applicable to all metals, both ferrous and nonferrous. Changes in metals afforded by heat treatment involve changes in the nature, form, size, or distribution of the structural constituents, although frequently metals are heat-treated merely to decrease or relieve internal stresses.

Heat treatment consists of subjecting a metal to a definite time-temperature cycle. Basically, this cycle can be divided into three parts: (1) heating, (2) holding, and (3) cooling. The heating medium also is important, since it affects the rate of heating and causes or prevents chemical changes, such as oxidation, that proceed inward from the surface of the metal. Although in some instances, such as in the case of pure metal or certain alloys, the rate of cooling is likely to be unimportant, when the structure of the material being heat-treated is different at the maximum temperature from that at low temperatures, the rate of cooling is of great importance. Iron-carbon alloys that change from one crystal structure to another (gamma to

alpha iron) on cooling from above the transformation range are particularly sensitive to cooling rate.

**Aging, or precipitation, reaction.** In heat treatment, three types of reactions are of importance industrially and form the basis for most heat-treating operations: the aging, or precipitation reaction, the allotropic transformation reaction, and the decomposition reaction. The aging reaction occurs when the solubility of a constituent in the basic material (matrix) is greater at high temperature than at low temperature. In this process, the alloys are heated to a temperature sufficiently high to cause a constituent that is more soluble in the matrix at high than low temperature to dissolve. The alloys are then quenched to room temperature at a rate sufficiently rapid to prevent apparent change in structure by precipitation of the constituent. When the quenched materials are reheated within the proper temperature range, however, precipitation does take place. By controlling the conditions for precipitation, the precipitated particles can be maintained within a critical size, and considerable variation in mechanical and other properties of the alloys can be achieved. Maximum property changes are achieved with a particular combination of time and temperature for the precipitating reaction, which determines the size and distribution of the precipitated particles, and for the compositions of the alloys. Certain copper, aluminum, and magnesium alloys are among the engineering metals whose mechanical properties are vastly improved through the mechanism of precipitation hardening.

**Allotropic transformation reaction.** Allotropy is the capacity of a material to exist in more than one crystallographic structure. Materials that have this capacity are termed allotropic. Allotropic transformation occurs in some metals upon heating and cooling. It serves as the basis for most heat-treating changes that occur in steel. Steel at high temperatures, for example, is composed primarily of a solid solution of carbon having a particular crystal structure known as gamma iron. The solid solution is called austenite. Gamma iron is capable of taking into solution fairly large quantities of carbon. The solid solution on cooling converts to a mechanical mixture of alpha iron (which has another crystal structure), called ferrite, and iron carbide, called cementite. Alpha iron has a crystal structure in which carbon has an extremely low solubility. As a consequence of this low solubility, the carbon in the steel separates as iron carbide.

The rate of cooling affects the transformation of austenite and largely determines the final structure of a given steel and hence its physical and mechanical properties.

**Decomposition reaction.** This reaction involves the decomposition of certain constituents into one or more other constituents that possess more desirable properties. Its importance is illustrated by the production of malleable cast iron from the hard, brittle cast iron known as white cast iron. The iron carbide or cementite in the white cast iron is decomposed to ferrite and a spheroidal form of graphite after a prolonged heating in the temperature range of 1,380° F (750° C) and 1,750° F (955° C). This graphitized material is considerably more ductile and more easily machined than the parent material, and hence much more useful.

#### Physical metallurgy

##### METALLOGRAPHY

Metallography is the study of the constitution and structure of metals and alloys as revealed by the unaided eye or by such tools as low-powered magnifiers, optical microscopes, electron microscopes, and X-ray diffraction techniques (see below). All metallic materials are crystalline, and their characteristics are determined by the nature of the minute crystals of which they are composed or by the manner in which these crystals are aggregated into larger masses. Not until H.C. Sorby's microscopic studies on meteorites and on iron and steel in England in the period from 1863–1887, were these simple facts appreciated. Sorby's pioneering work gave birth to the modern science of metallography and was largely responsible for the impetus that turned metallurgy into a science. Metallography has provided the method of cor-

Production of malleable cast iron

The time-temperature cycle

relating the structure of the metallic materials with their composition and treatment, and with the mechanical and physical properties that determine their ultimate application.

**Metal and alloy structures.** A pure metal is composed metallographically of grains and grain boundaries. The orientation of the grains varies and gives rise to grain boundaries in the structure that define the regions where the mutually adjacent grains have met. Grain boundary regions can be made visible by applying an etching reagent, which attacks these regions more vigorously than other regions.

The metallographic structure of an alloy can be understood completely only with the aid of an equilibrium or phase diagram of the alloy system in question. Such diagrams are used to express the relationships between phases in an alloy under conditions of equilibrium; *i.e.*, conditions in which two or more phases can exist together. For binary (two-component) alloys, for example, these diagrams are two-dimensional plots in which temperature is plotted vertically and composition horizontally. This diagramming provides a graphical representation of the equilibrium temperature and composition. For the more complex alloys several two-dimensional diagrams are required for complete representation of the temperature-composition variables.

The components of an alloy are limited in the ways in which they can combine. Each of these combinations is called a phase and each influences the overall characteristics of the alloy to an extent determined by the amount present and the manner in which it is dispersed. By examining metals using metallographic techniques valuable information can be secured relative to the character and distribution of the phases and to their probable influence on properties.

**Macroscopic examinations.** In macroscopic examination—*i.e.*, examination using the unaided eye or a magnifying glass—the interest is confined largely to gross structural details and defects arising from processing and other causes. A variety of defects may be visible, such as cracks and porosity; additional details of crystalline, chemical, and mechanical heterogeneities may be revealed after a prepared or ground surface is subjected to etching.

**Optical metallography.** A greater abundance of structural knowledge can be secured through microscopic examination of a metal specimen made flat and smooth by polishing, at magnifications ranging from about 100 to 1,500 diameters. Nonmetallic inclusions and gross porosity are visible without etching. By etching with some chemical reagent that attacks the different constituents of the structure differently, such pertinent information as size and shape of grains, the size, shape, and distribution of structural phases and nonmetallic inclusions, microsegregation, and other structural features in the metal specimen can be revealed. For appraising the structure revealed under the microscope, the etchant used needs to be known, as well as the magnification. The use of polarized light (*i.e.*, light in which all the waves vibrate in one direction) in connection with optical microscopes is helpful in obtaining a variety of information.

**Electron metallography.** The electron microscope can give very much greater magnifications and is being applied in some metallographic studies, the results of which contribute greatly to man's knowledge of the microstructure of metals. The instrument's ability to separate details that are very close together (resolving power) results from the very short wavelength of the radiation from the electron beam. It is capable of much greater initial magnification and resolution (about 0.0002 micron, a micron being equal to 0.001 millimetre) than either the light or ultraviolet microscope (0.25 micron and 0.1 micron, respectively; see MICROSCOPE).

**X-ray metallography.** The application of X-ray diffraction techniques to metallurgical problems has contributed much to man's basic knowledge of metals and alloys. The technique is employed principally to study phenomena that are related to groupings of atoms themselves and is capable of resolving structures at magni-

fications equivalent to 1,000 times the lower limit of the optical microscope.

#### CORROSION

Corrosion is the gradual chemical or electrochemical attack of a metal by atmosphere, moisture, or other agents. Reactions occurring within these environments are a very important factor in the treatment and serviceability of a metal. The attack may be uniform (that is, the metal may corrode evenly) or it may be intensely localized (that is, concentrated upon small areas, a form of attack known as pitting). Two general types of reactions are recognized: direct oxidation and electrochemical. In the course of direct oxidation a solid film may form, such as the scale formed on some metals when heated at elevated temperatures. In the electrochemical reaction, the corrosion can be divided into anodic and cathodic parts (see below). Prevention of corrosion and the protection of metals against it are of vital importance to modern industry. Corrosion processes are sometimes brought about intentionally by industry, as in manufacturing the pigment white lead by the corrosion of metallic lead; but normally the processes are undesired and involve damage to the metal and expense for its replacement. The damage caused by corrosion is intensified in pitting, one of the most destructive forms of corrosion and one most difficult to guard against.

**Direct oxidation.** In direct oxidation, which results particularly when metals and alloys are heated in oxidizing environments, the nature and extent of the attack are determined largely by the properties of the scale formed; that is, its structure, chemical composition, specific volume, melting point, and boiling point. Specific volume (volume per unit mass) of the scale with respect to the specific volume of the metal is especially significant. Progress of oxidation under conditions in which the specific volume of the scale is equal to or somewhat greater than that of the underlying metal can be very rapid at the start but diminishes perceptibly with time as a result of the protection offered by the scale, provided the scale remains continuous and does not flake off. When the specific volume of the scale is smaller than that of the metal, however, the rate of attack normally is proportional with time. The resultant scale is porous and crumbly, so that progress of oxidation is controlled only by the specific reactivity of the metal and the composition and temperature of the gas atmosphere.

There are exceptions, of course, one being the case of molybdenum metal. Its oxide has a higher specific volume than the metal itself, yet its oxide is nonprotective and increases in weight at high temperatures in proportion to the reaction time. Such behaviour comes about as a result of unusual characteristics of the oxide, which melts and is continuously being evaporated from the metal surface.

Some alloy additions (*e.g.*, silicon, aluminum, and chromium in steel) form oxides adjacent to the metal surface that markedly decrease the rate of oxidation. The intermediate chromium steels and the ferritic and austenitic stainless steels at high temperatures have much higher oxidation resistances than the carbon and low-chromium steels. When sufficient oxygen is present, moderate quantities of chromium in steel form tenacious and impervious films of oxide that protect the underlying metal. For each grade of chromium-bearing steel, the limiting temperature above which scaling becomes significant is directly related to the chromium content. The extremely high temperatures encountered in jet engines and gas turbines necessitated the development of new alloys that have sufficient resistance to corrosion by the hot combustion gases as well as adequate mechanical properties at the high temperatures reached.

Compounds of such elements as sulfur, vanadium, and sodium in the products of combustion of fuel can change the nature of oxidation of metals exposed to these compounds, sometimes increasing it to a catastrophic level. No commercial alloys are known that will resist this type of corrosive attack.

Although it was originally thought that the oxidation of

Intentional  
corrosion

Value of  
etching

Corrosion  
from  
combustion  
products

metals at high temperature was a direct chemical reaction, later studies suggested that oxidation and tarnish are electrochemical phenomena, the oxide film serving both as internal and external circuits of a closed cell. Such studies have been used to account for the formation of the invisible oxide film and tarnish that isolate metal from air at ordinary temperatures.

**Electrochemical corrosion.** Most corrosion takes place in gaseous or aqueous mediums and involves oxidation and reduction reactions (reactions in which an atom loses or gains electrons, respectively) occurring at metal interfaces. These reactions, which are electrochemical in nature and which determine the rates of corrosion, are controlled by the flow of electrons through the metal. They divide into anodic and cathodic parts, each of which involves an oxidation-reduction system. The transfer of electrons in these reactions constitutes the corrosion current, and the magnitude of its voltage provides the driving force of corrosion. When the flow of electrons stops, electrochemical corrosion ceases.

The corroding effect of any medium is determined by a host of factors. In natural corrosion the rate of attack is usually limited by the supply of some essential substance. When metal undergoing corrosion becomes the anode in an electrolytic cell supplied with current from an external source, there is no such limitation, and the rate of attack, in the absence of other complications, becomes dependent on the current forced through the cell.

**Prevention of corrosion.** Protection against corrosion usually is secured by physical means, using inert or less active covering materials, or by chemical means, either by alloying and thus changing the chemical activity, by the use of coatings of greater chemical activity than the base metal, or by modifying the corroding conditions in some manner. On many metals, aluminum for example, the reaction product, often the oxide of the metal, adheres so tightly that it serves to protect against further attack.

More often the protection of metal exposed to normal environments is obtained by applying suitable coatings, such as anticorrosive paints made from anticorrosive substances, and pigments embedded in organic mediums. Paints made from these substances and pigments (such as zinc chromate and other chromates, iron oxides, red lead, white leads, basic lead sulfate and finely divided flakes of aluminum) form durable and protective coatings on metals. The coatings, in turn, may be covered with other types of paints chosen for their physical, mechanical, and aesthetic characteristics.

Instead of paints, metallic coats and porcelain enamels can be used to protect iron and steel. Zinc and aluminum are particularly effective as coatings in preventing the corrosion of iron exposed to the atmosphere. These coatings may be applied by dipping the iron in a molten bath or may be deposited electrically. They can also be applied by metal spraying, the sprayed metal producing a layer of overlapping scale.

Pipelines or other metallic objects buried underground require protection against corrosion arising from stray electrical currents entering and leaving the metal at different points or from the acidity of the soil or some chemical constituent in it. Plastic coatings are extensively used as a preventive measure in these instances. Another very effective system of protection known as cathodic protection is widely used. In this, the metal to be protected is connected electrically to a more easily corroded metal, such as magnesium. An electric circuit is set up such that the magnesium corrodes as a sacrificial anode, while the less active metal serves as the cathode and is not itself attacked.

#### INSPECTION AND TESTING

Of equal importance with the various processes in making metal products is the thorough inspection and testing to which the products are subjected during processing and after finishing to determine whether, from a quality standpoint, they will meet consumer needs. In order that the producer and consumer may speak a common language in discussing quality, it is necessary that quality be

described in precise terms. This situation has led to establishing definite specifications that define quality and test procedures.

At one time, chemical analysis was the primary specification in the evaluation of metal products, but only a rough measure of the attributes of a material was obtainable through chemical analysis alone. More sophisticated methods of inspection and testing have followed that are now accepted as essential in the control of metal quality.

**Mechanical testing.** The mechanical-property tests most commonly used in evaluating the quality of metal products include tensile, hardness, torsion (twisting), creep (deformation under constant stress over a period of time), and certain types of bending tests. The primary purpose of these tests is to determine conformance or nonconformance with specifications. The data obtained serve as an index of quality of a product in comparison with similar products obtained previously or from other sources. Such data also are frequently used by manufacturers of metal products for control of manufacturing methods as well as for guidance in improving the products and in the development of new materials. Because of the limitations of the conventional tests, there is a need for more specialized tests, particularly for those intended to duplicate or approach actual conditions in service. Among the attributes not revealed by the conventional tests, but desired for many production purposes, are formability, weldability, machinability, and corrosion and wear resistance. Tests to gain some measure of these attributes have been devised and are in constant use throughout the metal industry.

**Nondestructive testing.** Nondestructive inspection or testing—that is, inspection by methods that do not destroy the part—is applied extensively to certain metals and alloys that must pass rigid specifications with regard to surface discontinuities and internal flaws.

In the metal industries, radiography (X-ray examination) has been used primarily as a routine method of inspection of welds and castings. Defects in welds and shrinkage and blowholes in castings are relatively easily discerned by radiographic methods.

Magnetic particle inspection will detect the presence of cracks, flaws, and similar surface or near-surface discontinuities, but only in ferromagnetic materials, such as iron and steel. For nonmagnetic materials, such as the nonferrous alloys, fluorescent penetrant inspection serves this purpose. In magnetic particle inspection the part being tested is magnetized and then covered with fine magnetic powder. The powder is easily removed where no crack or flaw exists but clings to such defects. In fluorescent penetrant inspection a fluorescent liquid is applied to the surface of the workpiece and enters the surface discontinuities. The excess penetrant is removed before the piece is examined under intense ultraviolet light. Indications of discontinuities show up brilliantly.

Control of internal quality of heavy sections of metals has been greatly extended by ultrasonic (or supersonic) inspection. Sound waves with frequencies as high as several million vibrations per second are sent through the sections. Large flaws will cast an acoustical shadow on the face of the piece opposite the face through which the waves entered. Small flaws are detected by measuring the small amount of sound energy the flaws reflect back to the point of origin.

## Metalogic

Metalogic may be defined as the study of the syntax, or relations between expressions, and the semantics, or relations between expressions and their meanings, of formal languages and formal systems (such as those of logic and mathematics). It is related to, but does not include, the formal treatment of natural languages.

### NATURE, ORIGINS, AND INFLUENCES OF METALOGIC

**Syntax and semantics.** A formal language usually requires a set of formation rules; *i.e.*, a complete specification of the kinds of expressions that shall count as well-formed formulas (sentences or meaningful expressions), applicable mechanically, in the sense that a machine could check whether a candidate satisfies the requirements. This specification usually contains three parts: (1) a list of primitive symbols (basic units) given mechanically; (2) certain combinations of these symbols, singled out mechanically as forming the simple (atomic) sentences; and (3) a set of inductive clauses—inductive inasmuch as they stipulate that natural combinations of given sentences formed by such logical connectives as the disjunction "Either . . . or," which is symbolized " $\vee$ ," "Not," symbolized " $\sim$ ," and "For every . . .," symbolized " $(\forall -)$ ," are again sentences. [ $(\forall -)$ , or  $(\exists -)$ —"There is some . . ."—is called a quantifier.] Since these specifications are concerned only with symbols and their combinations and not with meanings, they involve only the syntax of the language.

An interpretation of a formal language is determined by formulating an interpretation of the atomic sentences of the language with regard to a domain of objects; *i.e.*, by stipulating which objects of the domain are denoted by which constants of the language and which relations and functions are denoted by which predicate letters and function symbols. The truth-value (whether "true" or

"false") of every sentence is thus determined according to the standard interpretation of logical connectives. For example,  $p \cdot q$  is true if and only if  $p$  and  $q$  are true. (Here, the dot means the conjunction "and," not the multiplication operation "times.") Thus, given any interpretation of a formal language, a formal concept of truth is obtained. Thus, truth, meaning, and denotation are semantic concepts.

If, in addition, a formal system in a formal language is introduced, certain syntactic concepts arise; *viz.*, axioms, rules of inference, and theorems. Certain sentences are singled out as axioms. These are (the basic) theorems. Each rule of inference is an inductive clause, stating that if certain sentences are theorems, then another sentence related to them in a suitable way is also a theorem. If  $p$  and "Either not- $p$  or  $q$ " ( $\sim p \vee q$ ) are theorems, for example, then  $q$  is a theorem. In general, a theorem is either an axiom or the conclusion of a rule of inference whose premises are theorems.

In 1931 the fundamental discovery was made by Kurt Gödel, the prominent Czechoslovakian-U.S. logician, that in most of the interesting (or significant) formal systems not all true sentences are theorems. It follows from this finding that semantics cannot be reduced to syntax; thus syntax, which is closely related to proof theory, must often be distinguished from semantics, which is closely related to model theory (see below). Roughly speaking, syntax—as conceived in the philosophy of mathematics—is a branch of number theory (*q.v.*), and semantics is a branch of set theory (*q.v.*), which deals with the nature and relations of aggregates.

Historically, as logic and axiomatic systems became more and more exact, there emerged, in response to a desire for greater lucidity, a tendency to pay greater attention to the syntactic features of the languages employed rather than to concentrate exclusively on intuitive meanings. In this way, logic, the axiomatic method (such as that employed in geometry), and semiotic (the general science of signs) converged toward metalogic.

**The axiomatic method.** The best known axiomatic system is that of Euclid for geometry. In a manner similar to that of Euclid, every scientific theory involves a body of meaningful concepts and a collection of true or believed assertions. The meaning of a concept can often be explained or defined in terms of other concepts; and, similarly, the truth of an assertion or the reason for believing it can usually be clarified by indicating that it can be deduced from certain other assertions already accepted. The axiomatic method proceeds in a sequence of steps, beginning with a set of primitive concepts and propositions and then defining or deducing all other concepts and propositions in the theory from them.

The realization that arose in the 19th century that there are different possible geometries led to a desire to separate abstract mathematics from spatial intuition; and, in consequence, many hidden axioms were uncovered in Euclid's geometry. These discoveries were organized into a more rigorous axiomatic system by David Hilbert, an influential German mathematician, in his *Grundlagen der Geometrie* (1899; *The Foundations of Geometry*, 1902). In this and related systems, however, logical connectives and their properties are taken for granted and remain implicit. If the logic involved is taken to be that of the predicate calculus (see below), the logician can then arrive at such formal systems as that discussed above.

Once such formal systems are obtained, it is possible to transform certain semantic problems into sharper syntactic problems. It has been asserted, for example, that non-Euclidean geometries must be self-consistent systems because they have models (or interpretations) in Euclidean geometry, which in turn has a model in the theory of real numbers. It may then be asked, however, how it is known that the theory of real numbers is consistent in the sense that no contradiction can be derived within it. Obviously, modelling can only establish a relative consistency and has to come to a stop somewhere. Having arrived at a formal system (say of real numbers), however, the consistency problem then has the sharper focus of a syntactic problem, *viz.*, of considering all of the possible

Specifi-  
cation of  
a formal  
language

Trans-  
formations  
from  
semantics  
to  
syntax

proofs (as syntactic objects) and asking whether any of them ever has (say)  $0 = 1$  as the last sentence.

As another example, the question whether a system is categorical—that is, whether it determines essentially a unique interpretation in the sense that any two interpretations are isomorphic—may be explored. This semantic question can to some extent be replaced by a related syntactic question, that of completeness: whether there is in the system any sentence having a definite truth-value in the intended interpretation such that neither that sentence nor its negation is a theorem. Even though it is now known that the semantic and syntactic concepts are different, the vague requirement that a system be “adequate” is clarified by both concepts. The study of such sharp syntactic questions as those of consistency and completeness, which was emphasized by Hilbert, was named “metamathematics” (or “proof theory”) by him around 1920.

**Logic and metalogic.** In one sense, logic is to be identified with the predicate calculus of the first order, the calculus in which the variables are confined to individuals of a fixed domain—though it may include as well the logic of equality symbolized “=,” which takes the ordinary properties of equality as part of logic. In this sense, Gottlob Frege, a pioneer of modern logic, achieved a formal calculus of logic as early as 1879. Sometimes logic is construed, however, as including also higher order predicate calculi, which admit variables of higher types, such as those ranging over predicates (or classes and relations) and so on. But then it is a small step to the inclusion of set theory; and, in fact, axiomatic set theory is often regarded as a part of logic. For the purposes of this article, however, it is more appropriate to confine the discussion to logic in the first sense, especially since there is a separate article SET THEORY.

It is hard to separate out significant findings in logic from those in metalogic because all theorems of interest to logicians are about logic and therefore belong to metalogic. If  $p$  is a mathematical theorem—in particular, one about logic—and  $P$  is the conjunction of the mathematical axioms employed for proving  $p$ , then every  $p$  can be turned into a theorem, “Either not- $P$  or  $p$ ,” in logic. Mathematics is not done, however, by carrying out explicitly all of the steps as formalized in logic; the selection and intuitive grasp of the axioms is important both for mathematics and for metamathematics. Actual derivations in logic, such as those carried out just prior to World War I by Alfred North Whitehead, who later became renowned as a metaphysician, and Bertrand Russell, a philosopher of science and of mathematics, are of little intrinsic interest to logicians. It might therefore appear redundant to introduce the term metalogic. In the present classification, however, metalogic is conceived as dealing not only with findings about logical calculi but also with studies of formal systems and formal languages in general.

Formal systems and logical calculi

An ordinary formal system differs from a logical calculus in that the system usually has an intended interpretation, whereas the logical calculus deliberately leaves the possible interpretations open. Thus, one speaks, for example, of the truth or falsity of sentences in a formal system; but with respect to a logical calculus one speaks of validity (*i.e.*, being true in all interpretations or in all possible worlds) and of satisfiability (or having a model; *i.e.*, being true in some particular interpretation). Hence, the completeness of a logical calculus has quite a different meaning from that of a formal system: a logical calculus permits many sentences, such that neither the sentence nor its negation is a theorem because it is true in some interpretations and false in others, and requires only that every valid sentence be a theorem.

**Semiotic.** Originally, the word “semiotic” meant the medical theory of symptoms; however, an Empiricist, John Locke, used the term in the 17th century for a science of signs and significations. The current usage was recommended especially by Rudolf Carnap, one of the foremost semanticists and philosophers of science of the 20th century—see his *Introduction to Semantics* (1942) and his reference there to Charles William Morris, who

suggested a threefold distinction. According to this usage, semiotic is the general science of signs and languages, consisting of three parts: (1) pragmatics (in which reference is made to the user of the language); (2) semantics (in which one abstracts from the user and analyzes only the expressions and their meanings); and (3) syntax (in which one abstracts also from the meanings and studies only the relations between expressions).

Pragmatics is at present a rather loose designation covering a wide range of scientific investigations of language—physiological, psychological, ethnological, and sociological. Since pragmatics is conspicuously incapable of formal treatment, it is usually not considered to be a part of metalogic.

At first Carnap exclusively emphasized syntax. But gradually he came to realize the importance of semantics, and the door was thus reopened to many difficult philosophical problems.

Certain aspects of metalogic have been instrumental in the development of a whole new approach to philosophy commonly associated with the label of Logical Positivism. In his *Tractatus Logico-Philosophicus* (1922; originally published under a different title, 1921), the Austrian-born Cambridge philosopher Ludwig Wittgenstein, one of the most seminal thinkers in the philosophy of language, presented an appealing exposition of logical truths as sentences that are true in all possible worlds. One may say, for example, “It is raining or it is not raining,” and in every possible world one of the disjuncts is true. On the basis of this observation and certain broader developments in logic, Carnap attempted to develop formal treatments of science and philosophy.

It has been thought that the success that metalogic had achieved in the mathematical disciplines could be carried over into physics and even into biology or psychology. In so doing, the logician gives a branch of science a formal language in which there are logically true sentences having universal logical ranges and factually true ones having more restricted ranges. (Roughly speaking, the logical range of a sentence is the set of all possible worlds in which it is true.)

A formal solution of the problem of meaning has also been proposed for these disciplines. Given the formal language of a science, it is possible to define a notion of truth. Such a truth definition determines the truth condition for every sentence; *i.e.*, the necessary and sufficient conditions for its truth. The meaning of a sentence is then identified with its truth condition because, as Carnap wrote:

To understand a sentence, to know what is asserted by it, is the same as to know under what conditions it would be true. . . . To know the truth condition of a sentence is (in most cases) much less than to know its truth-value, but it is the necessary starting point for finding out its truth-value.

**Influences in other directions.** In recent years, metalogic has led to a great deal of work of a mathematical nature in axiomatic set theory, model theory, and recursion theory (in which functions that are computable in a finite number of steps are studied). (See MATHEMATICS, FOUNDATIONS OF: *The crisis in foundations following 1900: Logicism, formalism, and the metamathematical method*; and SET THEORY: *Axiomatic set theory*; and below *Model theory*.)

In a different direction, the devising of Turing computing machines, involving abstract designs for the explication of mechanical logical procedures, has led to the investigation of idealized computers, with ramifications in the theory of finite automata and mathematical linguistics.

Logical Positivism and the formalization of science

Turing machines, philosophy of logic, and ontology

Among philosophers of language, there is a widespread tendency to stress the philosophy of logic (see LOGIC, PHILOSOPHY OF). The contrast, for example, between intensional concepts and extensional concepts; the role of meaning in natural languages as providing truth conditions; the relation between formal and natural logic (*i.e.*, the logic of natural languages); and the relation of ontology, the study of the kinds of entities that exist, to the use of quantifiers—all of these areas are receiving extensive consideration and discussion. There are also efforts to

produce formal systems for empirical sciences such as physics, biology, and even psychology. Many scholars have doubted, however, whether these efforts have been fruitful.

#### NATURE OF A FORMAL SYSTEM AND OF ITS FORMAL LANGUAGE

**Example of a formal system.** In order to clarify the abstract concepts of metalogic, a formal system  $N$  (with its formal language) may be considered for illustration.

**Formation rules.** The system may be set up by employing the following formation rules:

1. The following are primitive symbols:  $\sim$ ,  $\vee$ ,  $\forall$ , and  $=$ , and the symbols used for grouping, (, and ); the function symbols for arithmetical addition and multiplication  $+$  and  $\cdot$ ; constants 0, 1; and variables  $x, y, z, \dots$

2. The following are terms: a constant is a term; a variable is a term; if  $a$  and  $b$  are terms,  $a + b$  and  $a \cdot b$  are terms.

3. Atomic sentences are thus specified: if  $a$  and  $b$  are terms,  $a = b$  is a sentence.

4. Other sentences can be defined as follows: if  $A$  and  $B$  are sentences and  $v$  is a variable, then  $\sim A$ ,  $A \vee B$ , and  $(\forall v)A$  are sentences.

**Axioms and rules of inference.** The system may be developed by adopting certain sentences as axioms and following certain rules of inference.

1. The basic axioms and rules are to be those of the first-order predicate calculus, including the propositional calculus (the logic of unanalyzed statements; see LOGIC, FORMAL).

2. The following additional axioms of  $N$  are stipulated: (a) Zero is not a successor (*i.e.*, does not follow any number immediately):

$$\sim(x + 1) = 0.$$

(b) No two numbers have the same successor:

$$\sim(x + 1 = y + 1) \vee x = y.$$

(c) Recursive definition of addition:

$$\begin{aligned} x + 0 &= x \\ x + (y + 1) &= (x + y) + 1. \end{aligned}$$

(d) Recursive definition of multiplication:

$$x \cdot 0 = 0; x \cdot (y + 1) = (x \cdot y) + x.$$

3. Rule of inference (the principle of mathematical induction): Every number has a property if zero has it and the successor of a number has it if the number has it; more explicitly, if  $A(0)$  and  $\forall x[\sim A(x) \vee A(x + 1)]$  are theorems, then  $\forall x A(x)$  is a theorem.

The system  $N$  as specified by the foregoing rules and axioms is a formal system in the sense that, given any combination of the primitive symbols, it is possible to check mechanically whether it is a sentence of  $N$ ; and given a finite sequence of sentences, it is possible to check mechanically whether it is a (correct) proof in  $N$ ; *i.e.*, whether each sentence either is an axiom or follows from preceding sentences in the sequence by a rule of inference. Viewed in this way, a sentence is a theorem if and only if there exists a proof in which it appears as the last sentence. It is not required of a formal system, however, that it be possible to decide mechanically whether a given sentence is a theorem; and, in fact, it has been proved that no such mechanical method exists.

**Truth definition of the given language.** The formal system  $N$  admits of different interpretations, according to findings of Gödel (from 1931) and of the Norwegian mathematician Thoralf Skolem, a pioneer in metalogic (from 1933). The originally intended, or standard, interpretation takes the ordinary non-negative integers  $\{0, 1, 2, \dots\}$  as the domain, the symbols 0 and 1 as denoting zero and one, and the symbols  $+$  and  $\cdot$  as standing for ordinary addition and multiplication. Relative to this interpretation, it is possible to give a truth definition of the language of  $N$ .

It is necessary first to distinguish between open and closed sentences. An open sentence, such as  $x = 1$ , is one that may be either true or false depending on the value of  $x$ ; but a closed sentence, such as  $0 = 1$  and  $(\forall x)(x = 0)$  or "All  $x$ 's are zero," is one that has a definite truth-value—in this case, false (in the intended interpretation).

1. A closed atomic sentence is true if and only if it is true in the intuitive sense; for example,  $0 = 0$  is true,  $0 + 1 = 0$  is false.

This specification as it stands is not syntactic; but with some care, it is possible to give an explicit and mechanical specification of those closed atomic sentences that are true in the intuitive sense.

2. A closed sentence  $\sim A$  is true if and only if  $A$  is not true.

3. A closed sentence  $A \vee B$  is true if and only if either  $A$  or  $B$  is true.

4. A closed sentence  $(\forall v)A(v)$  is true if and only if  $A(v)$  is true for every value of  $v$ ; *i.e.*, if  $A(0)$ ,  $A(1)$ ,  $A(1 + 1)$ ,  $\dots$  are all true.

The above definition of truth is not an explicit definition; it is an inductive one. Using concepts from set theory, however, it is possible to obtain an explicit definition that yields a set of sentences that consists of all of the true ones and only them. If Gödel's method of representing symbols and sentences by numbers is employed, it is then possible to obtain in set theory a set of natural numbers that are just the Gödel numbers of the true sentences of  $N$ .

There is a definite sense in which it is impossible to define the truth of a language in itself. This is proved by the liar paradox: if the sentence "I am lying," or alternatively,

This sentence is not true . . . (1)

is considered, it is clear—since (1) is "This sentence"—that if (1) is true, then (1) is false; on the other hand, if (1) is false, then (1) is true. In the case of the system  $N$ , if the concept of truth were definable in the system itself, then (using a device invented by Gödel) it would be possible to obtain in  $N$  a sentence that amounts to (1) and that thereby yields a contradiction.

#### DISCOVERIES ABOUT FORMAL MATHEMATICAL SYSTEMS

The two central questions of metalogic are those of the completeness and consistency of a formal system based on axioms. In 1931, Gödel made fundamental discoveries in these areas for the most interesting formal systems. In particular, he discovered that if such a system is  $\omega$ -consistent—*i.e.*, devoid of contradiction in a sense to be explained below—then it is not complete, and that if a system is consistent, then the statement of its consistency, easily expressible in the system, is not provable in it.

Soon afterward, in 1934, Gödel modified a suggestion that had been offered by Jacques Herbrand, a French mathematician, and introduced a general concept of recursive functions; *i.e.*, of functions mechanically computable by a finite series of purely combinatorial steps. In 1936, Alonzo Church, a mathematical logician; Alan Mathison Turing, originator of a theory of computability; and Emil L. Post, a specialist in recursive unsolvability, all argued for this concept (and certain equivalent notions), thereby arriving at stable and exact conceptions of "mechanical," "computable," "recursive," and "formal" that explicate the intuitive concept of what a mechanical computing procedure is. As a result of the development of recursion theory, it is now possible to prove not only that certain classes of problems are mechanically solvable (which could be done without the theory) but also that certain others are mechanically unsolvable (or absolutely unsolvable). The most notable example of such unsolvability is the discovery, made in 1970, that there is no algorithm, or rule of repetitive procedure, for solving all Diophantine equations; *i.e.*, equations of which the coefficients and roots are whole numbers. This solution gives a negative solution to the 10th problem in the famous list presented by Hilbert at the International Mathematical Congress in 1900; compare MATHEMATICS, FOUNDATIONS OF: *Logicism, formalism, and the metamathematical method*).

In this way, logicians have finally arrived at a sharp concept of a formal axiomatic system because it is no longer necessary to leave "mechanical" as a vague non-mathematical concept. In this way, too, they have arrived at sharp concepts of decidability. In one sense, decidability is a property of sets (of sentences): that of being

Recursive functions and decidability

Open and closed sentences

subject (or not) to mechanical methods by which to decide, for any closed sentence of a given formal system (e.g., of  $N$ ), whether it is true; or—as a different question—whether it is a theorem. In another sense, decidability can refer to a single closed sentence: the sentence is called undecidable in a formal system if neither it nor its negation is a theorem. Using this concept, Gödel's incompleteness theorem is sometimes stated thus: "Every interesting (or significant) formal system has some undecidable sentences."

Given these developments, it was easy to extend Gödel's findings, as Church did in 1936, to show that interesting formal systems such as  $N$  are undecidable (both with regard to theorems and with regard to true sentences).

**The two incompleteness theorems.** The first and most central finding in this field is that systems such as  $N$  are incomplete and incompletable because Gödel's theorem applies to any reasonable and moderately rich system. The proof of this incompleteness may be viewed as a modification of the liar paradox, which shows that truth cannot be defined in the language itself. Since provability in a formal system can often be expressed in the system itself, one is led to the conclusion of incompleteness.

Let us consider the sentence

This sentence is not provable in the system (2)

In particular,  $N$  may be thought of as the system being studied. Representing expressions by numbers and using an ingenious substitution function, Gödel was able to find in the system a sentence  $p$  that could be viewed as expressing (2).

Once such a sentence is obtained, some strong conclusions result. If the system is complete, then either the sentence  $p$  or its negation is a theorem of the system. If  $p$  is a theorem, then intuitively  $p$  or (2) is false, and there is in some sense a false theorem in the system. Similarly, if  $\sim p$  is a theorem, then it says that  $\sim(2)$  or that  $p$  is provable in the system. Since  $\sim p$  is a theorem, it should be true, and there seem then to be two conflicting sentences that are both true, viz.,  $p$  is provable in the system, and  $\sim p$  is provable in it. This can be the case only if the system is inconsistent.

Gödel's exact theorem

A careful examination of this inexact line of reasoning leads to Gödel's exact theorem, which says that if a system is reasonably rich and  $\omega$ -consistent, then  $p$  is undecidable in it. The notion of  $\omega$ -consistency is stronger than consistency, but it is a very reasonable requirement since it demands merely that one cannot prove in a system both that some number does not have the property  $A$  and yet that each number does have the property  $A$ ; i.e., that  $(\exists x)\sim A(x)$  and also all of  $A(0), A(1), \dots$  are theorems. An American mathematician J. Barkley Rosser, who also contributed to number theory and applied mathematics, weakened the hypothesis to mere consistency in 1936, at the expense of complicating somewhat the initial sentence (2).

More exactly, Gödel showed that if the system is consistent, then  $p$  is not provable; if it is  $\omega$ -consistent, then  $\sim p$  is not provable. The first half leads to Gödel's theorem on consistency proofs, viz., that if a system is consistent, then the arithmetic sentence expressing the consistency of the system cannot be proved in the system. This is usually stated briefly thus: that no interesting system can prove its own consistency or that there exists no consistency proof of a system that can be formalized in the system itself.

The proof of this theorem consists essentially of a formalization in arithmetic of the arithmetized version of the proof of the statement, "If a system is consistent, then  $p$  is not provable"; i.e., it consists of a derivation within number theory of  $p$  itself from the arithmetic sentence that says that the system is consistent. Hence, if the arithmetic sentence were provable,  $p$  would also be provable—contradicting the previous result. This proof, which was only briefly outlined by Gödel, has been carried out in detail by Paul Bernays in his joint work with Hilbert. Moreover, the undecidable sentence  $p$  is always of a relatively simple form, viz., of the form  $(\forall x)A(x)$ , "For every  $x, x$  is  $A$ ," in which  $A$  is a recursive, in fact a primitive recursive, predicate.

**Decidability and undecidability.** The first incompleteness theorem yields directly the fact that truth in a system (e.g., in  $N$ ) to which the theorem applies is undecidable. If it were decidable, then all true sentences would form a recursive set, and they could be taken as the axioms of a formal system that would be complete. This claim depends on the reasonable and widely accepted assumption that all that is required of the axioms of a formal system is that they make it possible to decide effectively whether a given sentence is an axiom.

Alternatively, the above assumption can be avoided by resorting to a familiar lemma, or auxiliary truth: that all recursive or computable functions and relations are representable in the system (e.g., in  $N$ ). Since truth in the language of a system is itself not representable (definable) in the system, it cannot, by the lemma, be recursive (i.e., decidable).

The same lemma also yields the undecidability of such systems with regard to theorems. Thus, if there were a decision procedure, there would be a computable function  $f$  such that  $f(i)$  equals 1 or 0 according as the  $i$ th sentence is a theorem or not. But then what  $f(i) = 0$  says is just that the  $i$ th sentence is not provable. Hence, using Gödel's device, a sentence (say the  $i$ th) is again obtained saying of itself that it is not provable. If  $f(i) = 0$  is true then, because  $f$  is representable in the system, it is a theorem of the system. But then, because  $f(i) = 0$  is (equivalent to) the  $i$ th sentence,  $f(i) = 1$  is also true and therefore provable in the system. Hence, the system, if consistent, is undecidable with regard to theorems.

Although the system  $N$  is incompletable and undecidable, it has been discovered by the Polish logician M. Presburger and by Skolem (both in 1930) that arithmetic with addition alone or multiplication alone is decidable (with regard to truth) and therefore has complete formal systems. Another well-known positive finding is that of Alfred Tarski, a Polish-American semanticist and logician, who developed a decision procedure for elementary geometry and elementary algebra (1951).

A discovery made by Turing in 1936, which at first sight seems very surprising, may be mentioned in passing: that every complete formal system (though not every logical calculus) is decidable. If a system is complete, then for every closed sentence  $A$ , either that sentence or its negation is a theorem. Being a formal system, all of its theorems can be enumerated mechanically. But then, for each  $A$ , one sooner or later reaches either  $A$  or  $\sim A$ . In the first case,  $A$  is a theorem (and true); in the second case,  $A$  is not a theorem (and false). This finding illustrates an impractical aspect of the concept of mechanical procedures, for all that is required is that a conclusion can be reached at some finite time and there need not be any useful estimate of how long it will take.

**Consistency proofs.** The best known consistency proof is that of the German mathematician Gerhard Gentzen (1936) for the system  $N$  of classical (or ordinary, in contrast to intuitionistic) number theory. Taking  $\omega$  (omega) to represent the next number beyond the natural numbers (called the "first transfinite number"), Gentzen's proof employs an induction in the realm of transfinite numbers ( $\omega + 1, \omega + 2, \dots; 2\omega, 2\omega + 1, \dots; \omega^2, \omega^2 + 1, \dots$ ), which is extended to the first epsilon-number,  $\epsilon_0$  (defined as the limit of  $\omega, \omega^\omega, \omega^{\omega^\omega}, \dots$ ), which is not formalizable in  $N$ . This proof, which has appeared in several variants, has opened up an area of rather extensive work.

Intuitionistic number theory, which denies the classical concept of truth and consequently eschews certain general laws such as "Either  $A$  or  $\sim A$ ," and its relation to classical number theory have also been investigated (see the article MATHEMATICS, FOUNDATIONS OF: *The crisis in foundations following 1900; Intuitionism*). This investigation is considered significant because intuitionism is believed to be more constructive and more evident than classical number theory. In 1932, Gödel found an interpretation of classical number theory in the intuitionistic theory (also found by Gentzen and by Bernays). In 1958, Gödel extended his findings to obtain constructive interpretations of sentences of classical number theory in terms of primitive recursive functionals.

More recently, work has been done to extend Gentzen's findings to ramified theories of types and to fragments of classical analysis, and to extend Gödel's interpretation and to relate classical analysis to intuitionistic analysis. Also, in connection with these consistency proofs, various proposals have been made to present constructive notations for the ordinals of segments of the German mathematician Georg Cantor's second number class, which includes  $\omega$  and the first epsilon-number and much more. A good deal of discussion has been devoted to the significance of the consistency proofs and the relative interpretations for epistemology (the theory of knowledge).

**DISCOVERIES ABOUT LOGICAL CALCULI**

**The calculi of formal logic.** The two main branches of formal logic are the propositional calculus and the predicate calculus.

*The propositional calculus.* This calculus (abbreviated PC) is described in detail in the article LOGIC, FORMAL: II. *The propositional calculus.* It is easy to show that this calculus is complete in the sense that every valid sentence in it—i.e., every tautology, or sentence true in all possible worlds (in all interpretations)—is a theorem, as may be seen in the following example. "Either  $p$  or not- $p$ " ( $p \vee \sim p$ ) is always true because  $p$  is either true or false. In the former case,  $p \vee \sim p$  is true because  $p$  is true; in the latter case, because  $\sim p$  is true. One way to prove the completeness of this calculus is to observe that it is sufficient to reduce every sentence to a conjunctive normal form; i.e., to a conjunction of disjunctions of single letters and their negations. But any such conjunction is valid if and only if every conjunct is valid; and a conjunct is valid if and only if it contains some letter  $p$  as well as  $\sim p$  as parts of the whole disjunction. Completeness follows because (1) such conjuncts can all be proved in the calculus, and (2) if these conjuncts are theorems, then the whole conjunction is also a theorem.

The consistency of the calculus (its freedom from contradiction) is more or less obvious because it can easily be checked that all of its axioms are valid—i.e., true in all possible worlds—and that the rules of inference carry from valid sentences to valid sentences. But a contradiction is not valid; hence, the calculus is consistent. The conclusion, in fact, asserts more than consistency, for it holds that only valid sentences are provable.

The calculus is also easily decidable. Since all valid sentences, and only these, are theorems, each sentence can be tested mechanically by putting true and false for each letter in the sentence. If there are  $n$  letters, there are  $2^n$  possible substitutions. A sentence is then a theorem if and only if it comes out true in every one of the  $2^n$  possibilities.

The independence of the axioms is usually proved by using more than two truth-values. These values are divided into two classes: the desired and the undesired. The axiom to be shown independent can then acquire some undesired value, whereas all of the theorems that are provable without this axiom always get the desired values. This technique is what originally suggested the many-valued logics (see LOGIC, FORMAL: II. B.2: *Three-valued logics*).

*The first-order predicate calculus.* This calculus (abbreviated LPC—for "lower predicate calculus"), like the propositional calculus, is also described in detail in the article LOGIC, FORMAL: III. *The predicate calculus.* It includes the propositional calculus as a part and may or may not include the logic of equality. (It will here be assumed that equality is included.)

The problem of consistency for the predicate calculus is relatively simple. A world may be assumed in which there is only one object  $a$ . In this case, both the universally quantified and the existentially quantified sentences  $(\forall x)A(x)$  and  $(\exists x)A(x)$  reduce to the simple sentence  $A(a)$ ; and all quantifiers can be eliminated. It may easily be confirmed that, after the reduction, all theorems of the calculus become tautologies (i.e., theorems in the propositional calculus). If  $F$  is any predicate, such a sentence as "Every  $x$  is  $F$  and not every  $x$  is  $F$ "—i.e.,  $(\forall x)F(x) \cdot \sim(\exists x)F(x)$ —is then reduced to "a

is both  $A$  and not- $A$ "— $A(a) \cdot \sim A(a)$ —which is not a tautology; therefore, the original sentence is not a theorem; and hence, no contradiction can be a theorem. If  $F$  is simple, then  $F$  and  $A$  are the same. If  $F$  is complex and contains  $(\forall y)$  or  $(\exists z)$ , etc., then  $A$  is the result obtained by iterating the transformation of eliminating  $(\forall y)$ , etc. In fact, it can be proved quite directly not only that the calculus is consistent but also that all of its theorems are valid.

The discoveries that the calculus is complete and undecidable are much more profound than the discovery of its consistency. Its completeness was proved by Gödel in 1930; its undecidability was established with quite different methods by Church and Turing in 1936. Given the general developments that occurred up to 1936, its undecidability also follows in another way from Theorem X of Gödel's paper of 1931.

Completeness means that every valid sentence of the calculus is a theorem. It follows that if  $\sim A$  is not a theorem, then  $\sim A$  is not valid; and, therefore,  $A$  is satisfiable; i.e., it has an interpretation or a model. But to say that  $A$  is consistent means nothing other than that  $\sim A$  is not a theorem. Hence, from the completeness, it follows that if  $A$  is consistent, then  $A$  is satisfiable. Therefore, the semantic concepts of validity and satisfiability are seen to coincide with the syntactic concepts of derivability and consistency.

A finding closely related to the completeness theorem is the Löwenheim-Skolem theorem (1915, 1920), named after Leopold Löwenheim, a German school teacher, and Skolem, which says that if a sentence (or a formal system) has any model, it has a countable or enumerable model, i.e., a model whose members can be matched with the positive integers. In the most direct method of proving this theorem, the logician is provided with very useful tools in model theory and in studies on relative consistency and independence in set theory.

*The Löwenheim-Skolem theorem.* In the predicate calculus, there are certain reduction or normal-form theorems. One useful example is the prenex normal form: every sentence can be reduced to an equivalent sentence expressed in the prenex form, viz., in a form such that all of the quantifiers appear at the beginning. This form is specially useful for displaying the central ideas of some of the proofs of the Löwenheim-Skolem theorem.

For illustration one may consider a simple schema in prenex form, "For every  $x$ , there is some  $y$  such that  $x$  bears the (arbitrary) relation  $M$  to  $y$ "; i.e.,

$$(\forall x)(\exists y)Mxy \tag{3}$$

If (3) now has a model with a nonempty domain  $D$ , then by a principle from set theory (the axiom of choice), there exists a function  $f$  of  $x$ , written  $f(x)$ , that singles out for each  $x$  a corresponding  $y$ . Hence, "For every  $x$ ,  $x$  bears the relation  $M$  to  $f(x)$ "; i.e.,

$$(\forall x)Mxf(x). \tag{4}$$

If  $a$  is now any object in  $D$ , then the countable sub-domain  $\{a, f(a), f[f(a)], \dots\}$  already contains enough objects to satisfy (4) and therefore to satisfy (3). Hence, if (3) has any model, it has a countable model, which is in fact a submodel of the original.

An alternative proof, developed by Skolem in 1922 to avoid appealing to the principles of set theory, has turned out to be useful also for establishing the completeness of the calculus. Instead of using the function  $f$  as before,  $a$  can be arbitrarily denoted by  $I$ . Since equation (3) is true, there must be some object  $y$  such that the number  $I$  bears the relation  $M$  to  $y$ , or symbolically  $M_I y$ , and one of these  $y$ 's may be called 2. When this process is repeated indefinitely, one obtains

$$M_{12}; M_{12} \cdot M_{23}; M_{12} \cdot M_{23} \cdot M_{34}; \dots, \tag{5}$$

all of which are true in the given model. The argument is elementary because in each instance one merely argues from "There exists some  $y$  such that  $n$  is  $M$  of  $y$ "—i.e.,  $(\exists y)Mny$ —to "Let one such  $y$  be  $n + 1$ ." Consequently, every member of (5) is true in some model. It is then

Completeness and undecidability of LPC

Consistency and decidability of PC

Proof independent of set theory

possible to infer that all members of (5) are simultaneously true in some model; *i.e.*, that there is some way of assigning truth-values to all of its atomic parts so that all members of (5) will be true. Hence, it follows that (3) is true in some countable model.

*The completeness theorem.* Gödel's original proof of the completeness theorem is closely related to the second proof above. Consideration may again be given to all of the sentences in (5) that contain no more quantifiers. If they are all satisfiable, then, as before, they are simultaneously satisfiable and (3) has a model. On the other hand, if (3) has no model, some of its terms—say  $M_{12} \dots M_{89}$ —are not satisfiable; *i.e.*, their negations are tautologies (theorems of the propositional calculus). Thus,  $\sim M_{12} \vee \dots \vee \sim M_{89}$  is a tautology, and this remains true if 1, 2, . . . , 9 are replaced by variables, such as  $r, s, \dots, z$ ; hence,  $\sim Mrs \vee \dots \vee \sim Myz$ , being a tautology expressed in the predicate calculus as usually formulated, is a theorem in it. It is then easy to use the usual rules of the predicate calculus to derive also the statement, "There exists an  $x$  such that, for every  $y$ ,  $x$  is not  $M$  of  $y$ "; *i.e.*,  $(\exists x)(\forall y) \sim Mxy$ . In other words, the negation of (3) is a theorem of the predicate calculus. Hence, if (3) has no model, then its negation is a theorem of the predicate calculus. And, finally, if a sentence is valid (*i.e.*, if its negation has no model), then it is itself a theorem of the predicate calculus.

*The undecidability theorem and reduction classes.* Given the completeness theorem, it follows that the task of deciding whether any sentence is a theorem of the predicate calculus is equivalent to that of deciding whether any sentence is valid or whether it is satisfiable.

Turing's undecidability proof

Turing's method of proving that this class of problems is undecidable is particularly suggestive. Once the concept of mechanical procedure was crystallized, it was relatively easy to find absolutely unsolvable problems; *e.g.*, the halting problem, which asks for each Turing machine the question of whether it will ever stop, beginning with a blank tape. In other words, each Turing machine operates in a predetermined manner according to what is given initially on the (input) tape; we consider now the special case of a blank tape and ask the special question whether the machine will eventually stop. This infinite class of questions (one for each machine) is known to be unsolvable.

Turing's method shows that each such question about a single Turing machine can be expressed by a single sentence of the predicate calculus so that the machine will stop if and only if that sentence is not satisfiable. Hence, if there were a decision procedure of validity (or satisfiability) for all sentences of the predicate calculus, then the halting problem would be solvable.

In more recent years (1962), Turing's formulation has been improved to the extent that all that is needed are sentences of the relatively simple form  $(\forall x)(\exists y)(\forall z) Mxyz$ , in which all of the quantifiers are at the beginning; *i.e.*,  $M$  contains no more quantifiers. Hence, given the unsolvability of the halting problem, it follows that, even for the simple class of sentences in the predicate calculus having the quantifiers  $\forall \exists \forall$ , the decision problem is unsolvable. Moreover, the method of proof also yields a procedure by which every sentence of the predicate calculus can be correlated with one in the simple form given above. Thus, the class of  $\forall \exists \forall$  sentences forms a "reduction class." (There are also various other reduction classes.)

**MODEL THEORY**

**Background and typical problems.** In model theory one studies the interpretations (models) of theories formalized in the framework of formal logic, especially in that of the first-order predicate calculus with equality; *i.e.*, in elementary logic. A first-order language is given by a collection  $S$  of symbols for relations, functions, and constants, which, in combination with the symbols of elementary logic, single out certain combinations of symbols as sentences. Thus, for example, in the case of the system  $N$  (see above *Example of a formal system*), the formation rules yield a language that is determined in

accordance with a uniform procedure by the set (indicated by braces) of uninterpreted extralogical symbols:

$$S = \{+, \cdot, 0, 1\}.$$

A first-order theory is determined by a language and a set of selected sentences of the language—those sentences of the theory that are, in an arbitrary, generalized sense, the "true" ones (called the "distinguished elements" of the set). In the particular case of the system  $N$ , one theory  $T_a$  is built up on the basis of the language and the set of theorems of  $N$ , and another theory  $T_b$  is determined by the true sentences of  $N$  according to the natural interpretation or meaning of its language. In general, the language of  $N$  and any set of sentences of the language can be used to make up a theory.

*Satisfaction of a theory by a structure: finite and infinite models.* A realization of a language (for example, the one based on  $S$ ) is a structure  $\mathfrak{A}$  identified by the five elements so arranged

$$\mathfrak{A} = \langle A, +_{\mathfrak{A}}, \cdot_{\mathfrak{A}}, 0_{\mathfrak{A}}, 1_{\mathfrak{A}} \rangle,$$

in which  $A$  is a nonempty set (called the domain of  $\mathfrak{A}$ ), the last two terms are members of  $A$ , and the other two terms are functions correlating each member of the Cartesian product  $A \times A$  (*i.e.*, from the set of ordered pairs  $\langle a, b \rangle$  such that  $a, b$  belong to  $A$ ) with a member of  $A$ . The structure  $\mathfrak{A}$  satisfies or is a model of the theory  $T_a$  (or  $T_b$ ) if all of the distinguished sentences of  $T_a$  (or  $T_b$ ) are true in  $\mathfrak{A}$  (or satisfied by  $\mathfrak{A}$ ). Thus, if  $\mathfrak{A}$  is the structure of the ordinary non-negative integers  $\langle \omega, +, \cdot, 0, 1 \rangle$ , in which  $\omega$  is the set of all such integers and  $+, \cdot, 0$ , and  $1$  the elements for their generation, then it is not only a realization of the language based on  $S$  but also a model of both  $T_a$  and  $T_b$ . Gödel's incompleteness theorem permits nonstandard models of  $T_a$  that contain more objects than  $\omega$  but in which all of the distinguished sentences of  $T_a$  (*viz.*, the theorems of the system  $N$ ) are true. Skolem's constructions (related to ultraproducts, see below) yield nonstandard models for both theory  $T_a$  and theory  $T_b$ .

The use of the relation of satisfaction, or being-a-model-of, between a structure and a theory (or a sentence) can be traced to the book *Wissenschaftslehre* (1837; "Theory of Knowledge") by Bernard Bolzano, a Czech theologian and mathematician, and, in a more concrete context, to the introduction of models of non-Euclidean geometries around that time. In the mathematical treatment of logic, these concepts can be found in works of Ernst Schröder, a late-19th-century German mathematician, and in Löwenheim (in particular, in his paper of 1915). The basic tools and results achieved in model theory—such as the Löwenheim-Skolem theorem, the completeness theorem of elementary logic, and Skolem's construction of nonstandard models of arithmetic—were developed during the period from 1915 to 1933. A more general and abstract study of model theory began after 1950, in the work of Tarski and others.

One group of new developments may be classified as refinements and extensions of the Löwenheim-Skolem theorem. These developments employ the concept of a "cardinal number," which—for a finite set—is simply the number at which one stops in counting its elements. For infinite sets, however, the elements must be matched from set to set instead of being counted, and the "sizes" of these sets must thus be designated by transfinite numbers. A rather direct generalization can be drawn that says that, if a theory has any infinite model, then, for any infinite cardinal number, it has a model of that cardinality. It follows that no theory with any infinite model can be categorical or such that any two models of the theory are isomorphic (*i.e.*, matchable in one-to-one correspondence) because models of different cardinalities can obviously not be so matched. A natural question is whether a theory can be categorical in certain infinite cardinalities; *i.e.*, whether there are cardinal numbers such that any two models of the theory of the same cardinality are isomorphic. According to a central discovery made in

Cate-  
gorical  
theories  
in various  
cardinal-  
ities

1963 by Michael Morley, a U.S. mathematician, if a theory is categorical in any uncountable cardinality (*i.e.*, any cardinality higher than the countable), then it is categorical in every uncountable cardinality. On the other hand, examples are known for all four combinations of countable and uncountable cardinalities: specifically, there are theories that are categorical (1) in every infinite cardinality; (2) in the countable cardinality but in no uncountable cardinality; (3) in every uncountable cardinality but not in the countable; and (4) in no infinite cardinality.

In another direction, there are "two-cardinal" problems that arise from the possibilities of changing, from one model to another, not only the cardinality of the domain of the first model but also the cardinality of some chosen property (such as being a prime number). Various answers to these questions have been found, including proofs of independence (based on the ordinary axioms employed in set theory) and proofs of conditional theorems made on the basis of certain familiar hypotheses of set theory.

*Elementary logic.* An area that is perhaps of more philosophical interest is that of the nature of elementary logic itself. On the one hand, the completeness discoveries seem to show in some sense that elementary logic is what the logician naturally wishes to have. On the other hand, he is still inclined to ask whether there might be some principle of uniqueness according to which elementary logic is the only solution that satisfies certain natural requirements on what a logic should be. The recent development of model theory has led to a more general outlook that enabled Per Lindström, a Swedish logician, to prove, in 1969, a general theorem to the effect that, roughly speaking, within a broad class of possible logics, elementary logic is the only one that satisfies the requirements of axiomatizability of the Löwenheim-Skolem theorem. Although Lindström's theorem does not settle satisfactorily whether or not elementary logic is the right logic, it does seem to suggest that mathematical findings can help the logician to clarify his concepts of logic and of logical truth.

Com-  
pounded  
models

A particularly useful tool for obtaining new models from the given models of a theory is the construction of a special combination called the "ultraproduct" of a family of structures (see below *Ultrafilters, ultraproducts, and ultrapowers*)—in particular, the ultrapower when the structures are all copies of the same structure (just as the product of  $a_1, \dots, a_n$  is the same as the power  $a^n$ , if  $a_i = a$  for each  $i$ ). The intuitive idea in this method is to establish that a sentence is true in the ultraproduct if and only if it is true in "almost all" of the given structures (*i.e.*, "almost everywhere"—an idea that was present in a different form in Skolem's construction of a nonstandard model of arithmetic in 1933). It follows that if the given structures are models of a theory, then their ultraproduct is such a model also, because every sentence in the theory is true everywhere (which is a special case of "almost everywhere" in the technical sense employed). Ultraproducts have been applied, for example, to provide a foundation for what is known as "nonstandard analysis" that yields an unambiguous interpretation of the classical concept of infinitesimals—the division into units as small as one pleases. They have also been applied by two mathematicians, James Ax and S.B. Kochen, to problems in the field of algebra (on  $p$ -adic fields).

*Nonelementary logic and future developments.* There are also studies that develop the model theory of nonelementary logic: such as second-order logic and infinitary logics. Second-order logic contains, in addition to variables that range over individual objects, a second kind of variable ranging over sets of objects so that the model  $\mathfrak{A}$  of a second-order sentence or theory also involves, beyond the basic domain, a larger set (called its "power set") that encompasses all of the subsets of the domain. Infinitary logics may include functions or relations with infinitely many arguments, infinitely long conjunctions and disjunctions, or infinite strings of quantifiers. From studies on infinitary logics, William Hanf, an American logician, was able to define certain cardinals, some of

which have been studied in connection with the large cardinals in set theory. In yet another direction, logicians are developing model theories for modal logics—those dealing with such modalities as necessity and possibility—and for the intuitionistic logic.

There is a large gap between the general theory of models and the construction of interesting particular models such as those employed in the proofs of the independence (and consistency) of special axioms and hypotheses in set theory. It is natural to look for further developments of model theory that will yield more systematic methods for constructing models of axioms with interesting particular properties, especially in deciding whether certain given sentences are derivable from the axioms. Relative to the present state of knowledge, such goals appear fairly remote. The gap is not unlike that between the abstract theory of computers and the basic properties of actual computers.

**Characterizations of the first-order logic.** There has been outlined above a proof of the completeness of elementary logic without including sentences asserting equality or identity. The proof can be extended, however, to the full elementary logic in a fairly direct manner. Thus, if  $F$  is a sentence containing equality, a sentence  $G$  can be adjoined to it that embodies the special properties of equality relevant to the sentence  $F$ . The conjunction of  $F$  and  $G$  can then be treated as a sentence not containing equality (*i.e.*,  $=$  can be treated as an arbitrary relation symbol). Hence, the conjunction has a model in the sense of logic-without-equality if and only if  $F$  has a model in the sense of logic-with-equality; and the completeness of elementary logic (with equality) can thus be inferred.

Extension  
to  
include  
equality

A concept more general than validity is that of the relation of logical entailment or implication between a possibly infinite set  $X$  of sentences and a single sentence  $p$  that holds if and only if  $p$  is true in every model of  $X$ . In particular,  $p$  is valid if the empty set, defined as having no members, logically entails  $p$ —for this is just another way of saying that  $p$  is true in every model. This suggests a stronger requirement on a formal system of logic, *viz.*, that  $p$  be derivable from  $X$  by the system whenever  $X$  logically entails  $p$ . The usual systems of logic satisfy this requirement because, besides the completeness theorem, there is also a compactness theorem:

A theory  $X$  has a model if every finite subset of  $X$  has a model.

Roughly speaking, this theorem enables the logician to reduce an infinite set  $X$  to a finite subset  $X_1$  in each individual case, and the case of entailment when  $X_1$  is finite is taken care of by the completeness of the system.

These findings show that the ordinary systems of elementary logic comprise the correct formulation, provided that the actual choice of the truth functions (say negation and disjunction) of the quantifiers, and of equality as the "logical constants" is assumed to be the correct one. There remains the question, however, of justifying the particular choice of logical constants. One might ask, for example, whether "For most  $x$ " or "For finitely many  $x$ " should not be counted as logical constants. Lindström has formulated a general concept of logic and shown that logics that apparently extend the first-order logic all end up being the same as that logic, provided that they satisfy the Löwenheim-Skolem theorem and either have the compactness property or are formally axiomatizable. There remains the question, however, of whether or why these requirements (especially that of the Löwenheim-Skolem theorem) are intrinsic to the nature of logic.

**Generalizations and extensions of the Löwenheim-Skolem theorem.** A generalized theorem can be proved using basically the same ideas as those employed in the more special case discussed above.

If a theory has any infinite model, then, for any infinite cardinality  $\alpha$ , that theory has a model of cardinality  $\alpha$ . More explicitly, this theorem contains two parts: (1) If a theory has a model of infinite cardinality  $\beta$ , then, for each infinite cardinal  $\alpha$  that is greater than  $\beta$ , the theory has a model of cardinality  $\alpha$ . (2) If a theory has a model of infinite cardinality  $\beta$ , then, for each infinite cardinal  $\alpha$  less than  $\beta$ , the theory has a model of cardinality  $\alpha$ .

It follows immediately that any theory having an infinite model has two nonisomorphic models and is, therefore, not categorical. This applies, in particular, to the aforementioned theories  $T_a$  and  $T_b$  of arithmetic (based on the language of  $\mathbb{N}$ ), the natural models of which are countable, as well as to theories dealing with real numbers and arbitrary sets, the natural models of which are uncountable; both kinds of theory have both countable and uncountable models. There is much philosophical discussion about this phenomenon.

The possibility is not excluded that a theory may be categorical in some infinite cardinality. The theory  $T_a$ , for example, of dense linear ordering (such as that of the rational numbers) is categorical in the countable cardinality. One application of the Löwenheim-Skolem theorem is: If a theory has no finite models and is categorical in some infinite cardinality  $\alpha$ , then the theory is complete; *i.e.*, for every closed sentence in the language of the theory, either that sentence or its negation belongs to the theory. An immediate consequence of this application of the theorem is that the theory of dense linear ordering is complete.

Morley's theorem

A theorem that is generally regarded as one of the most difficult to prove in model theory is the theorem by Morley, as follows:

A theory that is categorical in one uncountable cardinality is categorical in every uncountable cardinality.

The two-cardinal theorems deal with languages that have some distinguished predicate  $U$ . A theory is said to admit the pair  $\langle \alpha, \beta \rangle$  of cardinals if the theory has a model (with its domain) of cardinality  $\alpha$  in which the value of  $U$  is a set of cardinality  $\beta$ . The central two-cardinal theorem says:

If a theory admits the pair  $\langle \alpha, \beta \rangle$  of infinite cardinals with  $\beta$  less than  $\alpha$ , then for each regular cardinal  $\gamma$ , the theory admits  $\langle \gamma^+, \gamma \rangle$ , in which  $\gamma^+$  is the next larger cardinal after  $\gamma$ .

The most interesting case is when  $\gamma$  is the least infinite cardinal,  $\aleph_0$ . (The general theorem can be established only when the "generalized continuum hypothesis" is assumed, according to which the next highest cardinality for an infinite set is that of its power set.)

**Ultrafilters, ultraproducts, and ultrapowers.** An ultrafilter on a nonempty set  $I$  is defined as a set  $D$  of subsets of  $I$  such that:

1. the empty set does not belong to  $D$ ;
2. if  $A, B$  are in  $D$ , so is their intersection,  $A \cap B$ , the set of elements common to both;
3. if  $A$  is a subset of  $B$ , and  $A$  is in  $D$ , then  $B$  is in  $D$ ;
4. for every subset  $A$  of  $I$ , either  $A$  is in  $D$  or  $I$  minus  $A$  is in  $D$ .

Roughly stated, each ultrafilter of a set  $I$  conveys a notion of large subsets of  $I$  so that any property applying to a member of  $D$  applies to  $I$  "almost everywhere."

The set  $\{\mathfrak{A}_i\}$  where  $\mathfrak{A}_i = \langle A_i, R_i \rangle$  and the  $i$  are members of the set  $I$ , is taken to be a family of structures indexed by  $I$ , and  $D$  to be an ultrafilter on  $I$ . Consider now the Cartesian product  $B$  of  $\{A_i\}$  (for example, if  $I$  is  $\{0,1,2, \dots\}$ , then  $B$  is the set of all sequences  $f$  such that  $f(i)$  belong to  $A_i$ ). The members of  $B$  are divided into equivalence classes with the help of  $D$ :  $f \equiv g$  if and only if  $\{i | f(i) = g(i)\} \in D$ ; in other words, the set of indices  $i$  such that  $f(i) = g(i)$  belong to  $D$  [or  $f(i)$  and  $g(i)$  are equal "almost everywhere"]. Let  $W$  be the set of these equivalence classes, *i.e.*, the set of all  $f^*$  such that  $f^*$  is the set of all members  $g$  of  $B$  with  $g \equiv f$ . We introduce similarly a relation  $S$  such that  $Sfg$  if and only if  $R_i$  holds between  $f(i)$  and  $g(i)$  for "almost all"  $i$ , *i.e.*,

$$\{i | R_i [f(i), g(i)]\} \in D.$$

In this way, we arrive at a new structure  $U = \langle W, S \rangle$  which is called the ultraproduct of the original family  $\{\mathfrak{A}_i\}$  over  $D$ . In the special case when all the  $\mathfrak{A}_i$  are the same, the resulting structure  $U$  is called the ultrapower of the original family over  $D$ .

The central theorems are the following:

1. If  $\mathfrak{A}_i$  ( $i \in I$ ) are realizations of the same language, then a sentence  $p$  is true in the ultraproduct  $U$  if and only

if the set of  $i$  such that  $p$  is true in  $\mathfrak{A}_i$ , belongs to  $D$ . In particular, if each  $\mathfrak{A}_i$  is a model of a theory, then  $U$  is also a model of the theory.

2. Two realizations of the same language are said to be elementarily equivalent if they have the same set of true sentences. A necessary and sufficient condition for two realizations to be elementarily equivalent is that they admit ultrapowers that are isomorphic.

One application of these theorems is in the introduction of nonstandard analysis, which was originally instituted by other considerations. By using a suitable ultrapower of the structure of the field  $\mathfrak{R}$  of real numbers, a real closed field that is elementarily equivalent to  $\mathfrak{R}$  is obtained that is non-Archimedean; *i.e.*, which permits numbers  $a$  and  $b$  such that no  $n$  can make  $na$  greater than  $b$ . This development supplies an unexpected exact foundation for the classical differential calculus using infinitesimals, which has considerable historical, pedagogical, and philosophical interest.

A widely known application to the area of algebra is that which deals with certain fields of rational numbers  $Q_p$ , called the  $p$ -adic completion of the rational numbers (see ALGEBRAIC STRUCTURES). The conjecture has been made that every form of degree  $d$  (in the same sense as degrees of ordinary polynomials) over  $Q_p$ , in which the number of variables exceeds  $d^2$ , has a nontrivial zero in  $Q_p$ . Using ultraproducts, it has been shown that the conjecture is true for arbitrary  $d$  with the possible exception of a finite set of primes  $p$  (depending on  $d$ ). Subsequently, it was found that the original conjecture is not true when extended to full generality.

Other useful tools in model theory include the pigeon-hole principles, of which the basic principle is that, if a set of large cardinality is partitioned into a small number of classes, some one class will have large cardinality. Those elements of the set that lie in the same class cannot be distinguished by the property defining that class.

A related concept is that of "indiscernibles," which also has rather extensive applications in set theory. An ordered subset of the domain of a model  $\mathfrak{A}$  of a theory is a homogeneous set, or a set of indiscernibles for  $\mathfrak{A}$ , if  $\mathfrak{A}$  cannot distinguish the members of the subset from one another. More exactly, given any  $x_1 < \dots < x_n, y_1 < \dots < y_n$  in the subset, then for any sentence  $F(a_1, \dots, a_n)$  of the language of the theory, that sentence (with argument  $x$ ) is satisfied by (symbolized  $\models$ ) the structure; *i.e.*,

$$\mathfrak{A} \models F(x_1, \dots, x_n),$$

if and only if that sentence (with argument  $y$ ) is also satisfied by it; *i.e.*,

$$\mathfrak{A} \models F(y_1, \dots, y_n).$$

There is also a first theorem on this notion that says that, given a theory with an infinite model and a linearly ordered set  $X$ , there is then a model  $\mathfrak{A}$  of the theory such that  $X$  is a set of indiscernibles for  $\mathfrak{A}$ .

the role of the interaction among electrons in metals; a third on the study of superconductivity (the disappearance of electrical resistivity in metals at temperatures near absolute zero, at which matter is drained of all heat energy), which had been discovered in 1911.

#### STRUCTURAL PROPERTIES OF METALS AND ALLOYS

Lattice structures

The arrangement of atoms in any crystal structure is orderly, forming a lattice in three dimensions, and this arrangement may be determined from the pattern of deflections the atoms impose on radiation with wavelength close to the interatomic spacing or by particles which can be represented by waves of such a wavelength, a phenomenon called diffraction; the diffraction of X-rays or neutrons by the lattice reveals the specific structure of a sample crystal. In metals, atomic arrangements are characterized by dense packing, similar to packing billiard balls in a box. Two of the most common metallic crystalline structures can in fact be understood in just this way. The first layer of atoms is visualized as on a flat surface as shown in Figure 2, each atom

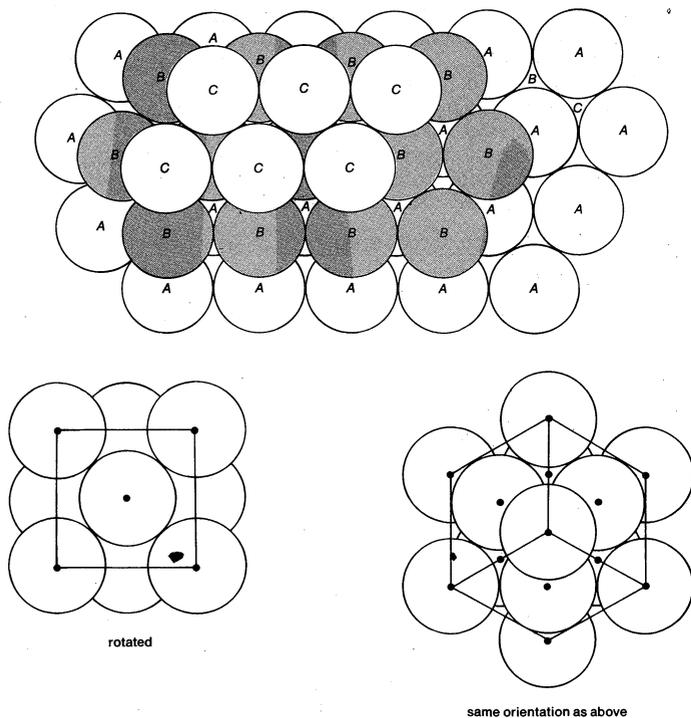

Figure 2: Derivation of face-centred cubic structure from planes of hexagonally close-packed atoms (see text).

touching its six nearest neighbours. The point at the centre of each atom is labelled *A*. The next layer of atoms is placed with each atom nestled into position *B* (position *C* could also be selected) between three atoms of the first layer. Again, for the third layer there are two available positions: *A*, directly over the first layer, or *C*. If *A* is used, and the pattern repeated, *ABABAB*, the hexagonal close-packed structure characteristic of magnesium results. In the figure, the position *C* is used for the third layer. Repeating this pattern, *ABCABCABC*, produces the face-centred cubic structure characteristic of aluminum. The term face-centred derives from the fact that this arrangement, viewed from a different angle, can be seen to be made up of cubes with one atom at each corner and one at the centre of each cube face.

The hexagonal close-packed and face-centred cubic structures correspond to the densest possible packing of spheres. The other common structure is obtained by beginning on the bottom layer with a square arrangement of atoms and then nestling a similar square array on top. This arrangement is the body-centred cubic structure and is only slightly less densely packed than the face-centred structure. Sodium at room temperature occurs in this pattern.

Ordinarily, metals occur in polycrystalline form; that is, consisting of a large number of small crystals, or grains, separated by thin grain boundaries. In some cases, such as the zinc coating on a galvanized pail, the grains are large enough to be easily discerned with the naked eye. In ordinary iron or steel, the grains are so small that they can be seen only under magnification. Large, single crystals of metal can be grown from a melt or from a metallic vapour under special controlled conditions.

When a metal is melted, the regularity of the crystalline lattice is destroyed, just as if the box of closely packed balls described above was shaken, and the density is correspondingly reduced (*i.e.*, the sample expands). Semiconductors, such as silicon and germanium, which are not classed as true metals because of their electrical properties, become metallic when melted; but, in contrast to metals, their density increases with melting. In liquids, the atoms are constantly rearranging themselves. Solids that do not have crystalline structure, such as glass, are called amorphous. It is possible to obtain such noncrystalline, amorphous structures by depositing metals upon very cold surfaces, but this amorphous form of metal is unstable and will crystallize when warmed. Grain boundaries in polycrystalline metals may be considered amorphous.

Alloys

Metallic alloys are obtained by first dissolving one metallic element in another under heat and then solidifying the melt, the solid alloy assuming a crystalline form. Most alloys are substitutional; when the atoms are of similar size, the atoms of one element replace those of another in the lattice. A binary alloy consists of two metallic elements. In some cases, as when carbon or hydrogen are added to iron, the atoms of the added element are small enough to fit between the larger atoms of the host crystal to form what are called interstitial alloys. In both the substitutional and interstitial alloys, there is some misfit of the constituent atoms and a distortion of the crystalline lattice from that which occurs in the pure metal.

Many alloys become ordered at low temperatures; that is, the different kinds of atoms are arranged in a regular sequence throughout the crystal volume. An example is beta ( $\beta$ -) brass, which consists of equal numbers of copper and zinc atoms. This alloy occurs in a body-centred cubic structure, atoms of copper and zinc alternating in the ordered manner shown in Figure 3. The copper atoms form a cubic superlattice as do the zinc atoms. (In some alloys, this tendency to order is so strong that the properties are much the same as those of a compound; in these instances an intermetallic compound is said to have been formed.)

If the temperature of this brass is raised, it becomes disordered at 470° C (880° F). This phase transition is comparable to that of the disappearance of crystalline order of a pure metal at the melting point. In both cases, the transition leads to higher entropy (condition of unavailable energy), corresponding to greater disorder in the high temperature phase.

Many pure metals and alloys undergo phase transitions to different crystalline structures as the temperature is changed. Sodium makes such a transition from body-centred cubic to hexagonal close-packed with decrease in temperature. Again, the entropy of the higher temperature phase is larger; in this case, the additional disorder arises because the body-centred cubic phase is softer, and therefore the thermal vibrations of the lattice, another kind of disorder, are larger.

In all such cases, the disordering of the material provides an additional mechanism for the storage of heat energy and therefore an increase in the heat content. The disorder also disrupts the flow of electrons so that ordinarily, though not always, the higher temperature phase will have higher electrical resistance.

Structural defects are common to all metallic crystals because there are always substitutional or interstitial impurities; missing atoms, called vacancies, or holes; and, occasionally, a misplaced atom in an interstitial position. Subtler defects in terms of the stacking of close-packed structures described above are also possible. For exam-

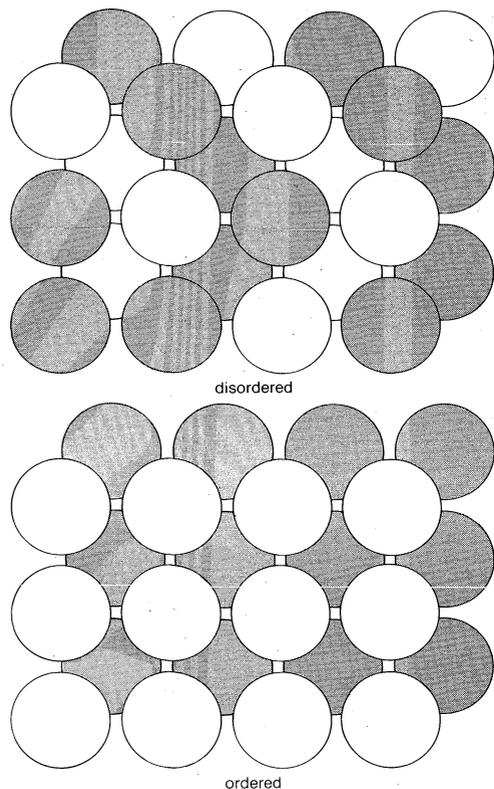

Figure 3: The body-centred cubic structure of beta brass, composed of zinc and copper atoms.

ple, a stacking of layers of atoms such as *ABCACAB-CABCABC* preserves a close-packed configuration but contains a stacking fault (a missing *B* layer) between the fourth and fifth planes. On either side of the stacking fault, the structure is face-centred cubic. All defects such as these cause scattering of the conduction electrons and increase the resistivity.

Dislocations

Another type of defect, the dislocation, plays an extremely important part in the deformation (that is, a change of shape) of metals. One characteristic type of dislocation may be visualized as in Figure 4: a representation of a crystal cut halfway through between two planes of atoms, the upper half being then slid one atom width toward the edge of the cut. The crystal structure is appreciably distorted only at the edge of the cut, and the disruption of the structure along this line is called an edge dislocation.

Edge dislocations play an important role in the response of a crystal to applied stresses. A force upon the top

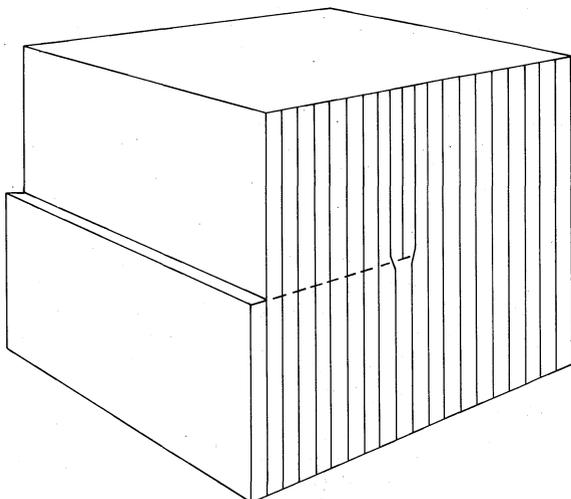

Figure 4: Formation of an edge dislocation. Planes of atoms are shown schematically on the front face (see text).

surface tending to push it to the right will drive the dislocation toward the right. If it emerges from the right surface, it will leave a step there and a permanent deformation. Any metallic crystal contains many dislocations, which are continually regenerated during deformation of the crystal. Thus, plastic deformation of a metallic crystal results from the motion of dislocations through the lattice, and can occur under relatively low stresses, just as a heavy rug may easily be moved across the floor by successively pushing small ripples across the rug. Without dislocations, it would be necessary to move an entire plane at one time, and, just as in attempting to move the entire rug by pulling on one edge, the required forces would be much larger.

The ability of a metal to deform plastically prevents its being brittle. In any other solid, stresses tend to build up near the edge of cracks, and cracks tend to propagate, as in shattering glass. In metal, however, the material flows in that region, relieving the stresses.

Alloying tends to harden crystals and to inhibit plastic deformation. The addition of impurity atoms acts to impede the motion of a dislocation line. For example, an oversized impurity is likely to sit near the dislocation, where the atoms have been pulled slightly apart, with the result that greater force will be required to move the dislocation away from the impurity.

Other types of dislocations may be generated by making similar cuts in a crystal but displacing the portion above the cut in a different direction from that shown in Figure 4. In all cases the resulting defect is called a dislocation line, and all types affect the plastic properties.

#### ELEMENTARY DESCRIPTION OF METALS

**Free-electron model.** Electrical properties of metals are best explained by reference to the free-electron concept. In the simple (that is, nontransition) metals there is a clear distinction between the conduction electrons and the tightly bound core electrons closer to the nucleus. The number of conduction electrons per atom, called the metallic valence, is equal in these metals to the number of the column in the periodic table; for example, I for sodium, II for magnesium, III for aluminum, and so on (see Figure 1).

Quantum theory, which describes the emission or absorption of energy by atoms or molecules as taking place by steps, each step being the emission or absorption of an amount of energy called a quantum, must be used to describe the states of these conduction electrons in the metal. Free electrons may travel through the entire metal, but because they are waves, they may move only with a specific set of velocities. The electron wavelength must be such that a whole number of wavelengths (or half wavelengths for some methods of treating the crystal boundaries) equals the length of the crystal. It is more convenient to specify a particular electronic state by its wave number, which is  $2\pi$  ( $2 \times 3.1416$ ) divided by the wavelength.

Although the electron can move in any direction in the crystal, which is visualized in the shape of a cube, it is evident that the motion of the electron is similarly restricted in the other two dimensions. Thus, the wave number represents a value in the direction of the electron motion, restricted in each of the three dimensions to one of the discrete (specific) velocities. The possible electronic states in a crystal, then, are represented by a lattice of points in wave-number space, each state corresponding to a wave number  $k$ , which terminates on one of these points. The larger the crystal, the more closely spaced are the possible states.

The Pauli principle states that not more than two electrons (spinning in opposite directions) can have the same wave number. Since the smaller the wave number, the lower the energy, the most stable arrangement of electrons is obtained by letting two electrons have each of the wave numbers in a region in wave-number space bounded by a sphere, called the Fermi sphere, large enough to encompass all the conduction electrons (see Figure 5). The states outside the Fermi sphere have higher energy than those inside and are not occupied. In simple metals

Wave number

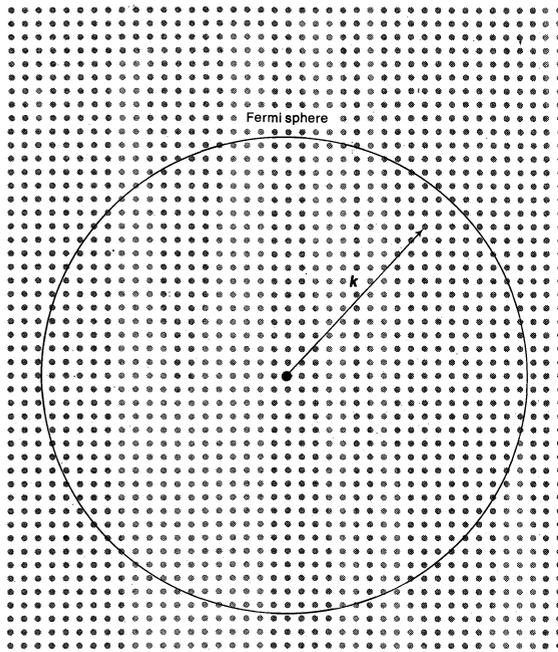

Figure 5: The Fermi surface, which separates conduction electrons from nonconducting space. Each dot represents an electron state and, if it is occupied by an electron, it represents the electron's velocity and a wave number  $k$ . The wave number may be represented by an arrow from the centre to the dot. Because no electron has an energy high enough—i.e., a wave number high enough—to place it outside the surface of the sphere, no arrow can be drawn to any point outside the surface (see text).

there are so many conduction electrons that the states with wave numbers near the Fermi sphere are very energetic, the electrons having velocities corresponding to 1 percent of the speed of light.

**Conduction of electric current.** In the ground state of a metal, the most stable state, there are as many electrons going one way as another, and no net current flows. If an electric field is applied, however, each electron is accelerated, and correspondingly its wave number shifts in the direction of the force. This results in a displacement of the Fermi sphere and in an electronic current.

If the electrons were truly free, they would accelerate indefinitely in the presence of an electric field, and the current would continue to grow. Impurities, defects, and thermal vibrations of the lattice, however, scatter the electrons and keep the current at a constant value. An electron of mass  $m$ , on the average, will move for a time symbolized by the Greek letter tau,  $\tau$ , the scattering time, before it is deflected. During that time it will be propelled by a force equal to its own charge ( $e$ ) multiplied by the electric field symbolized by  $E$  (i.e., as  $eE$ ) and will increase its velocity by an amount  $eE\tau/m$ . The electron contributes to the current its charge times the added velocity, and the current density, if  $N$  represents the number of electrons in unit volume, is  $Ne^2E\tau/m$ . Thus, the current density is proportional to the electrical field (Ohm's law); the proportionality constant, symbolized by the Greek letter sigma,  $\sigma$  (with  $\sigma = Ne^2\tau/m$ ), is the conductivity. It is large in metals because of the high density of conduction electrons, particularly large if the number of defects is small and the temperature is low, conditions that lead to a long scattering time,  $\tau$ .

**Conduction of heat.** The theory of thermal conductivity is quite similar. The large number of essentially free electrons, which transport thermal energy from hotter to cooler sections of the material, accounts for the high thermal conductivity of metals. Difference in temperature in two parts of the metal produces the flow of thermal energy, and the proportionality constant is the thermal conductivity. The ratio of the thermal to the electrical conductivity is equal to a constant (the Wiedemann-Franz ratio) times the temperature. There are also ther-

moelectric effects, involving both electric fields and temperature differences, which are understood on the same basis, and are brought to use in the thermocouple, which measures temperatures electrically.

Although the Pauli principle has little effect on conduction properties, it becomes quite important in the heat capacity. In the classical physics preceding quantum theory, electrons were expected, because of their large numbers, to make a major contribution to the heat capacity of a metal. In the quantum mechanical description, however, electrons lying well within the Fermi sphere cannot take on this thermal energy, because all the electron states in this energy range are already occupied. The contribution of the electrons to the heat capacity is reduced to the point that the ratio is of the order of 1:400 in most metals at room temperature. There is a similar suppression of the response of a metal to a magnetic field. Each electron behaves as a tiny magnet by virtue of its spin, and in the presence of a magnetic field, it tends to align with that field, leading to a magnetization within the metal. Because only those electrons near the Fermi sphere may reverse their spins, however, the resulting contribution, known as Pauli magnetic susceptibility, is much smaller than would be expected according to classical theory.

In the above description the electrons are free to move within the metal but not to leave the metal. The forces that hold the electron in the metal are the same electrostatic forces that hold the metal itself together. They were first calculated for the alkali metals; then, comparison with the corresponding binding of electrons to the isolated atom led to determination of the cohesive energy for the metal. Cohesion in metals derives from closer proximity of the free negative electrons to the positive metallic ions in the metal than exists for electrons bound to isolated atoms.

#### ELECTRONIC STRUCTURE OF METALS AND RELATED EFFECTS

**Pseudopotentials.** In the free-electron representation, interaction between free electrons and the lattice of ions was neglected except in the general sense that applies to cohesion. While this interaction is known to be strong, the success of the foregoing assumptions seems to indicate that the effect of the interaction is insignificant. This paradox is resolved through the concept of a pseudopotential. Conduction electrons, having high energy, move past the ions with very little deflection, as a speeding car rides relatively smoothly over a bumpy road and a slower car rises and falls with every bump and depression. This effect may be incorporated in the quantum theory of the electron motion by mathematically considering only conduction electron states and deliberately excluding the core electrons bound to the nuclei.

Although the interaction between conduction electrons and the lattice is then represented by a weak pseudopotential, there are inevitable effects of that interaction. In the same manner that an X-ray moving through a crystal may be diffracted, the electron wave may be diffracted by the pseudopotential. Either diffraction can occur, however, only if the wave in question satisfies the so-called Bragg condition; i.e., that the wave number terminate on a Bragg reflection plane in wave-number space. These planes contain wave numbers with magnitudes of the order of  $2\pi$  ( $2 \times 3.1416$ ) divided by atomic spacing. For electromagnetic waves, this condition is satisfied by X-rays.

**Bragg planes and Fermi spheres.** Because of the high density of electrons in metals, the wavelengths of free electrons in the Fermi sphere are also comparable to spacing between atoms, so that it frequently happens that Bragg reflection planes intersect the Fermi sphere in wave-number space. Only a small number of states, however, lie exactly at the plane and can be diffracted. The others traverse the crystal without diffraction and behave as if completely free.

The Bragg condition presumes perfect arrangement of atoms in the periodic lattice. When there are defects or thermal distortions, even electrons not at Bragg planes may be diffracted. Such diffraction caused by defects is

Diffraction by pseudopotential

Thermal conductivity

called electron scattering and is the process that limits the conductivity. The strength of this scattering may be directly calculated from a knowledge of the pseudopotential associated with each ion and of the arrangement of ions in the defective crystal. Electrical resistivity, which is the inverse of the conductivity, tends to be proportional to the number of defects. Usually the change in resistivity of a metal is about one micro-ohm-centimetre per atomic percent of defects (one ohm is the resistance of a circuit in which a potential difference of one volt generates a current of one ampere).

When a metal crystal is melted, the distinction between diffraction and scattering of electrons becomes unclear. It is nevertheless possible, again in terms of pseudopotentials, to calculate the rate of transitions and therefore the conductivity of the liquid metal.

Although only a tiny fraction of the electrons in a perfect metallic crystal are diffracted, the effects of the diffraction may be seen by the application of a magnetic field. An electron moving in a magnetic field reacts to a force perpendicular to its motion (this is exactly the force that drives the armature in an electric motor). An electron with its wave number at the Fermi surface will change its direction of motion by moving along the Fermi sphere. In the absence of diffraction it moves around the Fermi sphere, returning periodically to its initial wave number with a frequency called the cyclotron frequency. The motion on the Fermi sphere would be along a circle made by the intersection of the Fermi sphere and a plane perpendicular to the magnetic field.

Such motion of electron states across the sphere brings many to the Bragg plane, where they can be diffracted. In doing so, they jump to the Fermi sphere at the opposite Bragg plane and continue on their way. The wave number returns to its initial value after traversing a shorter set of arcs than would be the case if there were no diffraction planes; therefore, its cyclotron frequency is correspondingly higher.

It is not difficult to visualize the real orbit of the diffracted electron within the crystal in a magnetic field. The diffraction causes its velocity to change abruptly, but it cannot jump instantaneously from one place to another in the crystal. Thus, its orbit is made up of a series of arcs, always combined into a large orbit on an atomic scale, extending over many thousands of atom distances.

**Reduced-zone representation.** Studies of the electronic properties of metals in which such orbit shapes are of direct interest can be more easily done by means of a different representation of the electron states, the reduced-zone representation.

The region so defined, called the Brillouin (or reduced) zone, is bounded by Bragg reflection planes and can be constructed for three-dimensional lattices. The Fermi surface is constructed in the reduced zone by translating each segment of the Fermi sphere so that every pair of states between which diffraction can occur appears at the same wave number. Such translations of the arcs in which diffracted electrons move lead to a segment of the Fermi surface in the reduced zone that is precisely the shape of the electron orbit in real space.

Such a three-dimensional construction of the Fermi surface of aluminum is shown in Figure 6. All possible orbital paths in a magnetic field may be obtained by constructing intersections of planes perpendicular to the magnetic field with these surfaces. Thus, they provide a tremendous amount of information at a glance.

A wide range of properties is affected by the existence of diffraction and the corresponding changes in the Fermi surface. One of the simplest is the Hall effect, which arises when a magnetic field is applied perpendicularly to the direction of a current flow: the electrons are deflected and accumulate at the surface, causing an electric field, the Hall field, just large enough to prevent further accumulation. Thus, the Hall field is a transverse field proportional to both the current and to the applied magnetic field. The proportionality proves to depend only on the density of electrons and their charge if there is no diffraction.

The presence of diffraction strongly modifies the Hall

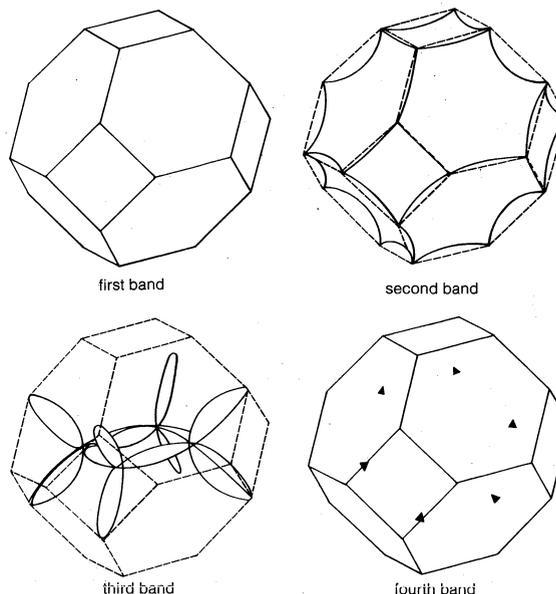

Figure 6: The Fermi surface of aluminum.

field, and thus the Hall effect may be used as an experimental tool to study the Fermi surface. The magnetic field also reduces the current along the applied electric field, an effect called magnetoresistance, which also gives information about the Fermi surface.

Certain other effects give more direct information about the orbits in a magnetic field. One, called cyclotron resonance, is a measurement of the cyclotron frequencies of various orbits in the metal. Another, the magneto-acoustic effect, uses sound waves to measure the diameter of electron orbits and therefore of the Fermi surface. The most precise measurements of the Fermi surface have been made with the De Haas-Van Alphen effect, in which fluctuations in magnetic susceptibility are measured by increasing or decreasing a magnetic field. These fluctuations depend only upon the cross-sectional areas of the Fermi surface and give precise measurements of the Fermi surface areas.

Studies of the Fermi surfaces using these techniques have confirmed the general features of this diffraction theory of the Fermi surface. Discrepancies found in calculations of areas and dimensions are believed to be due to the fact that the pseudopotential is not arbitrarily weak. Because of the pseudopotential influence, an electron begins to diffract before it quite reaches the Bragg reflection plane; the true orbits do not have sharp cusps of the type shown; rather the cusps are rounded off and the Fermi surfaces are correspondingly rounded off by the effects of the finite pseudopotential. The pseudopotentials themselves and their resulting effects may be calculated and again tested by experiment.

#### BAND STRUCTURE AND PROPERTIES OF METAL GROUPS

In the monovalent metals, those in Groups Ia and Ib of the periodic table (see Figure 1), the free-electron Fermi sphere lies entirely in the reduced zone and no diffraction is expected. The electrons in the Ia metals are expected and found to be like free electrons. The pseudopotential, however, is so strong in the noble metals, copper, silver, and gold, that the Fermi surface bows out toward the zone faces.

The polyvalent metals (those of Groups IIa, IIIa, IVa, and IIb) have complicated Fermi surfaces, such as the aluminum surface shown in Figure 6. All have been thoroughly studied, and the reduced-zone representation has proven a good starting point in all cases.

Electronic structures of the transition metals are more complicated. In addition to the conduction electrons there are electrons, called *d* electrons as in the atom, which have energies near the Fermi energy but which retain much of their nucleus-bound character rather than becoming free. It is possible to describe the conduction

The  
Hall  
effect

Atomic  
*d* states

electrons and  $d$  electrons together in terms of very complicated Fermi surfaces, but for many purposes it is preferable to separate the  $d$  electrons conceptually. This separation is particularly appropriate in the rare earths where the states in question are  $f$  states rather than  $d$  states.

In the noble metals,  $d$  electrons lie below the Fermi energy and therefore have no Fermi surface. Conduction-electron states, however, and  $d$  states in the noble metals interact to produce a large pseudopotential and the distortion of the Fermi surface mentioned above. The presence of the  $d$  states also leads to a contraction of the lattice in the noble metals in comparison to the other monovalent metals and the corresponding high density of electrons makes the conductivity high.

Transition metals have varying numbers of  $d$  electrons. Many properties depend principally upon the electron-to-atom ratio, the continuation of metallic valence through the transition series indicated at the top of the periodic table. The properties of transition metal alloys depend upon the average electron-to-atom ratio for the alloy system. In all cases the  $d$  states give a large concentration of states near the Fermi energy and therefore an enhancement of the properties such as the specific heat and the Pauli paramagnetism.

The  $d$  states also give rise to the possibility of ferromagnetism in transition metals. Imagine a pair of such states, with opposite electron spins, which lie just below the Fermi energy. If there are electrons in both of these states, there will be an electrostatic repulsion between them. In some cases this repulsion causes only one of the states to be occupied, but it could be occupied with either spin. A local moment (something that behaves as a tiny bar magnet) is said to have been formed. Such a system will have a large response to an applied magnetic field. The field will tend to align the magnetic moments of these electrons, and in this case the alignment can take place without any increase in electronic energy.

Exchange  
interaction

When local moments are formed in transition metals, there will ordinarily be an interaction between the moments on different atoms (usually called an exchange interaction) just as there are interactions between bar magnets; thus, in iron, the exchange interaction favours the parallel alignment of the moments on neighbouring atoms so that the lowest energy will be obtained with all moments aligned, which is the ferromagnetic state, the state of ordinary magnetic iron. In some materials the exchange interaction favours an antiparallel alignment, and the lowest state is called anti-ferromagnetic. In either case, the magnetic state is well ordered, but a phase transition will occur if the temperature is raised sufficiently. At this temperature, called the Curie temperature for ferromagnets, the magnetic system becomes disordered, just as the crystalline system becomes disordered at the melting temperature, although there are fundamental differences in the two transitions.

#### LATTICE VIBRATIONS

As has been indicated, the vibrations of the atoms in a crystal provide most of the heat content in metals because the heat capacity arising from the conduction electrons is suppressed on account of the Pauli principle. The heat capacity arising from these vibrations is relatively constant at high temperatures, as expected theoretically, but it drops to low values at low temperatures because of another quantum mechanical effect. In one of the earliest quantum theories of heat capacity, Einstein proposed that each atom could vibrate independently. This proposal was recognized as an oversimplification because the motions of different atoms may be related as in sound waves in which neighbouring atoms move together. Regarding the vibrations as sound waves gave an improved account of the specific heat at low temperatures.

That picture, however, was also an oversimplification of the true spectrum of vibration frequencies in a solid; later, quite complete experimental studies of vibration spectra were made using the diffraction of neutrons.

The theory of the lattice vibrations requires an understanding of the interactions between the ions in a metal.

There are two important factors involved in these interactions: the direct electrostatic interaction, and an indirect interaction, which arises as conduction electrons are successively deflected by two ions. The latter can be calculated in terms of the pseudopotential and, when added to the direct interaction, gives an effective interaction between ions.

Calculations of the vibration characteristics in terms of these interactions have not proved very reliable; but, with minor adjustments, they can be made to agree with experimental results for simple metals. The application to transition metals has not been made.

Lattice vibrations, called phonons in quantum theory, affect many of the properties of a metal. The effect of thermal vibrations on conductivity was mentioned earlier. The interaction of a vibration of a given intensity with an electron, called the electron-phonon interaction, may be calculated from the pseudopotential. Probability of a vibration scattering an electron is proportional to the intensity of the vibration; that intensity is, in turn, proportional to the absolute temperature at high temperatures, where the resistivity is found to be proportional to temperature. At low temperatures, the resistivity drops, although, because of scattering by impurities and defects, a residual resistance remains. Another effect of the vibrations is that the speed with which electrons at the Fermi surface move is decreased.

The lattice vibrations can also cause an indirect interaction between pairs of electrons comparable to the interaction electrons cause between pairs of ions. An electron moving through the lattice may jostle the ions, producing a distortion that lowers the energy of an electron subsequently passing through the region. This type of interaction may cause the electronic system to become unstable and form a new phase.

This new phase of the electron system is called superconductivity. In many metals (lead, for example) resistivity drops slowly as the temperature drops until at a critical temperature, the resistivity suddenly becomes zero. This phenomenon does not mean that the electrons are no longer scattered, only that scattering no longer reduces the current. The nature of this superconducting state is understood in terms of the indirect interaction between electrons. Electrons moving in opposite directions form so-called Cooper pairs. In the superconducting state one electron scatters inevitably when the other does, and the current carried by the pair is unchanged. The superconducting state represents a kind of order in the electronic system that is analogous to the magnetic order in ferromagnetism.

Supercon-  
ductivity

#### METAL SURFACE PHENOMENA

Extensive theoretical study has been devoted to the metallic surface as well as to the behaviour of electrons and ions within the metal, which concern the bulk properties of metals. An understanding of the metal surface requires an understanding of the forces that hold electrons within the metal. An electron striking the surface from within moves slightly beyond the last plane of atoms before returning. There is a layer of negative charge, caused by these electrons, beyond the metallic surface and a compensating positive charge from the ions slightly inside. This double layer of charge provides the electric field that prevents the electrons from escaping. The calculations of the force of this field lead to the finding that an electron with the Fermi energy lacks, by a few electron volts, the energy required to escape from the metal. The barrier is known as the work function of the metal. The work function is very sensitive to the nature of the surface and to any adsorbed (adhering to the surface) atoms, and this theory tells little about surfaces of real metals. It does, however, describe the physics of the work function.

Electrons can escape from a metal if the temperature is high enough; then a small number of electrons will have sufficient energy to overcome the work function and escape. This is thermionic emission, the mechanism by which electrons are introduced into the vacuum by a hot cathode in a vacuum tube. Electrons may also escape by the photoelectric effect, which results from the quantum-

mechanical nature of light. The light arrives in quanta of energy, called photons, which vary according to the wavelength of the light. In light of short wavelengths, ordinarily in the visible, the photon energies may be greater than the few electron volts required to free the electron from the metal surface.

## Tunnelling

There has been extensive research on the removal of electrons through quantum-mechanical tunnelling. A thin layer of oxide is formed on the surface of the metal and a second metal deposited upon the oxide. The oxide is an insulator, and the electrons respond to it much as they would to a narrow evacuated space; an electron at the Fermi energy does not have the energy needed to traverse it. There is, however, a small probability that, because of the wave nature of the electron, it will nevertheless be transmitted; this is the tunnel effect. Such tunnelling is of particular interest when one or both of the metals are superconductors, because it provides a way of studying the electronic states near the Fermi energy in the superconductor (this is called Giaever tunnelling). If the oxide is sufficiently thin, it is possible for supercurrents to flow without impedance through the oxide, a phenomenon known as the Josephson effect.

Because of the high conductivity of metals, electromagnetic waves are reflected from a metal surface (this is particularly familiar in the case of light waves that give a fresh metal surface its shiny appearance). The reflection occurs by the generation of electric currents in the surface, which act as antennas reradiating the light outward. Thus, when light is reflected, there are always currents flowing in the surface of the metal, but they are restricted to quite near the surface. This is the skin effect, and the depth of penetration is called the skin depth. It is the field within the skin depth that can give conduction electrons the energy necessary for photoelectric emission. It is the current within the skin depth that, because of metallic resistance, may heat the metal with energy extracted from the reflecting light, resulting in imperfect reflection. This aspect of optical absorption was understood in the earliest days of the free-electron theory of metals and is called Drude absorption, after the German physicist Paul Drude.

Some other aspects of optical absorption could not be understood before the introduction of quantum theory, such as interband transitions, in which photons are absorbed and individual electrons make transitions between states of greatly different energy. Such transitions are particularly familiar in the noble metals (gold, silver, copper), where they take place between occupied *d* states and unoccupied conduction states just above the Fermi energy. It is these absorptions in the blue that cause the colour of copper and gold. It is also thought that such an interband transition is the first step in most photoemission processes for electrons.

## Metallic colours

MANY-BODY EFFECTS

Most of the theory of metals, as elaborated above, has been based on a one-electron approximation, a simplified approach to solving problems. The states of a particular electron are discussed without concern for what other electrons are doing at the same time, or only considering the effects of another electron in a general way. In a real metal, the electron motions are correlated with each other and collectively are extraordinarily complicated. As in the case of the interaction of the electrons with the ions, however, the effects are not as large as the interactions that cause them.

There are two particular ways, other than in causing superconductivity as already described, in which the electron interactions do make themselves felt. Because metals are good conductors, the electrons tend to move in order to reduce or eliminate any electric field that may be present. In particular, if a charge is introduced into the metal, the electrons flow to eliminate the long-range electrostatic field that would otherwise arise. This phenomenon is called screening of a charge in the metal. In the same way, the charge of each electron is screened by the motion of other electrons in the metal, and the net long-range interaction between any given pair of electrons

becomes small. Thus screening is one important effect of the electron-electron interactions. The other arises when fields change so rapidly that the electrons have difficulty keeping up. Then plasma oscillations occur, which are very high-frequency vibrations of the electron gas as a whole.

An additional class of effects that arise from the interaction between electrons, concerning what are called shake-off electrons, has been the centre of intense theoretical activity. In some situations, notably when a conduction electron drops to a deep core state with the emission of an X-ray, other electrons must take some of the energy and be raised above the Fermi energy; these are shake-off electrons. As a result, not all of the energy of the transition is in the X-ray, and the energies of the emitted X-rays are all smaller than would be predicted by simple theory.

To a large extent the simple theory of metals based upon the one-electron approximation has been extraordinarily successful. More complete studies of the effects of electron-electron interactions have explained these successes and have also shown that in some cases the one-electron picture is inadequate.

**Metalwork**

Man's first materials were stone, wood, bone, and earth. It was not until he had reached a later stage of evolution that he was able to extract and work with metals. This article deals with the objects that man has fashioned from copper, bronze and brass, gold and silver, iron, and lead: vessels, utensils, ceremonial and ritualistic objects, decorative objects, architectural ornamentation, personal ornament, sculpture, and weapons. (For a more detailed discussion of weapons, ceremonial and ritualistic objects, personal ornaments, and sculpture, see ARMS DESIGN AND DECORATION; CEREMONIAL AND RITUALISTIC OBJECTS; JEWELRY; and SCULPTURE, ART OF). This article treats the processes and techniques and the stylistic characteristics and historical developments of metalworking. Aspects of metalwork are discussed in the following related articles: VISUAL ARTS, EAST ASIAN; VISUAL ARTS, WESTERN; SOUTH ASIAN PEOPLES, ARTS OF; CENTRAL ASIAN PEOPLES, ARTS OF; SOUTHEAST ASIAN PEOPLES, ARTS OF; ISLAMIC PEOPLES, ARTS OF; JEWISH PEOPLES, ARTS OF; AFRICAN PEOPLES, ARTS OF; and AMERICAN INDIAN PEOPLES, ARTS OF.

### I. General processes and techniques

Many of the technical processes in use today are essentially the same as those employed in ancient times. The early metalworker was familiar, for example, with hammering, embossing, chasing, inlaying, gilding, wiredrawing, and the application of niello, enamel, and gems.

*Hammering and casting.* All decorative metalwork was originally executed with the hammer. The several parts were hammered out separately and then put together by means of rivets or pinned on a solid core (for soldering had not yet been invented). Plates of hammered copper could be shaped also into statues, the separate pieces being joined together with copper rivets. A life-size Egyptian statue of the pharaoh Pepi I in the Egyptian museum, Cairo, is an outstanding example of such work.

Lost-wax  
process

After about 2500 BC, the two standard methods of fabricating metal—hammering and casting—were developed side by side. The lost-wax, or *cire perdue* (casting with a wax mold), process was being employed in Egypt by about 2500 BC, the Egyptians probably having learned the technique from Sumerian craftsmen (see SCULPTURE, ART OF). Long after the method of casting statues in molds with cores had superseded the primitive and tedious rivetting process, the hammer continued as the main instrument for producing art works in precious metals. Everything attributable to Assyrian, Etruscan, and Greek goldsmiths was wrought by the hammer and the punch.

*Embossing, or repoussé.* Embossing (or *repoussé*) is the art of raising ornament in relief from the reverse side. The design is first drawn on the surface of the metal and the motifs outlined with a tracer, which transfers the essential parts of the drawing to the back of the plate. The plate is then embedded face down in an asphalt block and the portions to be raised are hammered down into the yielding asphalt. Next the plate is removed and re-embedded with the face uppermost. The hammering is continued, this time forcing the background of the design into the asphalt. By a series of these processes of hammering and re-embedding, followed finally by chasing, the metal attains its finished appearance. There are three essential types of tools—for tracing, for bossing, and for chasing—as well as a specialized tool, a snarling iron or spring bar, which is used to reach otherwise inaccessible areas. Ornament in relief is also produced by mechanical means. A thin, pliable sheet of metal may be pressed into molds, between dies, or over stamps. All of these methods have been known from antiquity.

*Chasing.* Chasing is accomplished with hammer and punches on the face of the metal. These punches are so shaped that they are capable of producing any effect—either in *intaglio* (incising beneath the surface of the

metal) or in relief—that the metalworker may require. The design is traced on the surface, and the relief may be obtained by beating down the adjacent areas to form the background. Such chased relief work sometimes simulates embossed work, but in the latter process the design is bossed up from the back. The detailed finish of embossed work is accomplished by chasing; the term is applied also to the touching up and finishing of cast work with hand-held punches.

*Engraving.* To engrave is to cut or incise a line. Engraving is always done with a cutting tool, generally by pressure from the hand. It detaches material in cutting. When pressure is applied with a hammer, the process is called carving.

*Inlaying.* The system of ornamentation known as damascening is Oriental in origin and was much practiced by the early goldsmiths of Damascus; hence the name. It is the art of encrusting gold wire (sometimes silver or copper) on the surface of iron, steel, or bronze. The surface upon which the pattern is to be traced is finely undercut with a sharp instrument. The gold thread is forced into the minute furrows of the cut surface by hammering and is securely held.

Niello is the process of inlaying engraved ornamental designs with niello, a silver sulfide or mixture of sulfides. The first authors to write on the preparation of niello and its application to silver were Eraclius and Theophilus, in or about the 12th century, and Benvenuto Cellini, during the 16th. According to each of these authors, niello is made by fusing together silver, copper, and lead and then mixing the molten alloy with sulfur. The black product (a mixture of the sulfides of silver, copper, and lead) is powdered; and after the engraved metal, usually silver, has been moistened with a flux (a substance used to promote fusion), some of the powder is spread on it and the metal strongly heated; the niello melts and runs into the engraved channels. The excess niello is removed by scraping until the filled channels are visible, and finally the surface is polished.

*Enamelling.* There are two methods of applying enamel to metal: *champlevé*, in which hollows made in the metal are filled with enamel; and *cloisonné*, in which strips of metal are applied to the metal surface, forming cells, which are then filled with enamel. (For a detailed discussion, see ENAMELWORK.) (S.V.G.)

Damascening and niello

Champlevé and cloisonné

*Gilding.* Gilding is the art of decorating wood, metal, plaster, glass, or other objects with a covering or design of gold in leaf or powder form. The term also embraces the similar application of silver, palladium, aluminum, and copper alloys.

The earliest of historical peoples had masterly gilders, as evidenced by overlays of thin gold leaf on royal mummy cases and furniture of ancient Egypt. From early times, the Chinese ornamented wood, pottery, and textiles with beautiful designs in gold. The Greeks not only gilded wood, masonry, and marble sculpture but also fire-gilded metal by applying a gold amalgam to it and driving off the mercury with heat, leaving a coating of gold on the metal surface. From the Greeks, the Romans acquired the art that made their temples and palaces resplendent with brilliant gilding. Extant examples of ancient gilding reveal that the gold was applied to a ground prepared with chalk or marble dust and an animal size or glue.

Beating mint gold into leaves as thin as  $\frac{1}{280,000}$  inch (0.00001 centimetre) is done largely by hand, though machines are utilized to some extent. After being cut to a standard  $3\frac{1}{8}$  inches (9.84 centimetres) square, the leaves are packed between the tissue-paper leaves of small books, ready for the gilder's use.

The many substances to which the gilder can apply his art and the novel and beautiful effects he can produce may require special modifications and applications of his methods and materials. Certain basic procedures, however, are pertinent to all types of gilding. For example, the ground to be gilded must be carefully prepared by priming. Flat paints, lacquers, or sealing glues are used, according to the nature of the ground material. Metals subject to corrosion may be primed (and protected) by

red lead or iron oxide paints. With pencil or chalk the gilder lays out his design on the ground after the ground has been prepared and is thoroughly dry. Patterns may also be laid down by forcing, or pouncing, powdered chalk or dry pigment through paper containing perforations made with pricking wheels mounted on swivels; the swivel arrangement permits the attainment of the most intricate of designs.

To create an adhesive surface to which the gold will be securely held, the area to be gilded is sized. The type of size used depends on the kind of surface to be gilded and on whether it is desirable for the size to dry quickly or slowly. When the size has dried enough so that it just adheres to the fingertips, it is ready to receive and retain the gold leaf or powder.

Appli-  
cation of  
gold leaf

Gold leaf may be rolled onto the sized surface from the tissue book. Generally, however, the gilder holds the book firmly in his left hand with the tissue folded back to expose as much leaf as is needed and detaches that amount with a pointed tool, such as a sharpened skewer. He then picks up the leaf segment with his gilder's tip, a brush of camel's hair set in a thin cardboard holder, and carefully transfers it to its place in his design. The leaf is held to the tip by static electricity, which the gilder generates by brushing the tip gently over his hair. For some gilding operations the gilder uses a cushion to hold his pieces of leaf. This is a rectangular piece of wood, about 9 by 6 inches (23 by 15 centimetres) in size, which is padded with flannel and covered with dressed calfskin; a parchment shield around one end protects the delicate leaf from disturbance by drafts of air. When the gilding is completed, the leaf-covered area should be pounced with a wad of soft cotton of surgical grade. Rubbing with cotton burnishes the gold to a high lustre. Application of a gilder's burnisher—that is, a highly polished agate stone set in a handle—also imparts a fine, high finish to the metal. Loose bits of gold, or skewings, may be removed from the finished work with a camel's hair brush.

Leaf gold may be powdered by being rubbed through a fine-mesh sieve. Powdered gold is so costly, however, that bronze powders have been substituted almost universally for the precious metal. When gold leaf is employed in the gilding of domes and the roofs of buildings, it is used in ribbon form. For finishing processes, such as burnishing and polishing, see SCULPTURE, ART OF. (E.L.Y.)

## II. Western metalwork

### COPPER

Copper  
alloys

The first nonprecious metal to be used by man was copper. But in the 4th millennium BC, Eastern craftsmen discovered that copper alloys using tin or zinc were both more durable and easier to work with, with the result that from then on the use of unalloyed copper declined sharply. Artists and craftsmen working in the West also discovered this, which is why pure copper work was relatively rare.

Pure copper is a reddish colour and has a metallic glow. When it is exposed to damp, it becomes coated with green basic copper carbonate (incorrectly known as verdigris). This patina is a drawback if copper is to be used for functional objects, for the oxide is poisonous to man. This means that utensils that come into contact with food must be lined with tin.

As copper is a relatively soft metal, it is sensitive to such influences as stress and impact. But unlike bronze it is malleable and can be hammered and chased in much the same way as silver. The surface of copper can be successfully gilded, and its reddish colouring makes the gilding seem even brighter. Because of these properties, copper was sometimes able to compete somewhat with silver.

Pure copper is not particularly good for casting, as it can easily become blistered when the gases escape. The surface of sheet copper can be engraved, however, and this technique was often used for decorating purely ornamental objects. In copperplate etching, engraving became the basis of printing. Enamel is often applied to copper, using both the *champlevé* and *cloisonné* techniques. Sheet copper was also used as a base for painted enamel.

(H.-U.H.)

**Antiquity. Mesopotamia.** In the museum at Baghdad, in the British Museum, and in the University of Pennsylvania at Philadelphia are finely executed objects in beaten copper from the royal graves at Ur (modern Tall al-Muqayyar) in ancient Sumer. Outstanding is a copper relief that decorated the front of the temple at Al 'Ubaid. This remarkable decoration represents an eagle with a lion's head, holding two stags by their tails. The stags' antlers—also made of wrought copper—were developed in high relief and were soldered into their sockets with lead. This relief illustrates the high level of art and technical skill attained by the Sumerians in the days of the 1st dynasty of Ur (c. 2650–2500 BC). In the Metropolitan Museum of Art, New York City, is a Sumerian bull's head of copper, probably an ornamental feature on a lyre, which is contemporary with the Ur finds.

Copper  
relief at  
Al  
'Ubaid

The malleability of unalloyed copper, which renders it too soft for weapons, is peculiarly valuable in the formation of vessels of every variety of form; and it has been put to this use in almost every age. Copper domestic vessels were regularly made in Sumer during the 4th millennium BC and in Egypt a little later.

**Egypt.** From whatever source Egypt may have obtained its metalworking processes, Egyptian work at a remote period possesses an excellence that, in some respects, has never been surpassed. Throughout Egyptian history, the same smiths who worked in the precious metals worked also in copper and bronze.

Nearly every fashionable Egyptian, man or woman, possessed a hand mirror of polished copper, bronze, or silver. Copper pitchers and basins for hand washing at meals were placed in the tombs. An unusual example in the Metropolitan Museum of Art is plated with antimony to imitate silver, which was very rare in the Old Kingdom (c. 2686–c. 2160 BC). The basins and the bodies of the ewers were hammered from single sheets of copper. The spouts of the ewers were cast in molds and attached to the bodies by means of copper rivets or were simply inserted in place and crimped to the bodies by cold hammering.

(S.V.G.)

"Tassilo Chalice," copper gilt with silver and niello, c. 780. In the Kremsmünster Abbey, Austria. Height 25 cm. Bildarchiv Foto Marburg

**Middle Ages. Europe.** The first well-designed copper objects to survive in the West date from about the middle of the Carolingian period, the 8th century AD. Who made them is not known, but one can assume that in the early Middle Ages they were mainly the work of monks. Indeed, the earliest copper and copper-gilt pieces are exclusively liturgical implements.

Decrees issued by the church synods held in the 8th and 9th centuries invariably expressly prohibited the use of copper and bronze for consecrated chalices, but in fact a few copper-gilt chalices like the "Tassilo Chalice" (Kremsmünster Abbey, Austria) have survived. The care

## Copper-gilt religious objects

and artistry with which they were worked and their rich engraved and niello decoration show that they were valued as highly as altar vessels made of precious metals.

From the 12th century onward, but particularly in the 13th and 14th centuries, copper-gilt chalices were relatively common, especially in Italy, where they were virtually mass-produced. Reliquaries, portable altars, shrines, and processional crosses dating from the Ottonian and Romanesque periods are also very frequently made of gilded copper and are generally decorated with enamel, niello work, or engraving or set with precious stones. One group of copper-gilt reliquaries, dating from the 12th century and after, takes the form of the head, or head and shoulders, of a saint. Others are in the shape of various parts of the body, such as an arm or a foot. These were also made in silver and in cast bronze. Ciboria (covered vessels for holding the wafers of the Eucharist), monstrances (receptacles for the Host), incense vessels, and other liturgical implements were also made in copper gilt, as well as in bronze and silver. Some of these copper-gilt implements were made as late as the Baroque period. (H.-U.H.)

*Islām.* The most magnificent example of Muslim enamel work in existence is a copper plate in the Tiroler Landes museum Ferdinandeum at Innsbruck, Austria, decorated in polychrome enamel, with figure subjects, birds and animals within medallions separated by palm trees and dancers (first half of the 12th century). The Mesopotamian, or Mosul, style, which flourished from the early part of the 13th century, is characterized by a predominant use of figures of men and animals and by the lavish use of silver inlay. The most famous example of figured Mosul work in Europe is the so-called Baptistry of St. Louis in the Louvre. This splendid bowl, which belongs in style to the Mosul work of the 13th century, measures five feet (150 centimetres) in circumference and is covered with figures richly inlaid with silver, so that little of the copper is visible. It is signed by the artist. (S.V.G.)

**Renaissance to modern.** In the second half of the 16th century, copper gilt began to be used less and less often for liturgical implements because silver had become cheaper and was therefore preferred.

In the late 16th century, Italian smiths used copper for water beakers and water jugs, decorating the surfaces with chased ornaments, whereas the rest of Europe used brass.

High-quality copper objects dating from the 17th and 18th centuries were sometimes designed and worked in the same way as the silver of the period. Most were probably trial pieces made for the guild rank of journeyman or master by silversmiths who were too poor to supply objects in precious metal. Some may have been used as workshop models or given to clients as specimen pieces.

Another type of copper vessel, known as a "Herregrund cup," is purely ornamental and closely resembles the showpieces made in the 16th and 17th centuries. These drinking mugs are made of copper that was extracted by a process known as cementation, in which water containing copper forms a deposit on iron. Production was limited to three places in the county of Sohl in Hungary. In those days the process seemed to many people most mysterious, and many of the inscriptions on "Herregrund cups" refer to this mystery. The design of the beakers is modelled very closely on that of silver vessels produced in southern Germany, Bohemia, and Silesia. The most sumptuous examples are chased, engraved, or gilded or, more rarely, enamelled or set with precious stones. Many of them are decorated with mining scenes peopled with little figures. Most were made in the 17th century; a decline set in in the 18th century, though individual pieces continued to be made right down to the Empire period.

In the 17th and 18th centuries, copper enjoyed a period of relative prosperity in middle class households on the continent of Europe. For example, copper bread bins lined with tin were used; they were often richly decorated with chased motifs or brass fittings. There were also sumptuous wine coolers, cake and pudding molds, bowls,

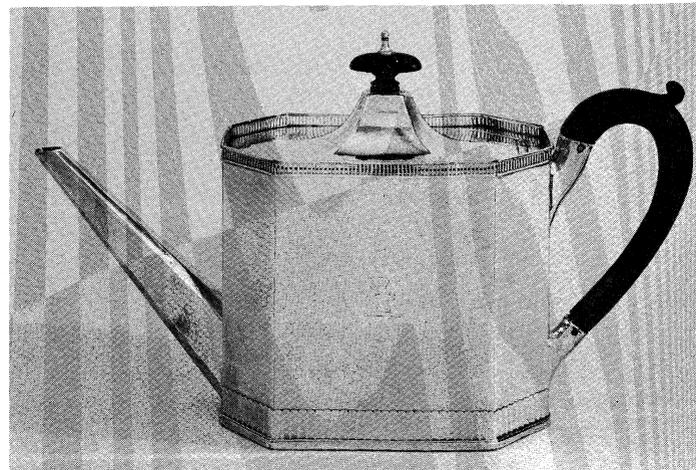

buckets, jugs, jars, screw-top flasks, sausage pans, and many other items, all polished until they shone and thus used as kitchen decorations as well as utility items.

In 18th-century Holland, jugs for tea and coffee were made in copper with a dark-brown patina and with various parts, such as the handle and the knob, in brass gilt. The sides were chased with interlaced foliage and other Rococo decorative motifs.

Copper was also the main metal used for Sheffield plate, which has a silvered surface. In 1742 Thomas Bolsover invented a method of fusing copper and silver together so that the result was highly durable, and he produced this type of silver-plated ware on a large scale. Although 18th-century England was a relatively wealthy society

Sheffield plate

Crown Copyright, Victoria and Albert Museum, London

Sheffield plate teapot, English, late 18th century. In the Victoria and Albert Museum, London. Height 16.5 cm.

and solid silver utensils of all kinds were used fairly widely, the middle classes, who were not all that well off, liked to buy these implements that looked like silver yet cost only a third of the price. The makers of Sheffield plate therefore adopted the designs used for English silverware at that date, and their work was often as courtly and elegant as that of the silversmiths.

Copper ware was no longer important in the 19th century, though it was occasionally used for pieces designed to follow earlier styles or for copies of historical pieces. The method now used was electroplating, which is a purely technical process and has nothing to do with craftsmanship.

Toward the end of the 19th century, attempts were made to create a new and individual style for copper; and there were occasional signs that its inherent properties were understood and used to full effect. But there was no renaissance in the true sense of the word. (H.-U.H.)

**BRONZE AND BRASS**

Bronze is an alloy of copper and tin. In the period of classical antiquity it had a low tin content, generally containing less than 10 percent, because tin was less common and therefore difficult to obtain. Like bronze, brass is an alloy, this time of copper plus zinc.

It is often very difficult to distinguish between bronze and brass merely by their appearance. The colour of the different alloys ranges over various shades from gold to a reddish tinge, to silvery, greenish, and yellowish shades, according to the proportions of the basic constituents. The patina on both alloys ranges from dark brown to a dark greenish tinge, particularly in the earliest pieces. Since it is often difficult to differentiate between bronze and brass with the naked eye and since metalworkers and metal casters of previous centuries did not make an express distinction between them, they will be considered together here. From a very early date bronze was used mainly for casting. Because it is so brittle, it has only rarely been hammered or chased; brass or copper were preferred for such work because they are more malleable. Down to the Middle Ages, bronze was cast by the cire

Bronze casting

perdue, or lost-wax, method. By this process, the mold can be used only once. This method of casting is the most exclusive, not only because it is the most expensive but also because it produces the finest work from the aesthetic point of view. Later, the casting process used models made up of a number of different pieces that could be taken apart and therefore re-used. These were generally made of wood and could be pressed down into a sand mold so that the shape of the object being cast emerged as a hollow. The hollow was then filled with molten bronze, which was poured in through casting ducts. When the resulting piece had been removed from the sand mold, the surface was smoothed over and the casting seams removed. The wooden model could then be used again to make as many copies as were required, which meant that economical production was possible. Brass was cast by the same methods but over and above this a process of hammering and chasing was used to fashion sheet brass. Brass platters were often decorated with relief work ornament, which was embossed from the reverse side by means of a type of die. The brass worker could also create an ornamental frieze made up of small motifs by using a series of punches made of iron. The surface of bronze or brass objects was also occasionally decorated with engraving. (H.-U.H.)

**Antiquity.** *Mesopotamia.* In the Metropolitan Museum of Art is the bronze sword of King Adad-nirari I, a unique example from the palace of one of the early kings of the period (14th–13th century BC) during which Assyria first began to play a prominent part in Mesopotamian history. A magnificent example of Assyrian bronze embossed work is to be seen in the gates of Shahmaneser III, erected about 845 BC, to commemorate that king's campaigns. The gates were made of wood; and the bronze bands, embossed with a wealth of figures in relief, are only about  $\frac{1}{16}$  inch (1.6 millimetres) thick. The bands were obviously intended for decoration, not to strengthen the gates against attack.

*Iran.* The Persian bronze industry was also influenced by Mesopotamia. Luristan, near the western border of Persia (Iran), is the source of many bronzes that have been dated from 1500 to 500 BC and include chariot or harness fittings, rein rings, elaborate horse bits, and various decorative rings, as well as weapons, personal ornaments, different types of cult objects, and a number of household vessels. Many of these objects show a decided originality in the development of the animal style.

*Egypt.* The bronzes that have survived are mainly votive statues placed in the temples from the Saite to the Ptolemaic period (305–30 BC), and amuletic bronzes that were buried with the dead. In its simplest form the decoration consisted of lines, representing details of clothing, ornaments, and the like, cut in the bronze with engraving tools, sometimes also combined with gilding. A fine example of inlay work of the 22nd dynasty (945–c. 730 BC) is a bronze menat damascened with gold wire (Metropolitan Museum of Art).

*Crete.* A sword, found in the palace of Mallia and dated to the Middle Minoan period (2000–1600 BC), is an example of the extraordinary skill of the Cretan metalworker in casting bronze. The hilt of the sword is of gold-plated ivory and crystal. A dagger blade found in the Lasithi plain, dating about 1800 BC (Metropolitan Museum of Art), is the earliest known predecessor of ornamented dagger blades from Mycenae. It is engraved with two spirited scenes: a fight between two bulls and a man spearing a boar. Somewhat later (c. 1400 BC) are a series of splendid blades from mainland Greece, which must be attributed to Cretan craftsmen, with ornament in relief, incised, or inlaid with varicoloured metals, gold, silver, and niello. The most elaborate inlays—pictures of men hunting lions and of cats hunting birds—are on daggers from the shaft graves of Mycenae, Nilotic scenes showing Egyptian influence. The bronze was oxidized to a blackish-brown tint; the gold inlays were hammered in and polished and the details then engraved on them. The gold was in two colours, a deeper red being obtained by an admixture of copper; and there was a sparing use of niello.

Dagger blades

*Greece.* The Greeks, who learned much about metalwork from the Egyptians, excelled in hammering, casting, embossing, chasing, engraving, soldering, and metal intaglio. Among the ancients, the great emphasis of technology was on aesthetic expression, not on practical utilization. Greek coin dies rank with the finest work of this kind that the world has ever seen. Pottery and bronze hammer-and-cast work were important crafts of ancient Greece. Vases of terra-cotta were often designed to resemble those of bronze, and both kinds were widely used in antiquity. Unlike terra-cotta, which is breakable but otherwise practically indestructible, bronze is subject to corrosion; and a surviving Greek bronze vase in good condition is therefore something of a rarity. The body of the vase, which was hammered out of a sheet of malleable bronze, was usually left plain; the handles, feet, and overhanging lip, which were cast, were decorated. The applied elements were rivetted or soldered.

It was in the time of Lysippus, the distinguished sculptor who flourished about 330 BC, that the fine Greek beaten work for decoration of armour, vases, and objects of domestic use reached its perfection. It was executed by a hammer worked from behind, the outlines being afterward emphasized by chisel or punch; or metal plate was beaten into a mold formed by carving the subject in intaglio upon a resisting material. The embossed shoulder straps of a cuirass, called the "Bronzes of Siris" (4th century BC; British Museum, London), are in exceedingly high relief and are beaten into form with wonderful skill with the hammer. The relief depicts the combat between the Greeks and the Amazons.

Greek bronze statuettes—originally dedicatory offerings in shrines, ornamental figures on utensils, or decorative works of art—have survived in large numbers. They were usually cast solid, rarely hollow. Sometimes even large statuettes were cast solid. (The advantage of solid casting is that the mold can be used repeatedly, whereas in the hollow-casting process the mold is destroyed.) Greek bronzes were originally golden and bright, and they were often decorated with silver or niello for colour contrast. Bronze statuary hardly existed before the introduction of hollow casting, about the middle of the 6th century BC, after which bronze became the most important medium of monumental sculpture; its strength and lightness admitted poses that could not be reproduced in stone.

*Etruria.* The Etruscans used bronze for cast and beaten work; and although few large works remain, the museums of Europe display a marvellous variety of admira-

Statuettes and monumental sculpture

bly formed small bronzes. A masterpiece of bronze Etruscan sculpture is the "Chimera" (a mythological beast with a goat's body, a lion's head, and a serpent's tail) from Arezzo, a 5th-century BC ex-voto from a sacred building, found in 1553 and partly restored by Benvenuto Cellini (Museo Archeologico di Firenze). Etruscan bronze workers produced, often for export, votive statuettes, vessels, furniture, helmets, swords, lamps, candelabra, mirrors, and even chariots. An Etruscan chariot of c. 600 BC in the Metropolitan Museum of Art has a body and wheels of wood, sheathing of bronze, and tires of iron, the high front embossed with archaic figures of considerable grace. The Etruscans inlaid bronze with silver and gold in a manner that proves that their skill in this mode of enrichment equalled that of the Greeks and Romans. Many delicately engraved bronze objects were made in the Latin town of Praeneste (modern Palestrina), which possessed a highly developed bronze-working industry. From Praeneste came a remarkable cylindrical container of the late 4th century BC, now in the Villa Giulia, Rome; its richly engraved surface provides a good example of the perfection of ancient drawing.

**Rome.** Etruscan cities, like those of Greece, were crowded with bronze statues of gods and heroes; and Rome derived its best adornment from the pillage of Etruria and then of Greece. Distinctly Roman work is hard to trace, as the conquered Greeks worked for their masters, and the Romans copied wholesale from the Greeks. Temple statues were nearly always of bronze, but after about 190 BC the metal was chiefly used for architectural decorations and portraiture. The bronze doors of the Pantheon and of the Temple of Romulus in the Roman Forum still occupy their original positions. Two bronze doors in the Lateran Baptistery are supposed to have been brought from the Baths of Caracalla by Pope Hilarius in the 5th century. Also in the Lateran church are four fine gilt-bronze fluted Corinthian columns.

Much Roman small work was exceedingly fine, though it is generally conceded that Roman productions are less aesthetically attractive than those of the Greeks. Pompeii and Herculaneum were essentially Greek towns, and the many beautiful bronzes in the Museo e Gallerie Nazionali di Capodimonte, Naples, collected from the ruins of private houses there, are of Greek workmanship. These included statuettes, mirrors, and all kinds of bronze work useful in a house. Many of these pieces were originally attached to pieces of furniture.

During the closing years of the republic, brass, produced by what came later to be known as the calamine (zinc-carbonate) method, became an important material for the first time. Its various uses included parade armour, as may be seen in a Roman embossed brass helmet in the Castle Museum, Norwich, England.

**Teutonic tribes.** The Teutonic tribes who conquered and divided the Roman Empire were little versed in the monumental arts and unskilled in figure representation; but in metalworking, in the making of weapons and other utilitarian objects, and in the delicate ornament of the goldsmith's art they excelled. They were among the earliest in Western Europe to develop the use of enamel decoration on bronze in the *champlevé* technique.

**Middle Ages: Byzantine Empire.** Syria, Egypt, and Anatolia were first the teachers and then the rivals of Constantinople (Istanbul). The fusion of antique and Eastern elements resulted in the Byzantine style, the great period of which dates from the 9th to the end of the 12th century. The extensive use of embossed work, with filigree, cabochon gems, and small plaques of enamel, may be seen in both the East and the West during the early Middle Ages. The most conspicuous examples of large Byzantine metalwork are bronze church doors inlaid with silver. Many objects are still preserved in various European treasuries, which were enriched by the spoils of the sack of Constantinople in 1204. Venice, in the Treasury of St. Mark's, has an unrivalled series of Byzantine chalices, bookbindings, and other treasures of metalwork; but it is in Kiev, Moscow, and Leningrad that broadly representative series of all the categories of Byzantine artistic production may be found.

The art of bronze casting had been preserved in the Byzantine Empire. The first bronze doors to be made after the art had died out in Rome were those for Hagia Sophia at Constantinople, which bear the date 838; the panels, with monograms and other ornament damascened in silver, are framed in borders cast in relief and enriched with bosses and scrolls, the whole in an admirable style. Two sets of doors in St. Mark's, Venice, of Greek workmanship and considerable but uncertain antiquity, are supposed by some to have been removed from St. Mark's at Alexandria. Next in date among surviving doors of Byzantine workmanship is a series ordered by the Pantaleone family (about 1066-87) and destined for cities in southern Italy—Amalfi, Trani, Salerno, Canosa di Puglia, and Monte Sant'Angelo. (S.V.G.)

**Middle Ages: Islām.** Animals in the Sāsānian style—lions, dragons, sphinxes, peacocks, doves, cocks, and the like—were cast in bronze in three dimensions and served, like their ceramic counterparts, as basins, braziers, and so on. They were particularly sought after in the later Abbāsīd, Fātimid, and Seljuq periods, and from Egypt they became prototypes of similar European forms. It was the Seljuqs, apparently, who introduced a round bronze mirror, the reverse of which shows in low relief two sphinxes face to face, surrounded by a twined pattern, or two friezes with the astrological symbols of the seven chief heavenly bodies (Sun, Moon, and the five nearest planets) and the 12 signs of the zodiac, surrounded by a band of script; this goes back ultimately to Chinese origins.

Early vessels, such as mugs, were ornamented with animals in low relief, but engraving quickly supplanted this. Under the later Seljuqs (particularly the Artuqid atabegs of Mosul) and the Mamlūks, engraving became almost the only form of decoration, but only to serve as a basis for the yet richer technique of inlaying, or damascening: small silver plates and wires, themselves delicately engraved, were hammered into the ribs and surfaces, which were hollowed out and undercut at the edges.

In place of this, in an Artuqid bowl in the provincial museum at Innsbruck the spaces are filled in with cellular enamel. This was a method of evading the prohibition of precious metals, just as gold lustre was in pottery. The ornament consisted of friezes and medallions in lattice work and arabesque work, the interstices being filled with figures of warriors, hunters, musicians, animals, and astrological symbols. These were superseded later by Mamlūk coats of arms and inscriptions. In the 15th century the technique was imported from Syria to Venice, where productions of the same kind, *alla damaschina* or *all'azzimina*, were made right into the 16th century by Islāmīc masters and were in great demand. In the East the process is still common, but both technically and artistically it has decayed.

In the 15th century there was a renaissance of pure metal engraving, but the design—inscriptions and arabesques in the Timūrid and Šafavid styles—was not cut into the material but left free in the manner of a relief, the background being etched in black. Decoration was applied to bowls, basins, mugs, vases, mortars, braziers, warming pans, candlesticks, smoking utensils, inkstands, jewel cases, Qur'ān holders, and mosque lamps. These are generally in the simplest possible forms—spherical, cylindrical, prismatic; the subjects include motifs of vegetation and animal life, the former mainly in the necks and feet of vessels, the latter for handles and ears, feet, and sometimes small spouts. (H.Go.)

**Europe from the Middle Ages.** After several centuries of artistic decline, the art of bronze casting was revived in c. 800 by Charlemagne, who had monumental bronze portals made for the Palatine Chapel in his residence in Aachen, with bronze grilles placed inside it. The artists, who probably came from Lombardy, followed the styles of classical antiquity.

For many centuries the Christian Church remained the bronze caster's chief patron. Like the stonemasons, who also were heavily patronized by the church, they joined together to form associations, or foundries. These casting foundries hired themselves out to the large ecclesiastical

Bronze doors

building sites. They cast bells—almost every church had at least one bell—and monumental doors decorated with relief work; for instance, doors for Mainz (c. 1000) and Hildesheim (1015) cathedrals, for the cathedrals at Gneissen and Augsburg (11th century), and for St. Zeno Maggiore in Verona (12th century). They also made large fountains, the most famous being the one made by Reiner of Huy in 1107–18 for the church of Notre Dame aux Fonts in Liège (now in the church of St. Barthélemy in Liège). The Dinant workshops, which formed the main centre for bronze casting in the Meuse district in the Middle Ages, specialized in what are known as “eagle lecterns.” These are book stands with ornamental pedestals, with the panel supporting the enormous missals taking the form of the outspread wings of an eagle, a griffin, or a pelican. The earliest documented eagle lectern was made in 965, but the earliest example to have survived dates from 1372. It was made by Jean Joses of Dinant for the Church of Our Lady at Tongeren (Tongres), near Liège.

Records show that from the 11th to the 15th century there were more than 50 monumental seven-branched candlesticks (menorah) in various churches in Germany, England, France, Bohemia, and Italy, though only a few of these have survived. Documents relating to the Carolingian period speak of monumental bronze crucifixes and statues of the Virgin and of the saints, though the earliest surviving statues date from the 11th century; the crucifix in the abbey church at Werden, for example, dates from c. 1060 and was probably cast in a foundry in Lower Saxony.

Among the most outstanding examples of figurative bronze sculpture dating from the Romanesque period are a group of reliquaries designed in the shape of heads or heads and shoulders or occasionally arms, hands, or feet, according to the type of relics they contain. They were made in Lower Saxony or in France.

A few large chandeliers have survived from the 11th and 12th centuries, representing a sort of halfway stage between sculpture and functional objects. A far larger number are known to have existed from documents and contemporary accounts, but these have disappeared over the centuries. Examples from Germany, the southern half of the Low Countries, and France have survived or are documented. Romanesque chandeliers are always designed in the form of a crown. Candleholders, with architectural structures and figures placed in between them, project from the crown.

Besides the monumental bronzes that have survived from the 8th to the 12th century, there are also smaller pieces, such as processional crosses, altar crucifixes, chests, reliquaries, and similar articles. Another group of liturgical objects consists of candlesticks used to adorn altars. Their design often shows a wealth of invention, and they are decorated in the most sumptuous fashion. Yet another group of candlesticks, secular ones this time, embodies the ideal of chivalry. They are cast in the shape of human figures: an armed warrior on horseback bearing a candleholder with a spike on which the candle is placed; a kneeling page in court dress holding a candle socket in his outstretched hands; or Samson perched on the lion's back, brandishing a candleholder. These candlestick figures are rare and precious examples of courtly life in the Romanesque period in Germany, France, England, and Scandinavia. Even then they were thought of as rare, deluxe articles within the reach of only a few privileged people.

Toward the end of the Romanesque period a simpler type of candlestick appeared, mainly intended for religious purposes, though they were found in private homes as well. They are circular, with a round base, a slender column-like shaft, and a large grease pan with a spike for the candle. This design exercised a strong influence throughout the Gothic period and right down to the Baroque period, though it varied considerably over the years according to the styles then prevailing.

Some of the finest bronze articles of the High Middle Ages were modelled on Oriental pieces brought back from the Holy Land by the crusaders. They are known as

aquamaniles, a type of ewer used for pouring water for washing one's hands. Made by bronze casters in France, Germany, England, and Scandinavia, they are usually in

Bronze aquamanile in the shape of a lion, German, 13th century. In the Metropolitan Museum of Art, New York. Height 26.7 cm.

the shape of lions—symbols of valour, pride, physical strength, and power. Also common are those shaped like knights in armour, with a wealth of courtly detail that was obviously popular. A few aquamaniles are in the shape of winged dragons, doves, cockerels, centaurs, or sirens; but such designs are rare. Christian themes, too, played a part, some examples depicting Samson overcoming the lion with his knee planted on its back. The golden age of these vessels was the 12th, 13th, and 14th centuries. The end of the age of chivalry also saw a decline in such work, for the emergent bourgeoisie found other ways of marking the ceremony of hand washing.

Basins were also needed for washing one's hands; they are often mentioned in medieval documents, where they are referred to as *bacina*, *pelves*, or *pelvicula*. The majority of these bowls—which date from the 12th and 13th centuries—have been found in the cultural area that extends from the Baltic down to the Lower Rhine district and across to England. Because this area was once dominated by the Hanseatic League (a commercial association of free towns), the basins are known as Hanseatic bowls. They are round, some being more convex than others; and the inside is engraved with scenes from classical mythology, with themes from the Old and New Testaments and the legends of the saints, or with allegorical figures personifying the virtues and the vices, the liberal arts, the seasons, and so on. Hanseatic bowls were probably made in the bronze-casting centres where candlesticks and aquamaniles (and indeed all medieval cast bronze) were made: in the Meuse district and Lorraine, in Lower Saxony and the Harz Mountains, and also in England. The decoration on these bowls may have been added elsewhere.

In the Romanesque period and later, in the Gothic period, the churches and their patrons were still the bronze caster's main clients, ordering both functional objects and decorative pieces. Bronze fountains were relatively common in the 14th and 15th centuries, particularly in churches in northern Germany. Another common item, which was made mainly in England and in the Netherlands, was a large brass tombstone decorated with engraving. Other objects included door fittings, candlesticks, candelabra, chandeliers, pulpits, and sculptured tombs portraying the deceased.

*Italy.* Until the 12th century in Italy the art of bronze casting had been virtually neglected since the period of classical antiquity, when it had been a flourishing industry. A few churches in Italy have bronze doors inlaid with

Candlesticks

Aquamaniles and basins

Byzantine  
influence  
in Italy

Byzantine niello work made by Byzantine craftsmen in the 11th and 12th centuries. The same technique was used by Bohemond I of Antioch for a bronze door at Canosa (1111) and by Oderisius of Benevento when casting a pair of doors for Troia Cathedral in 1119 and 1127. In the second half of the 12th century, however, Barisano da Trani made relief door panels for churches in Astrano, in Ravello (a town near Amalfi), and in Monreale. Bronze relief doors were also made in the 12th century for S. Paolo fuori le mura in Rome and for churches in northern Italy (S. Zeno Maggiore in Verona; St. Mark's in Venice) and Tuscany (Pisa and Monreale, by Bonanno of Pisa) and in the 13th century for the Baptistery in Florence, by Andrea Pisano.

Lorenzo Ghiberti's doors for the Baptistery in Florence, made in 1403–24 and 1425–52, marked the beginning of a golden age of bronze casting in Florence that lasted throughout the Renaissance and right down to the Baroque era. Whereas bronze sculpture had been relatively rare before the 15th century, many Italian artists of the Renaissance now designed cast bronze statues, statuettes, reliefs, and various objects in the shape of human figures. Among the sculptors who worked in full-scale bronzes were Lorenzo Ghiberti, Donatello, Andrea del Verrocchio, Antonio Pollaiuolo, and Lucca della Robbia. Besides large-scale cast-bronze work there were also small figures, statuettes, busts, plaques, and functional objects such as candelabra, mortars, candlesticks, and inkwells. Dating from the middle of the 15th century onward, they are characterized by rich figural and ornamental design. Their style influenced work produced in northern Europe, particularly in the 16th century.

In the first half of the 16th century, bronze casting

Allinari

declined somewhat in Italy, though it found a new lease on life in the middle of the century and, indeed, became even more important than before. Benvenuto Cellini and Giovanni da Bologna are two of the most famous artists of this period. Cellini designed a number of statues, one of the best known being his "Perseus" in the Loggia dei Lanzi in Florence, as well as portrait busts, reliefs, and smaller articles in bronze. Giovanna da Bologna, a Fleming by birth, was active in Rome and Florence, where he made fountains, equestrian monuments, allegorical figures, crucifixes, statuettes, groups of figures, animals, and many other objects. He founded a school of sculptors who were influenced by his work for many years. Many other bronze sculptors were active in the 16th and 17th centuries, notably in Venice, which was a particularly fruitful area for bronze casting, and at a school in Padua led by Riccio Andrea (Briosco). Italian bronze casters worked abroad as well as in their homeland, working on commission for foreign potentates, mainly in France and England.

In the 16th century, beautifully made bronze pieces, which were very much more than functional objects, played an important part in the art of the bronze caster. For instance, sumptuous mortars were designed and made by artists whose names have been handed down to posterity, such as Cavadini, Lenotti, Julianio da Navi, Alessandro Leopardi, Antonio Viteni, and Crescimbeni da Perugia. Elaborate brass dishes were made in Venice, under the influence of Eastern art (to which Venice had always been very receptive); indeed, the first people to produce these large dishes with engraved motifs were Islāmic artists who had settled in the town, though the local artists soon adopted both their style and their technique.

*Germany and the Low Countries.* Unlike their Italian counterparts, 15th-century bronze artists in Germany and the Low Countries were still very much under the spell of Gothic art. Ecclesiastical implements predominated in this part of the world.

The Dinant workshops, in the Meuse district, continued to dominate production until well past the middle of the 15th century, just as they had since the days of Charlemagne. But when Philippe III le Bon, duke of Burgundy, laid siege to the town in 1466, then took it by storm and eventually completely destroyed it, the bronze casters who survived moved elsewhere, settling mainly in the Low Countries. As a result, from that date onward the trade enjoyed a sudden upsurge in Brussels and Namur, in Tournai and Bruges (Flemish Brugges), in Malines (Flemish Mechelen), Louvain (Flemish Leuven), and Middelburg. There was another centre of the bronze trade in Lower Saxony, since the mines in the Harz Mountains produced a generous supply of copper and calamine. The chief bronze-working towns in this area were Hildesheim, Goslar, and Minden. In the 16th century, a period when trade and commerce were developing very rapidly in Germany, the bronze-casting trade was no longer compelled to function close to the place where the raw material was extracted. Thus, Nürnberg, at this time the most powerful and lively town in Germany, not only traded in copper, bronze, and brass but also soon allowed its bronze casters and metalworkers to develop a flourishing industry. Brass articles from Nürnberg became famous throughout the world.

Nürnberg  
brass  
work

The earliest documented brass workers were those known as "basin-beaters" (*Beckenschläger*), who were first referred to as such in 1373. They made bowls and dishes with various types of relief decoration on the bottom. In the late Gothic period, religious themes were very

Crown Copyright. Victoria and Albert Museum, London

Brass dish with embossed Annunciation scene, German, c. 1500. In the Victoria and Albert Museum, London. Diameter 45 cm.

popular for this decoration and were more common than secular images. During the Renaissance, beginning in about 1520, the design changed; instead of deep bowls there were large, flat dishes with decoration that consists of purely ornamental motifs or friezes as well as scenes and figures. The decoration includes the typically Gothic "fishbladder" design and also interlaced motifs and bands of lettering. The trade of the basin beaters continued to flourish in Nürnberg down to about 1550, when a decline set in, culminating in its eventual collapse just before the Thirty Years' War in 1618. The reason for this decline may have been the emergence of what is known as display pewter (see below *Pewter*), which, from about 1570 onward, swept the wealthy bourgeoisie market.

Until the Gothic era, bronze chandeliers were made solely for the churches; it was not until the 15th century

Bronze chandelier, Dutch, 15th century. In the Rijksmuseum, Amsterdam. Height 1.09 m.

By courtesy of the Rijksmuseum, Amsterdam

that people began to consider lighting their homes by means of a central source of light hanging from the ceiling. In the Low Countries, one of the centres of the art of bronze casting, a type of chandelier was developed at this time that remained standard for many years. It is a type of hoop with a shaft, made up of a molded vertical centrepiece and a series of curving branches bearing drip trays and spikes. The arms, or branches, are decorated with tracery, foliage scrolls, and other motifs characteristic of the late Gothic style. In the middle of the 16th century, the central shaft took on the shape of a spherical baluster, with a large sphere jutting out just below the point where the curving arms branch off. This design continued to predominate in the Baroque period and is found as late as the 18th century. Because chandeliers of this type were most common in the Low Countries, one can assume that they originated there and were produced in large numbers and that they spread to England and Germany. Another centre was in Poland, presumably because brass founders had moved there from Nürnberg.

Besides these chandeliers—which until the 19th century were exclusive to court circles, the aristocracy, and the upper ranks of the bourgeoisie—there were also candlesticks. Their design was a later development of that used for altar candlesticks. The principle of a disk-shaped foot and a baluster shaft with a spike on top remained standard from the Middle Ages well into the 19th century, though the design of the individual components was affected by the styles current in any particular period. In Dinant and Flanders in the 15th century, for instance, the shaft began to be fashioned into the shape of a human figure. This style also became popular in Germany at the end of the century.

Whereas bronze sculpture reached its peak in Italy in the 15th century, monumental bronze figures were still rare in northern Europe at this time. Thus, the full-length equestrian statue of St. George (1373) on Hradčany Castle in Prague, which was cast by Martin and Georg von Klausenberg, did not set a trend, though rich figure decoration is often found on large fonts dating

Bronze effigy of Henry III, by William Torel, 13th century. In Westminster Abbey, London. Length 1.50 m.  
J.R. Freeman & Co. Ltd.

from the 13th to the 15th century. Engraved tombstones and entire tombs based on earlier traditions continued to be made until the late Gothic era (the beginning of the 16th century), as did tabernacles and lecterns.

The intellectual content of the Renaissance and the styles it engendered entered the world of the northern sculptors in the second decade of the 16th century. The Nürnberg workshop run by the Vischer family, which had been flourishing since the 15th century, continued to work in the late Gothic style until it had completed the St. Sebald's Shrine (1516), but shortly after this the style and intellectual concepts current in Italy were adopted by bronze casters in northern art centres as well. Small-scale bronze sculpture was particularly popular at this time, though some workshops were still casting monumental bronzes as late as the 18th century. (H.-U.H.)

*England.* Casting in bronze reached high perfection in England during the Middle Ages. The most remarkable of the sanctuary rings, or knockers, that exist at Norwich and elsewhere is that on the north door of the nave of Durham cathedral, from the first half of the 12th century. The Gloucester candlestick, in the Victoria and Albert Museum, London, displays the power and imagination of the designer as well as an extraordinary manipulative skill on the part of the founder. According to its inscription, this candlestick, which stands about two feet (60 centimetres) high and is cast in bell metal and gilded, was made for Abbot Peter (the cathedral was originally an abbey church), who ruled early in the 12th century. While the outline is carefully preserved, the ornament consists of a mass of figures of monsters, birds, and men, mixed and intertwined to the verge of confusion. As a piece of casting, it is a triumph of technique.

There remain in England 10 effigies cast in bronze over a period of two centuries (1290–1518), among them some of the finest examples of figure work and metal casting to be found in Europe. In several instances, particulars for the contracts of the tombs survive, together with the names of the artists who designed and made them. The earliest examples are the effigies of Queen Eleanor, wife of Edward I (1290), and that of Henry III (1291), both in Westminster Abbey. They are the work of William Torel, goldsmith of London; and it is evident that they are the first English attempt to produce large figures in metal. Torel cast his large figures by the same process (lost-wax) he had employed for small shrines and images.

Monumental brasses were exceedingly numerous in England, where some 4,000 still exist. From the 13th through the 16th centuries, in France, northern Germany, Belgium, and particularly England, it became the vogue to set into the stone slab covering a floor tomb a brass plate engraved with the figure of the deceased. The art began in Flanders and Germany, and many of the English brasses were of foreign origin; in some cases, brass sheets were imported and engraved by English artists. The manufacture of unornamented brass plates centred chiefly at Cologne. The oldest English brass in existence is that of Sir John D'Abernon (died 1277) at

Stoke d'Abernon, Surrey. Traces can still be seen in many brasses of the colours that originally enlivened them.

(S.V.G.)

*France.* In France, bronze was common from the late 16th century through the 17th, 18th, and 19th centuries, and it is still popular with French sculptors today. Eighteenth-century artists made use of ormulu, or fire gilding, for bronze articles such as candlesticks, brackets, and mounts for furniture. This tradition continued in France and, to a lesser extent, in the areas under French influence, until the Empire period in the early 19th century. Subdued classical designs executed in simple brass or in bronze, generally unglazed, are typical of the period following the reign of Napoleon.

The second quarter of the 19th century and, with it, the onset of industrialization, brought about a decline in bronze casting, as it did in all spheres of craftsmanship. The age of steel production now began. At the end of the 19th century, during the Art Nouveau period, attempts were made to revive the craft of casting bronze articles; but these did not have any lasting success. Bronze continued to be used by a few individual sculptors, however, throughout the 19th century and into the present day.

(H.-U.H.)

#### SILVER AND GOLD

*Antiquity.* *Pre-Mycenaean.* Gold and silver and their natural or artificial mixture, called electrum or white gold, were worked in ancient Greece and Italy for personal ornaments, vessels, arrows and weapons, coinage, and inlaid and plated decoration of baser metals.

Aegean lands were rich in precious metals. The considerable deposits of treasure found in the earliest prehistoric strata on the site of Troy are not likely to be later than 2000 B.C. The largest of them, called Priam's Treasure, is a representative collection of jewels and plate. Packed in a large silver cup were gold ornaments consisting of elaborate diadems or pectorals, six bracelets, 60 earrings or hair rings, and nearly 9,000 beads. Trojan vases have bold and simple forms, mostly without ornament; but some are lightly fluted. Many are wrought from single sheets of metal. The characteristic handle is a heavy rolled loop, soldered or rivetted to the body. Bases are sometimes round or pointed, sometimes fitted with separate collars but more often slightly cupped to make a low ring foot. One oddly shaped vessel in gold is an oval bowl or cup with a broad lip at each end and two large roll handles in the middle. The oval body has Sumerian affinities. A plain, spouted bowl in the Louvre is a typical specimen of goldsmith's work from pre-Mycenaean Greece. The scarcity of precious metals points to lack of wealth as prime cause of the artistic backwardness of these regions. Silver seems to have been more plentiful in the Greek islands; but only a few simple vessels, headbands, pins, and rings survive.

*Minoan and Mycenaean.* A profusion of gold jewelry was found in early Minoan burials at Mókhlós and three silver dagger blades in a communal tomb at Kumasa. Silver seals and ornaments of the same age are not uncommon. An elegant silver cup from Gournia belongs to

furniture

the next epoch (Middle Minoan I, c. 2000 BC). Numerous imitations of its conical and carinated (ridged) form in clay and of its metallic sheen in glazed and painted decoration prove that such vessels were common. Minoan plate and jewelry are amply represented in the wealth of mainland tombs at Mycenae and Vaphio. The vases from Mycenae are made indifferently of silver, gold, and bronze; but drinking cups, small phials, and boxes are generally made only of gold; and jugs are made of silver. Much funeral furniture is gold, notably masks that hid the faces or adorned the coffins of the dead. It has been thought that small gold disks, found in prodigious quantities (700 in one grave), were nailed on wooden coffins; but they may have been sewn on clothes. They are impressed with geometrical designs based on circular and spiral figures, stars and rosettes, and natural forms such as leaves, butterflies, and octopods. Smaller bossed disks bearing similar patterns may be button covers. Models of shrines and other amulets are also made of gold. A splendid piece of plate is a silver counterpart of a black steatite, or soapstone, libation vase from Knossos in the form of a bull's head, with gold horns, a gold rosette on the forehead, and gold-plated muzzle, ears, and eyes. (The gold here and in other Mycenaean plating is not laid on the silver but on inserted copper strips.)

Gold cups from Mycenae are of two main types: plain curved or carinated forms related to the silverware and pottery of Troy and embossed conical vessels of the Minoan tradition. Some of the plain pieces, such as the so-called Nestor's cup (National Archaeological Museum, Athens), have handles ending in animals, which bite the rim or peer into the cup. The embossed ornament consists of vertical and horizontal bands of rosettes and spiral coils and of floral, foliate, marine, and animal figures. The designs are beaten through the walls and are consequently visible on the insides of most of the vessels; but the finest examples of their class, two gold cups (National Archaeological Museum, Athens) from the Vaphio tomb near Sparta, have a plain gold lining that overlaps the embossed sides at the lip. The reliefs on the Vaphio cups represent men handling wild and domesticated cattle among trees in a rocky landscape. (Steatite vases carved with similar pictorial reliefs were evidently made to imitate embossed gold.) The handles show the typical Minoan form: two horizontal plates rivetted to the body at one end and joined at the other by a vertical cylinder.

Weapons

Cretan and mainland tombs have produced many examples of weapons adorned with gold. Modest ornaments are gold caps on the rivets that join hilt and blade, but the whole hilt is often cased in gold. An example from Mycenae has a cylindrical grip of openwork gold flowers with lapis lazuli in their petals and crystal filling between

them; the guard is formed by dragons, similarly inlaid. The most splendid Mycenaean blades are bronze inlaid with gold, electrum, silver, and niello. Here again the work is done on inserted copper plates. This kind of flat inlay seems to have been originally Egyptian; it occurs on daggers from the tomb of Queen Aah-Hotep, which are contemporary with the Mycenaean (c. 1600 BC). Moreover, it is significant that two of the Mycenaean designs have Egyptian subjects (cats hunting ducks among papyrus clumps beside a river in which fish are swimming), though their style is purely Minoan. Another blade bears Minoan warriors fighting lions and lions chasing deer. A dagger from Thira has inlaid ax heads; one from Argos, dolphins; and fragments from the Vaphio tomb show men swimming among flying fish. These are masterpieces of Minoan craftsmanship. In the long, subsequent decadence of the Mycenaean age, however, there seems to have been no invention, and later pieces of goldsmiths' work repeat conventional forms and ornaments.

(E.J.F./M.C.R.)

*Iran.* The Persians have been skillful metalworkers since the Achaemenid period (559–330 BC), when they were already acquainted with various techniques such as chasing, embossing, casting, and setting with precious stones. Statuettes of gold and silver are known from the 5th century BC, and vessels of silver and gold from this time take the form of phials, conical cups, vases, and rhyta (drinking cups in the shape of an animal's head). The Oxus treasure in the British Museum and the Susa find in the Louvre, Paris, are good examples of such work. During the Parthian period (247 BC–AD 224), silverwork and goldwork was strongly influenced by Hellenistic predilection for richly decorated bowls and dishes. The zenith of old Iranian metalwork, however, was reached during the Sāsānid period (AD 224–651), when craftsmen achieved great variety in shape, decoration, and technique. Drinking vessels (stem cups and cups with handles), ewers, oval dishes, platters, and bowls are the dominant forms; hunting scenes, drinking scenes, and

animals are represented in high relief. The patterns were cut out of solid silver or made separately in sheets and then soldered to the vessel. From this time onward cloisonné enamel was used for jewelry. (B.V.Gy.)

*Greek and Etruscan.* The period of transition from the Bronze to the Iron Age, when Aegean external relations were violently interrupted, was not favourable either to wealth or art; and the only considerable pieces of plate that have come from Greece are embossed and engraved silver bowls made by Phoenicians. Most of them bear elaborate pictorial designs of Egyptian or Assyrian character and are evidently foreign to Greece; but some simpler types, decorated with rows of animals in relief or wrought in the shape of conventional flower bowls, can hardly be distinguished from the first Hellenic products.

A severe and elegant silver bowl in the Metropolitan Museum of Art represents the flower type in its finest style. It is cast and chased and probably belongs to the 5th century BC.

Silver vases and toilet articles have been found beside the more common bronze in Etruscan tombs; for example, a chased powder box of the 4th century BC in the Metropolitan Museum of Art. Bronze reliefs of an archaic chariot in the same collection have their opulent counterparts in some hammered silver and electrum fragments in London, Munich, and Perugia. The electrum details are attached with rivets.

*Roman.* About the 4th century BC, the fashion of ornamenting silver vessels with relief was revived; and this type of work, elaborated in the Hellenistic Age and particularly at Antioch and Alexandria, remained the usual mode of decoration for silver articles until the end of the Roman Empire.

The scholar Pliny the Elder (1st century AD) names Greek silversmiths whose work was valued highly at Rome and laments the disappearance of the art in his own day. He must refer only to its quality, for Roman silverware has been abundantly preserved. Many rich hoards in modern collections were buried by design during the calamitous last centuries of the ancient world; and the most sumptuous, the Boscoreale treasure (mostly in

By courtesy of the Musée du Louvre, Paris; Cliche Musées Nationaux

Roman silver pitcher, from the villa at Boscoreale, near Pompeii, Italy, c. 1st century BC. In the Louvre, Paris. Height 25 cm.

the Louvre), was accidentally saved by the same volcanic catastrophe that destroyed Herculaneum and killed Pliny in AD 79. A slightly smaller hoard found at Hildesheim (now in Berlin) also belongs to the early empire. The acquisition and appreciation of silver plate was a sort of cult in Rome. Technical names for various kinds of reliefs were in common use (*emblemata, sigilla, crustae*); weights were recorded and compared and ostentatiously exaggerated. Large quantities of bullion came to Rome with the spoils of Greece and Asia in the 2nd century BC; and Pliny says that even in republican times there were more than 150 silver dishes of a hundredweight apiece in the city. (Weights of vessels are often marked on their bases.)

Cups and jugs of Augustan style are usually covered with ornament in high relief. The subjects are very diverse: historical, mythological, and mystic scenes, formal and naturalistic designs of flowers and foliage, graceful studies of animals and birds. Some cups and jugs have conventional fluting, petals, or gadroons (ornamental

bands embellished with continuous patterns, such as beading); Bacchic masks; and embossed or engraved wreaths, gilt or inlaid with niello. Silver and niello inlay was commonly applied to bronze plates. A singular type of silver bowl (*patera clipeata*) has a central ornament in high relief or even in the round; the ornament frequently contains a portrait bust. In the course of time the ornament was restricted; and later Roman plate is largely plain with narrow border friezes, small central medallions, and handles embossed in low relief. One of the very few gold pieces that survive, a shallow bowl found at Rennes (Bibliothèque Nationale), is exceedingly elaborate. It measures 10 inches (25 centimetres) across and weighs 46 ounces (1,315 grams). The central medallion and its surrounding frieze contain scenes of a drinking contest between Bacchus and Hercules; between the frieze and the edge of the bowl is a row of 16 gold coins, each framed in a foliate wreath. The coins range from Hadrian to Caracalla. In the same collection are several examples of very large silver plates (*clipei* or *missoria*), in which the whole field is embossed with mythological or historical subjects. The largest (called the Shield of Scipio) is 28 inches (72 centimetres) in diameter and weighs 363 ounces (10,300 grams). (E.J.F./M.C.R.)

*Early Christian and Byzantine.* The earliest Christian silverwork closely resembles the pagan work of the period in its naturalistic grace, ornament, and use of the traditional techniques of embossing and chasing. Even the subject matter is sometimes classical: the late-4th-century marriage casket of Projecta and Secundus, part of the Esquiline treasure found at Rome (British Museum), is decorated with pagan scenes; and only the inscription shows that it was made for a Christian marriage. Among the few pieces with Christian subjects are small Roman cruets (condiment bottles) from Taprain, Scotland (Royal Scottish Museum, Edinburgh, and the British Museum), and a small pyx (casket for the reserved Host) from Pula, Yugoslavia (Kunsthistorisches Museum, Vienna).

Most of the silver of the latter part of the period has been found in the Christian East—in Syria, Egypt, Cyprus, Asia Minor, and Russia—and is mostly "church" plate (chalices, censers, candlesticks, and bowls and dishes probably used to hold the eucharistic bread). Secular plate was also decorated with religious subjects—for example, dishes depicting the life of David (Cyprus Treasure, Cyprus Museum, Nicosia, and Metropolitan Museum); both dishes and vessels were produced with pagan subjects—for example, the Concesti amphora and the Silenus Dish (both in the Hermitage, Leningrad). The figure style is often harder and flatter than previously, characterized by strictly frontal positions and symmetry. The techniques of chasing and embossing still predominated, but abstract patterns and Christian symbols inlaid in niello were used increasingly. The appearance of imperial "control stamps," early forerunners of hallmarks, show most of this material to be of the 6th and 7th centuries. It is not known which cities were important centres of production; but the Eastern capital, Constantinople, must have been foremost among them.

Of work in gold of the earliest Christian period, only personal jewelry has survived; but from the 6th and 7th centuries onward other pieces are also extant. Among the most important of the latter are votive crowns and crosses offered to churches in Spain and Italy by royal patrons. The finest of these pieces are those found in Guarrazar in Toledo Province (National Archaeological Museum, Madrid, and Musée de Cluny, Paris), inlaid with garnets and jewels; the cross of King Agilulf (cathedral of Monza, Italy); and a pair of gold book covers inscribed by Queen Theodelinda (cathedral of Monza, Italy). The book covers are set with pearls, gems, and cameos and decorated with gold cloisonné work inlaid with garnets, a popular style among the Germanic peoples. Inlaid cloisonné jewelry reached an especially high standard of workmanship in Britain, as is shown by a purse lid, a sword, and jewelry from the cenotaph (monument honouring a dead person whose body lies elsewhere) to a 7th-century East Anglian king discovered at Sutton Hoo, Suffolk (British Museum). Major works in silver and gold were also produced in the northern Hiberno-Saxon school and in the service of the Celtic Church; work in precious metal, such as the buckle on the Moylough belt reliquary and the Ardagh Chalice in the National Museum of Ireland, Dublin, displays a masterly synthesis of the northern arts and humanist Mediterranean tradition.

**Middle Ages.** *Carolingian and Ottonian.* The earliest works of the Carolingian renaissance, made in the last quarter of the 8th century, resemble Hiberno-Saxon art of the 8th century in their abstract treatment of the human figure, their animal ornament, and their use of niello and "chip-carving" technique; examples are the Tassilo Chalice (Kremsmünster Abbey, Austria) and the Lindau Gospels book cover (Pierpont Morgan Library, New York City). From about 800 onward, however, the influence of the Mediterranean tradition gained strength at Charlemagne's court at Aachen and later spread through the whole empire. Triumphant arches (now lost) given by the Emperor's biographer Einhard to Maastricht cathedral were typical of this movement; miniature versions nine inches (22 centimetres) high of great marble triumphal arches of antiquity, they were embossed in silver with Christian subjects. The bulk of work in precious metals that survives from the Middle Ages is ecclesiastical: golden altars, like that of S. Ambrogio in Milan (c. 850), where scenes from the life of Christ and St. Ambrose are framed by panels of cloisonné enamel and filigree (openwork); and reliquaries and book covers in gold and silver, set with gems and decorated by embossed figures and scenes, such as the cover of the Codex Aureus of St. Emmeram (c. 870; Bayerische Staatsbibliothek, Munich). These pieces testify to the magnificence of Carolingian work, the techniques of which were to dominate the goldsmith's craft until the 11th century.

Patronage throughout this period was mainly in the hands of the emperors and great princes of the church; and the form of liturgical plate and reliquaries, altar crosses, and the like underwent no fundamental change; Ottonian work of the later 10th and 11th centuries can be distinguished from that of the 9th only in the development of style. For example, the larger, more massive figures, with their strict pattern of folds, on the golden altar (c. 1023) given by Henry II to Basel Minster (Musée de Cluny, Paris), are markedly different from the nervous, elongated figures of the Carolingian period.

*Romanesque.* In the 12th century the church supplanted secular rulers as the chief patron of the arts, and the work was carried out in the larger monasteries. Under the direction of such great churchmen as Henry, bishop of Winchester, and Abbot Suger of Saint-Denis, near Paris, a new emphasis was given to subject matter and symbolism.

Craftsmen were no longer anonymous; work by Roger of Helmarshausen, Reiner of Huy, Godefroid de Claire (de Huy), Nicholas of Verdun, and others can be identified; and the parts they played as leaders of the great centres of metalwork on the Rhine and the Meuse are recognizable. Their greatest achievement was the development of the brilliant champlevé enamelling, a method

that replaced the earlier cloisonné technique. Gold and silver continued to be used as rich settings for enamels; as the framework of portable altars, or small devotional diptychs or triptychs; for embossed figure work in reliquary shrines; and for liturgical plate.

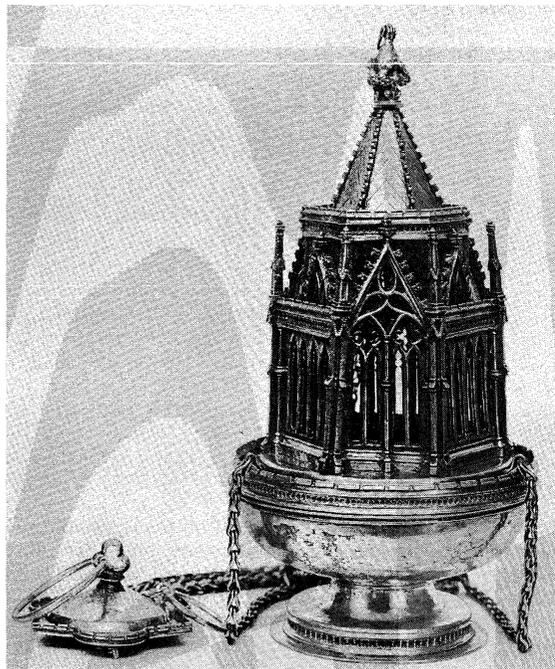

The masterpieces of the period are great house-shaped shrines made to contain the relics of saints; for example, the shrine of St. Heribert at Deutz (c. 1160) and Nicholas of Verdun's Shrine of the Three Kings at Cologne (c. 1200). In the latter, the figures are almost freestanding, and in their fine, rhythmic draperies and naturalistic movement they approach the new Gothic style.

*Gothic.* The growing naturalism of the 13th century is notable in the work of Nicholas' follower Hugo d'Oignies, whose reliquary for the rib of St. Peter at Namur (1228) foreshadows the partly crystal reliquaries in which the freestanding relic is exposed to the view of the faithful; it is decorated with Hugo's particularly fine filigree and enriched by naturalistic cutout leaves and little cast animals and birds.

The increasing wealth of the royal courts, of the aristocracy, and, later, of the merchants led to the establishment of secular workshops in the great cities and the foundation of confraternities, or guilds, of goldsmiths and silversmiths, the first being that of Paris in 1202.

As in architecture, monumental sculpture, and ivory carving, the lead held by Germany and the Low Countries during the Romanesque period now passed to France. Architectural forms continued to be the basis of design in precious metal; the silver shrine of St. Taurin at Évreux (c. 1250), for example, is a Gothic chapel in miniature, with saints under pointed arches, clustered columns, and small turrets. In England, the few pieces that survived the dissolution of the monasteries in the 16th century follow the same architectural pattern. Notable examples are the 14th-century Ramsey Abbey censer

Crown Copyright. Victoria and Albert Museum, London

Ramsey Abbey censer, cast, embossed, and gilt silver, English Gothic, 14th century. In the Victoria and Albert Museum, London. Height 27.6 cm.

(Victoria and Albert Museum) and the magnificent crosier made for William of Wykeham (New College, Oxford). Germany first produced work in the Gothic style in the second half of the 14th century with a large Gothic head reliquary of Charlemagne and the splendid "Three-Tower" reliquary, both still at Aachen. In Italy, despite the undercurrent of classical taste, the Gothic style predominated in the 14th century, especially at Siena; it was also probably in Italy around 1280 that basse-taille enamel—a technique in which intaglio relief

Eccle-  
siastical  
work

Basse-  
taille  
enamel

carving in the metal below its surface is filled with translucent enamel—originated, whence it spread rapidly through the upper Rhine region to France and England. The Parisian school of enamellers predominated in the latter half of the 14th century. For the first time, enough secular plate survives to show that it equalled the ecclesiastical in opulence: two fine pieces are the Royal Gold Cup made in Paris around 1380 (British Museum) and the so-called King John's Cup, probably English work of around 1340 (King's Lynn, Norfolk).

The late Gothic period produced court treasures such as the "Goldenes Rössel" (1403; Stiftskirche, Altötting, West Germany), and the Thorn reliquary (British Museum), both early 15th century. There was also an increased output of secular silver because of the rise of the middle classes; the English mazers (wooden drinking bowls with silver mounts) and the silver spoons with a large variety of finials are examples of this more modest plate. Numerous large reliquaries and altar plate of all kinds were still produced. At the end of the Middle Ages the style of these pieces and of secular plate developed more distinctive national characteristics, strongly influenced by architectural style: in England, by the geometric patterns of the Perpendicular; in Germany, by heavy and bizarre themes of almost Baroque exuberance; and in France, by the fragile elegance of the Flamboyant.

"Hall-marking"

The purity standards of silver became rigorously controlled, and "hallmarking" was enforced; the marking of silver in England, especially, was carefully observed.

(P.E.L.)

*Islām.* The use of gold and silver in Islāmic lands was limited because it was forbidden by the Qur'ān, and although the prohibition was often ignored, the great value of such objects led to their early destruction and melting down. Islāmic jewelry of the early period is therefore of extreme rarity, represented only by a few items, such as buckles and bracelets of the Fātimid and Mongol periods and such pieces as the Gerona silver chest (akin to similar ivory coffers) in Spain and the Berlin silver tankard of the 13th century, with embossed reliefs of Sāsānian animal friezes.

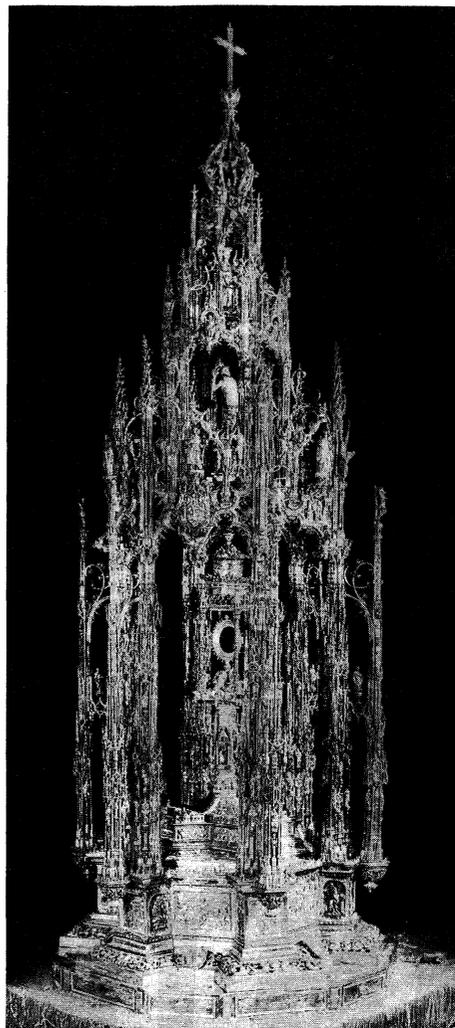

(H.Go.)

**Renaissance to modern.** 16th century. Italian goldsmiths preceded the rest of Europe in reverting to the style of Roman antiquity; but in the absence of antique goldsmiths' work, vases of marble or bronze had to serve as models. Goldsmiths often worked from very free interpretations of the antique made by artists in other media. Many of these designs but very few of the actual pieces have survived; the most famous is an enamelled gold saltcellar (Kunsthistorisches Museum, Vienna) made for Francis I by the celebrated Florentine Benvenuto Cellini. In the second half of the 16th century many gifted Italian and immigrant goldsmiths worked at the court of Cosimo I, grand duke of Tuscany, specializing in vessels of hardstone mounted in enamelled and jewelled gold; their work is well represented in the Museo degli Argenti in the Pitti Palace, Florence, and in the Kunsthistorisches Museum; similar work was done by the Sarachi family in Milan.

Little French goldwork is extant, and most of the surviving material is in the Galerie d'Apollon in the Louvre. Among the most sumptuous pieces are a sardonyx (a type of onyx) and gold ewer, the gold St. Michael's Cup (both at the Kunsthistorisches Museum), and a sardonyx-covered cup in the Louvre, all of which display northern features. The massive plate of the Ordre du Saint-Esprit (Louvre), dating from 1581–82, is of quite individual character; and an enamelled gold helmet and shield of Charles IX (1560–74) in the Louvre have no parallel either for quality or opulence.

Spanish and Portuguese goldsmiths

In other parts of Europe, goldsmiths clung to Gothic forms until well into the first half of the century, especially in the provincial towns. Immensely rich in ecclesiastical silver, Spain has little early domestic silver; Spanish silversmiths, *platería*, gave their name to the heavily ornamented style of the period, *Plateresque*. Using precious metal from the New World, goldsmiths such as Enrique and Juan de Arfe produced vast containers for the Host

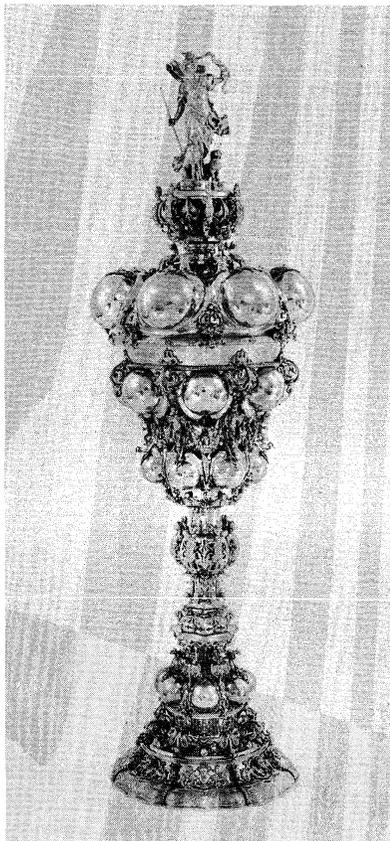

*Custodia* of goldwork, silverwork, and enamel work (1515–23), by Enrique de Arfe. In the Toledo Cathedral, Spain. Height 2.50 m. Archivo Mas, Barcelona

known as *custodia*. The most important Portuguese work, the Belém monstrance, or container for the Host, created by Gil Vicente in 1506 for Belém Monastery near Lisbon, is still Gothic in style; later, Portugal developed its own style, related to Spanish work but not copied from it.

Some of the finest 16th-century goldsmiths' work was executed in Antwerp and elsewhere by such Flemish goldsmiths as Hans of Antwerp, goldsmith to Henry VIII, and Jacopo Delfe, called Biliverti, goldsmith to Cosimo I. The Flemish masters showed particular sympathy for the Mannerist style, derived from Italy but transformed by such native engravers as Cornelis Bos and Cornelis Floris. By about 1580, Dutch goldsmiths had begun to rival the Flemish; the van Vianen family of Utrecht won international renown, especially Adam, who excelled at embossing, and his brother Paulus, who worked in Italy, Munich, and in the workshop of Rudolph II at Prague.

The principal centres in the north were Nürnberg and Augsburg, the former particularly notable for the exuberant Mannerism of the Jamnitzer family, the latter for its ebony caskets with silver-gilt mounts. Many German princes, especially the dukes of Bavaria, maintained their own court workshops. Production was on a vast scale, and great quantities survive. Characteristic German forms are columbine cups (the trial piece for entry into the Nürnberg Goldsmith's Guild) and standing cups such as the Diana Cup (c. 1610; Kunstgewerbemuseum, West Berlin) by Hans Petzolt.

England is rich in 16th-century secular silver, but

Diana Cup, silver standing cup by Hans Petzolt, Nürnberg, c. 1610. In the Kunstgewerbemuseum, West Berlin. Height 80.01 cm.

church plate was mostly destroyed during the Reformation. The Renaissance style, introduced by the painter Hans Holbein the Younger, who designed vessels for the court, follows that of the Low Countries and Germany. Certain individual forms also were produced, such as standing saltcellars with tiered covers and "steeple" cups, which had a tall finial on the cover.

*Baroque.* In the first half of the 17th century Dutch goldsmiths, such as the van Vianens and, later, Johannes Lutma the Elder of Amsterdam, developed a fleshy form of ornament known as auricular, which became common in northern Europe, including England—where Christian van Vianen worked as court goldsmith to Charles I—and Germany—where the Thirty Years' War (1618–48) reduced both the quantity and quality of production. After midcentury, bold Dutch floral ornament—usually embossed in thin metal, as though the pieces were for display rather than use—was characteristic and influential. France, however, undoubtedly led fashion with its state workshops at the Gobelins, the refined French acanthus ornament contrasting sharply with the coarser Dutch designs. Since Louis XIV melted the royal plate to pay his troops, no French work of this period remains; but its quality is demonstrated in the work of the Huguenot silversmiths who left France after the revocation of the Edict of Nantes in 1685. Mostly provincials, they brought new standards of taste and craftsmanship wherever they settled—particularly in England, where the foremost names of the late 17th and earlier 18th centuries were of French origin: Pierre Harache, Pierre Platel, David Guillaume, Simon Pantin, Paul de Lamerie, Paul Crespin, to mention but a few.

Silver furniture, a feature of the state rooms at Versailles, became fashionable among kings and noblemen. It was constructed of silver plates attached to a wooden frame; and each suite contained a dressing table, a looking glass, and a pair of candlestands. In France such furniture did not survive the Revolution; but much remains in England, Denmark, Germany, and Russia.

After the Thirty Years' War, Germany did not regain its eminence; even the enamelled goldwork from the court workshops at Prague and Munich, which became larger and more ostentatious in colour, was inferior in design and finish. In Scandinavia, particularly Sweden, goldsmiths evolved forms of beakers and tankards showing strong German influence. Spanish silver was of massive architectural design, oval *champlevé* enamelled bosses being set at intervals over the surface of the larger pieces. The few extant Italian pieces suggest that the goldsmiths worked their material with the skill of sculptors.

*18th century.* Early 18th-century English work combined functional simplicity with grace of form, while the work of Dutch and German goldsmiths is in a similar style but of less pleasing proportions. The pre-eminence of the English work, however, is due to the destruction of all but a fraction of French silver of the same period; for what survives is outstanding in originality of design and fineness of finish. The superiority of French work lay in its excellence of design and the high quality of the cast and chased work. Where other goldsmiths worked in embossed metal, the French modelled and cast their ornament and then applied it—a technique that consumed much more of the precious material.

In France, provincial goldsmiths competed successfully with those of the capital; but in England all the best artists went to London. In the early 1730s the French Rococo style was imported to England and adopted by goldsmiths of both Huguenot and English descent, one of the latter being Thomas Heming, goldsmith to George III. English silver in the 18th-century classical style of Robert and James Adam is of unequal merit owing to the use of industrial methods by some large producers.

In France, Robert Auguste created pieces of great refinement in the Neoclassical style, which was copied in Turin and in Rome, for example, by L. Valadini. A notable workshop was founded in Madrid in 1778 by D. Antonio Martínez, who favoured severely classical designs. In both the northern and southern Netherlands, local production followed French precept, but more individuality survived in Germany. In Augsburg, excellent table silver was produced, but more important were the pictorial panels embossed in the highest relief by members of the Thelot family and the silver furniture made by the Billers and the Drentwets. At Dresden, Augustus II the Strong established under Johann Melchior Dinglinger a court workshop that produced jewels and enamelled goldwork unequalled since the Renaissance; and the gold snuffboxes made by Johann Christian Neuber rivalled those of the Parisian goldsmiths. (J.F.Ha.)

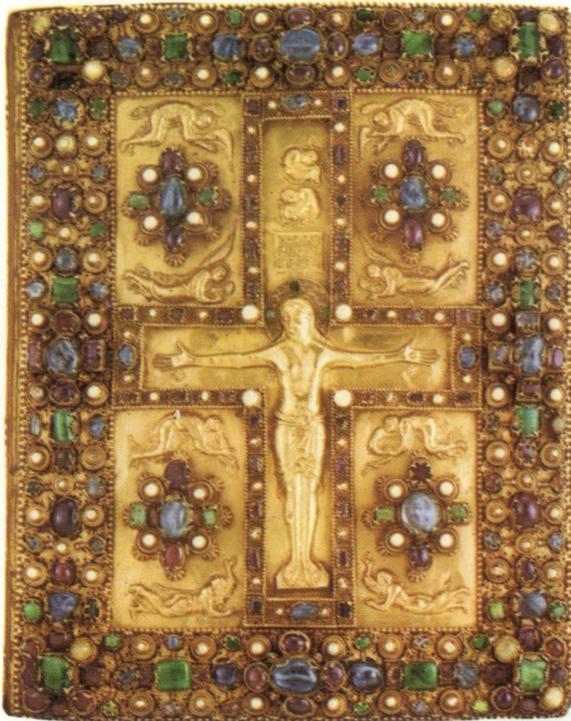

*Colonial America.* Silversmithing in the New World in the colonial period is more or less derivative from Europe and England. In North America it was first brought to New England by English craftsmen in the 17th century. The most important centres were Boston, Newport, New York City, Philadelphia, Baltimore, and Annapolis. Outstanding collections include the Mabel Brady Garvan collection at Yale University and those in the Boston Museum of Fine Arts, the American Wing of the Metropolitan Museum of Art, and in the Philadelphia Museum of Art. North American colonial silver is distinguished for its simplicity and graceful forms, copied or adapted from English silver of the period. On the other hand, the colonial silver of Mexico, Brazil, Colombia, Peru, Chile, and Bolivia, while European in concept, shows a blending of Iberian designs and forms, with indigenous influences that trace back to pre-Hispanic times. Most of these relics survive in churches as sacramental vessels; but there are some notable private collections. (D.T.E.)

*19th century.* The Napoleonic adventure brought French fashions back into prominence, and the Empire style was widely followed on the Continent. In England the Regency goldsmiths, of whom Paul Storr was the foremost, created their own more robust version of the Empire style. Perhaps the most impressive monument of the period is a service made in Lisbon between 1813 and 1816 and presented to the Duke of Wellington for his liberation of Portugal (now in Apsley House, London).

Celtic bronze shield, originally gilt, 2nd century AD. In the British Museum. Height 78 cm.

Egyptian bronze plaque damascened with gold wire, 22nd dynasty (945–c. 730 BC). In the Metropolitan Museum of Art, New York City. Length 19 cm.

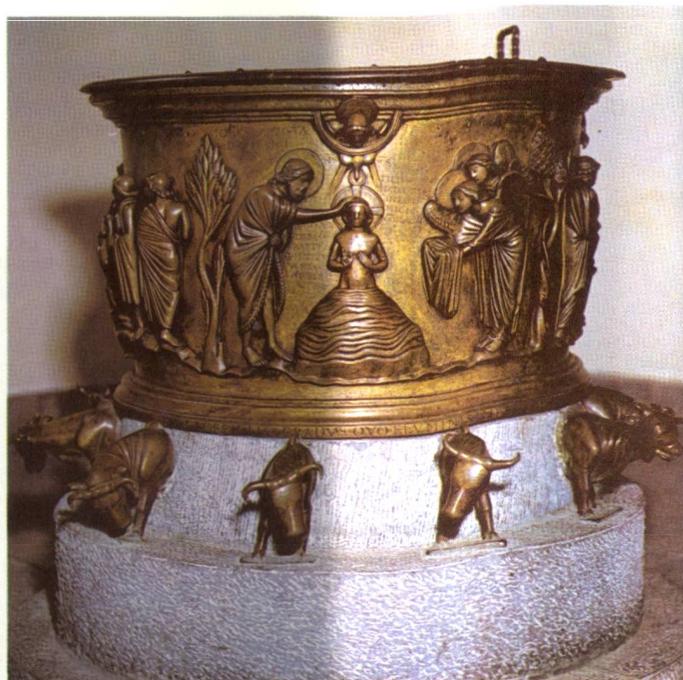

Nepalese statue of Krsna, gilded bronze with turquoise and gems, 18th century. In the Prince of Wales Museum of Western India, Bombay.

The Chimera of Arezzo, bronze, Etruscan, 4th century BC. In the Museo Archeologico, Florence. Height 80 cm.

Chinese bronze *chung*, late Chou dynasty (c. 1122–221 BC). In the Freer Gallery of Art, Washington, D.C. Height 67 cm.

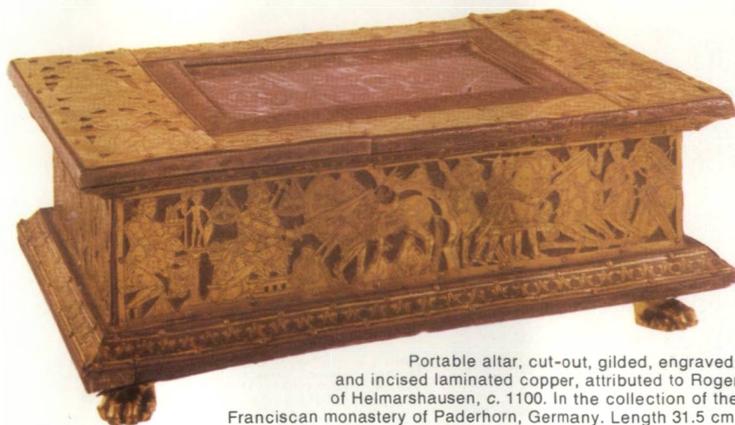

Cast bronze baptismal font by Renier de Huy, 1107–18. In the church of Saint-Barthelemy, Leige, Belgium. Height 64 cm.

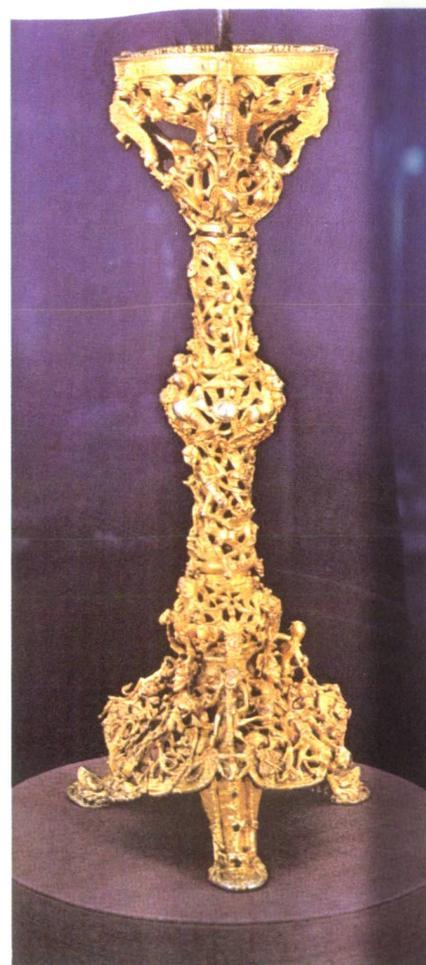

Mycenaean dagger, bronze with gold, silver, and niello, 16th century BC. In the National Archaeological Museum of Athens. Length 16.3 cm.

Syrian *pome*, or handwarmer, openwork copper with silver inlay, c. 13th century. In the British Museum. Diameter 18.5 cm.

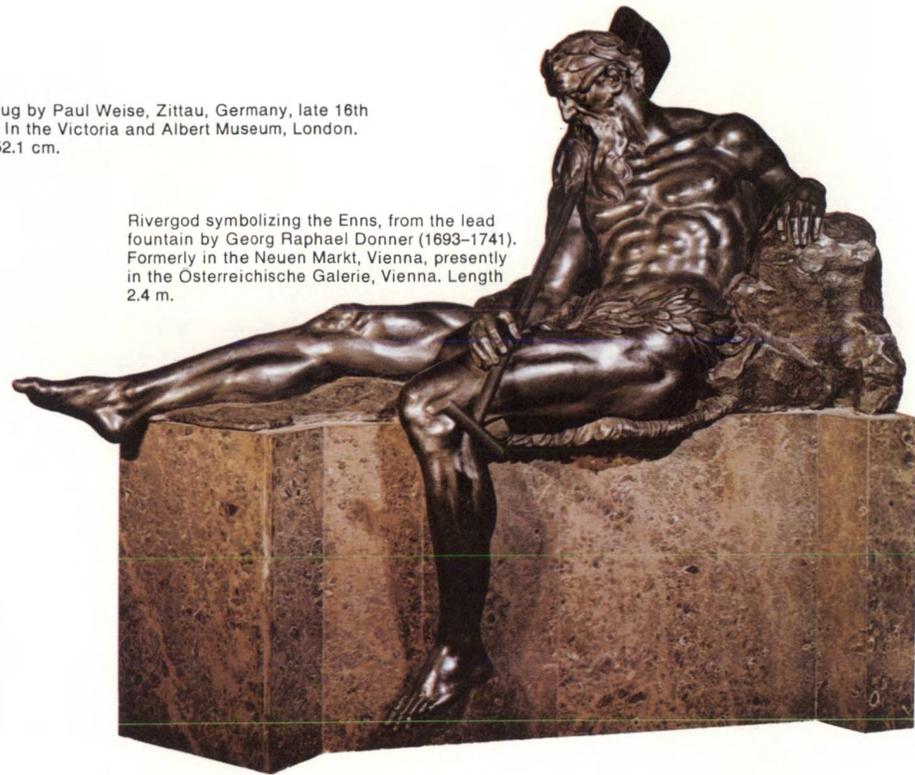

Portable altar, cut-out, gilded, engraved, and incised laminated copper, attributed to Roger of Helmarshausen, c. 1100. In the collection of the Franciscan monastery of Paderhorn, Germany. Length 31.5 cm.

Gloucester candlestick, carved and chased gilt bronze, 12th century. In the Victoria and Albert Museum, London. Height 58 cm.

Pewter jug by Paul Weise, Zittau, Germany, late 16th century. In the Victoria and Albert Museum, London. Height 52.1 cm.

Rivergod symbolizing the Enns, from the lead fountain by Georg Raphael Donner (1693–1741). Formerly in the Neuen Markt, Vienna, presently in the Österreichische Galerie, Vienna. Length 2.4 m.

Japanese *tsuba* (sword guard), iron with openwork design, Muromachi period, 1338–1573. In the National Museum, Tokyo. Diameter 10 cm.

### Pewter, iron, and lead

Detail of a wrought-iron *reja* (choir screen) by Pedro Juan, 1668, gilded in 1764. Originally in the cathedral of Valladolid, Spain, presently in the Metropolitan Museum of Art, New York City. Height 19 m.

The craft  
as industry

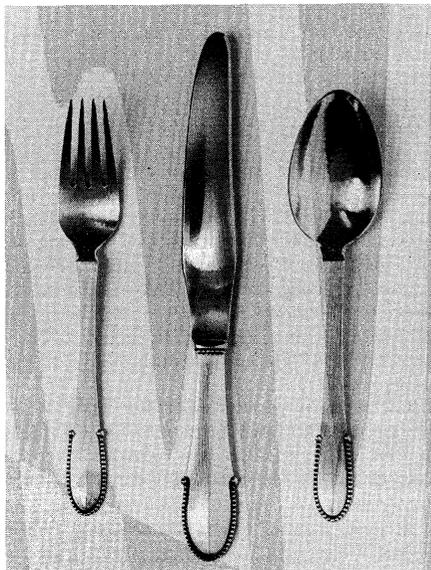

By midcentury most of the earlier styles had been revived fleetingly and a recognizable Victorian style evolved, based on details drawn from diverse sources. Craftsmanship was at its best, but the design of domestic silver was derivative and selective, while that of presentation pieces strove too consciously for naturalistic effect. In the latter half-century the craft became an industry and the goldsmith a factory worker. In this respect Matthew Boulton was the great pioneer: his Soho manufactory near Birmingham, which dominated the British "toy" industry from the 1770s, produced high-quality steel buckles, buttons, coins, sterling silver, and Sheffield plate, establishing standards of design and of factory management and welfare services that rivalled those of the 20th century. At the end of the 19th century, standards deteriorated, and a second pioneering movement started—the craft revival associated with William Morris and the Art Nouveau style (see below *Modern*), which led to the production of original pieces, some of highly mannered design. In England the most interesting work was done by the sculptor Sir Alfred Gilbert, who, following the lead of William Burges, the architect and designer, combined silver with ivory and semiprecious stones in romantic confections. (J.F.Ha.)

Decline of  
creativity

*Modern.* The structure of trade, following the drastic social changes that have taken place since 1914, is similar in all industrial countries. A few artist-craftsmen maintain independent studio workshops, producing commercially unprofitable but artistically significant work. Many of them also teach in art schools or work part-time in factories as industrial designers. Factories using modern equipment—for example, stamping, pressing, spinning, casting, and mechanical polishing—account for nearly all the financial turnover but seldom break new ground artistically. Retail shops buy stock almost entirely from the factories and wholesalers and usually sell it anonymously. Thus, the evolution of style is impeded by the cost of new machinery; by the natural caution of wholesalers and retailers; by the buying public, which prefers precious ornaments to be timeless; and by the consideration that buying is an investment for value rather than for beauty. In consequence, the most lively designs are often those for costume jewelry; and the best modern work usually has been on a tiny scale, making little impact on the trade.

In Paris, designs by René Lalique inspired Art Nouveau, which spread to Belgium and then through Europe and the United States. In Moscow, Peter Carl Fabergé set a superb standard of craftsmanship for small ornaments. In Denmark, Georg Jensen, with Johan Rohde and others, achieved not only an individual Danish style but built up

Sterling silver knife, fork, and spoon, designed by Georg Jensen, Copenhagen, 1916.

several large factories with retail outlets all over the world, thus proving that good modern design in silver and jewelry need not be confined to artists' studios; their influence spread throughout Scandinavia. In the 1960s only Germany approached Scandinavia in the number and quality of its artist-craftsmen; WMF (Württembergische Metallwarenfabrik) at Geislingen is probably the biggest silverware factory in Europe. In England, notable for the most varied work, the Worshipful Company of Goldsmiths has helped a vigorous group of designers to emerge since 1945, including Gerald Benney, Eric Clements, David Mellor, and Roger King. (G.McK.H.)

## PEWTER

In its pure form, tin is far from suitable for making into implements because it is too brittle for casting successfully and is not easy to melt down. For this reason it has always been alloyed with certain other metals, mainly lead, in the proportion of 10:1, or copper, alloyed about 100:4, to make what is known as pewter. In medieval Germany, the municipal authorities and the guilds laid down permissible ratios to be used for tin alloys. The authorities also kept an eye on the pewterers and their products to make sure that regulations were adhered to. So that pewter ware could be kept under constant surveillance, a system was worked out whereby every single article had to be marked by one, two, or more hallmarks, or "touches." The first decrees of this kind to be issued in Germany date from the 14th century. In France and England, written sources refer to the pewterer's obligation to hallmark his wares from the end of the 15th century onward. These regulations do not seem to have been followed very closely in practice, for pieces surviving from the period before 1550 rarely have the regulation marks. In the second half of the 16th century, however, which was the golden age of pewter, almost all work began to be clearly marked. This means that modern collectors have a good chance of being able to identify their pieces.

Pewter  
molds

Pewter ware is cast in molds. It is not suitable for chasing or stamping. Molds for simple utensils such as plates, bowls, and jugs were made of clay mixed with calves' hair or of plaster, stone, or slate. From the 16th century, when pewter ware began to be decorated with relief work, molds made of brass or copper were used instead. Relief decoration can be applied by two different methods. The pewterer could either chisel the relief decoration (consisting of little scenes, figures, or decorative motifs) into the copper mold in intaglio, which enabled him to make the details as three-dimensional as he wished; or he could etch it in, which involved covering the plain copper mold with wax, scratching the decoration into it, and then allowing caustic acid to act on it. This second method resulted in a rather flat, two-dimensional relief, which is reminiscent of woodcuts in its sharp outlines and overall style; thus, the technique is known as the "woodcut style." It was common practice in Nürnberg in the last quarter of the 16th century. Pewter utensils (exclusively plates and dishes at this time) were cast in molds prepared in this manner. It was very seldom that decorative motifs were etched straight onto the pewter surface.

Another type of decoration is engraving, which involves cutting decorative motifs, figures, or inscriptions with a burin into the surface of pewter objects. The most expensive and aesthetically important pieces of engraved pewter were produced in the late Gothic period, about 1500. In the 16th and 17th centuries, engraving was common for guild articles; and in the 18th century engraved mottoes, names, dates, and motifs taken from popular art were widely used. The type of strokes used fall into three categories: long, engraved lines; dots set close together to form a pattern; and a technique known in German as *Flecheln*, in which the straight line made by the burin is broken up into a series of long or short zigzag strokes. The last method makes the design look fuller and broader and also makes it stand out more sharply. This type of decoration first appeared in the 16th century and was very popular in the 17th and 18th centuries.

After they had been cast and then turned on a lathe, many pewter articles, especially plates and dishes, were hammered. The idea was to smooth over the surface of the object and strengthen the material by means of a series of light and regular blows. Sometimes pewterers punched their wares with decorative motifs stamped close together to form a sort of frieze. This technique is known as tooling and is commonly found on bronze and silver articles. Occasionally, pewter pieces were embellished by the addition of brass fittings, such as handles, knobs, spouts, or scroll panels. But pewter ware has rarely been gilded, partly because it is difficult to make a layer of gilding adhere to the surface, partly because there seems little point in covering a material that is attractive in itself with a metal that is ostensibly more precious. This is also why pewter ware has rarely been painted.

Pewter  
inlay

A type of pewter inlay is found on what are known as Lichtenhain tankards. Most of these tankards were made in Lower Franconia and in Thuringia in the 18th and 19th centuries. They have wooden staves running down them, and their sides are inlaid with decorative motifs and figures made of thin sheets of engraved pewter. In the early 18th century, furniture was also occasionally inlaid with pewter. Such furniture was clearly inspired by the inlay work of the French cabinetmaker André-Charles Boulle.

**Antiquity.** On the whole, excavations have unearthed little pewter ware dating from antiquity, not only because it has tended to perish over the years but presumably also because it was not nearly as common as glass, bronze, silver, or clay. Excavations on the Esqueline Hill and finds from the Tiber River have produced some small pewter statuettes of divinities that may well be votive offerings. Miniature versions of household articles such as amphorae, oil lamps, and pieces of furniture were found in graves.

A number of pewter ampullae (flasks with a globular body and two handles) with inscriptions or highly stylized images or symbols date from the Early Christian period. They were sold to pilgrims and were used to hold water from the Jordan River, consecrated water, or oil. (Similar pouch-shaped ampullae reappeared in France in the 14th and 15th centuries; but unlike the early Christian examples, they are ornamented with abstract motifs rather than figure decoration.)

**Middle Ages.** Besides the ampullae, hundreds and thousands of pilgrim badges were sold to devout visitors to places of pilgrimage in the Middle Ages. These little plaques and *agraffes* (hat badges) were generally miniature versions of religious images worshipped at the place where they were on sale. A number of these Italian, English, French, and German pilgrim badges, dating from the 13th to the 16th century, have survived.

Instead of jewelry made of gold, silver, or precious stones, the less wealthy people of the Middle Ages wore pewter badges sewn onto their clothes or hats. The badges often took the form of amulets.

Because pewter was highly prized in all periods, damaged or old-fashioned utensils were melted down over and over again to make new ones. Thus, the earliest surviving functional objects and vessels made of pewter date from the Gothic era, though a few written sources refer to pewter being used earlier than this. Most of these documents are concerned with the question of whether communion chalices should be made of anything other than gold or silver. Pewter Communion chalices were permitted in certain periods and prohibited in others, and the church never managed to draw up an absolute ruling that applied to all religious communities.

Guild  
flagons

Some of the finest and most important pewter pieces ever cast were made in Silesia in about 1500. Large guild flagons of a characteristic polygonal design, only 11 of them have been preserved. Their faceted surfaces are engraved with figures of saints surrounded by interlaced foliage scrolls, arches, arcades, and other late Gothic decorative motifs. Hidden among these motifs, one sometimes finds secular scenes, some of which are downright lewd. Pewterers in the neighbouring districts of Moravia and Bohemia also made guild flagons; but theirs were

cylindrical, with raised horizontal bands. The areas between the bands were generally decorated with friezelike inscriptions made up of Gothic or Gothic-style characters.

The 15th century saw the emergence of a jug set on a slender stem, easily recognizable by its disk-shaped base, surmounted by another slender stem; the main body of the vessel is generally spherical and has a long, thin neck. The municipal authorities often possessed a set of six or 12 flagons of this kind. They came back into fashion in the 17th century and were very widely used, as they had been at the beginning of the 15th century. Unfortunately, only a very few have survived from the earlier periods.

Another early type of vessel belongs to a group known as Hanseatic tankards. These tankards have a heavy-looking, potbellied body set on a shallow circular base and a slightly convex lid. They were used in the coastal regions of Germany—that is, along the North Sea and Baltic coasts—and also in the Low Countries and Scandinavia. These regions comprise the area dominated by the Hanseatic League in the Middle Ages, hence the name of the tankards. Other regions of Europe were evolving their own special types of vessels for beer and wine, which, with a few modifications, remained standard for centuries. Thus, it is a very simple matter to distinguish between baluster jugs from London and *pichets* from Paris or between wine flagons from Switzerland and those made in the Low Countries, Burgundy, the Main regions of Franconia, southern Germany, and the Rhineland. The type of a baluster jug made in the region around Frankfurt-am-Oder and in Brandenburg in north-eastern Germany is particularly elegant and distinguished looking. The few jugs of this type that have survived date from about 1500.

In all of the districts bordering the Rhine, vessels with flat lenticular (the shape of a double-convex lens) bodies are relatively common. They were used as canteens—sometimes as tankards, in which case they had a base that acted as a stand.

**16th century to modern.** The Baroque era saw the production of many different types of drinking and pouring vessels, often made of pewter. The guilds, for instance, commissioned drinking vessels in the shape of larger than life-size versions of the tools of their trade or their coats of arms. Another type of vessel was called the *Welcome*, a drinking vessel that was handed around as a form of greeting or when a toast was being drunk. The body of these vessels was generally cylindrical or potbellied, with a lid and a short shaft set on a circular base.

Far fewer plain everyday plates have survived from the 15th and 16th centuries than drinking vessels and containers of the same period. The earliest pewter plates and bowls to have survived in any quantity date from the 17th century.

In the last half of the 16th century two places in Europe evolved quite independently, though simultaneously, a new technique for casting pewter. The product was a type of relief-decorated ware known as “display pewter” (*Edelzinn*), and it gave a new and brilliant impetus to the trade. The first examples were made between 1560 and 1570, and the main centres of production were Nürnberg and Lyon. In the beginning the technique used was not the same in both towns. Whereas in France, relief pewter was cast in engraved brass molds worked with a burin, in Nürnberg etched molds were used. This suggests that the two towns were not influenced by each other in any way. Later on, however, Nürnberg pewterers were strongly influenced by the work of a celebrated French pewterer, François Briot, who was active in Montbeliard, in the county of Württemberg.

The first master pewterer documented to have made relief pieces in Lyon is Roland Greffet, between 1528 and 1568. One can assume that it was he who invented this type of work. A school producing tankards and dishes with relief decoration soon grew up in Lyon. The most common decorative motif was an arabesque, which was used in a variety of ways and can be thought of as the leitmotif for the work of this group of artists. The master of relief pewter was François Briot. His most famous

“Display  
pewter”

piece is the *Temperantia Dish*, which takes its name from the allegorical figure of Temperance or *Temperantia* that appears in the centre of it. It dates from 1585–90.

Giraudon

Temperantia Dish, relief-decorated "display pewter," by François Briot, 16th century. In the Louvre, Paris. Diameter 45 cm.

Pewter with etched relief decoration was made by Nürnberg pewterers from the last third of the 16th century onward. The earliest piece made by Nicholas Horchhaimer, bearing the date 1567, is a dish cast in an etched mold with an allegorical figure representing Fame, or *Fama*, in the centre and historical scenes or incidents from classical mythology around the edge. Other large dishes made by Horchhaimer and his contemporary Albrecht Preissensin are again decorated with themes from classical antiquity or sometimes with biblical scenes; for smaller plates they kept to abstract decoration.

The use of etched molds did not remain fashionable in Nürnberg for long, and toward the end of the 16th century engraved molds were being used here as well. The work of François Briot was copied by Caspar Enderlein, who modelled his own *Temperantia Dish* directly on Briot's. The decoration on the ewer that went with it was modelled on Briot's *Mars Dish* and on a piece known as the *Suzannah Dish*, which is also attributed to Briot.

In the second quarter of the 17th century, smaller relief plates superseded the big dishes and jugs made in Nürnberg. The Mannerist allegories that had been in favour completely disappeared, to be replaced by scenes from the Old and New Testaments, equestrian portraits of the German emperors with the electors round the edge, and luxuriant floral decorations. These plates are no more than about seven inches (18 centimetres) in diameter and are generally flat and disk-shaped. The molds were no longer made by the pewterers themselves but by professional mold cutters, who occasionally added their own monograms. Since molds were often sold by one workshop to another and then to another, one sometimes finds plates cast in the same mold but with different touches. Small decorative plates of this type were so popular that they continued to be made as late as the 18th century. There are no less than nine different models for a plate with an equestrian portrait of Ferdinand III of the House of Habsburg, who was crowned emperor of Germany in Nürnberg in 1637. Similar plates depicting Gustavus Adolphus of Sweden, the Emperor of Turkey, and Duke Eberhard im Bart of Württemberg were also produced. Few places, apart from Nürnberg and France, had a

flourishing trade in relief pewter. A few master pewterers in Saxony did execute relief decoration, however, mainly on jugs; they adapted their motifs from lead or bronze plaquettes made in southern Germany. Plates bearing the arms of Switzerland were also produced by Swiss pewterers in the 17th century. They have scenes taken from the history of Switzerland. The golden age of relief pewter, which had begun about 1570, ended in the third quarter of the 17th century. During this period, individual craftsmen had elevated pewter from its humble status as a material from which functional articles were made to one in which brilliant artistic feats could be performed. Relief pewter pieces were solely works of art, nonfunctional objects valued as showpieces.

Pewter dishes made in Italy in the 16th and 17th centuries have chased, etched, engraved, or chiselled decoration and lean heavily on artists working in brass or bronze for their designs. An independent pewter trade does not seem to have existed in Italy on anything like a large scale until the 18th century.

After the Thirty Years' War the production of functional articles in pewter noticeably increased in northern Europe. Besides a very large number of different types of jugs, each region specializing in its own characteristic design, there were plates and dishes used at table and also basins and bowls, drinking mugs, and screw-top flasks.

Yet pewter was already feeling the draught of competition by the end of the 17th century. In this time pewter began to be superseded by products of other branches of the decorative arts. Its first rival, faience ware, was initially no more than an inferior substitute for porcelain; but because the factories that were soon springing up everywhere were able to produce very large quantities of faience, they inflicted heavy damage on the pewter trade. Faced with this situation, the pewterers switched to imitating the designs used by the silversmiths, in the hope of gaining favor in the more ambitious middle class circles. This attempt was successful; and, from the first quarter of the 18th century onward, "silver-type pewter" gained a firm hold, soon influencing the production and appearance of pewter ware made in the Regency and Rococo periods.

By about the middle of the 18th century, an ever-widening variety of articles was being made: the pewterers were able to supply anything from a spoon to a whole dinner service, including mustard pots, sauceboats, and spoons for serving punch. But this period of prosperity was short-lived. By the third quarter of the 18th century, pewter was rivalled both by porcelain, which could now be produced relatively cheaply by several factories in Europe, and by the even cheaper English earthenware that flooded markets on the Continent. This new development sealed the fate of the pewter trade. Towns that once had 20 or 30 busy and successful workshops had no more than one or two by the beginning of the 19th century.

Although in Germany the demand for pewter seems to have increased for a few years after the Napoleonic era, particularly in country districts, by the middle of the 19th century industrialization finally put an end to a trade that had flourished for centuries.

In the second half of the century, when stylistic imitations were all the rage, pewter vessels were produced in the Neo-Baroque, Neo-Rococo, Neo-Gothic, Neo-Renaissance, and other styles that followed the many historicizing trends that emerged. Yet these pieces were made more often by mechanized metalworking factories than by pewterers. The Art Nouveau style that became fashionable at the end of the 19th century brought about a revival of pewter production; and individual firms succeeded in making original, well-designed pieces that are often of considerable aesthetic importance. The firm of Kayser in Oppum near Krefeld played a leading part in this revival. But the outbreak of World War I spelled the end of Art Nouveau—whose heady run of success had anyway been short-lived—and with it the end of old pewter.

(H.-U.H.)

#### IRON

Ironwork is fashioned either by forging or casting. Wrought iron is the type of ironwork that is forged on an

Domestic  
pewter in  
northern  
Europe

Pewter watering can in Art Nouveau style, by the firm Kayser, at Oppum near Krefeld, Germany, c. 1900. In the Museum für Kunsthandwerk, Frankfurt am Main. Height 21.5 cm. By courtesy of the Museum für Kunsthandwerk, Frankfurt am Main

anvil. There are no fabrication similarities to cast iron, which is poured in a molten state into prepared sand molds.

Wrought  
iron

Wrought iron is fibrous in structure and light gray in colour. It can be hammered, twisted, or stretched when hot or cold. The more it is hammered, the more brittle and hard it becomes; but it can be brought back to its original state by annealing (heating and then cooling slowly). It will not shatter when dropped.

From earliest times, the smith has had a forge to heat the iron, an adjacent water tank in which to cool it, an anvil on which to form it, in addition to a wide assortment of hammers and tools. The most important tool is the anvil. The English type, generally used for forging wrought iron, has a flat top surface, which is used as a solid base for hammering the heated iron into shape, for welding, for splitting, or for incising decorative chisel marks in the hot iron. One end of the anvil is shaped like a pointed cone and is used for forming curved surfaces. The other blunt end, or heel, has one or two square or rectangular holes on top, into which fit various tools. From the anvil is derived the expression "to strike while the iron is hot," and this implies spontaneity and rapid hammer blows. The wrought-iron craftsman should not be expected to repeat with meticulous exactitude one intricate component after another. In fact, wrought iron by a master craftsman is esteemed for the variations that naturally occur.

Compo-  
nents of  
wrought-  
iron  
design

The individual components of a wrought-iron design are often plain or twisted rods, with or without chisel-mark incisions. They are frequently composed as a series of straight, parallel members or in combination with scrolls, or as a repeat design of some geometric shape such as the quatrefoil. Where two curved members are tangent, they are characteristically secured together by bands or collars, rather than by welding. Where two straight bars intersect, it is accredited craftsmanship to make the vertical bar pierce or thread the horizontal member. Grilles consisting of two series of parallel small-diameter rods, one series at right angles to the other, were sometimes interlaced or woven.

Depending upon the depth of the relief, various fabrication techniques may be employed for repoussé, or three-dimensional, ornamental wrought ironwork. Sheets  $\frac{1}{16}$  inch (1.6 millimetres) or less in thickness generally are used. The general configuration of the modelling is obtained by beating the back of the sheet; the final details are embossed on the front face. The finer the scale and detail, the more work must be done when the iron is cold. A repoussé design may be pierced; but this term usually connotes a solid sheet forged into a mask, a shield, or an

entire embossed panel. The traditional means of setting off a cutout repoussé design was to superimpose it on a vermilion-coloured background panel. Modern approximations of repoussé work consist of mechanically stamped designs touched up with random hammer blows.

(G.K.Ge.)

The most difficult way of decorating iron is to carve it. This involves fashioning figurative or decorative motifs out of the metal ingot with especially strengthened tools, using the material in the same way that the sculptor handles wood or stone. Only very precious iron articles are carved, such as coats of arms or pieces that are specifically designed to be displayed as works of art.

(H.-U.H.)

Cast iron is melted in a furnace or cupola, stoked with alternate layers of coking iron, then poured into prepared sand molds. After the cast iron cools in the mold, the sand is cleaned off, and the work is virtually complete. Its shape is fixed, and while a casting can be slightly trued up by the judicious use of a hammer, it is in no sense as workable as wrought iron. Thus, ornamental features in cast iron cannot be chased and polished as in cast bronze. If the ornamental cast-iron details are not replicas of the original pattern, the only recourse is to make a new casting. Because it is brittle, cast iron is almost certain to shatter if dropped.

Cast iron

Since it is cast in a mold, certain forms are more suitable to cast iron than to wrought iron. For example, if repetitive balusters, or columns, or panels with low-relief ornamentation are desired, cast iron is the most suitable material.

(G.K.Ge.)

**Early history.** The earliest recorded iron artifacts are some beads, dating from about 3500 BC or earlier, found at Jirzah in Egypt. They are made from meteoric iron, as are a number of other objects of only slightly later date that have been found both in Egypt and Mesopotamia. The earliest known examples of the use of smelted iron are fragments of a dagger blade in a bronze hilt, dating from the 28th century BC, found at Tall al-Asmar (modern Eshnunna), in Mesopotamia, and some pieces of iron from Tell Chagar Bazar, in the same area, of approximately the same date. There is, however, no evidence of any extensive use of iron in either Egypt or Mesopotamia before the end of the 2nd millennium BC. In Asia Minor, on the other hand, iron was probably used regularly from at least as early as 2000 BC; and it seems likely that the first true iron industry was established there in the second half of the 2nd millennium BC.

From the ancient Near East the knowledge of iron working was transmitted to Greece and the Aegean, probably at the beginning of the 1st millennium BC, whence it spread gradually to the rest of Europe. By the 6th century BC, it had been widely disseminated over central and western Europe.

Iron was at first apparently regarded as a precious, semi-magical material, presumably because of its rarity and its connection with meteorites. But once it had become common, as a result of increased knowledge of the technique of smelting ore, it seems to have been used, at least in Europe, almost exclusively for objects of utility. A few Belgic firedogs and at least one amphora, skillfully forged in iron, with decorative terminals in the form of animal heads, are known; but the practice of forging iron into decorative shapes does not seem to have become general until the Middle Ages.

A few cast-iron objects dating from classical times have been found in Europe. The extreme rarity of these, however, suggests that they were only produced experimentally. The earliest known evidence for the general use of cast iron comes from China (see below), and it does not seem to have been produced regularly in Europe before the 15th century.

(C.Bl.)

**Belgium and Holland.** The ironwork of these two small countries prior to the 15th century was in no way inferior to that produced elsewhere. Yet so few pieces remain that the significance of craftsmen of the Low Countries has often been underestimated. During the 15th century, design and craftsmen from the Low Countries began to make their influence evident across the

Diversified forms of ironwork

channel in England. Representative examples of this period are in the Hervormde Kerk at Breda; the treasury door of the cathedral at Liège; and hinges of the church of Notre Dame, at Hal. The beautiful spires of Bruges, Ghent, and Antwerp should be mentioned.

During the first half of the 16th century, before the Spanish occupation, there were diversified forms of ironwork, such as protective grilles for doors, windows, and chapels, often in fleur-de-lis patterns; window gratings of vertical bars, frequently octagonal in section; and interlacing bars, producing rectangular or lozenge-shaped patterns. Only a few examples still exist: some lunettes in the Hôtel de Ville of Brussels; a tabernacle grille from the chapel of the counts of Flanders and a window grille from the Cathedral of St. Bavon, both from Ghent (Victoria and Albert Museum); and hinges at the Hôtels de Ville of Bruges and Ypres (Flemish Ieper). Few Renaissance screens have survived.

During the second half of the 16th century, the cruelty of the Duke of Alba and his 20,000 troops, together with the threat of the Inquisition, drove hundreds of artisans to England. After the Spanish domination there was little indigenous design in Holland and Belgium, and such ironwork as was produced fell under the spell of French imports. (G.K.Ge.)

**England.** The initial use of wrought iron was purely protective because violent attacks were frequent, and doors had to be strengthened with massive ironwork inside and out. Window openings, especially those of the treasuries of mansions and cathedrals, were for similar reasons filled with strong interlacing bars of solid iron; a good example remains at Canterbury cathedral. When, in the course of time, the need for protective barriers ended, there was greater freedom of work and a definite trend toward ornamentation. Throughout England, medieval church doors are found with massive iron hinges, the bands worked in rich ornamental designs of scrollwork, varying from the plain hinge band, with crescent, to the most elaborate filling of the door. Examples exist at Skipwith and Stillingfleet in Yorkshire, many in the eastern counties, others in Gloucester, Somerset, and the west Midlands. The next important application of ironwork came with the erection of the great cathedrals and churches, whose shrines and treasures demanded protection. Winchester Cathedral possesses the remains of one screen with a symmetrical arrangement of scrollwork. Tombs were enclosed within railings of vertical bars with ornamental finials at intervals, such as that of the Black Prince at Canterbury. A new development appeared in the early years of the 15th century when the smith, working in cold iron, attempted to reproduce Gothic stone tracery in metal. This work was more like that of a woodworker than of a smith, often consisting of small pieces of iron chiselled and rivetted, and fixed on a background of sheet iron. Many small objects such as door knockers, handles, and escutcheons were executed in the same manner. A typical monumental example is in Henry V's chantry at Westminster Abbey; but the most magnificent is the great grille at St. George's Chapel, Windsor, made to protect the tomb of Edward IV.

The development of the art of smithing during the Renaissance period was very uneven in the various countries of Europe. In 16th-century England the smith fell behind and seemed to have lost interest, producing no very great or important work. He continued to make iron railings, balconies, and small objects for architectural application, such as hinges, latches, locks, and weathercocks. But toward the end of the 17th century, there was a growing interest in beautifying houses and laying out gardens and squares, with a commensurate demand for balconies, staircases, and garden gates. The man to whom the credit is usually given for the revival of ironwork in England was Jean Tijou, a Frenchman who, together with many of his Protestant fellow craftsmen, had been forced to leave his country owing to the revocation of the Edict of Nantes in 1685. After some years in The Netherlands he went to England in 1689, where he enjoyed the patronage and favour of William III. His most important works for his royal patron are to be seen in the immense mass of

Decoration for church doors

screens and gates with which he embellished Hampton Court palace. He also executed work at Burleigh house, Stamford. Probably by the Queen's wish he was associated with the architect Sir Christopher Wren, then engaged on the rebuilding of St. Paul's Cathedral. Wren apparently did not particularly like ironwork and probably exercised some restraint on Tijou, with the result that his work at St. Paul's is more dignified and freer from appendages than that of Hampton Court.

There is a great amount of fine ironwork of the 18th century in London in the form of gates, railings, lamp holders, door brackets, balconies, and staircases; in almost every suburb there are gates and brackets. The precincts of the colleges of Oxford and Cambridge, as well as almost every old town in England, furnish a variety of handsome work. Throughout the 18th century the smith was a busy man; the general tendency of his work, unaffected by the Rococo movement on the Continent, was toward a less ornate but more characteristically English style—perpendicular, severe, lofty, and commanding, as contrasted with Tijou's French love of richness and mass of details.

At the end of the 18th century the work of the architect brothers Adam shows a departure from true smithing; its slender delicate bars are enriched with rosettes, anthemias, and other ornament in brass or lead. The effect is pleasing and harmonizes with the architecture with which it is incorporated.

During the first half of the 19th century, the art of the smith was largely eclipsed by that of the iron caster. But under the stimulus of the Victorian Gothic revival and later of the Art Nouveau movement, there was a renewal of interest in the decorative use of wrought iron, and much excellent work was produced.

**France.** Medieval door-hinge ornaments were not basically different from those in England; and beautiful work is found on church doors, especially in central and northern France. It reaches a height of greater elaboration and magnificence than in England, the culminating example being the west doors of Notre Dame, Paris, the ironwork of which is so wonderful that it was attributed to superhuman workmanship. Grilles at Troyes and Rouen also reveal a high standard of excellence. Working the iron cold and employing methods associated with carpentry was immensely popular; it was applied to small objects such as door handles, knockers, and above all to locks, which exhibit an amazing amount of detail and a remarkable delicacy of finish.

The Gothic tradition survived in France until well into the 16th century and was marked by the production of work of the highest skill, largely in the form of locks, knockers, and caskets of chiselled iron. The introduction of the Renaissance style did not radically alter the direction of the smith's art—a strange fact when it is remembered that Germany and Spain were fabricating works of enormous size and magnificence in wrought iron. France, like England at that time, was content to make door furniture, in the form of locks, keys, bolts, escutcheons, and the like, but did little ironwork of any great size. A school of locksmiths came into being under Francis I and Henry II, working from designs by Androuet du Cerceau in the 16th century and those by Mathurin Jousse and Antoine Jacquard in the 17th. The bows (a loop forming the handle) and wards (notches) of keys were of unusually intricate design and the locks of corresponding richness. Representative pieces may be seen at the Victoria and Albert Museum. Among them is the famous Strozzi key, said to have been made for the apartments of Henry III, the bow of which takes the favoured form of two grotesque figures back to back. But as far as architectural ironwork was concerned, France remained almost at a standstill until the accession of Louis XIII in 1610. Under that monarch, a worker at the forge himself, came a great revival, which, by the end of the 17th century, had attained a marvellous pitch of perfection. It proved to be the beginning of a new movement, the force of which made itself felt in the adjoining countries and inspired ironworkers with new energy. From the accession of Louis XIV, the French ironworkers must be acknowl-

in the  
reign of  
Louis XIV

edged as the cleverest in Europe, combining as they did good and fitting design with masterly execution. Their designs were often very daring, exploiting all the latent and previously unexplored possibilities of iron. They recognized its great adaptability and took every advantage of it, at the same time being conscious of its limitations. Their forms of expression were endless.

Screens and gates were needed for parks, gardens, and avenues, staircases for mansions and palaces, screens for churches and cathedrals. Among celebrated designers were Jean Lepautre, Daniel Marot, and Jean Berain. Earlier work had been of a simple character—balconies, for instance, being in the form of a succession of balusters—but as the smith became more versatile and imaginative, they took the form of panels of flowing curved scrolls, rendered with a freedom never attained before, while constructive strength was observed and symmetry maintained. Enrichments were usually attached in hammered sheet iron. These may be considered the distinguishing features of Louis XIV work, such as that at St. Cloud, Chantilly, Fontainebleau, and elsewhere. But under Louis XIV all previous efforts were surpassed in the work for his palace at Versailles.

Rococo  
design

The art of ironwork received a further impetus by the introduction of the Rococo style. The movement, initiated in 1723, was due principally to the imagination of two artists, Just-Aurèle Meissonier, architect, and Gilles-Marie Oppenordt. There was a balanced asymmetry in the design and fantastic curves with a luxury of applied ornamentation. To the French smith it furnished the opportunity for a yet greater display of his skill. He was clever enough to secure a feeling of stability in his work by counterbalancing swirling masses of ornament with straight constructional lines; he knew how to introduce an iron screen of Rococo style into a Gothic church or cathedral without giving offense to the eye or arousing any uncomfortable feeling of incongruity.

Later in the 18th century, ironwork took on a more classical appearance as a result of the general revival of interest in ancient art; and many Greek and Roman details were introduced into the ornamentation. The amount of work executed was prodigious, and its beauty and craftsmanship may be seen in most cities of France. Nearly all of the adjacent countries, with the exception of England, were seized with the desire to imitate the French Rococo style.

**Germany.** In the Romanesque period in Germany, bronze was preferred to iron; the earliest examples of ironwork are thus later than those of France and England. The first iron grilles were imitations of French work, with C-scrolls filling spaces between vertical bars. Typical examples of door hinges prior to the 14th century were those at Kaisheim, St. Magnus Church, Brunswick, and St. Elizabeth's Church, Marburg (the latter having a curious cross in the middle). Throughout the Gothic period in Germany, the imitation of natural foliage was the basis of design.

German  
door  
hinges

There were no new marked developments in ironwork during the 14th century. Smiths confined their efforts mostly to hinges. Until this period the vine had been the only motif for elaborate hinges; but flat, lozenge-shaped leaves were introduced, such as those at Schloss Lahneck on the Rhine.

During the 15th century, grilles became more popular. One of the best examples is the grille in the Monument of Bishop Ernst of Bavaria, Magdeburg cathedral (c. 1495), with elaborate Gothic tracery, nine columns, and a cornice. In hinges the cinquefoil displaced the quatrefoil, as at Orb, Oppenheim, and Magdeburg. The Erfurt cathedral was enriched with notable hinges having the vine pattern interpolated with rosettes and escutcheons of arms. Hinges for houses usually were the plain strap type, but when ornamented they consisted of superimposed layers of sheet iron. As in other parts of Europe at this time, pierced sheet iron was fashioned into tracery of a semi-architectural nature, much like Gothic windows. Pierced ornament and twisted rods were often combined to form grilles, with their extremities beaten into complicated foliage forms.

During the Renaissance, ironwork in Germany was in use everywhere and for every purpose: for screens in churches, window grilles, stove guards, gates, fountain railings, well heads, grave crosses, door knockers, handles, locks, iron signs, and small objects for domestic use. Smiths were their own designers and more often than not planned intricate devices merely to show their skill in executing them. They set no limits to their problems; and so far as manipulative excellence went, the German smiths were the foremost in Europe. But clever as their workmanship undoubtedly was, their designs frequently showed a lack of stability and a tendency to run riot. Thus, many of their most imposing works consist largely of filling panels with elaborate, interlacing scrollwork, and the sense of constructional and protective strength is missing.

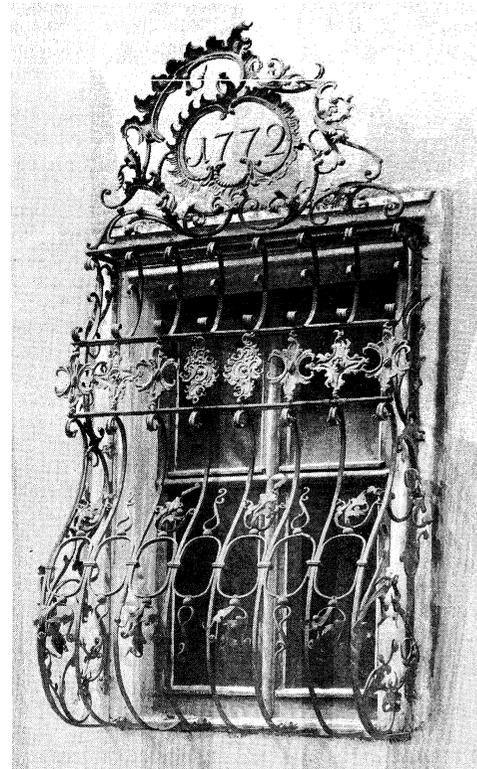

An abundance of smiths' work is to be found in the southern parts of Germany. Iron bars, circular in section, were most frequently used; and the most common features are interlacing bars and terminations of flowers with petals and twisted centres, foliage, or human heads. All of these characteristics occur with almost monotonous repetition, witnessing to skill but also to lack of imagination and sense of design. The style may be studied in many German and Austrian cities, such as Augsburg, Nürnberg, Frankfurt, Salzburg, Munich, and Innsbruck.

Southern  
German  
work

The German smith gave much attention to door knockers and handles, enclosing them in pierced and embossed escutcheons, and devised locks with very involved mechanism. German influence made itself strongly felt in Switzerland, Austria, and Czechoslovakia.

The Baroque and Rococo periods are distinguished by a perfection of detail that exceeded that of German Medieval or Renaissance ironwork. Smiths used wrought iron as though it were a plastic material, meant to be em-

Bildarchiv Foto Marburg

Rococo style wrought-iron window grille from a house on Winklerstrasse, Nürnberg, 1772.

ployed in extravagant forms wherever possible. Some examples are at Zwiefalten, Weingarten, and Klosterneuburg. In the late 18th and early 19th centuries, cast ironwork of outstanding quality was produced in Germany, notably at the Prussian royal foundry established in 1804.

**Italy.** The few extant examples of ironwork in Italy prior to the 14th century indicate a wide appreciation of

Italian  
ironwork  
before  
the 16th-  
century

how the material could best be worked with only the tools of the smith. Some noteworthy examples are the chancel grille at the left of the nave, Orvieto Cathedral (1337); the grille around the Scaligeri tombs of Verona (c. 1340); the grille at the baptistery of Prato cathedral (1348); the chancel screen in the sacristy chapel of Sta. Croce, Florence (1371); and the grille to the Capella degli Spagnoli, Sta. Maria Novello, Florence.

Until the 16th century, Italian smiths respected the natural characteristics of wrought iron by relying almost entirely upon those forms that could be wrought with hammer and anvil. The grille was usually made by dividing it into regular panels with vertical and horizontal bars (sometimes triangular in section and enriched with dentils, or small, projecting triangular blocks). Often the quatrefoil filled some or all of these panels; they were made in Tuscany from a pierced plate and in Venice from separate scrolls collared together. A noted example is in the Palazzo della Signoria, Siena, crowned by a repoussé frieze and surmounted by a cresting of flowers, spikes, and some animal heads.

It might have been thought that in the fountainhead of the Renaissance, ironwork would have proceeded at the same pace and with the same brilliant success as architecture, sculpture, bronze casting, and the other arts. Strangely enough, little use of it is found in connection with the fine buildings of the revival. Bronze was favoured; and what in other countries is found in iron has its counterpart in Italy in bronze. As time went on the smiths grew less inclined toward the more difficult processes of hammering and welding and contented themselves ultimately with thin ribbon iron, the various parts of which were fastened together by collars. Work of the later periods may be distinguished, apart from the design, by this feature, whereas the English and French smiths vigorously faced the hardest methods of work, and the German and Spanish smiths invented difficulties for the sheer pleasure of overcoming them.

Notable centres of artistic ironwork were Florence, Siena, Vicenza, Venice, Lucca, and Rome, where important pieces may be found in the form of gates, balconies, screens, fanlights (semicircular windows with radiating sash bars like the ribs of a fan), well covers, and a mass of objects for domestic use, such as bowl stands, brackets, and candlesticks.

Screen-  
work

In screenwork the favourite motif was the quatrefoil, which has been found with many variations ever since the 14th century. Early examples are strong and virile, but later ones tend to weakness. The C-shaped scroll is also used in many combinations. The churches and palaces of Venice contain many examples of these popular designs. Peculiar to Italy are the lanterns and banner holders such as may still be seen at Florence, Siena, and elsewhere, and the rare gondola prows of Venice. Of the ironworkers of the early Renaissance, the most famous was the late-15th-century craftsman Niccolo Grosso of Florence, nicknamed "Il Caparra" because he gave no credit but insisted on money on account. From his hand is the well-known lantern on the Palazzo Strozzi in Florence, repeated with variations elsewhere in the same city. Siena has lanterns and banner holders attached to the facades of its palaces, and lanterns are still to be seen at Lucca and a few other towns.

The decadence of 17th- and 18th-century ironwork paralleled that of architecture. Designs were borrowed directly from France and Germany. The metal was too often worked cold, using thin members; and the resulting construction was flimsy. Scrolls were often encased in thin, grasslike leaves. Conventional or naturalistic flowers were tacked on as seeming afterthoughts. Instead of using rods and bars, ribbonlike bands were used, with cast ornaments pinned on. Intersecting tracery was copied from Germany. The best examples of this period are confined to Venice and northern Italy, such as the screen in the south aisle chapel of S. Ambrogio, Milan; the chapel enclosure in S. Pietro, Mantua; and the screen in the Palazzo Capodilista, Padua.

**Spain.** Prior to the 15th century, Spanish ironwork was basically similar to that in France and England. The

Spanish smith accepted the limitations imposed by anvil and ancillary tools; but he skillfully exploited to the limit all manner of variations—twisting square rods, coiling flat bars into C-shaped scrolls of all sizes, and devising imaginative crestings to surmount the top of church chapel screens or domestic window grilles. Many Moorish craftsmen of extraordinary ability were enticed to remain in Spain as the Moors were slowly pushed southward; the resultant blending of Gothic with Moorish resulted in the Mudejar style.

Ironwork of the Renaissance period from about 1450 to 1525 reached a height of grandeur and magnificence attained in no other country. Of all the Spanish craftsmen the smiths were the busiest, especially during the 16th century. The ironwork products that for more than a century dominated the craft are the monumental screens (*rejas*) found in all the great cathedrals of Spain. These immense structures, rising 25 to 30 feet (7.5 to nine metres) show several horizontal bands, or tiers, of balusters, sometimes divided vertically by columns of hammered work and horizontally by friezes of hammered arabesque ornament. Usually such screens are surmounted by a cresting, which is sometimes of simple ornament but more often a very elaborate design into which are introduced a large number of human figures. Shields of arms are freely incorporated; and the use of bright colour, silvering, and gilding adds to their impressive beauty. The great balusters were always forged from the solid, and their presence in hundreds demonstrates the extraordinary skill and power of the Spanish smith. In many cathedrals two of these monumental *rejas* are found facing one another. There is at least one in every large cathedral—Barcelona, Saragossa, Toledo, Seville, Burgos, Granada, Córdoba, and many others.

Ironwork on a smaller scale is found in gates, balconies, and window screens; wrought-iron pulpits also exist. Panels of hammered and pierced iron, heightened with colours and gilding, were used in connection with domestic architecture; and many doors were ornamented with elaborate nailheads or embossed studs.

(W.W.W./G.K.Ge.)

**United States.** *Early history.* The characteristics of the earliest ironwork in the various colonies naturally reflected those of the parent countries. The English were more sparing in its use in the New England Colonies than were the Germans in Pennsylvania or the French in Louisiana. In the 17th and 18th centuries ironwork was used mostly for such practical purposes as weather vanes, foot scrapers, strap hinges, latches, locks, and particularly for the necessities and conveniences for fireplaces (firedogs, cranes, skewers, toasters, kettle warmers, and spits). It was not until the late 18th century, when the threat of Indian raids and food shortages had waned and the established communities enjoyed a sense of tranquillity and prosperity, that smiths fashioned wrought iron into railings, fences, grilles, gates, and balconies. Square or flat iron bars were generally used to produce designs that were usually light, airy, and graceful and rather in contrast to the contemporary European preference for sturdier forms.

Gradually, ironwork designs tended to develop characteristics of an American or composite nature, as a logical consequence of the diverse origins of colonists and smiths. An innovation that appeared toward the end of the 18th century was the combination of structural wrought-iron rods or bars with lead or cast-iron ornamental features. While the use of wrought iron declined in the 19th century, during its last quarter the use of cast-iron columns and panels for nonresidential buildings increased. These designs, timid or bold, decorative or structural, engendered the prototypes of commercial buildings for the ensuing decades.

Because the life of structures in U.S. cities has been short, there are few examples of 18th- or early 19th-century ironwork extant in New York City, not many more in Boston, some in Philadelphia, but more in and near Washington, D.C., such as the excellent balconies and railings at the Octagon (headquarters of the American Institute of Architects). Charleston, South Carolina, has

New  
Orleans  
ironwork

a rich legacy in gates, notably those at numbers 12, 23, and 36 Legare Street, 63 Meeting Street, and an unusually beautiful pair at St. Michael's Church.

New Orleans has more ironwork than other U.S. cities, thanks to a group of citizens dedicated to the preservation of the old French Quarter. Its earliest ironwork was forged by Spanish and French smiths. Unfortunately, fires, rust, and remodelling have so taken their toll of the Spanish ironwork that almost the only remaining example of importance is the gateway of the Cabildo (town hall). It has moldings beaten from solid bars, like many of the old *rejas* in Spanish cathedrals. After the Louisiana Purchase in 1803, the influx of ironworkers from northern states brought about a broadening of influences that is apparent in designs and techniques. Ironwork of New Orleans can be roughly divided into three periods: (1) forged wrought iron by French and Spanish artisans with strongly marked European characteristics; (2) a transitional period with wrought-iron structural members embellished with cast-iron ornaments in the Directoire and Empire styles of France, plus some U.S. innovations; and (3) entire grilles, screens, and trellises made entirely of cast iron. No other city in the U.S. has two- and even three-story iron porches and balconies that can compare with those of New Orleans. Some of these lacy structures,

Wrought- and cast-iron balconies along St. Peter Street, in the Vieux Carré, New Orleans, c. 1838-40.

such as those on St. Peter Street, were built above the sidewalks. Balconies sometimes not only extended across an entire facade but continued around a corner.

**Mid-19th century onward.** Distinctive national characteristics in the design of ironwork gradually tended to disappear in Europe because of increased travel and communications between countries. The influence of French Renaissance architecture (modified or revived) continued to exert a viable effect where the acceptance of the Art Nouveau (last quarter of the 19th century) was flaccid or denied. In England, however, 18th-century designs continued with slight modifications. In the U.S. probably the most important force, prior to World War I, was exercised by architects trained in Paris, with the result that ironwork designs were similar to French work of this period.

The increased mechanization of all forms of manufacture understandably affected the character and use of ironwork. As the cost of cast iron came down, its use increased. Because wrought iron is produced by hand by beating red-hot iron on an anvil, not much change was possible through increased mechanization, whereas the casting of molten iron lent itself to improved equipment and techniques. The lowered cost of duplicating ornamental cast-iron components and the introduction of structural steel parts expanded the usage of ironwork to the modest building, whereas it had been generally confined to public or monumental structures. Foundries in the U.S. established a flourishing business in pierced cast-iron panels, modelled after Louisiana porch trellises.

Compared with prior periods, the last half of the 19th century will scarcely be commemorated as introducing enduring or beautiful ironwork forms. It was not until the first quarter of the 20th century that a master craftsman-designer gave impetus to a new conception of design forms and textures. Edgar Brandt of Paris broadened the scope of decorative usage by the rich inventiveness of his compositions and by an entirely original approach that resulted in a wrought-iron texture that is akin to beaten silver. Examples of his work at the Exposition des Arts Décoratifs Modernes at Paris in 1925 had an immediate effect upon ironwork designed and executed in the U.S. during the great building boom that lasted until about 1930. During this period, both wrought and cast iron enjoyed an unprecedented period of popularity not only in the form of bank screens, entrance doors, and grilles in public buildings but as decorative grilles and gates in private homes. In many cases the craftsmanship equalled that of representative examples of the Gothic or Renaissance periods in Europe.

One of the most gifted and dedicated iron craftsmen in the U.S., Samuel Yellin of Philadelphia, raised the standards of wrought-iron craftsmanship to its apex during the 1920s. He not only trained an atelier of craftsmen for the first time in the U.S., but by his efforts wrought iron was recognized as capable of enriching even the most monumental building. Yellin's influence, however, was ended by the Depression of the early 1930s. As building activity declined after 1930, so did the use of ironwork; and it did not increase with the revival of building after World War II. (G.K.Ge.)

LEAD

Lead has two main uses in which some artistic purpose may be served: in architecture, as a material for roof coverings, gutters, piping, and cisterns; and in decorative art, as a material for sculpture and applied ornament. As an architectural material it has the advantage of being easily worked and yet offers great resistance to climatic conditions. The low melting point of lead and its relative freedom from contraction when solidifying make it particularly suitable for casting, and it has been used as a substitute for bronze or precious metals.

**Antiquity.** The earliest known lead sculptures are small votive figures found at Troy and Mycenae. In the Hellenistic period lead sarcophagi were known, and the Romans made much use of the metal. Large amounts of worked lead in various forms have been found in those parts of England where the Romans had permanent settlements.

**Middle Ages.** England was one of the main lead-producing areas in the Middle Ages, and lead was more widely employed there than on the continent of Europe. In the 12th century the German monk Theophilus, in his treatise on metalworking, refers to lead only in connection with casting rods for stained-glass windows and as a material through which silver sheets might be hammered; but in England at about the same time a remarkable series of lead fonts was cast, of which 16 still survive in position, the most famous being those at Walton-on-the-Hill, Surrey, and at Wareham and Dorchester in Dorset. Lead was also used in the Middle Ages for church roofing; and it was used, doubtless because of its cheapness, for the small badges or medallions sold to pilgrims at the great medieval shrines. Lead could even be useful, in the

Effects of  
increased  
mecha-  
nization

Earliest  
known  
lead  
sculp-  
tures

proper disguise, to simulate rich ecclesiastical objects, for not all religious institutions were wealthy: a group of 14th-century caskets covered with lead tracery, gilded to look like precious metal, have survived in church treasuries. These were used as reliquaries, but some were originally made for secular purposes.

**Renaissance to modern.** The Renaissance passion for collecting bronze medals and plaquettes led to a demand for cheap replicas, and these were made with great precision in lead. The metal also played an important role in the goldsmiths' trade. The fashion for elaborate relief ornament of the Renaissance and Mannerist periods called for a degree of skill in modelling that was beyond the powers of the average goldsmith. The practice therefore grew up for the pattern makers of Augsburg and Nürnberg, Germany, to sell lead models of ornamental details and figures from which goldsmiths working elsewhere could in turn make molds. An extensive collection of these models is preserved in the Historisches Museum, Basel, Switzerland. The trade expanded to include large medallions and plaquettes, the chief masters of which were the German goldsmiths Peter Flötner, Jonas Silber, and the Master H.G. (Hans Jamnitzer) and the Dutch goldsmith family of van Vianen. Lead in sculpture is more suitable for the production of small figures than life-size statues, which, if unsupported, become distorted through their own weight. Among the few life-size equestrian lead statues is one of Frederick Louis, prince of Wales, in the grounds of Hartwell House, Buckinghamshire, England. From the 16th century, lead appeared in England in the form of gutters and pipe heads (which carried rainwater down from the gutters), often with cast ornament. Some of the late-17th- and early-18th-century pipe heads, cast with the arms of the owner of the house and the date of erection, are important decorative features.

A great extension of the use of lead took place with the introduction of lead garden sculpture—figures, vases, and urns—in the late 17th century. An outstanding example of this work is a pair of garden vases 15 feet (4.5 metres) high at Schloss Scheissheim in Bavaria. The silvery gray colour of such sculpture and its resistance to the weather made it particularly suitable for use in the many formal gardens that were created at this time. English garden sculpture rarely achieves any particular aesthetic status; but in 18th-century Germany and Austria lead was used for more serious sculpture by a group of artists of the highest standing. In the 19th century, lead was out of favour with sculptors, partly because improved transport made it possible to bring marble from Italy at low cost. Its soft colouring and the fact that it does not reflect light give it advantages, however, and it has been used in the 20th century by Aristide Maillol and by Sir Jacob Epstein, who executed the lead figure of the Virgin and Child in Cavendish Square, London. (J.F.Ha.)

### III. Non-Western metalwork

#### SOUTH ASIA

**Iron.** The manufacture of iron by primitive small-scale methods has survived in southern India and Ceylon to the present day. The slag heaps of ancient furnaces are common, and the processes have probably been in use for more than 2,000 years; but it is unknown whether they are of indigenous invention or acquired. In southern India iron immediately succeeded stone as a material for tools and weapons, and prehistoric iron weapons began to come into use about 500 bc. The wrought-iron pillar of Delhi, set up about AD 400 by Kumāra Gupta I in honour of his father, is over 23 feet (seven metres) in height and weighs more than six tons. It demonstrates the abilities of Indian metalworkers in handling large masses of material, for not until the latter part of the 19th century could anything of the same kind have been made in Europe. There are other large iron pillars at Dhār and at Mt. Abu. (A.K.Co.)

**Gold and silver.** In India, gold jewelry has been found from the Indus culture. Excavations at Takshasila (Taxila) have revealed gold and silver drinking vessels and jewelry of Hellenistic types dating back to about the 1st

century AD. From the same time is the important Buddhist gold reliquary from Bimaran, Afghanistan, set in rubies and decorated with embossed figures in Gandhāra style (British Museum).

During the Gupta period (AD 320–647), vessels of Hellenistic and Persian shapes were evidently made, for they are represented in the sculpture and frescoes of the period. More Indian in style are a silver dish of the 3rd or 4th

Indian style embossed and chased silver dish showing a yaksha drinking, Kushan, found at Buddaghara, near Tank, Dera Ismāil Khān district, Pakistan, 3rd or 4th century AD, Gupta period. In the British Museum. Diameter 25.15 cm.

By courtesy of the trustees of the British Museum

century, decorated with a Bacchanalian scene of a yaksha drinking, and a silver bowl of the 7th century from northern India, which is embellished with medallions in low relief (both in the British Museum). Jewelry played a very important role, and, although no original pieces have survived, it can be studied in frescoes at Ajanta and on contemporary sculptures.

In spite of the fact that gold and silver vessels have been common in India since classical times, there is very little material extant before the 17th century, when all kinds of vessels were produced in bronze, brass, copper, and, for the royal houses, in silver. Shapes and decorations vary in different regions. Delhi was famous for its craftsmen, especially in the time of Akbar in the 16th century and Jahāngīr and Shāh Jahān in the 17th. Much work was done in precious metal, and vessels and ornaments of jade were inlaid with gold and gems. Northern India is famous for its enamels. Enamellers from Lahore were brought to Jaipur in the 16th century by Mān Singh, and enamel was employed extensively in combination with goldwork and silverwork in the 17th and 18th centuries there and elsewhere. The Punjab, Lucknow, and the districts of Chānda and Cutch in Gujarāt state were long celebrated for their metalworkers. In the south, silverwork in *svamin*-style is characterized by religious-figure scenes in relief, executed in three different techniques. Craftsmen in Tirupati put silver sheet on copper; Madras, Bangalore, and Tiruchirappalli are known for hammered vessels with traced decoration; and Thanjavūr (Tanjore) produced a more Baroque effect with inlays of silver in copper. From the former Travancore state, Mysore, and Bijaipur in the southwest come chased vessels with floral patterns, the lotus predominating. In the north the Hindu style is well represented by works from Vārānasi (Benares).

Persian-Islāmic influence is found in several vessel shapes; for example, ewers and basins for water and smoking furniture, such as hookas, which also have Islāmic patterns. Jewelry from the later periods employs precious stones, pearls, gold, and silver in great variety. The old types are repeated, with symmetrical arrangements of rosettes and leaves for bracelets, necklaces, pendants, rings, and foot ornaments. Very fine work in silver filigree was executed at Cuttack in Orissa and was used on jewelry and various larger items. (B.V.Gy.)

## CENTRAL AND SOUTHEAST ASIA:

## NEPAL, TIBET, BURMA, THAILAND, VIETNAM

Indian styles and techniques spread to the neighbouring countries. In Nepal precious metals were used in architecture; pagodas, temples, and palaces sometimes had facades richly decorated with ornaments embossed in gilt copper with settings of precious stones.

In Tibet copper and brass were usually used for vessels, but these metals were often decorated with applied silver or gold ornaments; and in eastern Tibet, especially, teapots were made of silver with gilt appliqué. While many of the ornaments are Chinese, Buddhist shapes and patterns of Indian origin were used for ritual vessels. Other ritual objects were sometimes made of silver or, more rarely, of gold, though bronze is again the common material. Silver is used for amulets and jewelry with rich settings of turquoises, carnelian, and lapis lazuli.

In Thailand, Buddhist vessels were made out of chased silver, very often in the shape of a lotus flower whose petals are decorated with other, embossed, floral and figure motifs.

Burmese  
gold and  
silver  
vessels

Burma is known for its chased silver vessels heavily decorated with figures and floral patterns in relief, related to the south Indian *svamin* work. The use of gold and silver vessels for domestic purposes was denied to all but those of royal blood. Good examples of earlier golden regalia are in the Victoria and Albert Museum.

In Vietnam, goldwork and silverwork of the Cham culture are preserved from the 10th century. It is exemplified by a crown and heavy jewelry made for a life-size statue found in the ruin of a temple at Mison. From later times there is a royal treasure with four crowns, various amulets, arm rings, and table services of gold, richly decorated with embossing and openwork. (B.V.Gy.)

## EAST ASIA

**China.** *Bronze.* Bronzes have been cast in China for about 3,700 years. Most bronzes of about 1500–300 BC, roughly the Bronze Age in China, may be described as ritual vessels intended for the worship of ancestors, who are often named in inscriptions on the bronzes. Many were specially cast to commemorate important events in the lives of their possessors. The vessels were also meant to serve as heirlooms, and the inscriptions often end with the admonishment "Let sons and grandsons for a myriad years cherish and use." These ritual vessels of ancient China include some of the loveliest objects ever made by man, and as a group they represent possibly the most remarkable achievement in the whole history of metalcraft before modern times. Since the vessels can be considered sculpture, they are discussed in VISUAL ARTS, EAST ASIAN.

Among other ritual bronzes, bells constitute an important group. Perhaps the oldest class is a small clappered bell called *ling*, but the best known is certainly the suspended, clapperless bell, *chung*. *Chung* were cast in sets of eight or more, to form a musical scale, and were probably played in the company of string and wind instruments. The section is a flattened ellipse, and on each side of the body appear 18 blunt spikes, or bosses, arranged in three double rows of three. These often show marks of filing, and it has been suggested that they were devices whereby the bell could be tuned to the requisite pitch by removing small quantities of the metal. The oldest specimen recovered in a closed excavation is one from P'u-tu Ts'un, dating from the 9th century BC.

Secular  
bronzes

Vast numbers of secular bronzes were cast. These include weapons, such as the *chih* and *ko* dagger axes and the short sword; chariot and harness fittings; trigger mechanisms for bows; weights, scales, and measures; belt hooks; and mirrors. The last appear in great numbers from the 5th century BC onward. They are flat disks, with a central perforated boss by which they could be mounted on a stand. Their backs are covered with a maze of intricate relief designs and feature a diversified series of well-defined subjects. (W.Y.W.)

*Iron.* Iron began to take its place in the brilliant Bronze Age culture of China during the Ch'in dynasty (221–206 BC) and the Han dynasty (206 BC–AD 220). By

Chinese mirror back, bronze with lacquer, T'ang dynasty (AD 618–907). In the Museum of Fine Arts, Boston. Diameter 21 cm.

the end of the 2nd century AD, bronze weapons had been almost completely supplanted, and iron had been generally substituted for bronze in common use in utensils and vessels of various kinds, tools, chariot fittings, and even small pieces of sculpture. These were commonly cast in sand molds, were patterned after bronze prototypes, and were typical of the Han period in style and decoration.

From the 9th century, iron increasingly took the place of bronze in China as a material for sculpture, especially in the north and under the Sung dynasty. The few extant examples from the 11th century and later show work done on a larger scale and in coarser technique than the bronzes, though the modelling is usually more naturalistic.

Several iron pagodas, dating from the 10th to the 14th century and ranging in size from miniature models to towers 100 feet or more in height, give further evidence of the dexterity of the Chinese iron caster. The pagodas imitate, in detail, both the structural and decorative effects of the more common tile-roofed brick pagodas. Iron for temple furniture has long been in use, and a large number of the braziers, censers, caldrons, and bells found today in the temples are of iron.

In China in the 17th century the iron picture was developed, the craftsmen seeking to reproduce in permanent form through the medium of wrought iron the effects of the popular ink sketches of the master painters. When completed, these pictorial compositions were mounted in windows, in lanterns, or in frames as pictures. When in the latter form, a paper or silk background often bore the signature and seal of the maker, heightening the resemblance to a painting. The craft flourished in Anhwei Province and is still practiced, though with less patience and fineness than formerly. (B.Ma.)

Iron  
pictures

*Gold and silver.* In ancient China gold and silver were rare. Gold was used as an inlay for bronzes in the Chou dynasty (1122–221 BC), and between the 6th and the 2nd centuries, gilding and silvering were common. Dress hooks and small items of jewelry were sometimes cast in gold and silver and imitated the more usual bronze forms. Granular work—a technique that probably has an Indian origin—was used for jewelry.

Silverwork first became important during the T'ang dynasty (AD 618–907), when the Chinese had learned from the Sāsānid Persians how to chase the silver. In the beginning, they followed their teachers very closely in the forms of the bowls and larger vessels as well as in the patterns. T'ang drinking vessels, ewers, trays, and lobed oval dishes on a stem are Persian shapes transformed by Chinese taste. Among the patterns are vine and palmette scrolls of great variety, hunting scenes, and landscapes of symmetrical flowers and trees with birds and animals; all of these have parallels in Persian silver and textiles but are more delicate in their Chinese version. The techniques used by the Sāsānid silversmiths were adopted by the Chinese; for example, double sheets for a bowl and

tracing of the patterns on ring-matted ground. T'ang jewelry is made of gold or gilt silver.

During the Sung dynasty (960–1279), silverwork declined in technical quality but jewelry played a more dominant role. Hair ornaments became increasingly intricate, with elaborate naturalistic flowers and various auspicious symbols.

Revival of silverwork in the Yüan and Ming periods

During the Yüan (1279–1368) and Ming (1368–1644) periods, skill in silverwork revived, and once again the smiths followed many Near Eastern styles. Drinking vessels (ewers and cups), boxes, and even large ceremonial gold vessels have been found in Ming tombs. During the excavation of the tomb of Emperor Wan-li (1573–1620), a series of gold vessels set with precious stones was found. All of the gold items are decorated with incised patterns of dragons, phoenixes, and similar subjects.

During the Ch'ing period (1644–1911), both silver and gold were used lavishly, and gold filigree work especially is common in the 18th century. Most of the forms and ornaments employed, however, are borrowed from lacquer and porcelain ware; and only jewelry has its own style, rich combinations of kingfisher feathers glued to the metal.

**Korea.** The Chinese colonists who settled Korea during the Han empire (206 BC–AD 220) first brought goldsmiths and silversmiths to Korea. By the 5th to 6th century AD Korean work, as exemplified by large gold crowns and various pieces of jewelry excavated from tombs at Kyōngju, was beginning to develop distinctive characteristics. At the time of the Unified Silla (668–635) and Koryō (935–1392) kingdoms, Chinese influence was strong, but the Korean style persisted in silverwork and goldwork. Several vessels with floral patterns in relief are preserved from these periods. (B.V.Gy.)

**Japan. Iron.** The Iron Age in Japan is supposed to have begun in the 2nd century BC, though the chief early remains are weapons from the dolmens of the 2nd to the 8th century AD. The Japanese iron founder attained a considerable skill at an early date and acquired a social position never attained by the bronze caster or by the ironworkers in China, where the Bronze Age tradition was much stronger. It is apparent that iron was used in China chiefly as a substitute or imitative medium, worked often with great skill but with little artistic invention. In Japan, however, the ironworker developed a distinctive and original means of expression and high artistic attainment in accessories for the sword. With the rise of feudalism and the establishment of the samurai class after the wars of the 12th century, the equipment of the warriors became an object for the efforts of the artist.

At first these efforts were devoted to the embellishment of defensive armour, but from the 15th century the sword became the centre of attention. The blade is not properly part of the subject of this article; but in the mountings, especially the guards (*tsuba*), is found exquisite artistry expressed chiefly in iron. A remarkably soft and pure variety of the metal especially free from sulfur was employed. It was worked by casting, hammering, and chiselling; and innumerable surface effects were obtained by tooling, inlaying, incrustation, combination with other metals, and patination by various, usually secret, processes. Simple conventional patterns, crests, and pictorial designs were the bases for the decoration. As these were often furnished by painters or designers, the criterion of connoisseurship in Japan is the unsurpassed technical quality of the handling of the iron itself. With the promulgation of the edict of 1876, prohibiting the wearing of swords, this art came to an end, but the skill of the Japanese ironworker may still be noted in numerous small decorative objects. (B.Ma.)

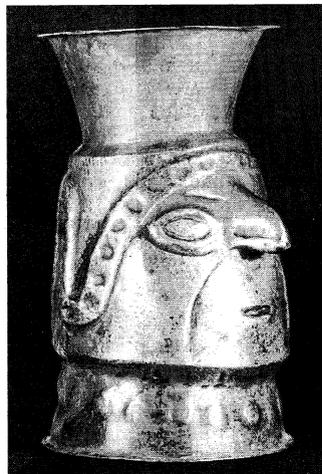

**Gold and silver.** Knowledge of metalwork seems to have spread to Japan by way of Korea during the Yayoi period (c. 250 BC–c. AD 250), but gold and silver never played any important role there. In the Nara period (AD 710–784), the Chinese T'ang style was dominant, and most of the goldwork and silverwork preserved in the Shōsōin at Nara was made under Chinese influence or by Chinese workmen. Silver vessels were used extensively among the aristocracy in the Heian period (794–1185),

though not many of these vessels have survived, and both gold and silver were often used for applied reliefs or as inlay on bronze. In the later periods the use of precious metals was practically confined to inlays in bronze or iron, and the highest technical skill is shown by the artists who made the sword fittings. (B.V.Gy.)

#### AMERICAN INDIAN PEOPLES

**Pre-Columbian.** In pre-Columbian America, gold, silver, and copper were the principal metals worked, with tin, lead, and platinum used less frequently. When the Spaniards arrived in the New World in the 16th century, they found a wide range of well-developed technical skills in fine metalwork in Mexico, Costa Rica, Panama, and the Andean region. They could offer little to the Indian smiths, who had already mastered cold hammering and annealing; embossed decoration and chasing; pressing sheet gold over or into carved molds to make a series of identical forms; sheathing wood, bone, resin, and shell ornaments with gold foil; decorating with metal inlays and incrustation with jade, rock crystal, turquoise, and other stones; joining by clinching, stapling, and soldering; possibly drawing gold wire (in Ecuador and western Mexico); casting by the lost-wax method of solid and hollow ornaments, often with false filigree or false granulation decoration; wash gilding; and colouring alloys containing gold by "pickling" in plant acids. There was some regional specialization: hammer work in "raising" a vessel from a flat disk of sheet gold or silver reached

D.T. Easby, Jr.

its apogee in Peru, and lost-wax casting was highly developed in Colombia, Panama, Costa Rica, and Mexico. Miniature, hollow lost-wax castings of the Mixtec goldsmiths in Mexico have never been surpassed in delicacy, realism, and precision; and some solid-cast frogs from Panama are so tiny and fine that they must be viewed through a magnifying glass to be appreciated. In Mexico bimetallic objects of gold and silver were made by two-stage casting; the gold part was cast first and the silver, which has a lower melting point, was then "cast on" to the gold in a separate operation. (A famous example is the pectoral of Teotitlán del Camino in the National Museum in Mexico City.) A silver llama in the American Museum of Natural History in New York indicates that the Peruvian smiths had taken the first step toward cloisonné, the cloisons being filled with cinnabar instead of enamel.

A truly great technological and artistic triumph of the pre-Hispanic workers in Ecuador was the making of complex beads of microscopic fineness from an alloy of gold and platinum, achieved by sintering (to combine by alternately hammering and heating without melting) gold dust and small grains of alluvial platinum. (Platinum was not used in Europe until 500 or 600 years later.)

Metalwork skills of pre-Columbian Indians

Social standing of pre-Hispanic goldsmiths

As in other early cultures, the pre-Hispanic goldsmiths were a privileged and highly respected group, sometimes having their own patron deity such as Xipe Totec in Mexico or Chibchachun in Colombia. In Peru just before and at the time of the Conquest, the goldsmith (*kori-camayoc*) is said to have been a full-time government worker, supported by the state and producing exclusively for the Inca. According to early Mexican picture writings (codices) and accounts of the Spanish chroniclers, the craft was hereditary, the secrets passed on from father to son.

The earliest examples of metalwork in the New World come from the "Old Copper" culture that flourished in the upper Great Lakes region of North America beginning about 4000 BC and continuing over the course of the next 2,000 years. The earliest goldwork is considerably later and consists of sheet-gold adornments with embossed decoration from Chongoyape, Peru, that were made sometime between 1000 and 500 BC. Casting seems to have begun in Mochica times early in the Christian Era in northern Peru, whence it is thought to have spread northward into Ecuador, Colombia, Panama, Costa Rica, and finally Mexico. Dating in the intervening areas is problematical, but it is generally accepted that fine metalwork in gold, silver, and copper did not reach the valley of Oaxaca in Mexico until about AD 900. Some finds in western Mexico suggest an earlier beginning date there and also that knowledge of the craft came by sea rather than overland from South America.

It is said that the Spaniards saw some pre-Columbian goldwork when they first arrived in Florida, but none seems to have survived. Some pre-European North American copper work, however, has survived. Metalwork was limited to a few regions in pre-European times. The "Old Copper" culture people took advantage of deposits of native copper (as opposed to smelting copper ores) to make tools and implements, and at a later period the Hopewell people extensively made copper ornaments and weapons, produced by cold hammering. A few copper bells also have been found in Arizona Hohokam sites, but these are imports that were manufactured in Mexico.

**Southwest Indian.** The famed Indian silverwork in the Southwest did not begin until 1853, when the craft was introduced to the Navajo by Mexican smiths. Although the origin is Mexican, certain ornament types and modes of decoration among the Navajo, as one scholar points out, trace back to earlier Indian silverworking in the eastern woodland, the plains, and the Rocky Mountains. It was not until 1872 that the first Zuni smith learned the craft from the Navajo. The Zuni had been carving turquoise long before the introduction of silversmithing, so it is not surprising that the most prominent characteristic of Zuni work is the extravagant use of turquoise insets. Navajo work is distinguished by die-stamped designs, whereas die work is very rare in Zuni silver. Authentic Navajo and Zuni pieces are still being made, but the tourist market has been flooded with cheap, commercial imitations.

**Modern.** The outstanding centre for fine handwork in silver in the Western Hemisphere is the little village of Taxco in the state of Guerrero, Mexico. An American resident, William Spratling, revived the ancient craft there in 1931 and trained a whole generation of talented silversmiths. (D.T.E.)

#### AFRICAN NEGRO PEOPLES

In Africa jewelry was fashioned from gold and silver as well as from nonprecious metals; heavy neck rings, anklets, and bracelets, for example, were made of forged iron or cast brass. Except for iron, metals were usually associated with prestige and/or leadership. Metals were also used for utilitarian objects such as Ashanti cast-brass weights (for weighing gold dust), which depict humans, other animals, vegetables, and geometric forms. The Nupe were excellent metalworkers, manufacturing a variety of vessels decorated with embossed designs.

Throwing knives of the Congo, often with punchwork

designs, exemplify finely forged, abstract forms of iron weapons. Blacksmiths produced such ritual utensils as single or double gongs; Bambara, Dogon, and Lubi staffs topped with equestrian, human, and animal figures; and Yoruba and Benin shrine pieces containing mammal and bird forms.

Brass figure sculpture, cast by the lost-wax process, was usually the prerogative of royalty, as in Dahomey, and at Ife and Benin in Nigeria. Ife castings appear quite naturalistic and are among the finest sub-Saharan art. They are mostly hollow-cast heads, possibly used in ancestral rites. Benin "bronzes" were reported as early as the 16th century, but not until the 1890s did they become well-known in Europe. Local traditions indicate that the technique and the first caster came from Ife, perhaps in the late 13th century. Predominant forms were heads

Memorial king's head, bronze, from Benin, Nigeria, 15th century. In the Museum für Völkerkunde, Vienna. Height 25.5 cm.

representing deceased Benin kings, often supporting a carved ivory tusk. These, with other figurative castings as well as bells, were placed on altars dedicated to early kings. Figurative plaques were used as architectural decoration. Excellent thinly cast pieces, fairly close to the style of Ife, gave way to heavy, overdecorated pieces of the later 19th century.

Although metals appear throughout Africa, the cast "bronzes" (often brass) of Nigeria are particularly noteworthy. The earliest, from Igbo Ukwu, may be as early as the 9th century, those of Ife as early as the 12th century; Benin castings are later, and those of the Yoruba most recent. Lower Niger Bronze Industries is a term referring to one or more as yet inadequately studied traditions of uncertain date from various places in southern Nigeria. (Ro.Si.)

**BIBLIOGRAPHY.** GEORGIUS AGRICOLA, *De re metallica* (1556; Eng. trans., 1912, reprinted 1950), a scholarly translation of a mining and metallurgical classic; LESLIE AITCHISON, *A History of Metals*, 2 vol. (1960), outstanding for its completeness, competence, and excellent index; *The Pyrotechnia of Vannoccio Biringuccio*, trans. from the Italian with introduction and notes by CYRIL STANLEY SMITH and MARTHA TEACH GNUDI (1942), a description of Biringuccio's practices of smelting and metallurgy; HERBERT H. COGHLAN, *Notes on the Prehistoric Metallurgy of Copper and Bronze in the Old World* (1951), an authoritative study with a chapter on various methods of working, such as forging, casting, and sheet metalworking; ROBERT J. FORBES, *Metalurgy in Antiquity*, 9 vol. (1950; new ed., *Studies in Ancient Technology*, 1964- ), vol. 8 devoted to the discussion of early metallurgy, the smith and his tools, gold, silver and lead, zinc and brass, and vol. 9 containing the chapters on copper, tin and bronze, and iron—these publications are authoritative and the bibliographies are comprehensive; HANNS U. HAEDEKE, *Metalwork*

Iron jewelry

(1970), a study of European metalwork from the Middle Ages to the 19th century that emphasizes the socio-economic aspects of decorative arts in copper, brass, bronze, iron, and pewter; R. GOOWDWIN-SMITH, *English Domestic Metalwork* (1937), deals with technology and style as well as types of domestic objects and utensils; RAYMOND LISTER, *The Craftsman in Metal* (1966), an enlightening discussion of the techniques of metalworking in various historical periods; THOMAS A. RICKARD, *Man and Metals: A History of Mining in Relation to the Development of Civilization*, 2 vol. (1932), shows that civilization was developed by the skillful use of metals in industry and the arts; CHARLES SINGER *et al.* (eds.), *A History of Technology*, 5 vol. (1954–58), the standard general reference book in the field of technology that covers the history of metalwork from early times to about 1900 AD—each subject is written by a master, the illustrations are numerous, well selected, and well explained; R.F. TYLCOOTE, *Metallurgy in Archaeology: A Prehistory of Metallurgy in the British Isles* (1962), includes chapters on gold, copper and copper alloys, tin and tin alloys, lead and silver, methods of fabrication, and cites extensive references (the last half of the book is devoted to the study of iron).
