Air pollution has inflicted widespread damage on plant life, buildings, and materials. Smog in the Los Angeles area contributed to the slow decline of citrus groves south of the city. Sulfur oxides released into the air by phosphate-fertilizer processing in Florida have blighted large numbers of pines and citrus orchards there. Air pollutants also damage man's most durable products: steel corrodes two to four times faster in urban industrial centres than in rural areas where much less sulfur-bearing coal and oil are burned. Sulfur oxides are also accelerating the erosion of statuary and buildings throughout the world; particulates not only settle as dirt but also speed up the corrosive action of other pollutants. Ozone accelerates the cracking of rubber.

Corrosion of steel and erosion of statuary and buildings

Techniques for combatting air pollution. Technological capabilities and control devices are available to abate many air-pollution problems, although some have not become economically feasible. Local air quality standards have long helped alleviate the pollution problem, and in the 1960s and 1970s the trend was toward regional and national enactments.

Automobiles. Specific legislative control of automobile pollution began in California, where devices to control emissions were required on domestic cars starting with the 1961 model year. National standards were enacted in the United States in 1968, requiring complete control of crankcase hydrocarbons and roughly a 50 percent control of exhaust hydrocarbons and carbon monoxide. Standards were later tightened, with the most stringent requiring a 90 percent reduction from 1968 levels of carbon monoxide and hydrocarbon emissions by 1975 and 90 percent reduction of nitrogen oxide by 1976.

By the early 1970s, similar measures had been taken in several other parts of the world, notably by the European Economic Community, which issued directives requiring a harmonization of the national legislation of the member nations. Restrictions of this type can bring a rapid decline in vehicle emissions, but, ultimately, levels will begin to rise again because of the constantly increasing number of automobiles on the world's streets and highways. The technological controls necessary in order for automobiles to comply with emission standards are varied. Emission of hydrocarbons from the crankcase was largely eliminated by ventilation systems that recycle crankcase ventilation air and blow-by gases to the engine intake instead of venting them to the atmosphere. For controlling evaporation of fuel, techniques have been developed to recycle the vapours to the engine. Evaporative emissions could also be decreased by changing the properties of gasoline.

The automobile exhaust problem

To meet the early exhaust-emission standards for hydrocarbons and carbon monoxide, auto manufacturers developed ways to induce further oxidation, and they redesigned cylinders and adjusted the fuel–air ratio and other variables to reduce the amounts of these pollutants in the exhaust. To meet more stringent standards, new techniques are being developed to give even higher degrees of oxidation. Methods of markedly reducing emission of nitrogen oxides in automobile exhaust are still in the development stage.

Motor-vehicle pollution is the product of a complex combustion system of engines, fuels, and fuel additives. Effective control cannot be achieved solely by redesigning engines and installing control devices, but it also will depend on improvements in fuel and fuel additives. The key additive in air-pollution control is tetraethyl lead in gasoline, which accounts for a significant portion of particulate pollution from cars. Major gasoline companies in the early 1970s introduced low-leaded or lead-free gasoline, the manufacturing cost of which was higher than the leaded variety.

Alternatives to the internal-combustion engine have also received attention. The most promising low-pollutant power sources for 1975–85 are the reciprocating steam engine and the gas turbine. Gas turbines are well along in development for vehicular use, but initially they will be economically feasible only in heavy-duty vehicles; research in developing steam engines, on the other hand, is aimed at mass-produced automobiles. As increased electric power becomes available, electrically powered automobiles may become attractive. Electric vehicles today perform a variety of special-purpose, short-range tasks (golf carts, internal-use and short-range trucks). More effective devices are needed for storing and converting electrical energy before such cars can be mass-produced. Another alternative is the hybrid car, with electric power for in-town driving and an internal-combustion engine for long-distance travel (see also AUTOMOBILE).

Electric-power plants. A consideration of electric power for automobiles brings up the question of pollutants emitted in power production. Electric-power plants fired by coal or oil emit sulfur oxides, nitrogen oxides, and particulates. In industrialized countries such plants account for up to 75 percent of the total of sulfur oxides, and, since the electric-power industry is rapidly proliferating, the potential increase of sulfur-oxide emissions is tremendous. Nuclear-power plants, which do not emit sulfur-oxide pollutants, produced only a modest amount of the world's electrical power in the 1970s. Thus, despite ambitious development programs in many countries, nuclear-power production will contribute little to the alleviation of the problem of pollution by sulfur oxides in the remainder of the century. The greatest source of energy will continue to be the burning of coal and oil. The amount of coal burned for power by the year 2000 will be several times greater than in the early 1970s, with total fossil fuel usage tripling in the same period.

Controlling sulfur oxide

A number of alternatives are available to control sulfur-oxide pollution; restrictive standards have been widely adopted. In Britain a construction program of nuclear plants brought their energy output to 6 percent of all electric-power production by 1972. That program, however, did not actually reduce sulfur-oxide pollution in the country, but it undoubtedly slowed its increase. The British had notable success however, in reducing such pollution in large cities and industrial areas by the Clean Air Act of 1956. That law gave local authorities the right to

set up "smokeless zones," which, in effect, banned the use of smoky fuels in the areas and forced a shift to oil, gas-firing, or nuclear plants. In Sweden and the United States, air quality standards that affect electric-power plants have been set on a national level for sulfur oxides, particulates, and nitrogen oxides.

A number of technical problems stand in the way, however. In many existing power plants low-sulfur coal cannot be burned without operational difficulties or incurring high capital costs for furnace modifications. Sulfur can be removed from coal before burning, but the procedure is costly. Content can be cut in half by pulverizing the coal to the consistency of talcum powder and removing the pyrites (sulfur compounds) or by one-third by washing the coal and removing noncarbonaceous material. But, even with as much as 70 percent of the sulfur removed, the final coal product might still be classified as a high-sulfur fuel.

Some oils are also low-sulfur fuels with less than 1 percent sulfur, but they are not always within economic transport range of oil-using industry. Technology available for desulfurizing fuel oil includes removing some of the sulfur at the refinery, diluting high-sulfur oil with low-sulfur oil, or both. The cost of reducing sulfur content from 2.6 percent to an acceptable 0.5 percent adds 35 percent to the oil's cost.

Natural gas, which is very low in sulfur content, is relatively scarce and is used primarily for nonpower purposes, such as space heating and in industrial processes.

Several methods of removing sulfur from stack gases were under study in Europe and the United States in the early 1970s. In one promising method pulverized limestone or dolomite is added to the boiler charge, creating oxides that react with the sulfur oxides to form solid sulfite and sulfate particles that can be removed by electrostatic precipitation. In another process, catalytic conversion, the sulfur dioxide is converted to sulfur trioxide, which combines with water in the stack gas to form a sulfuric acid mist that can be trapped and eliminated. Yet another method is to produce sulfuric acid, which can readily be removed from the stack gas by the addition of an activated char, a carbonaceous material. A similar process, using manganese dioxide, produces ammonium sulfate, which again can be removed. None of these processes, however, had reached the stage of large-scale use in the early 1970s.

Also emitted from the stack are particulates and fly ash; electrostatic precipitators and mechanical collectors can control such pollutants with 99 percent efficiency. The disposal problem that large quantities of fly ash poses is being attacked by researchers who are trying to convert the fly ash into a useful product, such as an additive to cement.

Work on abatement of nitrogen oxides emitted by power plants has been limited, and practical technology for achieving significant control is not yet available. Emissions can be reduced 40–50 percent in some furnaces by two-stage combustion, which limits peak combustion temperatures and thus the amount of nitrogen oxides formed. Efficiency is little affected. Only a few power boilers have been designed or modified to use two-stage combustion.

Industrial and other sources of air pollution. Industrial sources generate a range of air pollutants specific to the process involved. Integrated steel mills emit particles, smoke, carbon monoxide, and fluorides; cement plants produce particles and sulfur compounds; refineries emit sulfur compounds, hydrocarbons, smoke particles, and odours. The major industrial air polluters are inorganic and organic chemical plants, iron and steel mills, petroleum refineries, pulp and paper mills, and nonferrous metal smelters.

The chief industrial polluters

A wide variety of air-pollution-control technology is available to industry: filters, vapour collectors, electrical precipitators, cyclones (centrifugal devices for separating solid material from gases), scrubbers, absorbers, and combustion equipment such as afterburners and catalytic units.

In many industrial operations, however, air pollution cannot be controlled with current technology: nitrogen oxides formed in combustion processes and emissions from coke ovens in the steel industry cannot be adequately controlled. Odour abatement is an unsolved problem in kraft pulp mills. It does not seem likely that sulfur oxides formed by industrial combustion of fossil fuels can be controlled to any extent by stack gas treatment, although some limited successes have been reported. The solutions are substitutions of low-sulfur fuels, development of new combustion processes with reduced sulfur-oxide emissions, or removal of sulfur from fuels before combustion.

A growing contributor to air pollution is domestic and commercial space heating, the effect of which on urban air quality is proportionally greater than its aggregate weight, because the emissions enter the air in crowded areas at relatively low heights above the ground. Space heating causes a particularly difficult abatement problem because of the large numbers of its relatively small sources. Solutions include reducing the sulfur-oxide emissions by using a low-sulfur fuel, reducing particle emissions by not using high-ash-content coals, and upgrading the efficiency of combustion equipment.

Refuse disposal also contributes to air pollution. Few of the world's disposal sites on land are sanitary landfills (defined as having daily cover, no open burning, and no water-pollution problems); and few municipal incinerators have adequate air-pollution-control devices. Air quality requirements beginning to appear on local levels make control technologies for incinerators mandatory. Devices most commonly used are settling chambers and wetted baffles, cyclone collectors, direct-impaction scrubbers, electrostatic precipitators, and bag filters, all of which to some degree separate out and collect emissions of fly ash and other solid particles; only the last three have operating efficiencies of over 95 percent.

Requirements of sanitary landfills

WATER POLLUTION

Water, an almost universal solvent, even in its natural state contains dissolved materials, carries particles, and is the home of living organisms. When water is used for domestic and industrial purposes even more materials, of a wide range, are added to it. Although the composition of wastes in water varies widely, its main inorganic constituents are sodium, potassium, ammonium, calcium, magnesium, chloride, nitrate, nitrite, bicarbonate, sulfate, and phosphate. Organic compounds are numerous and not well-known, with the exception of pesticides, detergents, phenolic substances, and carboxylic acids in streams.

Water pollution by nitrates, toxic substances, bacteria, and viruses affects human health, and taste and odours can be unpleasant, even in water not harmful to human health. More subtle are long-term changes in the aquatic life of a water body: the decline of sport fish and increase in carp, sludge worms, and other life forms tolerant of pollution. Water pollution also speeds eutrophication, with resultant aging and clogging of lakes. In these ways, water pollution degrades the multiple uses of water for human supply, recreation, aquatic life, and other wildlife, agriculture, and industry. Fish kills often result from pollution. In 1969 in the United States, it is estimated that 70 percent of the kills were caused by industrial wastes that consume dissolved oxygen in the water or by excess of pesticides or other poisonous wastes.

Degradable and nondegradable wastes. The complex mixtures in the waters of rivers and lakes include many unknown chemicals. For practical purposes they may be divided into degradable and nondegradable wastes.

Degradable wastes in water are those that are reduced in quantity by natural processes. These include organic wastes and thermal discharges. A great source of organic materials in water is domestic sewage. If these materials do not constitute too heavy a load, they are converted to stable inorganic materials by bacteria and other organisms. The degradation process uses the oxygen in the water and constitutes natural "self-purification." If, however, the waters are too loaded with organic matter, degradation without sufficient free oxygen produces offensive odours, such as hydrogen sulfide and methane.

Nondegradable salts, gases, and particulates

Nondegradable wastes are salts—soluble in water—soluble gases, or particulate matter (tiny, suspended particles). These wastes may include a wide range of toxic metals arising from complex manufacturing processes; cadmium, mercury, and lead are examples. Generally, the effects of these substances on life is not fully understood, and permissible levels are not properly known. There have been incidences, however, of permanent neurological impairment and death among persons eating fish from waters heavily polluted by mercury.

Settleable and suspended solids that are nondegradable represent primarily an industrial problem. Suspended particles—of various sizes—absorb other substances, act as nuclei for bacterial growth, and, by sedimentation, deposit many substances, including insecticide residues such as DDT, in the bottom muds of bodies of water.

Municipal wastes. Municipal wastes come from homes, commercial establishments, and industries. With the widespread shortage of adequate treatment systems for normal sewage flow, the additional inflow of storm water, which collects rapidly in volume too great for treatment plants to handle, intensifies the disposal problem. In the usual combined sewer system, the wastewater cannot be separated from the large volume of rainwater. Therefore, when total flow exceeds the capacity of the system, most of the wastewater is included in the bypass flow that is discharged directly into the outlet river or stream. Separate storm-water systems, or holding reservoirs, are under study, but such solutions for large urban areas are costly.

If municipal wastes produced by industries contain toxic substances, the pollution is combatted by setting standards limiting the maximum concentrations of toxic effluent that may leave the plant. To comply with such standards, an industrial plant must either clean the effluent water before discharge or redesign the industrial process so that certain highly toxic substances are not discharged into the municipal system.

Primary, secondary, and tertiary treatment

Municipal water pollution is combatted under one of three levels of sewage treatment.

Primary treatment is simply the separation of solid materials by screens or by settling in still tanks, sometimes aided by chemical precipitation. Removal of grits and solids is accomplished by screening, grinding, flocculation (causing small particles to combine to form larger particles), and sedimentation. In primary treatment most of the settleable solid materials are removed.

Secondary treatment entails oxidizing and dissolving colloidal organic material by action of bacteria and other organisms with oxygen. This stage is accomplished by trickling filters, aeration, and passage through sludge activated with bacteria.

Advanced, or tertiary, treatment is a term used for all treatments beyond the secondary up to the purification of the water to a point where it is once again potable. At least one city in the world, Windhoek, South West Africa, reclaims one-third of the total municipal water after use and returns it to its drinking-water supply.

After sewage is treated by any of the three methods, the remaining sludge is digested with the help of bacteria and concentrated by drying in beds or in lagoons with filters or in centrifuges or by heat. The final sludge may be incinerated, used for landfill or to condition soil, or may be discharged into the sea (see also SEWAGE SYSTEMS).

Industrial wastes. Water-using industrial plants add pollutants that have a variety of effects. With the steady spread of industrialization, the wastes of industry have been growing several times faster than sewage. Four major world industries account for a large portion of wastewater discharge: paper, chemical, petroleum, and steel. In addition, great amounts of waste heat are discharged into water by power generation (see below).

Because industrial wastes are generated in bulk at the plants, they can more easily be controlled, and much has been done at the source either to change production to minimize waste or to treat wastes. Modern sulfate pulp and paper plants have reduced their wastes to only 7 percent of the volume under older methods. Many of the new complex chemicals are difficult to detect and control, however, and even small amounts can be dangerous. More than 9,000 organic chemicals are now manufactured. Commercial metallic compounds number in the hundreds, and hundreds of new chemicals are marketed each year. Substances such as compounds of mercury and cadmium and polychlorinated biphenyls (PCB) in plastics have known, or potential, hazards to human, animal, and plant life. Levels of tolerance are often not known, but it is certain that, because they accumulate in living tissues and are concentrated in the food chain before its use by man, originally small amounts can lead to concentrated hazard levels. Some chemical substances are regulated by approval prior to their being marketed in pesticide, food additive, and drug products. The release of other chemicals into the environment is subject to controls imposed by effluent standards. Toxic substances that are difficult to detect are not controlled by waste-treatment methods and may only be identified after damage has occurred. Both research and new controls are needed on such substances.

In early 1972, Britain, the Scandinavian countries, and eight other European governments signed the first major international agreement to prevent pollution of the seas by dumping from aircraft and ships. Covering the northwest Atlantic, this agreement bans dumping of many poisonous substances, including pesticides, mercury, cadmium, and persistent plastic waste. At the time of signing, other nations, specifically those of eastern Europe, were expected to join.

Agricultural wastes. While agricultural wastes contribute considerably to water pollution through the runoff from pesticides, herbicides, and fertilizers, they are generally less concentrated and have less aggravating effects than industrial and municipal sewage wastes originating in or near cities.

Where the land area is available, the wastes from farm animals, many times greater in volume in nearly all countries than that of the human population, are best disposed of by field spreading. Lagoons for anaerobic degradation may be constructed near feedlots.

Acid mine drainage. Another serious non-urban water pollutant is the drainage of acids from mines, mostly abandoned coal diggings, into neighbouring streams. The best method of control is at the source by sealing the mine to prevent air and water from entering to react with the substances that form the acids. Apart from prevention, most of the treatment is confined to neutralizing acids with lime at the source.

Waste heat. In addition to using water for flushing and carrying off wastes, industry also uses huge amounts for cooling. The largest such user is the electric-power industry. Steam-generating plants, which draw water from a natural source to cool their condensers, discharge it back at an average of about 13° F (7° C) higher temperature. Nuclear plants require almost 50 percent more water than equivalent fossil-fuel plants. With the growth of the electric-power industry certain to continue, the cooling of power generation plants is clearly becoming a major pollution problem. Such thermal pollution, as it has been termed, accelerates biological and chemical reactions and aggravates the diminution of dissolved oxygen. Water temperature may rise above the level tolerable for the fish and, at the same time, may promote the growth of undesirable algae, adding to the effects of other pollutants: excess nutrients, detergents, fertilizers, and human wastes. Waste heat, therefore, speeds the eutrophication of lakes.

Effects of thermal pollution

Technological innovations include using contained lakes and ponds or cooling towers to recycle the water. Ponds (2,000 acres per 1,000,000-kilowatt plant), either manmade or isolated from natural waters, do not harm natural ecologies. Furthermore, they may be turned to economic use by developing useful warm-water ecologies with fish that do well in warmer water and types of plants and algae that may be harvested for protein animal feed.

In cooling towers, heated water is dripped over a lattice while air enters from the bottom of the tower, passes upward through the lattice, evaporates part of the water, and cools the rest. Natural draft or fans carry the warm moisture-laden air out of the top. Though some of the

water is thus lost through evaporation, most is cooled and collects in a basin to be recirculated to the condenser.

Another type, the dry cooling tower, uses air alone to cool the hot water, which is contained in tubing exposed to the upward flow of air. Dry towers are more expensive, but many have been built in Europe.

Cooling towers, rising 500 feet (150 metres) in the air, are generally considered unsightly. Another drawback is that the heat and moisture added to the air may affect the nearby weather and climate by stimulating cumulus clouds, fog, or ice, although this effect is believed limited. The same amount of heat must be dissipated, whether in air or water, but it may be less damaging to the ecology in air. Only a fraction of the nuclear-power plants planned or operating in the early 1970s had cooling towers or cooling ponds; most drew in natural water and returned it to the source.

LAND AND SOIL POLLUTION

Agricultural wastes and mineral wastes, principally from mining, make up a very large proportion of the total solid wastes in all countries but constitute a proportionately less harmful pollutant because they are spread over wide areas, not concentrated as are most residential and industrial wastes.

Agricultural solid wastes. This largest single source of solid wastes includes animal manures and wastes from slaughterhouses and from all forms of crop harvesting. Food animals, principally cattle, hogs, sheep, and chickens, generate 1,000 times more manure than does the total human population. In the past, nutrients were returned to the soil by the livestock in pastures or on rangeland. Modern feedlots, with increasing numbers of food animals, concentrate these quantities, however. Corrective measures are to spread the wastes on areas where they will help crop production and minimize water pollution.

Sediment from soil erosion is another factor in the deterioration of the land and the adding of turbidity to the waters. Sediment production is an increasing problem from poorly managed forest rangelands and agricultural crops. Mining operations and construction add to the sediment bulk.

Fertilizer salts on the land also contribute to eutrophication of waters, either when more fertilizer is applied to the land than the crops can take up or when heavy rains wash off the salts. While fertilizer is essential to the growing of food, its side effects increase with increase of population. The densely populated Netherlands, for example, in 1965 used 10 times as much nitrogen per acre as the United States. Technical controls include better understanding of the movement of fertilizers in various soils, the innovation of slow-release, nitrogenous fertilizers, and regimes of application to minimize escape of fertilizers from the land.

The pesticide problem

Pesticides (including insecticides, nematocides, herbicides, and fungicides) contain hundreds of major chemicals; their impact on soil and water contamination is great. To feed a rising population, pesticide usage is not likely to decrease. Much work needs to be done to learn more about their persistence, their levels of tolerance in man, animals, and plants, and to understand the changes they undergo in soils. Basic chemical and soil research and studies of biological tolerance levels are especially relevant.

Mineral solid wastes. Mineral solid wastes come mostly from mining of minerals and fossil fuels and the associated milling and processing industries. Strip mining causes a particularly difficult form of pollution in that it not only produces mineral wastes that pollute streams and destroy watersheds but also leaves huge scars on the land. Power shovels that can take more than 200 cubic yards at a bite are used to remove the overburden of earth and expose coal or other valuable minerals beneath.

Efforts to repair the scars on the countryside have been attempted by some companies but are expensive. They include building parks, planting vetch on the spoil banks, and turning these areas into ranches for cattle raising. So far such constructive moves have been only partly successful. West Germany has adopted strict legislative controls for strip-mine operations, requiring advance planning for land renewal of the site.

Municipal solid wastes: residential and industrial. Individual householders and commercial enterprises in cities and communities generate a vast amount of solid wastes, including paper, food, metals, glass, wood, plastic, clothing, rags, rubber, leather, and dirt. Disposal has been largly into open dumps, with a fraction going into sanitary landfills and another fraction burned in incinerators. The remaining small proportion is flushed, composted, or salvaged.

Open dumps burn, contributing to air pollution; breed rats, a severe health hazard; pollute water sources; and are offensive eyesores. Incinerators are expensive and, if not properly designed, contribute to air pollution. Sanitary landfill is satisfactory if marginal land is filled and turned into useful residential, industrial, or recreation areas.

Technological means for meeting the municipal waste problem include improved collection, improved incineration, using the heat for power generation, and improvement of sanitary landfill. While all of these measures will be needed, it should be noted that none recovers the resources of the solid wastes.

Resource recovery by recycling

There is further hope for waste management in resource recovery by recycling. Such a comprehensive approach envisages the separation of the wastes so that some may be either converted to fuel or burned directly as fuel, some may be transformed by chemical processing into new by-products, while others may be reused or recycled in their original form. Paper, a major constituent of most municipal waste, is an excellent candidate for recycling; Japan recovers and reuses half of all the paper it consumes. In the early 1970s, progress was made in collecting and reusing glass products, principally beverage bottles.

Recycling, recovery, and reuse. Recycling, recovery, and reuse constitute what has been called the secondary materials industry, growing rapidly in the 1970s. The metals that are reused to the greatest extent are iron and steel, followed by copper, zinc, and aluminum. Reclaimed rubber constitutes an important fraction of the total consumption. The growing reuse-and-recovery industry is hampered, however, by the lack of economy of scale. Large photographic companies, for example, reclaim silver from the film they develop; but for small processors it is uneconomical to do so, and large amounts of silver are therefore lost.

Recycling plans and programs have been advanced in several countries, with both private and governmental support. Three basic steps are involved: collection, separation, and processing. The significance of recycling in the future from both the pollution-control and conservation viewpoints has been pointed out as one of the advantages of the "new city" concept. Such experimental cities, built from scratch, can plan all types of pollution control far better than can old, established cities, and extensive recycling can be economically realized.

Junked automobiles. The disastrous aesthetic impact of automobile graveyards makes this component of solid waste conspicuous in the public eye, but most automobiles were being scrap-processed for recycling in the early 1970s, with technology improving. Bundles of auto hulks compressed by the older methods contain up to 90 percent iron and 0.5 percent copper, the worst contaminant in the reuse of the iron. New types of shredders separate the ferrous from the nonferrous materials and increase the iron yields to 97 percent, reducing the copper to 0.2 percent or less. It is believed that the junk-car problem will be solved by reuse soon because of technological changes in steelmaking techniques and improvement of scrapping and shredding efforts.

Tires. A considerable proportion of the tires discarded annually can be reclaimed, but most are unfit for reclamation and constitute a disposal problem. They may be incorporated into asphalt for paving, but further work is required to identify and arrange for economical reuse of scrap rubber.

OTHER KINDS OF POLLUTION

Noise. Noise, unwanted sound, is one form of environmental contamination that disappears when the source is turned off. Yet, it is a form of environmental degradation and has implications for health that may be as serious as air or water pollution. It can change man's physiological state by speeding up pulse and respiratory rates, and it can impair hearing either permanently or temporarily; millions of industrial workers are threatened with hearing damage. There is medical evidence that noises can cause heart attacks in individuals with existing cardiac injury and that continued exposure to loud noises could cause such chronic effects as hypertension or ulcers. Noise is measured by intensity in decibels in a range from barely audible to shatteringly loud (see Table).

Weighted Sound Levels and Human Response

sound source	decibels*	response criteria
	150	
carrier deck jet operation	140	
		painfully loud
	130	limit amplified speech
jet takeoff (200 ft)	120	
discotheque		
auto horn (3 ft)		maximum vocal effort
riveting machine	110	
jet takeoff (2,000 ft)		
shout (0.5 ft)	100	
New York City subway station		very annoying
heavy truck (50 ft)	90	hearing damage (8 hours)
pneumatic drill (50 ft)		
	80	annoying
freight train (50 ft)		
freeway traffic (50 ft)	70	telephone use difficult
		intrusive
air-conditioning unit (20 ft)	60	
light auto traffic (50 ft)		
	50	quiet
living room		
bedroom	40	
library		
soft whisper (15 ft)	30	very quiet
broadcasting studio	20	
	10	just audible
	0	threshold of hearing

*Weighted sound levels taken with a sound-level meter and expressed as decibels on the scale approximating the frequency response of the human ear.
Source: Department of Transportation.

The rapid growth of air transportation after World War II and the development of jets created a major noise problem in and around airports. Millions of people live near enough to airports to be subjected to intense aircraft noise. In spite of acoustical advances in engine design, modified flight procedures, and design improvement, the problem of aircraft noise is becoming more serious because every year there are more and larger aircraft. Aircraft noise is abated by delaying flap retraction, holding speeds relatively low while making turns and while climbing, directing aircraft traffic away from communities, and soundproofing and air-conditioning residences near airports. But the most effective abatement is to control the source of the noise, the engine. With the switch from turbojet to turbofan engines, engine noise has been cut by new designs that increase mass flow and reduce velocity through the engine. Engineers are now working to reduce fan noise.

The sonic boom

One noise that cannot be eliminated is the sonic boom created by planes flying faster than the speed of sound. Sonic boom is a sudden pressure disturbance or shock wave in the air. The exposure zone ranges from eight to 50 miles (13 to 80 kilometres) on each side of the centre line of the flight path of a plane travelling at supersonic speeds at an altitude of 65,000 feet (20,000 metres). The French–British and the Soviet commercial supersonic planes promised to bring the problem to the fore in the mid-1970s. Supersonic military planes, though kept away from urban areas, have caused booms that have shattered glass, twisted metal window frames, and caused rockslides.

A considerable amount of legislation has been enacted to limit noise pollution. Most cities of the world have codes to govern noise levels in industrial, commercial, and residential areas. Curfew provisions often prohibit particular noisemaking activities or operations during certain days or hours.

Technological methods for reducing industrial and city noises include machines that can cut through asphalt and concrete at equal or greater speeds and much lower noise levels than conventional jackhammers, a quiet air compressor, layers of polymeric materials and metal in railroad-car wheels and saw blades that reduce their screeching noise, sound absorption materials on plant ceilings and walls, and sound-absorbing partitions around noise equipment. For high-level-noise work situations, personal protective devices include plastic-foam earmuffs and earplugs made of rubber, plastic, or disposable materials such as wax-impregnated cotton.

Radiation. Low-level, man-made radiation comes from X-rays, radioactive materials, and electronic devices, including television sets. Medical uses constitute 94 percent of all man-made radiation and 30 percent of all radiation to which the average individual is exposed.

High doses of radiation have been shown to be related to incidence of leukemia and other cancers, and low-level radiation may cause genetic damage and increase natural mutation. Radiation levels in the environment have declined markedly since the early 1960s because of an international agreement banning nuclear-weapons tests in the atmosphere, outer space, and underwater.

Nearly all of the radionuclides escaping into the environment do so at the site of nuclear-fuel reprocessing plants. The significant effluents discharged are krypton-85 and tritium, which move into the air and water system but which are not expected to increase the world population's radiation exposure significantly.

High-level and low-level radiation waste

Radioactive waste is divided into low-level and high-level wastes. Materials with low levels of radioactivity are the gaseous, liquid, and solid wastes from reactors and other nuclear facilities. These are packaged and buried in licensed burying grounds. High-level wastes, the by-products of the reprocessing of used fuel elements from nuclear reactors, will become an increasing problem as their volume increases with the world's expanded uses of radiation sources. Technology has been developed to reduce the high-level liquid wastes to solid form, thereby reducing the final volume to one-tenth that of the original liquid material. Nevertheless, dumping in the sea, storing in salt mines, and other suggested practices all carry with them hazards because of the radioactive materials' very long half-lives.

Other nonmaterial pollution. Several types of nonmaterial pollution annoy or offend the aesthetic sense rather than do physical or physiological harm. In the category

of what has been called visual pollution are such eyesores as billboards, neon signs, electric-power transmission lines, and garish roadside strip developments. Solutions include underground transmission lines and combining electricity, gas, oil, and rail traffic along the same corridors.

Light pollution, the glare of streetlights and advertising signs from the city and its environs, among other things, seriously hampers the observations of astronomers. Light pollution is closely related to air pollution in that the ultraviolet light and general overall glare are scattered by dust and other particles in the air. To the naked eye, nights are still black, yet, to the sensitive electronic eyes, the quality of darkness is strained. Astronomers' telescopes are sensitive enough to pick up stars 100,000,000,000 miles away, but flashes from a neon sign from a roadside 20 miles away can easily block out light from these distant stars. Compounding the problem, many of the celestial wavelengths are nearly identical with the ultraviolet rays emitted by mercury lamps along nearby streets and highways. Astronomers have pressed for regulation of future outdoor lighting.

GLOBAL ASPECTS OF POLLUTION

Pollution of the atmosphere. The Earth's atmosphere contains 21 percent oxygen and 0.032 percent carbon dioxide by volume, a ratio of 650 to 1. Man's activities, including burning of fossil fuels, land clearing, and making cement from limestone, are increasing the carbon dioxide content of air. In spite of its relatively small concentration in the air, carbon dioxide plays an important role in determining the temperature of the planet: the temperature rises when the amount of carbon dioxide in the atmosphere rises, for the gas absorbs sunlight and infrared radiation, preventing a portion of the heat from radiating back into space.

Worldwide temperature increase

The possibility of a worldwide increase in temperature from the addition to the atmosphere of carbon dioxide from the burning of fossil fuels was first posed in 1899. The problem has since become magnified, with predictions for larger yearly increases in rates of carbon-dioxide emissions until nuclear power provides more of the needed energy. Assuming an annual worldwide increase of 5 percent in fossil-fuel consumption, it is estimated that by 2020 the increase in carbon dioxide in the atmosphere would increase world temperatures by about 4° F (2° C) from the level of 1860, when mankind began to burn fossil fuels in appreciable quantities.

Techniques to reduce the carbon-dioxide content of the air or speed up its absorption by ocean waters are not economically feasible. A substantial increase in forest areas would reduce the carbon-dioxide content, but possibilities for this solution are limited. Means of preserving the status quo of carbon-dioxide levels in the atmosphere include using new power sources other than fossil fuels, such as nuclear energy, direct solar energy, and geothermal steam.

The upper atmosphere is also being threatened by man's technological activities. Supersonic planes could increase water vapour in the stratosphere, and nitric-oxide emissions from such planes could possibly reduce layers of ozone, the gas that absorbs the sun's ultraviolet rays. Other particles from supersonic aircraft could cause climatic changes, increasing the temperature of the stratosphere with possible changes in the Earth's surface temperatures.

Ocean pollution. The oceans, which cover more than 70 percent of the Earth and are a critical element in maintaining the world's environment, are the final receptacle for many wastes. Most wastes sink to the bottom, but solid wastes, oil, and garbage contain many floatable materials that are carried great distances by currents and winds. Pollution affects marine life directly through toxicity, which kills some plants and animals and causes reproductive failure in others; it also causes oxygen depletion, biostimulation, and economic losses in shellfish, fishing, and recreation industries.

Wastes dumped into the ocean include dredge spoils, industrial wastes, sewage sludge, construction and demolition debris, solid wastes, explosives, chemical munitions, and radioactive wastes. Spoil materials from dredging constitute the largest single ocean pollutant, followed by industrial wastes, such as acids and refinery, pesticide, and paper-mill wastes. Most are dumped from barges; highly toxic wastes are packed in drums.

In most cases, alternatives to ocean dumping exist. Industrial wastes can be treated on land or recycled, and solid wastes may often be used as landfills, for example, to fill in areas left by strip mining. Disposing of dredge spoils on land is not possible because of the enormous volume.

Ocean pollution from oil spills

A prominent source of ocean pollution comes from large oil spills, some of which have killed marine birds and plants, left layers of encrusted oil along shores, and have cost large sums to clean up. Such spills, while concentrated and disastrous, account for less than 20 percent of the large amounts of oil that man introduces directly into the world's waters every year. Most of the chronic pollution originates from the normal tank cleaning at sea of oil-carrying tankers, from normal operations of refineries and petrochemical plants, and by fallout of airborne hydrocarbons emitted by motor vehicles and industries. The danger of large-scale accidents increases, however, with the steadily increasing size of tankers; 300,000-ton ships are already in operation, and plans for 800,000-ton tankers have been projected. A single spill from one of the new large tankers could add 20 percent to the amount of petroleum entering the oceans in a single year.

A number of measures have been taken to reduce chronic oil pollution. Most tanker operators have stopped dumping wastewaters from tank cleaning into the oceans. Methods for combatting large accidental spills include the use of absorbants such as straw, sawdust, and shredded polyurethane foam; gelling agents that can solidify petroleum materials; burning the slicks; and using chemicals and detergents, most of which, however, are to some degree toxic to aquatic life. Some nations have made illegal the grossly negligent or willful distribution of oil from a vessel in navigable waterways, and international agencies have discussed establishing global protection and cleanup procedures.

Other aspects of international pollution. Prevailing currents of air may carry sulfur dioxide or particulates across national boundaries, and a river system often extends along or beyond national borders. The Rhine, rising above Lake Constance, in Switzerland, flows through West Germany and France before it reaches Rotterdam in The Netherlands, and the North Sea; the river is polluted for most of its length. In June 1969, millions of fish died in the Rhine as a result of a pesticide spill from a chemical industry in Frankfurt Am Main that imperilled the drinking-water supply in The Netherlands. The four riparian countries have agreed on methods for cleaning up and protecting the river.

Among other international efforts at pollution control in the early 1970s were the Environmental Committee for the Organisation for Economic Co-operation and Development, which studied international economic implications of domestic environmental quality standards; the Committee of the North Atlantic Treaty Organization on the Challenges of Modern Society, which is studying ocean oil pollution, low-polluting vehicles, and air-pollution monitoring; the Inter-Governmental Maritime Consultative Organization, which is working on conventions of rights and liabilities of oil spills; and the International Joint Commission, which completed a Canadian–U.S. agreement for measures to control Great Lakes pollution by 1975. The first worldwide meeting on environmental quality was the United Nations Conference on the Human Environment, held in Stockholm, in June 1972. The conference's aim was to develop methods to achieve international environmental quality through control, monitoring, resource management, and education. For developing countries, the aim of the conference was to find ways to advance economically with environmentally sound practices.

BIBLIOGRAPHY. The AMERICAN CHEMICAL SOCIETY, *Cleaning Our Environment: The Chemical Basis for Action* (1969);

and the NATIONAL RESEARCH COUNCIL, COMMITTEE ON POLLUTION, *Waste Management and Control* (1966), are basic reports on the technological state of the art of pollution control, covering air, water, and land pollution. For further details on water pollution, see CHARLES E. WARREN, *Biology and Water Pollution Control* (1971); and ALLEN V. KNEESE and BLAIR BOWER, *Managing Water Quality: Economics, Technology, Institutions* (1968). A worldwide analysis of pollution problems may be found in the STUDY OF CRITICAL ENVIRONMENT PROBLEMS, *Man's Impact on the Global Environment* (1970). *Environmental Quality*, the first and second annual reports of the Council on Environmental Quality, Washington, D.C. (1970–71, as well as additional annual reports), give a yearly analysis of pollution problems and pollution control in the United States. Specialized areas of pollution control are discussed in depth in the following: *Ocean Dumping: A National Policy*, Report to the President prepared by the Council on Environmental Quality (1970); *Oil Pollution: Problems and Policies*, Bureau of National Affairs Management Series (1969); and *Noise As a Public Health Hazard*, Proceedings of an American Speech and Hearing Association Conference, Washington, D.C. (1969). References to the most current literature on problems of pollution are given in *Air Pollution Abstracts* (1970–); *Selected Water Resources Abstracts* (1968–); and *Pollution Abstracts* (1970–).

Polo, Marco

Marco Polo, the most outstanding traveller and explorer from the West to journey to Asia during the Middle Ages, was born in Venice in about 1254; he died in the same city in 1324. His importance in European history is due not so much to the length and variety of his itineraries (both of which were indeed considerable) but to a lucky chain of events that made it possible for him to publish a profuse account of things seen, people met, and information gathered during some 25 years (1271–95) in Asia. The civilizations of Europe and of the Far East—walled off from each other by a formidable wedge of Muslim nations—had flourished for centuries in reciprocal ignorance of each other's existence. Though some travellers had bridged the physical gap between the two worlds, their voices somehow failed to reach a wide audience. Marco's account, on the contrary, created a sensation. This had its good and bad effects, however; on the one hand, new vistas opened to the medieval mind, but, on the other hand, much of the news appeared so fantastic that many considered the work a romance rather than an essentially factual work. But time has vindicated Marco and proven him a keen and generally reliable observer; as Western horizons expanded, Marco's influence became greater and greater. His description of Cipango (or "Zipangu," in Marco Polo's nomenclature; now Japan) set a definite goal for Columbus in his journey toward the setting sun in 1492, while his detailed localizations of spices encouraged Western merchants to seek out these areas and break the age-old Arab trading monopoly.

Influence of his book

Polo, title page of the first printed edition of *The Travels of Marco Polo*, 1477.

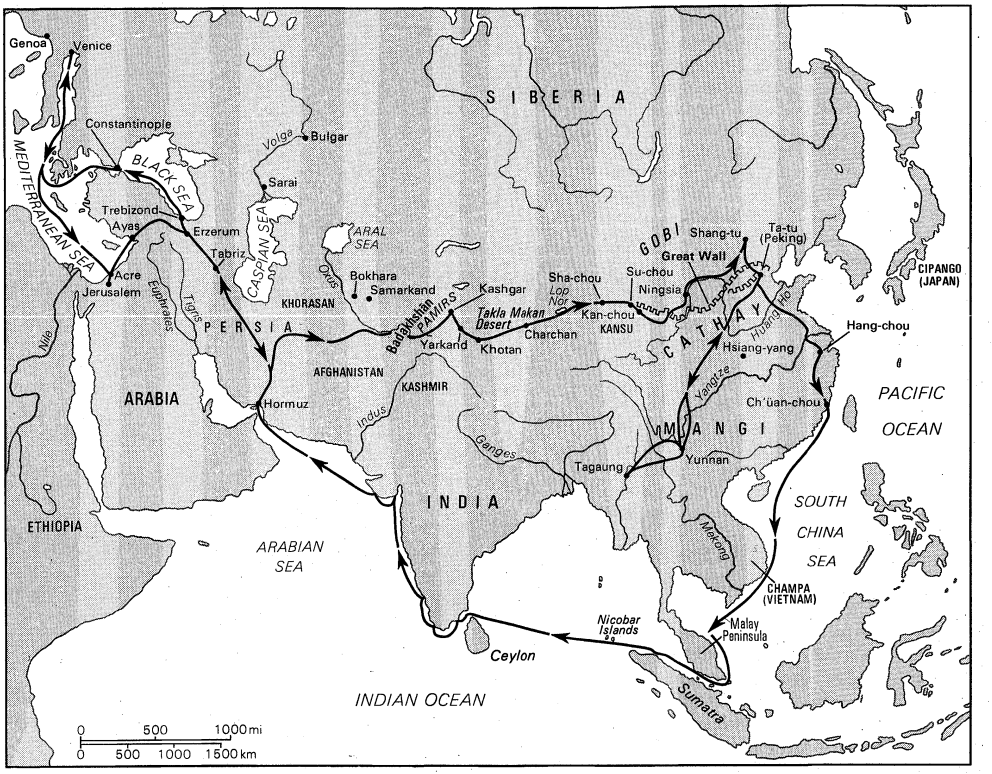
YEARS OF TRAVEL

Travels of the Polo family. Marco found his way paved by the pioneering efforts of his ancestors and especially of his father, Niccolò, and his uncle Maffeo. The family had traded with the Near East for a long time, apparently reaching a position of considerable wealth and prestige. Although it is not quite clear if the family was actually of the nobility, the point lost much of its typically medieval relevance in a city of republican and mercantile traditions, such as Venice.

The Polos appear to have been shrewd, alert, and courageous; in about 1260 they foresaw a political change in Constantinople, liquidated their property there, invested it in jewels, and set off for the Volga River, where Berke Khan, sovereign of the western territories in the Mongol Empire, held court at Sarai or Bulgar, according to the season. The Polos seem to have managed their affairs well at this provincial Mongol court, doubling their assets. When political events prevented their return to Venice, they travelled eastward to Bokhara, eventually ending their journey four years later (1265) at the capital of the Mongol Empire, probably the summer residence of the Grand Khan—called Shang-tu (the Xanadu of the English poet Samuel Taylor Coleridge). Establishing friendly relations with the great Kublai Khan himself, they were eventually sent back to Europe as Kublai's ambassadors to the Pope, carrying letters asking the Pope to send Kublai one hundred intelligent men "acquainted with the Seven Arts"; they also bore gifts and were asked to bring back some oil from the lamp burning at the Holy Sepulchre in Jerusalem.



Marco himself had meanwhile been born in or around 1254. (This date, like nearly all the others concerning major events in his life, is conjectural.) Nothing is known of his early years in Venice, although it seems fairly certain that he learned little or no Latin. He was a lad of 15 or 16 when he first met his father, on the latter's return from the East in 1269.

Marco's journey to Asia. When Niccolò and Maffeo returned, they found that the Pope (Clement IV) had recently died. They waited patiently in Venice for a new pontiff to be elected, but after two years a successor had not yet been chosen. Becoming restive, the Polos started off on their journey, taking the young Marco with them (1271). In Palestine the papal legate, Teobaldo of Piacenza, gave them letters for the Mongol emperor; the Polos had been only a few days on the road when they heard that their friend Teobaldo had been elected pope (Gregory X). Back they went to Acre, where they were given proper credentials and the company of two friars. The small expedition departed once more; the two friars, however, soon lost heart, and the Polos continued alone.

The journey across western Asia

From Acre the travellers proceeded to Ayas ("Laiazzo" in Marco's writings, now Yumurtalik, on the Gulf of İskenderun, also called Gulf of Alexandretta, in southeast Turkey). During the early part of 1272 they probably passed through Erzurum, in what is now eastern Turkey, and Tabriz, in what is now northern Iran, later crossing inhospitable deserts infested with brigands before reaching Hormuz on the Persian Gulf. There the Polos decided not to risk a sea passage to India and beyond but to proceed overland to the Mongol capital.

Soon they were on the road again, travelling through deserts of "surpassing aridity" toward the Khorasan region in what is now eastern Iran. Turning gradually to the northeast they reached more hospitable lands; Badakhshān ("Balascian"), in Afghanistan, in particular, pleased the travellers. Marco seems to suggest that they remained here for a year; a long illness (possibly malaria) was cured by the benign climate of the district. It has also been supposed that Marco, during this period, visited territories to the south (other parts of Afghanistan, Kafiristan in the Hindu Kush, Chitral in what is

Routes travelled by Marco Polo between 1271 and 1295.

now Pakistan, and perhaps Kashmir); it is, however, difficult to establish which districts he traversed and which he may be describing from information gathered en route.

Leaving Badakhshān, the Polos proceeded up the Vākhān ("Vocan") valleys toward the Pamirs, which were eventually crossed by an itinerary that has long been a subject of discussion and conjecture. Descending on the northeastern side of the chain, they reached Kashgar ("Cascar") in what is now the Sinkiang Uighur Autonomous Region of China. By now the Polos were on the main Silk Road, and their advance can be followed along the oases to the south and east of the Takla Makan Desert—Yarkand ("Yarcan"), Khotan ("Cotan"), Charchan ("Ciarcian"), and Lop Nor (Lop Lake)—stepping-stones on the way to Sha-chou ("Saciu") on the borders of China, a place now called Tun-huang (Kansu province).

Before reaching Sha-chou, the Polos had travelled primarily among Muslim peoples—also encountering sprinklings of Nestorian Christians, Buddhists, Manichaeans, and Zoroastrians; now, however, they entered the vast province of Kansu (called "Tangut" by Marco), where an entirely different civilization, mainly Buddhist in religion but partly Chinese in culture, prevailed. Their itinerary most probably took the travellers to Su-chou ("Sukchu") and Kan-chou ("Campiciu") before entering the Ningsia area. It is not clear whether the Venetians reached the Mongol summer capital of Shang-tu ("Cian-du") directly or after a detour; at all events, some time in 1275 (1274, according to recent researches by a Japanese scholar, M. Otagi), the Polos were again at the Mongol court, presenting the sacred oil from Jerusalem and the papal letters to their patron, Kublai Khan.

His sojourn in China. For the next 16 or 17 years the Polos lived in the Emperor's dominions—which included, among other countries, Cathay (now North China) and Mangi, or "Manzi" (now South China). Possibly they moved with the court from the summer residence, Shang-tu, to the winter one, Ta-tu or "Taidu"—modern Peking.

Unfortunately Marco's book *Il milione* ("The Million"), known in English as the *Travels of Marco Polo*, is only incidentally a biography and autobiography; it is therefore exceedingly difficult to ascertain where the Polos went and what they did during these years. It is well known that many foreigners were in the employ of the Mongol state, since Chinese were mistrusted; it was therefore natural for the Polos to fit in most honourably and successfully with this motley society.

But precisely how successfully? In what specific capacities did they make themselves useful? These and similar points have been discussed for centuries without definite conclusions being reached. The elder Polos were probably employed in some technical role. Once and very abruptly, a glimpse is obtained of them acting as military advisers during the siege of "Saianfu" (historically and presently Hsiang-yang), a city that was finally taken, says Marco, thanks to some "great mangonels" (missile-throwing engines) built according to their specifications. The whole episode is, however, dubious.

Marco himself reached Cathay very young (at the age of 20 or so). Although he knew little or no Chinese, he spoke some of the many languages then used in East Asia —most probably Turkish (in its Coman dialect) as spoken among the Mongols, Arabized Persian, perhaps Mongol, and Uigur Turkish. Marco was noticed very favourably by Kublai Khan, who took great delight in hearing of strange countries; the Emperor repeatedly sent him on fact-finding missions to distant parts of the empire. One such journey took Marco to Southwest China, to Yunnan, and perhaps as far as Tagaung in Burma; on another occasion he visited Southeast China, later giving an enthusiastic description of the city of "Quinsay" (now Hang-chou) and of the populous regions recently conquered by the Mongols. There is ample evidence that Marco considered himself an adoptive son of his new country.

The Polo legend

Marco's reticence concerning personal matters has left a void that has been eagerly filled in by romantic hero-worshippers, who see him as a brilliant young courtier enamouring princesses and governing provinces: indeed, a Marco Polo myth has been current for centuries and has often provided a theme for novelists, film makers, or dramatists. On the other hand, more sober critics point out that contemporary Chinese records show no trace of Marco. (But under what name was he known: who would recognize the 16th- and 17th-century Italian missionary Matteo Ricci under Li Matou or the 18th-century painter Giuseppe Castiglione under Lang Shih-ning?) They also observe that his reports sound more like echoes of bazaar gossip than gleanings from inner councils. The

truth probably lies somewhere in between. Apart from the missions he undertook for the Emperor, Marco's evident competence in matters pertaining to salt and the administration of its monopoly suggest that he may have held some responsibility in this branch of government. According to some texts of *Il milione*, Marco governed the city of Yang-chou (in Kansu) for three years, sometime between 1282 and 1287; but this seems hardly credible and hinges entirely on the reading of one word.

The return to Venice. Some time around 1292 (1290 according to Otagi), a Mongol princess was to be sent by sea to Persia, there to become the consort of Arghun Khan, and the Polos offered to accompany her. It seems that Kublai Khan was unwilling to let them go but finally granted permission. Kublai Khan was then nearing his 80th year, and his death (and the consequent change in regime) might well have been dangerous for a small group of isolated foreigners. They also, naturally, longed to see once more their native Venice and their families.

The princess, with some 600 courtiers and sailors, and the Polos boarded a fleet of 14 ships, which left the port of Ch'uan-chou ("Zaiton") and sailed southward. The fleet touched Champa ("Ciamba," modern Viet Nam), as well as a number of islands and the Malay Peninsula. On the island of Sumatra ("Lesser Giaua") a stop of five months was made to avoid monsoon storms. There, Marco was much impressed by the fact that the North Star appeared to have dipped below the horizon. The fleet then passed near the Nicobar Islands ("Necuveran"), touching land again in Ceylon ("Seilan"). The Chinese ships subsequently followed the west coast of India and the southern reaches of Persia, finally anchoring at Hormuz. The expedition then proceeded to Khorasan, handing over the princess not to Arghun, who had died, but to his son Maḥmūd Ghāzān.

The Polos eventually departed for Europe, but their movements at this point are not clear; possibly they stayed for a few months in Tabriz. Unfortunately, as soon as they left the Mongol dominions and set foot in a Christian country, at Trebizond in what is now Turkey, they were robbed of most of their hard-won earnings. After further delays, they reached Constantinople and finally Venice (1295). The story of their dramatic recognition by relatives and neighbours, who had thought them long since dead, is a part of Polo lore that is universally known.

"IL MILIONE" AND ITS INFLUENCE

Compilation of the book. Soon after his return to Venice, Marco was taken prisoner by the Genoese—great rivals of the Venetians at sea—during a skirmish or battle in the Mediterranean; Marco was then sent to Genoa and locked in one of the local prisons. There a most felicitous encounter occurred. The Venetian traveller met a prisoner from Pisa, who had possibly lost his liberty some ten years earlier at the Battle of Meloria—one Rustichello (or Rusticiano), a fairly well-known writer of romances and a specialist in chivalry and its lore, then a fashionable subject. Marco may have had it in mind to write a report of his 25 years in Asia but possibly did not feel sufficiently at home in either Venetian or Franco-Italian; but now Rustichello was at hand, and the traveller began dictating his tale. The language employed was Franco-Italian—a strange composite tongue fashionable during the 13th and 14th centuries. Page by page a great book was compiled, later to be known as *Il milione*.

Imprisonment in Genoa

Fortunately Marco was soon freed and returned to Venice. His subsequent life can be reconstructed, in part, through the testimony of some legal documents that have reached us. He seems to have led a somewhat retired life, managing a not too conspicuous fortune. He died in 1324, at the age of 70. A famous story relates how Marco was asked on his deathbed to retract the "fables" he had invented in his book; his answer was that he barely told half of what he actually saw. It is known that in his will he set free a "Tartar slave," who may possibly have followed him all the way from East Asia.

Nature and content of "Il milione." The actual personality of Marco is somewhat elusive. Practically all that is known about him derives from the text of his book; the traditional view is that Marco dictated the text, and certainly many portions sound like transcriptions from a tape recording. But was Rustichello always such a passive instrument? Scholarly research has shown that he often asserted his personality and familiar phraseology, especially in the somewhat standardized description of battles.

The book itself was an instant success. "Tutta Italia in pochi mesi ne fu piena" ("In a few months it spread throughout Italy"), wrote Giovanni Battista Ramusio, the 16th-century Italian geographer. Unfortunately, however, people read the book for the wrong reasons—not as history, geography, or travel but as a fantastic romance in which Kublai Khan was ranked with King Arthur and Cathay became a new province in the dreamy topography of chivalry.

Since all this happened long before the invention of printing, professional scribes or amateurs made dozens of copies of the book, as well as free translations and adaptations—often adding to or subtracting from the text with little or no respect for authenticity. There were also many unfamiliar names that rarely passed unharmed from one copy to another; as a result, modern commentators throw up their hands in despair when confronted with the task of reconstruction. In fact, an authentic and original copy of *Il milione* does not exist; there are some 140 different manuscript versions of the text, in a dozen different languages and dialects—an immensely complex and controversial body of material representing one of the most obdurate philological problems inherited from the Middle Ages.

Different versions of the book

Marco seems to have made additions and corrections himself, on various copies of the work, during the last 20 years or so of his life. Some editors—for instance, the friar Pipino, who made a good Latin translation of the original—found many of Marco's descriptions or interpretations impious or dangerously near to heresy and therefore heavily bowdlerized the text.

The book seems to have been conceived by Marco as a vast cosmography based on first-hand experience—the book to end all books on Asia. The original title—*Divisament dou Monde* ("Description of the World") is significant; Marco all too often sacrifices personal recollections to doctrinal ambitions. Details concerning travel, stages (*i.e.*, distances covered), seasons are rarely stated; the panorama is observed from an impersonal distance with a powerful wide-angle lens. In *Il milione* Marco follows a definite itinerary but often branches off into descriptions of places probably visited not by himself but by his relatives or people he knew. Typical digressions are those on Mesopotamia, the Assassins and their castles, Samarkand, Siberia, Japan, India, Ethiopia, and Madagascar. *Il milione* is better understood if considered as forming a part of the vernacular didactic literature, of which the Middle Ages offer many examples.

The origin of the popular title, *Il milione*, is not quite clear; it may have source relation with the idea of a "tall story," but it may also derive from a nickname running in the family, possibly traceable back to a corruption of Aemilione (Big Emil). The complete silence of the poet Dante Alighieri regarding his illustrious contemporary seems to be significant; he evidently considered the book a fable, an invention, and a dangerously heretical one at that. Marco's descriptions of peoples living under the Equator, where according to the orthodox views of the times there should have been nobody, may have appeared particularly alarming.

Marco Polo's subsequent reputation. As a result of such controversies, which have continued for nearly seven centuries, Marco's reputation has suffered dramatic ups and downs. For some he was a genius, a man of prodigious memory, a most conscientious observer, and a successful official at the Khan's court—a man at home in the cosmopolitan Asia of the great Mongol rulers. For others he was a braggart, who made too much of himself; a drifter ready to believe the gossip of ports and bazaars; a man with little culture, scant imagination, and a total lack of humour; a man who failed, among other things,

to mention the Great Wall of China, the use of tea, and the ideographic script of the Far East.

A more balanced view must take into account many factors, especially the textual problem and medieval ideas of the world. Modern scholarship and research have, however, given a new depth and scope to his work. It is now generally conceded that he reported faithfully what he saw and heard, even though much of what he heard was fabulous or distorted. His information about Japan and South China, for instance, reflects what the Mongols may have said and thought, rather than the actual facts.

Marco must have been endowed with a constitution of exceptional sturdiness to survive the stresses of his long journeys and must also have been well-balanced emotionally to adapt to the repeated changes of social environment. Certain stresses, however, seem to have left definite traces. The Polos had long been merchants, but events turned them into ambassadors and officials. Marco's book frequently reads like the recollections of a retired ambassador surveying men and events, and only secondarily like the report of a merchant. He may also have felt uncomfortable about his origins. Tatars despised merchants, employing mostly Muslims for trade. Marco's inner conflict about this is possibly revealed in his somewhat grudging mentions of his elders. Another detail: the wife he chose upon returning home, Donata, belonged to one of the oldest Venetian families (Badoer), and their three daughters married into the aristocracy. Much of what has been considered irresponsible bragging in Marco's writings may be the unconscious expression of great ambitions that were kindled by circumstances but thwarted by limitations of background and education.

BIBLIOGRAPHY. A Franco-Italian text of Marco Polo's book, generally considered very near to the lost original, has been edited, collated with many other early manuscripts, and published by L.F. BENEDETTO, *Il Milione, prima edizione integrale* (1928). This work is fundamental; a long and detailed introduction (in Italian) deals with the complex problems related to the text and its tradition. The French Orientalist M.G. PAUTHIER was the first modern scholar to confront *Il milione* seriously, but his translation, *Le Livre de Marco Polo, citoyen de Venise*, 2 vol. (1865), is in part superseded. The works by SIR HENRY YULE, now somewhat dated, have been standard texts for decades: *Cathay and the Way Thither: Being a Collection of Medieval Notices on China*, new and enl. ed., 4 vol. (1913–16, reprinted 1967) and *The Book of Ser Marco Polo, the Venetian, Concerning the Kingdoms and Marvels of the East*, 3rd ed. rev. and enl. by H. CORDIER (1903, reprinted many times). A.C. MOULE and P. PELLIOT have published a new composite translation based on the most reliable texts: *Marco Polo: The Description of the World*, 2 vol. (1938). A modern, readable, and dependable translation in English is *The Travels of Marco Polo*, trans. and with introduction by Ronald Latham (1958). The itineraries of the Polos are critically examined in N.M. PENZER'S introduction to *The Most Noble and Famous Travels of Marco Polo*, edited from the Elizabethan translation of JOHN FRAMPTON, 2nd ed. (1937); and in MILTON RUGOFF, *Marco Polo's Adventures in China* (1964), Marco Polo's tale followed brilliantly step by step with illustrations from many different sources. For further points of detail, see P. PELLIOT, *Notes on Marco Polo*, 2 vol. (1959–63); and ORIENTE POLIANO, *Studi e conferenze tenute all'Ismeo, in occasione del VII centenario della nascita di Marco Polo, 1254–1954* (1957). A scholarly and very readable introduction to the subject of Marco Polo, his journeys, his book, and his times is L. OLSCHKI, *L'Asia di Marco Polo* (1957; Eng. trans., *Marco Polo's Asia*, 1960). On a more popular level, see H.H. HART, *Venetian Adventurer* (1942, reissued as *Marco Polo, Venetian Adventurer*, 1967); and M. COLLIS, *Marco Polo* (1950). Partial translations, abridgements, adaptations are legion in all major languages, but some of these works are not reliable. EILEEN POWER, *Medieval People*, 10th ed. (1963), contains a first-rate chapter dealing with Marco Polo and his times.

(F.M.)

Polo

Polo, a stick-and-ball game played on horseback, is the oldest of all equestrian sports and, according to some authorities, the oldest organized sport of any kind.

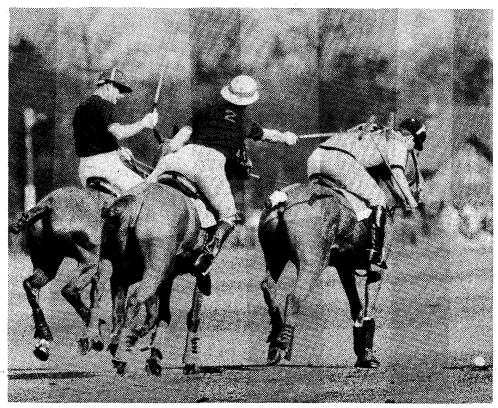
Origins of the game

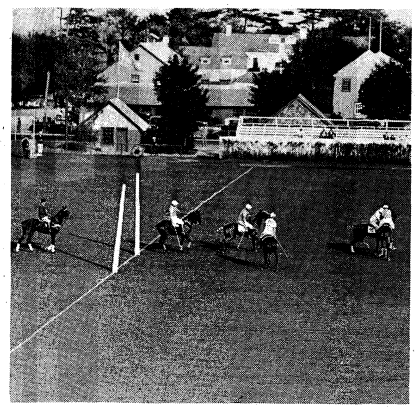
History. Definite historical references establish that polo was being played in Iran (Persia) during the 1st century AD. Some scholars claim an even earlier birth of the game and credit the Persians with its invention as far back as 2000 BC. In any case, Iran is generally held to be the nation that invented polo; the game is definitely of Oriental origin.

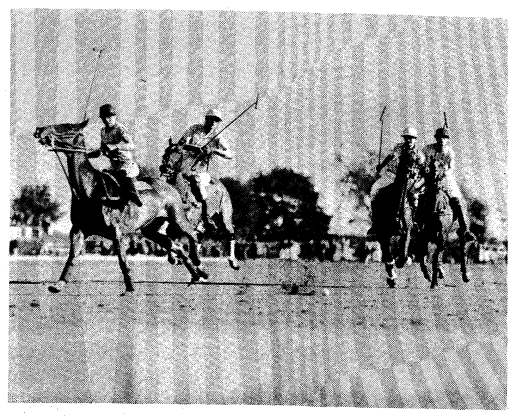
In its early forms, polo was less a sport, in the modern sense of the word, and more a training game for Oriental cavalry units, usually the king's guard or other elite mounted troops. Indeed, to the warlike tribesmen, polo was a miniature battle with as many as 100 "players" to the side.

Polo in time became a national sport and was played extensively by the Persian nobility. Sons of kings were trained in the use of "hawk, cheetah, polo, swordsmanship, and archery." Evidence that women as well as men played the game (in Persia called *Chaugan*, meaning "stick" or "mallet") includes poetical references to the Queen and her ladies playing King Khosrow II Parvez and his courtiers in the 6th century.

By courtesy of the Trustees of the British Museum







Persian princes playing polo, miniature from an illuminated manuscript, 1472. In the British Museum.

From Iran the game was carried to Arabia, and from there to Tibet (the English word polo is the Balti word meaning "ball"), China, where it found a great following, and Japan. Polo in China often involved more than pure sporting interest; in AD 910, the death of a favoured relative in a game prompted Emperor T'ai Tsu to order all surviving participants in the game beheaded.

Polo was introduced into India by the Mohammedan conquerors in the 13th century. It was there, six centuries later, that the sport was played for the first time by representatives of a Western culture. Although polo had been described in Sir Anthony Sherley's *Travels to Persia* (1613), the first Europeans known to play the game were some British tea planters in Assam, who had learned the game in nearby Manipur and formed the first European polo club in 1859 at Silchar. The Calcutta Polo Club was formed in the early 1860s. The spread of the game was both rapid and dramatic after a captain in the 10th Hussars stationed in India witnessed a match early in 1866 and, being taken with the fast, exciting play, immediately formed a team from among his fellow officers. Before the end of that year informal matches were being staged between British cavalry units in India, and, in 1870, a challenge round was initiated between the 10th Hussars and the 9th Lancers in England. In these early matches there were eight men to the side and almost no rules. Finding a ready interest among prospective players and spectators, polo grew rapidly in England, with matches at Richmond Park and Hurlingham attracting upward of 10,000 fans by 1875.

In 1876, James Gordon Bennett, publisher of the New York *Herald*, witnessed his first polo game, became infatuated, and introduced the game to the United States. By late in that year, informal games were being played in New York, first at Dickel's Riding Academy in Manhattan and then by 1877 at Jerome Park race track in West-

chester County. In the summer of 1877, the first North American polo club, the Westchester Polo Club, was formed. One of the early New York polo facilities was the famed Polo Grounds, located on 156th Street. In 1881 the Meadow Brook Club was formed by such outstanding early players as Thomas Hitchcock, Sr., August Belmont, and Benjamin Nicoll.

When polo was first played in the U.S., a team was still made up of eight players. Both in the U.S. and England, this number was later reduced to five and then, in 1881 in the U.S. and in 1883 in England, to four, the present number. Though the rules devised by the Hurlingham Club of England were at first used in the U.S., these were later modified to approximate the rules used today. In 1888 a system of handicapping (see below *The handicap system*) was devised to equalize tournament play, and formal organization was realized in 1890 with the establishment of the Polo Association (predecessor of the United States Polo Association). The Polo Association standardized the rules, and polo spread throughout many parts of the country.

In the 1970s there were more than 100 member clubs (including 10 university and scholastic clubs) in the United States Polo Association playing the game in 30 states, the District of Columbia, Manila, and three Canadian provinces.

Outside the United States, the governing body is the Hurlingham Polo Association, with which the associations of many other countries are associated, including, in the 1970s, India, Pakistan, Assam, New Zealand, Australia, South Africa, Rhodesia, Zambia, Kenya, Nigeria, Malaysia, Jamaica, Malta, Cyprus, the Republic of Ireland, Northern Ireland, Accra, Aden, Tangier, Hong Kong, and the Rhine Army Polo Club. Polo is also actively played in France, Spain, and Italy. There were at the time more clubs and more players participating in polo world-wide than ever before in the sport's history.

International competition. The first of the great international polo competitions was inaugurated in 1886 with the United States challenging Great Britain. The English, at that time the undisputed world leaders of polo, defeated the Americans two straight games in a best-of-three series and won the first Westchester Cup. The U.S. challenged again in 1902 but after winning the opening match lost the two succeeding games. The British again defended in 1909, when the U.S., paced by Harry Payne Whitney, struck hard to win the first two games and the Cup. The Cup was played for nine additional times (the last in 1939) with the Americans winning each time except in 1914. In 1971 the U.S. defeated England for the Coronation Cup in the first international match between the two countries since 1939.

Birth of modern game

The 1909 Westchester Cup series marked the birth of the modern game. Until that tournament polo had been played in the English style, which featured relatively slow play with short, controlled hitting. The Americans had devised a long-hitting, fast-moving, wide-open style of play that devastated the English and revolutionized the sport. Following the Westchester Cup series the rules of the two countries were assimilated. The U.S. adopted the English rule permitting a player to hook an adversary's stick with his mallet, and the English abandoned their offside rules, under which attacking players could not precede the ball, and adopted the handicap system, explained below.

From 1909 until 1950, the U.S. was supreme in polo. In the years before 1920 and throughout that decade and the 1930s, polo had gained in popularity in Argentina, and by 1928 a second great international rivalry had formed. In that year the first Copa de las Americas (Cup of the Americas) was contested between the U.S. and Argentina. The U.S., paced by Thomas Hitchcock, Jr., won that first encounter and repeated again in 1932. After that time, the Copa was played for in 1936, 1950, 1966, and 1969, with Argentina winning each time. In the 1970s Argentina was the unquestioned master of international polo.

With the resumption of the Copa series in 1966 and 1969 combined with the World 30 Goal Championship held in Buenos Aires in 1966 with teams from the United States, Argentina, and Great Britain competing (Argentina won the event) there has been renewed interest in international competition.

To that effect, a privately sponsored British side competed very favourably in the United States in the mid-1960s, and then in 1971 a United States team played in England for the Coronation Cup with the United States side victorious. While the Coronation Cup game (it was a match game, not a series) represents a step toward a possible resumption of the Westchester Cup series, it cannot rightly be placed in the same category as that event.

In another international polo series, between the U.S. and Mexico, the Camacho Cup has been played for three times (the last in 1946), with the U.S. winning on all three occasions.

The game. From its conception as a rough, disorganized, warlike spectacle, polo has evolved into a highly refined, sophisticated sport combining the excitement of horse racing, hockey, and soccer.

Polo is played on an outdoor grass field 300 yards (274.32 metres) long by 160 yards (146.3 metres) wide. There are lightweight goal posts at each end, 8 yards (7.3 metres) apart. A score is made by hitting the ball through these goals. Play commences with the two teams of four men each lined up parallel in the centre of the field. One of the umpires (there are two mounted umpires on the field and a referee on the sidelines) bowls the ball between the line of players. Then, with passes to teammates, speed, and manoeuvring, each team tries to score as the other attempts to prevent a score against it. A game consists of six periods (chukker, chukkar, or chukka) of 7½ minutes each. (Eight chukkers are played in Argentina,

while four is a common number in England and Europe.)

The players and positions

As in most other team sports, each player is assigned a position with certain responsibilities to the strategy of the game. But unlike other team sports, polo players are not known by position name (*e.g.*, forward, halfback, or shortstop) but rather by number. The fine points and intricacies of each position are learned over a period of time with practice and game experience being important factors. The basic duties of the players are as follows:

Number One. This position, usually assigned to the novice or weakest player on a team, is, in fact, one of the most difficult to play. Requiring great anticipation of the play, determination, and self-control, the Number One is theoretically responsible for scoring goals and neutralizing the opposing Number Four (defensive player). He places himself to receive passes from his teammates and generally serves as an offensive spearhead.

Number Two. The Number Two is the "hustler" or "scrambler." Always scrapping for the ball, he requires quick, fast ponies, a keen eye, and an optimistic, aggressive nature.

Number Three. The Number Three, sometimes referred to as the pivot man, "quarterbacks" the team. He must be a long, powerful hitter, capable of tactical leadership. The Three has a dual role: he must feed balls up to the Two and One but also help maintain a solid defense. The Number Three is usually the best player on a team.

Number Four. The Number Four (Back) is primarily a defensive player, who, though he may move anywhere on the field, has as his main function the prevention of the opposition's scoring.

Polo ponies

The polo pony (the term pony persists in polo nomenclature though the mount is really a horse, for there is no longer any height limit on the mounts used) is a unique animal combining the docility of a lady's hack, the quickness of a quarter horse, the speed and endurance of a thoroughbred, and the intelligence of the Arab.

Pure thoroughbreds are used but grade thoroughbreds (horses of mixed breeding—one-fourth or one-eighth quarter horse or other local bloods and three-fourths or seven-eighths thoroughbred) are predominant. Most of the best polo ponies are bred in Argentina or in the U.S., at southwestern or Rocky Mountain ranches where they are broken early and receive thorough work as cow ponies. Most prospective polo ponies begin a training period at about age five that may last from at least six months up to two years. Ponies reach their peak at about age 9 or 10 and with good care and lack of injury may play until age 18 or 20.

Each player is handicapped or rated from 0 to 10 according to his ability and relative worth to a team. (In England minus ratings—*e.g.*, −1, −2—are used, but this practice is not universal.) Players are rated on horsemanship, hitting ability, knowledge of the game, the quality of their horses (the pony is judged to be 60 to 75 percent of a player's ability), and sportsmanship. To indicate the relative difficulty in obtaining a 10 rating, in the early 1970s there were only four such players in the world, all from Argentina. In the U.S., approximately 50 percent of all players (there were about 1,000) were rated 0, 25 percent were rated 1, and the remaining 25 percent were 2 and above—with only 50 players rated at 4 or higher.

Equipment

Players wear a protective helmet, riding boots of a height just below the knee, riding breeches, and a coloured shirt bearing the number of the position each plays. A player may also wear knee pads and spurs (not sharp) and carry a whip.

The ball for outdoor polo is made of bamboo or willow root about 3.25 inches (8.3 centimetres) in diameter and weighing about 4 ounces (113.4 grams). The mallet consists of a bamboo head 9.5 inches in length and weighing about 7 ounces, a flexible bamboo-cane shaft, and a rubber-wrapped grip with a webbed thong for wrapping around the hand. The overall length of the mallet is from 48 to 53 inches (depending on pony size and length of the players' arms). The ball is struck with the side of the mallet head, not the end.

Saddles are English-style with deep seats similar to jumping saddles. The pony's front legs are bandaged from just below the knee to the ankle to prevent injury, and the pony's mane is clipped and his tail braided to prevent interference with the mallet swing.

Variations. Aside from the more common outdoor polo, the game may also be played indoors or in an arena. An indoor field or arena, the standard size of which is 50 yards (45.7 metres) wide by 100 yards (91.4 metres) long, is completely surrounded by wooden boards (called knee boards because they are "knee high" on a mounted player) approximately 4 to 4.5 feet (1.4 metres) high to keep the ball in play. The ball is inflatable leather, 4.5 inches (11.4 centimetres) in diameter and weighing at least 6 ounces (50.1 grams). A team consists of three players rather than four as in outdoor polo. With these exceptions and some minor rule changes, the game is the same as outdoor polo.

BIBLIOGRAPHY. Further information on the history of polo and details on how the game is played may be found in the following references: N. BENT, *American Polo* (1929); J. BOARD, *Polo* (1956); W.C. (R.C.L.)

Polybius

Polybius, a Greek who spent 17 years in detention in Rome in the 2nd century BC, is one of the great historians of the ancient world. Combining high moral earnestness and careful research, Polybius told with perception the dramatic story of Rome's rise to world power in the 3rd and 2nd centuries BC. He was born at Megalopolis, in Arcadia, the son of Lycortas, a distinguished Achaean statesman. The dates of his birth and death are inferred at about 200 and 118 BC.

Polybius received the upbringing appropriate for a son of rich landowners. His youthful biography of Philopoemen reflected his admiration for that great Achaean leader; and an interest in military matters found expression in his lost book, *Tactics*. He enjoyed riding and hunting, but his knowledge of literature was rather specialized (apart from the historians) and his acquaintance with philosophy superficial. Between 180 and 170/169, when he was hipparch (cavalry commander) in the Achaean Confederation, nothing is known of his career. But he then became involved in critical events. Encumbered by their war with Perseus of Macedonia, the Romans were watching for disloyalty in the Greek states. Although Polybius declared for open support of Rome and was sent with the cavalry to the consul Quintus Marcius Phillippus, Achaean help was rejected. After Perseus' defeat at Pydna in 168, Polybius was one of 1,000 eminent Achaeans who were deported to Rome and detained in Italy without trial.

Residence in Rome

At Rome, Polybius had the good fortune to attract the friendship of the great Roman general Scipio Aemilianus; he became Scipio's mentor and through his family's influence was allowed to remain in Rome. It is probable that Polybius accompanied Scipio to Spain in 151, went with him to Africa (where he saw the Numidian king Masinissa), and crossed the Alps in Hannibal's footsteps on his way back to Italy. Shortly afterward, when his political detention had ended, Polybius joined Scipio at Carthage and was present at its siege and destruction in 146; and it is likely that he then undertook a voyage of exploration in the Atlantic, which is related in Pliny the Elder's *Historia naturalis* (*Natural History*). Meanwhile, hostilities had broken out between Achaea and Rome, and Polybius was in Corinth shortly after its destruction, in 146. He devoted himself to securing as favourable a settlement as possible for his countrymen and to re-establishing order; and, as the geographer Pausanias states, Achaean gratitude found expression in the erection of statues in his honour at Tegea, Pallantium, Mantineia, Lycosura—where the inscription declared that "Greece

would never have come to grief, had she obeyed Polybius in all things, and having come to grief, she found succour through him alone"—and Megalopolis, where it was recorded that "he had roamed over all the earth and sea, had been the ally of the Romans, and had quenched their wrath against Greece." Of Polybius' life after 146 little is known. At some date he visited Alexandria and Sardis. He is known to have discussed political problems with Scipio and Panaetius of Rhodes. He wrote a history of the Numantine War, evidently after 133 BC, and also a treatise on the habitability of the equatorial region; but when he composed the latter is unknown.

Scope of the history. The history on which his reputation rests consisted of 40 books, the last being indexes. Books I–V are extant. For the rest there are various excerpts, including those contained in the collection of passages from Greek historians assembled in the 10th century and rediscovered and published by various editors from the 16th to the 19th centuries.

Polybius' original purpose was to narrate the history of the 53 years (220–168 BC)—from Hannibal's Spanish campaign to the Battle of Pydna—during which Rome had made itself master of the world. Books I–II form an introduction covering Roman history from the crossing into Sicily against the Carthaginians in 264 and including events in various other parts of the world (especially Achaea) between 264 and 220. In Book III, Polybius sketches a modified plan, proposing to add an account of how the Romans exercised their supremacy down to the destruction of Carthage, in 146.

The events of 168–146 were related in Books XXX–XXXIX. Polybius probably conceived his revision after 146, having by this date completed his narrative down to the end of the Second Punic War. At least Books I–VI seem to have been published by about 150; there is no information as to when the rest of the work, including the revised plan in Book III, appeared.

Conception of history. "All historians," according to Polybius,

> have insisted that the soundest education and training for political activity is the study of history, and that the surest and indeed the only way to learn how to bear bravely the vicissitudes of fortune is to recall the disasters of others.

Practical experience and fortitude in facing calamity are the rewards of studying history and are stressed repeatedly throughout the work. History is essentially didactic. Pleasure is not to be wholly excluded; but the scale comes down sharply on the side of profit. To be really profitable, history must deal with political and military matters; and this is *pragmatiké historia*, in contrast to other sorts of history (IX, 1–2)—genealogies and mythical stories, appealing to the casual reader, and accounts of colonies, foundations of cities, and ties of kindred, which attract the man with antiquarian interests. Its nature is austere, though it may include contemporary developments in art and science. He stands in contrast to the sensationalism of many of his predecessors, who confuse history with tragedy.

Polybius' criticism of other historians

In Book II, in which he attacks the Greek historian Phylarchus, for practices that might be called unprofessional today, Polybius states:

> . . . A historian should not try to astonish his readers by sensationalism, nor, like the tragic poets, seek after men's probable utterances and enumerate all the possible consequences of the events under consideration, but simply record what really happened and was said, however commonplace. For the object of history is the very opposite of that of tragedy. The tragic writer seeks by the most plausible language to thrill and charm the audience temporarily; the historian by real facts and real speeches seeks to instruct and convince serious students for all time. There it is the probable that counts, even though it be false, the object being to beguile the spectator; here it is the truth, the object being to benefit the student.

This attack on Phylarchus is not isolated. Similar faults are castigated in other historians judged guilty of sensationalism (*cf.* II, 16, 13–15; III, 48, 8; VII, 7, 1–2; XV, 34, 1–36). Nor are these their only weaknesses. Many historians are prone to exaggeration—and that for a special reason. As writers of monographs whose subjects are simple and monotonous, they are driven "to magnify small matters, to touch up and elaborate brief statements and to transform incidents of no importance into momentous events and actions" (XXIX, 12, 3). In contrast to such practices, Polybius stresses the universal character of his own theme, which is to narrate "how and thanks to what kind of constitution the Romans in under 53 years have subjected nearly the whole inhabited world to their sole government—a thing unique in history" (I, 1, 5).

Polybius believed that he had a particular reason for adopting a comprehensive view of history, apart from his own predilection for such a view. He wrote:

> Hitherto the affairs of the world had been as it were dispersed . . .; since this date [220 BC] history has formed an organic whole, and the affairs of Italy and Africa have been interlinked with those of Greece and Asia, all tending towards one end (I, 3, 3–4).

The role of Tyche

Indeed, only universal history is capable of adequately treating Rome's rise to world power—the historian's synoptic view matches the organic character of history itself:

> What gives my work its peculiar quality, and is nowadays most remarkable, is this. Tyche [Fortune] having guided almost all the world's affairs in one direction and having inclined them to one and the same goal, so the historian must bring under one conspectus for his readers the operations by which she has accomplished her general purpose. For it was chiefly this consideration, coupled with the fact that none of my contemporaries has attempted a general history, which incited and encouraged me to undertake my task (I, 4, 1–2).

The role here allotted to Fortune is somewhat unusual. For clearly the value of history as a source of practical lessons is diminished if cause and effect are at the mercy of an incalculable and capricious power. Usually, although Polybius uses Fortune to cover a variety of phenomena, ranging from pure chance to something very like a purposeful providence, much of the apparent inconsistency springs from his use of purely verbal elaboration or the careless adoption of current Hellenistic terminology, which habitually made Fortune a goddess. Here, however, Fortune seems to be a real directive power, which raised Rome to world dominion—because Rome deserved it. Normally, Polybius lays great emphasis on causality, and his distinction (III, 6) between the causes of an event (*aitiai*) and its immediate origins (*archai*) is useful up to a point, though it is more mechanical than that of the great Greek historian Thucydides and allows nothing for the dialectical character of real historical situations.

An important place in Polybius' work is occupied by his study of the Roman constitution and army and the early history of the city in Book VI. His analysis of the mixed constitution, which had enabled Rome to avoid the cycle of change and deterioration to which simple constitutional forms were liable, is full of problems, but it has exercised widespread influence, from Cicero's *De re publica* down to Machiavelli and Montesquieu.

Sources of information. Polybius defines the historian's task as the study and collation of documents, acquaintance with relevant geographical features, and, finally, political experience (XII, 25e); of these the last two are the most essential. And he practiced what he preached, for he possessed good political and military experience and had travelled widely throughout the Mediterranean and beyond. Nor did he neglect written sources; indeed, for his introductory books, covering the period from 264 to 220, they were essential. For the main part of his history, from 220 onward, he consulted many writers, Greek and Roman; but following precedent, he rarely names them.

Polybius' private sources

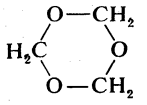
He had access to private sources; for example, Publius Cornelius Scipio's letter to Philip V of Macedonia describing the capture in Spain, in 209 BC, of New Carthage (X, 9, 3), and a letter of Scipio Nasica to some Hellenistic king about the campaigns of the Third Macedonian War (XXIX, 14, 3). He almost certainly consulted the Achaean record office and must have drawn on Roman records for such material as the treaty between Carthage and Philip V (VII, 9). It has not been proved that he had access to the Rhodian records. His detailed

figures for Hannibal's troop formations in Italy came from an inscription left by Hannibal, which he found in the Temple of Juno on the Lacinian promontory.

Polybius regarded oral sources as his most important, and the questioning of witnesses as the most vital part of a historian's task; indeed, this is one reason why he chose to begin his main history at the year 220. Anything else would be "hearsay at one remove," a safe foundation for neither judgments nor statements. Of the thousands whom he must have questioned, few names can be isolated; but at Rome he had opportunities of meeting men from many areas, including internees, ambassadors, and visitors.

Style and qualities as a historian. Writing in the 1st century BC, Dionysius of Halicarnassus reckons Polybius among those who "have left behind them compositions which no one endures to read to the end"; that his successors shared this view of Polybius' style is confirmed by the failure of his works to survive except in an incomplete form. The infelicity of Polybius' Greek (which frequently reproduces the conventional phrases of the Hellenistic chancelleries familiar from contemporary inscriptions) lies in its awkward use of long and cumbersome circumlocutions, vague abstract nouns, and pedantic repetitions. To the scholar his style is, however, no great obstacle; and, though in his anxiety to improve his reader he moralizes and belabours the obvious, the perennial interest and importance of his theme will always ensure him a following among those who can enjoy a historian who is accurate, serious, and sensible, understands the events of which he writes, and, above all, who asks the right questions.

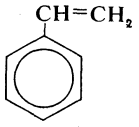
BIBLIOGRAPHY. Two works by FRANK W. WALBANK, *A Historical Commentary on Polybius*, 2 vol. (1957–67), and *Polybius* (1973), contain both general and detailed discussion and comprehensive bibliographies. The standard text is that of THEODORUS BUTTNER-WOBST, 5 vol. (1866–1904); but FRIDERICUS HULTSCH, 4 vol. (1870–92), gives a fuller description of manuscript variants; for the history of the text, JOHN M. MOORE, *The Manuscript Tradition of Polybius* (1965), is invaluable. There is a Greek text with an English translation by W.R. PATON, "Loeb Classical Library," 6 vol. (1922–27); and a translation by E.S. SCHUCKBURGH, 2 vol. (1889, reprinted 1962). Three fascicles (covering about half) of a *Lexicon Polybianum* (1956–) by ARNO HAUERSBERGER have so far been published.



(F.W.W.)

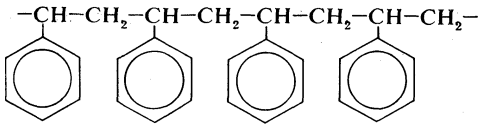
Polymers

Polymers are essential to the existence of man and his civilization. The human body, all animal and plant tissues, and most structural substances of organic nature—such as proteins, wood, resin, and chitin, the hard coating of insects—consist of polymeric (macromolecular) materials. Many minerals, such as diamond, quartz, and feldspar, are inorganic polymers, and numerous products of ancient and modern industry, such as concrete, porcelain, glass, textiles, paper, rubbers, and plastics, are either entirely or substantially polymeric. Only in the first half of the 20th century, however, was it clearly recognized that these substances all possess one essential common feature, namely, that they consist of very large (macro) molecules.



Definition

A polymer (Greek *polys*, "many"; *meros*, "part" or "unit") is a substance the molecules of which are multiples of low-molecular-weight units, molecular weight being, as the name suggests, a measure of the weight of a molecule relative to a chosen standard (for practical purposes, an atom of hydrogen has a weight of one). The low-molecular-weight unit making up the polymer is referred to as the monomer. As long as a polymer is strictly uniform in molecular weight and molecular structure, its degree of polymerization is indicated by the Greek word for the number of monomers it contains; thus, for example, dimers, trimers, tetramers, and pentamers indicate twofold, threefold, fourfold, and fivefold polymers. The term polymer, however, is used to designate a combination of an unspecified number of monomer units. Trioxymethylene, for example, is a (cyclic) trimer of formaldehyde (CH_2O):



trioxymethylene

and polystyrene is the polymer prepared from the monomer styrene:

styrene

polystyrene

If the number of monomer units in a polymer becomes very large, the latter is sometimes called a high polymer. According to present-day usage, a polymer or high polymer need not consist of individual molecules all having exactly the same molecular weight or precisely the same chemical composition and molecular structure.

In the case of some natural polymers, such as the proteins, the individual molecules all have the same molecular weight and molecular structure. This identity of the polymer molecules results from highly specific cellular processes that produce them according to fixed patterns. With most synthetic and natural polymers, however, significant differences occur in the molecular weight of the individual macromolecules, with the result that the material itself is a mixture of homologous polymeric constituents—that is, of individual molecules differing in the number of monomer units they contain. Methods are not available for preparing synthetic polymers of fixed molecular weight, nor can the prepared mixture be separated completely into fractions with uniform molecular weights. Variability in the composition and molecular structures of polymers results from the presence of different end groups that terminate the chains, occasional branches in the chain, variations in the arrangement of the monomeric units, and irregularity in the sequence of monomeric units of different types if more than one type is present.

A completely rigorous system of classifying and naming polymers, conforming to the practice in naming ordinary organic and inorganic molecules, is impossible because of the common variations in structure between individual molecules of most polymer types—variations that cannot be eliminated, or even determined quantitatively in nature or amount by available methods. Nevertheless, it is convenient to treat a particular type of polymer as a single molecular species for purposes of discussion because these variations in structure do not significantly affect the physical and chemical properties of the substance and do not affect its practical application.

NATURAL POLYMERS

All living beings—animals and plants alike—are composed to a very large extent of organic polymers, which not only provide structural materials for the maintenance of life functions but also participate in carrying out the life functions themselves. The solid portions of all plants consist of several polymers, the most important of which are cellulose, lignin, and various resins.

Cellulose and lignin

Cellulose in wood is intimately connected with lignin; but in other parts of plants, it is found in relatively pure form as fibres such as cotton and flax. Cellulose itself is a polysaccharide, that is to say, a polymer whose monomer units are individual sugar molecules. In cellulose the sugar glucose comprises the monomer units, and they are joined to give molecular weights of up to several millions.

In most fibres the polymer chains are combined to give laterally ordered crystalline units that, in turn, are separated by disordered or amorphous areas. This two-phase structure gives cellulose fibres their strength and, at the same time, their softness and pliability.

In all types of wood cellulose is accompanied by lignin, a second polymer, which shows much less regularity than cellulose. Lignin molecules consist of a complicated three-dimensional network of phenolic residues joined chemically by means of short hydrocarbon chains. Because of this molecular complexity, the molecular weight of lignin is not exactly known, but in any event it is very high. Wood also contains several types of resins, which are polymers of the simple hydrocarbon isoprene and have molecular weights ranging from a few thousand to several hundred thousand.

The most important terpene, as the isoprene polymers are called, is rubber that exists in the sap of many tropical trees, especially of the genus *Hevea*. Rubber is a polyhydrocarbon and consists, in the native state, of long chains of isoprene, which have molecular weights around 500,000. Balata, another natural, rubberlike resin, also is a polyisoprene; it differs from hevea rubber chiefly in the geometry of double bonds, or linkages, between carbon atoms in the molecular chains.

Proteins and nucleic acids

Life on Earth is based largely on the existence, properties, and reactions of two classes of polymers—the proteins and the nucleic acids. The monomeric units of proteins are amino acids, relatively small molecules containing amino ($-NH_2$) and carboxylic acid ($-COOH$) groups. The twenty amino acids that occur normally in proteins are always arranged in precise, but different, orders in different protein molecules. Certain proteins have molecular weights around 50,000; in others the molecular weight reaches several millions. All fibres and membranes of animal tissues consist of high-molecular-weight proteins; the processes of life—such as metabolism, vision, and respiration—are based on the protein materials known as enzymes, which act as catalysts for biochemical reactions. Generally, the exterior parts of the animal body—fur, hair, nails, horn, and skin—consist of proteins with molecular structures of three-dimensional networks of very high molecular weight (*e.g.*, keratin).

Other important natural polymers are the starches, which—like cellulose—are polymers of glucose. Starches are widely distributed in plants and play an important role as a food for animals of all kind. Starches differ from cellulose chiefly in the way the individual monomeric units are joined in the molecules; some varieties—amylose, for example—are simple chains with molecular weights around 100,000; others—called amylopectins—are three-dimensional networks (like lignin) with very high molecular weights. All hard, tough, and strong parts of insects and crustacea—shells, wings, and claws, for example—consist of a nitrogen-containing polysaccharide called chitin. Chitin is composed of long chains of glucose molecules that have been modified by acetylated amino groups; the molecular weights of typical chitin polymer chains are around 100,000.

Many inorganic polymers also are found in nature; these are characterized by their hardness, high melting range, and great mechanical strength. Some inorganic polymers are formed by atoms of the element alone; in others the monomeric units are inorganic compounds. Diamonds are a good example of the first class; this

Diamond, graphite, and silica

substance consists of a three-dimensional network of carbon atoms that are combined with each other exclusively by single bonds. In fact, diamond is the simplest crystalline, three-dimensional polymer that exists. Another polymeric form of the element carbon is graphite, the writing material in a lead pencil. Graphite consists of two-dimensional polymeric layers of carbon atoms joined together alternately by single and double bonds. Between these layers of densely packed carbon atoms are relatively large distances, a factor that causes the typical lamellar (layer-like) character of all graphitic materials. Elemental sulfur and selenium exist generally in crystalline modifications but also in a polymeric form consisting of long chains with molecular weights around 100,000.

The most important inorganic polymer is silica, or silicon dioxide, which exists in several crystalline modifications and in a glossy amorphous form; they are all three-dimensional networks—partly regular, partly random—held together by chemical bonds between silicon and oxygen. The strength of the silicon–oxygen bonds is responsible for the high softening range and the extreme hardness of these compounds.

The three-dimensional silica networks are capable of accepting electrons; in the process they are converted into polymeric ions that can be neutralized and stabilized by positively charged metal ions, such as those of sodium, potassium, magnesium, calcium, and aluminum. The result is a large and important family of silicates that, together with other metals, form most of the hard and high-melting natural rocks—including granite, feldspar, and agate.

SYNTHETIC POLYMERS

Organic. In the course of their studies, organic chemists of the 19th century frequently encountered materials that were neither ordinary liquids nor crystalline solids but of an amorphous semisolid or glassy character. These materials generally defied the classical methods of purification, isolation, and identification. As a consequence, most of these substances were only referred to in passing in scientific writings but were not further investigated. In a few instances, however, the yield of such a material was so considerable and its properties were so attractive for practical use that its preparation was more thoroughly studied, and a larger scale development of the product was carried out. Of these developments, probably the most important stemmed from the discovery in 1909 by Leo Baekeland, the Belgian-born U.S. chemist, of a viscous product from the reaction of phenol with formaldehyde. Baekeland discovered that many species of useful plastics could be prepared by varying the proportions of the components and the conditions of the reaction. This discovery led to the development of the Bakelite resins, which occupy an important position in the plastics industry. In the 1920s, when the structure and character of the most important natural polymers—cellulose, proteins, and rubber—were elucidated, a new, broadly based series of systematic studies of polymer formation was undertaken. These studies led to the production of a large number of synthetic polymers, which in turn permitted an amazing variety of industrial applications of polymers as fibres, plastics, synthetic rubbers, coatings, and adhesives.

This rapid development in the chemistry of synthetic polymers was aided by the fact that most building units for the preparation of synthetic polymers are products of the petroleum-refining industry, which also was undergoing rapid development at the same time.

It is convenient to classify the synthetic organic polymers according to the chemical character of their monomers, beginning with the simplest variety, the hydrocarbons.

Polyhydrocarbons. Many simple and inexpensive unsaturated hydrocarbons, such as ethylene, propylene, butadiene, and styrene, can be readily transformed into polymeric materials by simple addition polymerization, the repeated addition of one monomer unit after another to the growing polymer chain. In this way important thermoplastic and elastomeric (polymers with elastic properties) products are obtained.

Polyethylenes and polypropylenes

There are two ways to prepare polyethylene on an industrial scale: (1) polymerization with oxygen as catalyst at high pressure (1,000–2,000 atmospheres) and high temperatures (190–210° C) and (2) polymerization with organometallic catalysts at ordinary pressure and ordinary temperatures. The high-pressure polyethylenes have specific gravities between 0.92 and 0.93 (water = 1.000), melting points around 110° C, and molecular weights from 20,000 to 40,000. They represent relatively soft, but tough, thermoplastic materials with excellent electrical and mechanical properties and with outstanding resistance against most acids, bases, and solvents. Such high-pressure polyethylenes are widely used for the production

of synthetic fibres and for the preparation of bottles and small containers. The low-pressure polyethylenes have specific gravities between 0.95 and 0.97, melting points around 134° C, and molecular weights up to many hundred thousands. They represent hard, tough, strong thermoplastic materials with excellent electrical, mechanical, and chemical properties. They are widely used for the production of larger bottles, containers, pails, and trash cans.

There are two varieties of polypropylene: a soft, rubbery type of minor importance and a hard, crystalline, high-melting type, which is a valuable thermoplastic material of wide applications in certain areas of the textile industry and also used to make molded objects. The second type of polypropylene has crystalline character, melts at around 178° C, and has a density of about 0.90, and a molecular weight ranging from 50,000 to 200,000.

Polybutadienes and polystyrenes

Most polybutadienes are typical elastomers; they have many valuable properties. Butadiene can be polymerized in solution, suspension, or emulsion with different types of catalysts. Some of the products are crystalline, others are amorphous. All of them remain soft and resilient down to low temperatures and can be cured into elastomers of great strength and excellent abrasion resistance. The molecular weights range from 80,000 to 200,000. Most polybutadienes are soluble in aromatic solvents, such as benzene.

Styrene polymerizes readily in pure form or in solution, suspension, or emulsion—usually under the influence of peroxide catalysts. The polymer is a colourless, transparent, thermoplastic resin (polymer product used to make objects of plastic with the application of heat), which has a specific gravity around 1.08 and a molecular weight range from 50,000 to 200,000. Commercially produced polystyrene is amorphous, has useful electrical and mechanical properties, and softens around 90° C. It is highly resistant to moisture, acids, and bases but is easily attacked by organic solvents. Polystyrene and closely related polymers are the most popular resins for certain molding and extrusion procedures in the forming of plastic objects.

Particularly important are copolymers (polymers composed of several monomer units) of butadiene and styrene, which are made in emulsion with the aid of peroxide catalysts. During the 1940s and 1950s these amorphous elastomeric materials were the most important synthetic rubbers and, subsequent to that time, continued to be valuable and useful products. They can be compounded and used like natural rubber, and they exhibit excellent resistance to abrasion and deterioration caused by oxygen, heat, and light.

Polyvinyls and polyacrylics. Many derivatives of ethylene still retain the double bond and are able to polymerize. Among the materials produced in this way are several important families of polymers, the polyvinyls and polyacrylics.

Polyvinyl chlorides and polyvinyl esters

The replacement of one hydrogen atom in ethylene by chlorine leads to vinyl chloride, which polymerizes readily under the influence of peroxide catalysts in suspension or emulsion. The product, polyvinyl chloride, is a colourless, hard, tough thermoplastic material, which softens only at a high temperature. Its specific gravity is around 1.55; it is substantially amorphous and resistant to most destructive chemical agents, including hot organic solvents. The molecular weight ranges from 50,000 to 150,000. It is a very useful material prepared as sheets and as extruded or molded products.

Vinyl acetate and vinyl butyrate are liquid esters of vinyl alcohol (the hydroxide equivalent of vinyl chloride). They polymerize with peroxide catalysts in solution, suspension, and emulsion to give amorphous, soft resins with molecular weights between 30,000 and 100,000. The products find many uses as coatings and adhesives. Both vinyl acetate and vinyl butyrate copolymerize readily with vinyl chloride to give a large family of thermoplastic materials. In these substances the vinyl chloride contributes hardness and high-melting characteristics, whereas the vinyl esters act as internal (*i.e.*, chemically bonded) plasticizers, additives that impart favourable qualities to plastics. These copolymers exhibit a wide range of properties; hence they find many applications, such as for coatings, cohesives, films, and extruded or molded articles of many kinds.

Polyacrylics

The basic units for the large and important family of polymeric materials known as polyacrylics are acrylic acid (propenoic acid) and methacrylic acid (a methylacrylic acid with the methyl and carboxyl groups joined to the same carbon atom). The methyl esters of these acids are readily polymerized with the aid of peroxide catalysts in the pure material or in solution, suspension, or emulsion. Polymethyl methacrylate is a hard, colourless, brilliantly transparent thermoplastic material that is widely used to manufacture extruded and molded articles. Equally important is the polymer of acrylonitrile (vinyl cyanide) that is usually made in suspension or emulsion with the aid of peroxide catalysts. The product has a molecular weight in the range 70,000 to 120,000; it represents a white, hard, moderately crystalline, material, which softens at a high temperature and is soluble only in a few selected high-boiling organic liquids, such as *N*,*N*-dimethylformamide and dimethyl sulfoxide. Copolymers of acrylonitrile (80–90 percent) and methyl acrylate or vinyl acetate occupy an important place in the man-made fibre industry. Copolymers of acrylonitrile (10–15 percent) and styrene represent thermoplastics for extrusion and molding. The products possess superior hardness, higher softening ranges, and better impact resistance than the polymers prepared from either monomer alone. Finally, copolymers of acrylonitrile (20–30 percent) and butadiene, prepared in emulsion, represent a valuable species of synthetic elastomer. These so-called nitrile rubbers have excellent resistance to hot oils, oxygen, ozone, light, and heat; therefore, they find important applications in the construction of airplanes, automobiles, and electrical equipment.

Polyacetals and polyethers. In addition to the polymers whose backbone chains consist of a continuous sequence of carbon–carbon bonds, there are many important polymers with oxygen or nitrogen atoms in the backbone chain along with carbon atoms. Among those with oxygen atoms in the backbone are the polyacetals and polyethers. One of the simplest polyacetals is polyformaldehyde, a hard, high-melting, crystalline material with excellent resistance against abrasion and against the action of solvents. It is prepared by polymerization of formaldehyde—a very simple and inexpensive monomer—in the gaseous state with anionic catalysts. It is used for making machine parts in place of, or in conjunction with, certain metals. Polyoxyethylene, a polyether, is prepared in bulk or in solution from ethylene oxide with cationic catalysts. The product is a white, crystalline, water-soluble material with a melting point of about 75° C; it is a particularly useful thickener of aqueous solutions and a material used for coatings for textiles and paper.

Polyesters. When a bifunctional carboxylic acid, such as adipic acid, $HO_2C(CH_2)_4CO_2H$, reacts with a bifunctional alcohol, such as ethylene glycol, $HO(CH_2)_2OH$, under conditions that lead to the elimination of water, a linear macromolecule is formed that is characterized by a repetition of ester groups (–COO–) along the chain and is called, therefore, a polyester. Each combination of a specific dicarboxylic acid and a specific glycol leads to a particular polyester.

Nomenclature of linear polymers

In a convenient naming system for linear polyesters, the number of carbon atoms in the glycol and in the dicarboxylic acid are used after the word polyester. For example, hexamethylene glycol, $HO(CH_2)_6OH$, with six carbon atoms, and adipic acid, $HOOC(CH_2)_4COOH$, also with six carbon atoms, give a polyhexamethylene glycol adipate commonly referred to as polyester-6,6. Similarly, polydecamethylene succinate is polyester-10,4. Polyesters can also be formed by the self-condensation of hydroxycarboxylic acids, such as hydroxyundecanoic acid, $HO(CH_2)_{10}COOH$. The resulting polymers need only one figure to characterize them; in this case, the product polymer is called polyester-11.

All linear polyesters made with bifunctional open-chain glycols and dicarboxylic acids are colourless, crystalline,

thermoplastic materials. Their melting points and solubilities vary over a wide range and depend on the length of the methylenic ($-CH_2-$) segments between the ester bonds in the chain. Because of the polarity (separation of electrical charge) of these bonds, they are mainly responsible for the intermolecular attraction between the chains, and hence for their softening and solubility behaviour. The closer the ester bonds, the higher is the melting point of the polyester and the less is its solubility. Polyethylene glycol oxalate, polyester-2,2, melts around 200° C, whereas polyester-6,6 melts around 80° C. The former is soluble in only a few selected organic liquids; the latter dissolves readily in most ordinary organic solvents, such as benzene, ethyl methyl ketone, and butyl acetate.

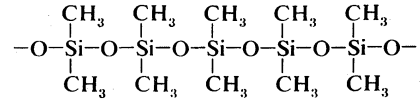
Low-molecular-weight polyesters (molecular weight up to 5,000) are excellent plasticizers for many natural and synthetic resins; the high-molecular-weight species (above 10,000–15,000) are valuable thermoplastics themselves and are used for the manufacture of films and molded objects. Polyesters with high melting points (250° C and above) are obtained from aromatic (cyclic) constituents. Examples are the polymer made from ethylene glycol and terephthalic acid (benzene-1,4-dicarboxylic acid)—the so-called polyester-2T—and the material made by the self-esterification of 4-hydroxybenzoic acid —the HOB-polyester—both of which melt above 250° C and do not dissolve in most organic solvents. Because of their high melting points and insolubility, they represent valuable materials for the formation of films used in electrical insulation, photography, and packaging, and also for fibres used in fabrics and tire cord. When the polyesterification is carried out in the presence of a polyfunctional component—such as pentaerythritol, a tetrahydroxy compound, or a tricarboxylic acid—the product is not a linear macromolecule but a highly branched species that, after sufficient removal of water, is converted into a three-dimensional network. Unlike the thermoplastic linear polyesters, systems of this kind are thermosetting—that is, the original material softens on heating, but once set in a new shape it is extremely resistant to further heating. The thermoset polyesters are insoluble, hard, and tough materials of extremely high molecular weight. They are widely used as coatings, laminating agents, and in making molded objects. They are usually applied as thermosetting compositions that are cured into the thermoset state.

Polyamides. When a bifunctional amine (two $-NH_2$ groups) reacts with a bifunctional acid (two $-CO_2H$ groups) with elimination of water, a linear macromolecule is formed that contains in the chain a regular repetition of amide groups (–CO–NH–) and is therefore called a polyamide. More commonly, these materials are known as nylons. The same nomenclature is used for polyester as for polyamides. Thus, the nylon made of hexamethylenediamine, $H_2N(CH_2)_6NH_2$, and adipic acid, $HOOC(CH_2)_4COOH$, is nylon-6,6; the polymer made from the same diamine and sebacic acid, $HOOC(CH_2)_8COOH$, is nylon-6,10; and the material made by the self-polymerization of aminocaproic acid, $H_2N(CH_2)_5COOH$, is nylon-6. All polyamides consisting of linear, bifunctional components are hard, tough, colourless, crystalline, thermoplastic materials. Their softening and solubility behaviour is controlled by the magnitude of the intermolecular forces between the individual chains; the major contribution to these forces comes from the amide bonds (–CO–NH–), which are polar themselves and also capable of establishing hydrogen bridges ($>C=O\cdots H-N<$) between adjacent macromolecular chains. The closer the amide groups are in the chain, the stronger is the cohesion between chains, and the stronger the cohesion, the higher the melting point, and the greater the insolubility. For example, the polyamide of ethylenediamine and oxalic acid, nylon-2,2, melts above 300° C (with decomposition), whereas nylon-6,6 melts around 260° C and nylon-6,10 at 215° C. An interesting contrast exists between the polyester series and the polyamide series: corresponding members—such as the polyester-6,6 and the polyamide-6,6—differ substantially in softening temperature and solubility, the nylons having much higher melting points and much lower solubilities than the esters. This difference is usually attributed to the fact that the polyamides can develop hydrogen bridges whereas the polyesters cannot.

Polyamides and polyesters compared

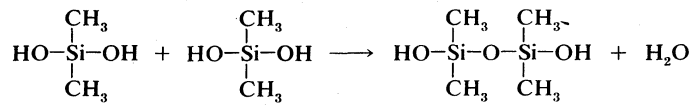
Although nylons find many important applications in the field of extrusion and molding, their outstanding use is in the man-made fibre industry. Nylons dominate all other synthetic fibres in quantity and quality and find successful use in fabrics, tire cords, and many industrial fibres.

Polyurethanes. Another important family of synthetic organic polymers is obtained by the reaction of bifunctional isocyanates (containing two –NCO groups) with bifunctional alcohols (two –OH groups). Again, one obtains linear macromolecules that, in this case, are characterized by the regular repetition of the urethane groups (–O–CO–NH–). The presence of the urethane groups permits the buildup of a three-dimensional network because of the reaction of the hydrogen of the –NH– group with the terminal isocyanate group of a chain. These networks are either elastomeric or rigid; they are used with great success in the field of elastomeric fibres (spandex) and in making both soft and rigid foams.



Inorganic. Although the synthetic organic polymers are a very large family of useful materials, are the product of a very large industry, and although world production in 1970 exceeded 50,000,000 tons, synthetic inorganic polymers have not found any large-scale industrial applications. Synthetic polysilicates (in the form of colloidal particles) are used as fillers and reinforcing agents for plastics used as dentures as well as in synthetic rubbers. Certain polyphosphates with medium molecular weight find some use as flameproofing agents.

Synthetic polysilicates



The only linear inorganic polymer of known structure and molecular weight is made by the interaction of phosphorus pentachloride (PCl_5) and ammonia (NH_3), with the elimination of hydrogen chloride (HCl). The product is known as polyphosphonitrile chloride; the molecular chains, which have a molecular weight of about 100,000, are composed of repeating $PNCl_2$ units. The substance is a yellow, amorphous, soft, rubbery material that dissolves in many organic solvents and, if stretched to a few hundred percent, shows a distinct fibre X-ray diagram, an indication of a regular pattern in the structure of the fibres. Because the material is easily hydrolyzed (broken apart with water), it has found little use as a structural elastomer, but it does have potential use as a polymeric flameproofing agent.

Mixed organic–inorganic. Considerable progress was made during the 1950s and 1960s in the synthesis, characterization, and use of linear polymers containing substantial amounts of inorganic elements in the backbone of the chain, together with organic groups attached to the backbone. The most important representatives of this relatively young family of polymers are the polysiloxanes—or silicones, as they are generally called—which have a backbone chain of alternating silicon and oxygen atoms. Also attached to each of the silicon atoms are two monovalent organic groups, such as the methyl ($-CH_3$), or phenyl ($-C_6H_5$) groups. The structure of polydimethyl siloxane is as follows:

Silicones

Polymers of this type are prepared from monomeric dialkylsilanediols by removal of water between molecules. Preparation of the dimer of dimethylsilanediol demonstrates how the process occurs.

Polysiloxanes of low molecular weight, which sometimes have a closed-ring instead of an open-chain structure, are

oils and greases. Higher-molecular-weight types are versatile elastomeric materials; they remain soft and rubbery even at temperatures as low as −80° C and, at the same time, are more stable at high temperatures (3,000° C and above) than most conventional plastics and rubbers. Similar polymer chains, in which oxygen atoms alternate with boron, phosphorus, or aluminum atoms, also have been studied, but generally their molecular weights are too low (not higher than 2,000) to provide useful mechanical strength.

STRUCTURE OF POLYMERS

The fundamental consideration in the chemical study of polymers, as of any molecular substance, is the composition of the material in terms of its content of the various kinds of atoms and its structure or arrangement of the atoms in the molecules. Determining the composition is substantially a matter of elemental analysis and does not differ from the procedures used in the study of ordinary inorganic and organic compounds. Furthermore, the composition of the polymer follows simply from the compositions of the monomer, or monomers, used to build it up—with due consideration for such additives as catalysts, activators, modifiers, and stabilizers, some of which may become incorporated in the polymer molecules.

Molecular structure

It is much more complicated, however, to define and, consequently, to establish what is generally called the structure of a polymeric or macromolecular system. The term structure refers, first, to all of the information that can be collected concerning a representative, isolated macromolecule of the material, and second, to the manner in which the individual polymer molecules are geometrically arranged and physically bonded to one another in a macroscopic sample of the material. The former aspect of the structure may be called the molecular, or intramolecular, structure; whereas the latter is the supermolecular, or intermolecular, structure—also referred to as the texture, or morphology.

Molecular weights. In considering the molecular structure, it must always be borne in mind that, with the exception of proteins and certain nucleic acids, all natural and synthetic polymers are heteromolecular, or polymolecular, in character—*i.e.*, they do not consist of a single species of large molecules, but rather of a mixture of many species, which have different molecular weights but substantially the same chemical composition. The best characterization of a given polymer is, therefore, its molecular-weight distribution, which is a representation of the percentages of each molecular weight species in the sample. Determining such a distribution requires a delicate and, sometimes, difficult study of the system; this can always be achieved in a satisfactory manner, however, as long as it is possible to prepare a dilute solution (0.1–2.0 percent) of the polymer in an appropriate solvent and to reprecipitate the polymer from the solution without chemical changes. The procedures for establishing molecular weight distributions can be divided into analytical and preparative methods, depending upon whether one obtains information only about the distribution or whether one actually obtains the individual fractions with different molecular weights.

Methods of analysis

The oldest of the analytical methods is ultracentrifugation, a high-speed centrifugation process that separates molecules in solution according to their molecular weights. Analysis of the distribution of the polymer molecules after centrifugation makes it possible to arrive at a complete description of the spread of molecular weights in the original polymer material. Refinements of this method have increased its applicability to complicated polymeric systems and may make it possible to accomplish a physical separation of the different molecular species in this way.

Gel-permeation chromatography—*i.e.*, separation of molecular mixtures by filtration of a solution through a jellylike material—is a more recently discovered practical way to arrive at the molecular-weight distribution of soluble polymers and may, with further improvements, make it possible to obtain the individual fractions.

Extraction and precipitation are the standard preparation methods, which actually furnish more or less uniform fractions of a polymer, each of which is composed of a narrower molecular-weight distribution than is the original material. With the aid of repeated, careful extraction or precipitation steps or both, it is possible to obtain relatively large amounts of materials that are substantially more uniform than the raw polymer.

The systematic application of these methods has shown that all natural and synthetic polymers, such as cellulose, rubber, polyethylene, nylon, and polyvinyl chloride, have rather broad distribution functions; *i.e.*, they represent mixtures of molecules that differ considerably in their molecular weight. In nylon, for example, the 10 percent of the molecules with largest molecular weight have on the average about 10 times the molecular weight of the 10 percent of lowest molecular weight. For many purposes, it is satisfactory to approximate the molecular-weight distribution by a numerical average: doing this means that a mathematical function is replaced by a single number.

Number and weight averages

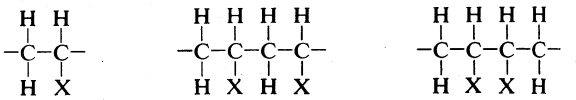
In statistical approaches to any subject it is customary to use different averages, which are characterized by the type of quantity averaged. If a polymer is divided into a number of fractions on the basis of molecular weight, two kinds of average molecular weight can be obtained: number-average and weight-average molecular weights. The number-average molecular weight is obtained by adding together the molecular weights of each fraction (*i.e.*, the number of molecules in each fraction times the molecular weight of that fraction) and dividing the total by the number of all molecules in the system. The number-average molecular weight can be measured experimentally by end-group analysis (detection of the ends of the polymer chains) or by measurements of the vapour pressure or osmotic pressure of solutions of the polymer, both effects depending on the numbers of molecules in the solution.

On the other hand, the weight-average molecular weight is obtained by adding together the actual weights of all molecular weight fractions (*i.e.*, the weight of each fraction times its molecular weight) and dividing this sum by the total weight of all molecules in the system. The weight-average molecular weight can be experimentally determined by light scattering, ultracentrifugation, or viscosity measurements of very dilute solutions, all of which are influenced by the weight of material present in the sample.

Separate determinations of the number- and weight-average molecular weights give an idea of the relative uniformity, or nonuniformity, of a given polymer sample. In an ideal case, in which all molecules have a single molecular weight, the number and weight averages are the same. When the polymer sample contains many molecular classes, however, each with a different molecular weight, the two averages are likely to be quite different. When experimental studies show that the number- and weight-average molecular weights are very similar, the polymer itself is relatively uniform—that is, its molecules all have about the same molecular weights. On the other hand, when the two averages are found to be quite different, then the polymer sample has a broad distribution function and the material is polymolecular and nonuniform.

Arrangement of monomer units. The second step in the description of the molecular structure of a polymeric material is the determination of the overall shape of the polymer molecules, or the arrangement of the individual units in the polymer. Clearly, the polymers with the simplest structures are the linear polymers. In such macromolecules the individual structural units, or monomers, are joined to one another in linear sequence. Each terminal unit is connected to only one other unit; each chain is connected to two others. At no point in the chain is any unit connected with three or more other units. Linear macromolecules invariably have only two end groups. Systems composed solely of polymers of this kind show reversible melting and solubility behaviour.

Nonlinear polymeric systems, such as branched mac-



romolecules in which certain of the monomer units are connected with three or four neighbours, are also known.

Linear and nonlinear systems

If the number of monomers joined to multiple neighbours is small, the shape of the molecule is essentially that of a linear backbone carrying a number of relatively short branches. In a system of this kind, the individual branched molecules can still be separated from one another without breaking chemical bonds and, as a consequence, materials consisting of branched macromolecules in most cases melt and dissolve reversibly. If, however, the number of multifunctional units in the individual chains becomes relatively large, each develops into a branch and the branches of different backbone chains join together to create a three-dimensional network in which backbone chains are no longer distinguishable from branches and in which all existing units are joined to a number of others by chemical bonds. Systems of this type are called polymeric networks, or cross-linked polymers. Materials in which this type of molecular bonding is preponderant are nonmelting and insoluble, although they may soften and swell to a certain extent when heated or exposed to certain solvents.

The third step in the description of the molecular structure of a polymeric material is the elucidation of the chain structure or the method of joining of the individual units, or monomers, within the chain.

Depending on the chemical character of the repeating unit, many different types of chain formation are possible even in the case of a linear chain.

(1) (2) (3)

A repeating unit of structure (1) (in which X is any constituent) may, for instance, be joined in two ways to give the structures (2) or (3). Structure (2) represents a "head-to-tail" juncture of the two units, whereas (3) is a "head-to-head" union. Most of the better known vinyl-type polymers have molecular chains composed substantially of units joined in head-to-tail fashion. It also is possible, however, for polymer chains to be composed exclusively or in part of units joined head-to-head.

Spatial arrangement in single carbon chains

In a single chain of carbon atoms joined by single bonds, each carbon atom that carries a substituent X is asymmetric—that is, it can exist in either of two forms, or configurations, termed *d* and *l*, which are mirror images of one another (like right and left hand gloves). The various forms of polymer chains that exist depend on the relative configurations of the asymmetric carbons in the chains. If all carbons in a head-to-tail chain, as in structure (2), have the same configuration, the polymer is called isotactic; if the configuration alternates regularly along the chain from *d* to *l*, the molecule is called syndiotactic; and finally, if there is random alternation between the two possible configurations, it is called atactic. (For a discussion of tacticity see below *Classification and nomenclature*.)

Although the structural unit (1) is derived from a particularly simple type of monomer, $H_2C=CHX$, it leads to the various possible structures just described. Even more possibilities arise from such monomers as $H_2C=CX-CH=CH_2$ or $XHC=CHY$. Polymer stereochemistry, the discipline that deals with these subjects, is of considerable practical importance, because polymers of different chain structures have distinctly different properties, even when they are derived from the same monomer.

Polymer morphology. Experience also has shown that the ultimate, practical properties of all polymeric materials depend not only on their molecular design—size, shape, and chain structure—but also to a considerable extent on the supermolecular character of the system. This quality, also known as texture, or morphology, of the polymer, is influenced chiefly by the fact that all macromolecules can assume a large number of conformations or spatial shapes, which result from free rotation about single bonds in the chains. These conformations include various helical (spiral) forms, as well as random tangles or coils.

To analyze the supermolecular structure of polymeric systems, it is necessary to focus attention not on any individual macromolecule but on a unit of volume within the investigated object—fibre, film, or molded structure—which contains many macromolecules. In general, a cube with 200-angstrom unit (1 angstrom $= 10^{-8}$ centimetre) edges contains many hundreds of polymer molecules and, as a consequence, many thousands of molecular segments. Experience shows that these segments can have several characteristic mutual relationships inside a volume element: (1) they can be randomly distributed in regard to their spatial orientation regardless of whether they belong to the same molecular chain or to different chains; (2) they can possess a degree of lateral (side-by-side) order through the folding of the individual chains; and (3) they can possess lateral order through the parallel arrangement of extended chains.

If all volume elements in the material belong to group (1), the material is an amorphous solid, or glass, which is homogeneous and isotropic (structurally uniform in all directions). It also is noncrystalline and unoriented. Systems of this type usually are obtained when a polymer melt is solidified rapidly by quenching (cooling by sudden immersion).

Orientation and crystallinity

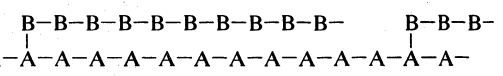
If all volume elements in a sample belong to group (2), the polymer is composed of single crystals, which can be either randomly distributed in space or in a preferred arrangement with respect to a fixed axis or plane. In the first case, the system is unoriented; in the second case, it has a definite orientation. Systems of this type are obtained when a polymer is precipitated slowly from a dilute solution or solidified slowly from a melt.

If all volume elements belong to group (3), the sample consists of extended chain crystallites—that is, crystalline areas or domains—which, again, may be unoriented or may possess particular spatial orientations. Systems of this type are obtained when concentrated solutions or melts are solidified while under the influence of mechanical forces, such as shear or stress.

In practice, any actual polymeric material—in the form of a fibre, film, sheet, or tube—represents a mixture of the three types of volume elements, and its macroscopic character is defined empirically by such expressions as "degree of orientation," "degree of crystallinity," or "later order." It is often difficult to decide whether any given sample has its segments laterally ordered in an intramolecular fashion by means of chain folding, or intermolecularly by way of extended chain crystallization. Extensive experimentation with different methods often is required to discriminate between the two. The degree of orientation is determined quantitatively by optical birefringence (splitting of light waves) or by the measurement of Young's modulus (a measure of elasticity), both properties being dependent on the relative degree of orientation of the chain. The degree of crystallinity, or lateral order, is determined qualitatively by such methods as X-ray and electron diffraction (interference effects observed with X-rays and with beams of electrons) and density, swelling volume, and isotope exchange, all properties influenced by the arrangement of the molecular chains.

Polymeric materials produced by spinning and related processes, with subsequent mechanical drawing or rolling of the product, consist of more or less oriented mixtures (50–90 percent orientation) of both amorphous and extended-chain crystalline domains (25–85 percent crystallinity). Larger pieces, made by extrusion, injection, or compression, have a typical spherulitic (composed of small spheres) texture containing all three possible segment organizations; the overall degree of orientation is usually low (less than 20 percent), the content of laterally ordered domains is high (up to 95 percent), and chain-folding crystallization is the predominant mode.

CLASSIFICATION AND NOMENCLATURE



A homopolymer consists of macromolecules formed either by a single type of unit or by two or more chemi-

cally different types in regular sequence. Homopolymers may, and frequently do, contain irregularities in minor amounts, especially at the ends of the chains and at junctions leading to branches.

Copolymers are macromolecules containing two or more chemically different monomeric units in a more-or-less irregular sequence. Normally, the relative numbers of the different types of units are not the same in different molecules, nor even in different portions of a single molecule. A mixture of different macromolecules is called a polyblend. A block copolymer is a type of copolymer in which distinct groups of monomeric units of each type are linked together by chemical bonds and then interspersed along the chain. If, for example, the monomer units are designated A and B, a block copolymer of them might have the following structure:

$$-A-A-A-A-A-B-B-B-B-A-A-A-A-$$

A graft copolymer, on the other hand, contains branches of varying length composed of monomer units of one type joined to a backbone chain made up of monomer units of a second type. Such a copolymer might be composed as follows:

In their structure and in their properties, graft and block copolymers represent an intermediate form partway between normal copolymers and polyblends.

Tacticity

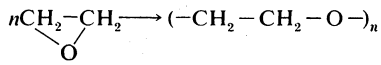
A tactic polymer consists of macromolecules whose monomeric units follow one another along the chain with their steric configurations (spatial orientations) ordered according to some pattern. The pattern, or tacticity, of the polymer, may consist of one or more simple rules. A eutactic polymer is a tactic polymer whose monomeric units are completely ordered, so that it is devoid of any element of structural disorder. An atactic polymer, on the other hand, is one in whose molecules the spatial configuration of the units is purely random. By way of example, a vinyl polymer prepared by conventional processes is generally atactic; it may possess a regular head-to-tail arrangement, but it is disordered with regard to the steric configurations of the tertiary carbon atoms that follow each other along chains. In isotactic polymers the asymmetric units are ordered in such a way that there is a continual, exact repetition of the unit configuration along the chain. A syndiotactic polymer consists of macromolecules whose monomeric units are asymmetric and ordered in such a way that there is a continual inversion of steric configuration from one monomeric unit to the next down the chain.

Polyelectrolytes are substances that dissociate in water (or other ionizing solvents) to give a polymeric material bearing a great many ionic, or electrically charged, groups, together with an equivalent number of counterions (ions of small charge and opposite sign). Polyelectrolytes can be polyacids (if they release hydrogen ions), polybases (if they release hydroxide ions), polysalts (if they release small cations or anions), or polyampholytes (if they release both hydrogen and hydroxide ions).

Under certain conditions chemical bonds may form between growing polymer chains. Such bonds, called cross-links, form whenever the monomeric units contain functional groups capable of reacting with one another, over and above those consumed in the initial polymerization reaction. The initial result of cross-linking is the formation of small domains, within which the macromolecules consist of random three-dimensional networks of chemically linked chains; such domains are called microgels. If a cross-linking reaction extends over macroscopic dimensions, and if the polymerizing system is taken up by a liquid solvent (or liquid monomer), the result is a gel, or jelly-like material. Drying converts such a gel into an insoluble and nonmelting material, composed entirely of a three-dimensional network at the molecular level. Such thermosetting resins as phenol–formaldehyde and urea–formaldehyde resins and copolymers of styrene and divinylbenzene fall into this category. Similar insoluble and infusible systems are obtained under certain conditions when a vinyl derivative is polymerized in the presence of a small amount of a divinyl compound. The materials thus obtained are called "popcorn" polymers; their exact structure has not been completely elucidated.

POLYMERIZATION PROCESSES

There are many processes by which small molecules can be bonded together to form large ones. Classification of these processes usually is based either on the chemical mechanisms by which the monomeric units are joined together or on the experimental conditions that exist during the reaction. Classifications by reaction mechanism distinguishes between polymerization by addition and polymerization by condensation.

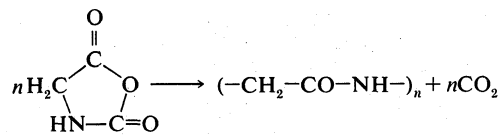


Polymerization mechanisms. *Addition.* Typical cases of addition polymerization are:

1. The addition of small molecules of one type to one another, accomplished by the opening of a multiple bond and without elimination of any part of the molecule, also called vinyl-type polymerization (in the following equations n is any number):

Vinyl-type polymerization

$$n\mathrm{H_2C{=}CHX} \longrightarrow (-\mathrm{CHX{-}CH_2}-)_n$$



2. The addition of small molecules of one type to one another by the opening of a ring and without elimination of any part of the molecule (epoxide-type polymerization):

3. The addition of small molecules, all of one type, to one another by opening of a multiple bond with elimination of part of the molecule (aliphatic diazo-type polymerization):

$$n\mathrm{RCH{=}N_2} \longrightarrow (-\mathrm{CHR}-)_n + n\mathrm{N_2}$$

4. The addition of small molecules of one type to one another by opening of a ring with elimination of part of the molecule (α-aminocarboxyanhydride-type polymerization):

5. The addition of small molecules of one type to those of another type by opening of a multiple bond (polyurethane, polyurea, and polyamide formation):

$$n\mathrm{HOCH_2CH_2OH} + n\mathrm{OCN(CH_2)_6NCO}$$

$$\longrightarrow [-\mathrm{OCH_2CH_2OCONH(CH_2)_6NHCO}-]_n$$

6. The addition to one another of biradicals of a single type formed by dehydrogenation (poly-*p*-xylylene polymerization):

$$n(\cdot\mathrm{H_2C{-}C_6H_4{-}CH_2}\cdot) \longrightarrow (-\mathrm{CH_2{-}C_6H_4{-}CH_2}-)_n$$

Condensation. A number of possible forms of condensation polymerization are also observed. Typical cases are as follows:

1. The formation of polyesters, polyamides (nylon), and polyethers by elimination of water, or alcohols, from single bifunctional molecules, such as ω-hydroxy- or ω-aminocarboxylic acids or from such combinations as glycols or diamines with diesters or dicarboxylic acids. The reaction of a glycol with a dicarboxylic acid, for example, proceeds as follows:

Polyester and polyamide formation

$$n\mathrm{HO(CH_2)}_x\mathrm{OH} + n\mathrm{HOOC(CH_2)}_y\mathrm{COOH}$$

$$\longrightarrow [-\mathrm{O(CH_2)}_x\mathrm{OOC(CH_2)}_y\mathrm{CO}-]_n + n\mathrm{H_2O}$$

2. The formation of polyhydrocarbons by the elimination of halogen or hydrogen halides with the aid of metal and metal halide catalysts:

$$n\mathrm{ClH_2C(CH_2)_xCH_2Cl} \longrightarrow [-\mathrm{H_2C(CH_2)_xCH_2}-]_n + n\mathrm{Cl_2}$$

3. The formation of polysulfides by the elimination of sodium chloride from bifunctional alkyl or aryl halides with alkali sulfides or by the oxidation of dimercaptans (a type of organic sulfur compound). The former proceeds as follows:

$$n\mathrm{ClH_2C(CH_2)_xCH_2Cl} + n\mathrm{Na_2S_4}$$

$$\longrightarrow [-\mathrm{H_2C(CH_2)_xCH_2S_4}-]_n + 2n\mathrm{NaCl}$$

Experimental conditions. In actual practice the experimental conditions under which polymerization reactions occur are more commonly used to classify the reactions. Commonly, then, polymerization processes are classified according to whether they occur in the gaseous phase, in the pure liquid phase, or as dispersions, solutions, or emulsions.

Gaseous phase polymerization

1. Polymerization in the gaseous phase may occur at normal, reduced, or elevated pressures. The most important process of this type is the polymerization of ethylene, which is usually carried out at pressures of about 1,500 atmospheres in the temperature range between 190 and 210° C. Poly-*p*-xylylene is prepared at reduced pressure by cooling the pyrolyzed monomer from 900° C to room temperature.

2. Polymerization of single or of several monomer types frequently takes place in the pure liquid phase (bulk polymerization). Many vinyl-type polymerizations are carried out in this manner, particularly when large, transparent pieces (such as plates, rods, lenses) of the final product are desired. Polyester and polyamide formation are carried out almost exclusively in the bulk phase, as is the polycondensation of alkylsilanediols and the formation of phenol–, urea–, and melamine–formaldehyde resins.

3. Polymerization of one or more monomers frequently is carried out by dispersion in the form of small droplets in a liquid that does not dissolve the monomer. (This process also is referred to as suspension, bead, or pearl polymerization.) Styrene, methyl methacrylate, vinyl chloride, and other monomers are polymerized in this manner to give beads of very uniform size and quality for use in certain molding techniques.

4. Polymerization of one or more monomers may take place in solution. If the polymer is soluble in its own monomer and in the solvent selected for the reaction, the system thickens increasingly as the reaction proceeds. If the polymer is insoluble in the liquid constituents, a slurry forms as the reaction proceeds, and the polymer settles as a more or less swollen powdery mass. Vinyl chloride, acrylonitrile, vinyl acetate, and other monomers usually are polymerized and copolymerized by this technique.

Emulsion polymerization

5. Polymerization of one or more monomers often is conducted in emulsion. It has been found that polymerization frequently takes place in a particularly favourable manner if the monomers are brought together in the form of an aqueous emulsion with the aid of emulsifying agents such as soaps. The polymer or copolymer is then obtained in the form of a latex, or milky liquid, which either can be used as such or can be coagulated by the addition of acids to form agglomerates of the product polymer. Studies of the mechanism of emulsion polymerization indicate that several important steps in the process occur in the micelles (little particles) of the emulsifying agent. The final growth of the macromolecules takes place in polymer particles swollen by monomers transferred by diffusion from the monomer droplets. Most rubbery polymers and copolymers, and some plastics, are produced on a very large scale by emulsion polymerization.

Several other polymerization methods, such as polymerization in the solid state, in a fine powder, or in a foam of small bubble size, have been studied in the laboratory but have not been employed on a large scale for commercial use.

Most polymerization techniques can be carried out in separate batches or as continuous processes. Batch processing still prevails in most large-scale operations, but there is a tendency toward the development of continuous methods for all polymerization processes. Continuous processes have been developed for production of acrylonitrile, nylon, polyester, and certain synthetic rubbers.

Catalysis. Catalysts, substances that promote chemical reactions without being consumed in the reactions, play an important role in most polymerization reactions. Addition polymerization can be accelerated by three different types of catalysts: free-radical, cationic, and anionic.

Free radical catalysis. Initiation of a polymerization reaction may take place through the initial formation of a free radical, which either is produced by decomposition of a labile (*i.e.*, easily reactive) molecule or is formed in the course of a chemical reaction. Typical cases of free-radical-forming catalysts are peroxides, hydroperoxides, and azo compounds. Various ways of forming free radicals are indicated by equations 1–5:

$$\mathrm{C_6H_5-\overset{O}{\overset{\|}{C}}-O-O-\overset{O}{\overset{\|}{C}}-C_6H_5} + \text{heat} \longrightarrow 2\mathrm{C_6H_5-\overset{O}{\overset{\|}{C}}-O\cdot} \qquad (1)$$

$$\mathrm{C_6H_5-\overset{O}{\overset{\|}{C}}-O-O-\overset{O}{\overset{\|}{C}}-C_6H_5} + \text{heat} \longrightarrow 2\mathrm{C_6H_5\cdot} + 2\mathrm{CO_2} \qquad (2)$$

$$\mathrm{C_6H_5-CH=CH_2} + \text{radiation} \longrightarrow \mathrm{C_6H_5-\dot{C}H-CH_2\cdot} \qquad (3)$$

$$\mathrm{C_6H_5-CH=CH_2} + \text{heat} \longrightarrow \mathrm{C_6H_5-\dot{C}H-CH_2\cdot} \qquad (4)$$

$$\mathrm{\begin{matrix}H_3C\\ \diagdown\\ H_3C-C\\ \diagup\\ NC\end{matrix}-N=N-\begin{matrix}CH_3\\ \diagup\\ C-CH_3\\ \diagdown\\ CN\end{matrix}} + \text{heat} \longrightarrow \mathrm{N_2} + 2\mathrm{\begin{matrix}H_3C\\ \diagdown\\ C\cdot\\ \diagup\\ NC\end{matrix}} \qquad (5)$$

The initiator decomposes either by thermal action at a sufficiently high temperature or at low temperatures under the influence of a photon (packet of light energy) or an electron. The activation energy required to break the critical bond in the molecule of the initiator, usually a O–O, C–N, or C–O bond, amounts to only about 15–30 kilocalories. Some initiators, such as certain hydroperoxides and aliphatic azodinitriles, act at relatively low temperatures (40–50° C); whereas others, such as peroxides or aliphatic azodiesters, require temperatures as high as 150–175° C. The free-radical initiator (produced in reactions such as those shown in equations 1–5) attacks the double bond of the monomer, attaches itself to it, and reproduces the free radical at the other end of the adduct:

$$\mathrm{C_6H_5-\overset{O}{\overset{\|}{C}}-O\cdot} + \mathrm{H_2C=CHX} \longrightarrow \mathrm{C_6H_5-\overset{O}{\overset{\|}{C}}-O-CH_2CHX\cdot}$$

The propagation reaction

This process is called the propagation reaction; as it is repeated again and again, it consumes the molecules of the monomer to form macromolecules:

$$\mathrm{C_6H_5-\overset{O}{\overset{\|}{C}}-O-CH_2-CHX\cdot} + n\mathrm{CH_2=CHX}$$

$$\longrightarrow \mathrm{C_6H_5-\overset{O}{\overset{\|}{C}}-O(-CH_2-CHX-)_nCH_2-CHX\cdot}$$

The activation energies of typical propagation reactions have been found to be 5–10 kilocalories.

A free radical at the end of a growing chain can also react with a monomer molecule in such a way that it abstracts a hydrogen atom from the latter and transfers the free radical character from the growing chain to the monomer:

$$\mathrm{R-CH_2-CHX\cdot} + \mathrm{CH_2=CHX}$$

$$\longrightarrow \mathrm{R-CH_2-CH_2X} + \mathrm{CH_2=C\dot{X}}$$

Such processes are called chain-transfer reactions; they occur between the growing chains and molecules of the monomer or of the already formed polymer. If two free-

radical chain ends react with each other, there results a pairing of the lone electrons either by recombination or by disproportionation. Either process leads to the termination of the propagation step and finishes the polymerization reaction by the formation of stable macromolecules. Examples of both are:

$$\ldots CH_2{-}CHX\cdot + \cdot XCH{-}CH_2\ldots$$

$$\xrightarrow{\text{recombination}} \ldots CH_2{-}CHX{-}CHX{-}CH_2\ldots$$

$$\xrightarrow{\text{disproportionation}} \ldots CH_2CH_2X + XCH{=}CH\ldots$$

The interplay of initiation, propagation, and termination reactions leads to average lifetimes for the free radical-type chain ends of 0.1 to 10 seconds and to steady-state free-radical concentrations of 10^{-6}–10^{-8} mole per litre.

To produce free radicals at lower temperatures, such as room temperature or below, the interaction of electron donors, such as iron (II) ions, Fe^{2+}, with electron acceptors, such as hydrogen peroxide, H_2O_2, is utilized. In this way, an oxidation–reduction system is set up, which acts as a permanent source of free radicals:

$$H_2O_2 + Fe^{2+} \longrightarrow Fe^{3+} + HO^- + HO\cdot$$

Such systems are capable of initiating polymerization reactions at temperatures as low as −20° C. This reaction activation is of great practical importance in emulsion polymerization, where many undesirable complications can be avoided, or at least suppressed, by working at low temperatures.

Free-radical initiation is employed in the bulk polymerization of styrene and methyl methacrylate, in the solution copolymerization of vinyl chloride–vinyl acetate, in the suspension polymerization of acrylonitrile and vinyl chloride, in the emulsion copolymerization of butadiene–styrene and butadiene–acrylonitrile, and in many other vinyl-type addition polymerizations.

Cationic catalysis. Certain vinyl-type monomers, such as propylene, isobutylene, and most vinyl ethers, do not respond to free-radical initiation but can be initiated by catalysts that produce protons by interaction with a cocatalyst. The protons attack the monomer to form a carbonium ion (a molecular fragment with a positive charge on a carbon atom), which then acts as the carrier for the propagation. A typical example of cationic polymerization is the formation of polyisobutylene from isobutylene under the influence of boron trifluoride as catalyst and water as cocatalyst. The process can be represented by a series of equations:

Boron trifluoride as catalyst

$$BF_3 + H_2O \rightleftharpoons H_2OBF_3 \rightleftharpoons H^+ + HOBF_3^- \qquad (1)$$

$$H^+ + CH_2{=}C(CH_3)_2 \longrightarrow CH_3 - \overset{+}{C}(CH_3)_2 \qquad (2)$$

$$CH_3 - \overset{+}{C}(CH_3)_2 + nCH_2{=}C(CH_3)_2 \longrightarrow$$
$$CH_3 - C(CH_3)_2[-CH_2-C(CH_3)_2-]_{n-1}CH_2 - \overset{+}{C}(CH_3)_2 \qquad (3)$$

$$CH_3 - C(CH_3)_2[-CH_2-C(CH_3)_2-]_{n-1}CH_2 - \overset{+}{C}(CH_3)_2 + HOBF_3^- \longrightarrow$$
$$CH_3 - C(CH_3)_2[-CH_2-C(CH_3)_2-]_{n-1}CH_2 - \underset{\displaystyle CH_3}{\overset{\displaystyle CH_2}{\overset{\|}{C}}} + H_2OBF_3 \qquad (4)$$

The interaction of catalyst and cocatalyst produces protons (1), the concentration of which is controlled by an equilibrium that depends upon the concentration of the reactants and on the temperature. Other catalysts of this type are aluminum chloride and stannic chloride; other cocatalysts are ethers and amines. The proton adds to the monomer to form a carbonium ion (2), which propagates the chain by subsequent addition to other monomers (3). No formation of free radicals by splitting of an electron pair is necessary; instead, the displacement of an electron pair within the interacting particles suffices to bring about the chemical changes required to combine the monomeric units into macromolecules. As a consequence, the activation energies for initiation and propagation by cationic initiation are much lower than by the free-radical mechanism, and cationic polymerization leads to rapid formation of large molecules even at temperatures as low as −80° C.

The termination of cationic polymerization takes place by the reaction of the negatively charged complex ion with the carbonium-ion chain end, a reaction that results in the formation of a terminal hydroxyl group or a terminal double bond (4). Essentially this reaction restores the molecule of the catalyst to its original state so that it can attack another monomer and begin another reaction cycle.

Anionic catalysis. Anions, or negative ions, such as hydroxide (OH^-), amide ion (NH_2^-), and various carbanions designated R^-, can also initiate vinyl-type addition polymerization under certain conditions. The reaction proceeds by conversion of the monomer to a carbanion, which then undergoes propagation reactions with further monomers. This mechanism is of great importance, and it has been established that most polymerizations initiated by alkali metals or alkali-metal alkyls are of this type. In certain cases the lifetime of the carbanions is very long, so that there is essentially no termination reaction. Polymers formed under such conditions are called living polymers.

Living polymers

Most addition polymerizations involving ring opening are subject to catalytic influence by positively or negatively charged ions. Thus the polymerization of ethylene oxide and other epoxides is strongly accelerated by bases, and the polymerization of α-aminocarboxyanhydrides by acids. Both types are initiated by water, alcohols, or amines.

Coordination-complex catalysis. A very important group of ionic initiators is formed when compounds of transition metals—such as titanium, zirconium, and vanadium—are mixed with metal alkyls—butyllithium, $LiCH_2CH_2CH_2CH_3$, diethylzinc, $Zn(CH_3CH_2)_2$, and triethylaluminum $Al(CH_3CH_2)_3$, for example. In such cases the result is a solid precipitate, that is able to polymerize ethylenic compounds by a suspension type process. Polymerizations of this type take place very rapidly under mild conditions and lead to many products of great importance; *e.g.*, linear polyethylene, isotactic polypropylene, *cis*-1,4-polybutadiene, and ethylene–propylene copolymers.

Condensation catalysis. Most polycondensation reactions also are influenced by acids and bases. In these cases it is important to distinguish between equilibrium and rate effects. Certain materials, such as catalysts, influence the rate, or speed, of chemical reactions without affecting the relative amount of product formed; other substances affect primarily the amount of product present at equilibrium. With many condensation reactions, water-binding agents, such as phosphoric anhydride, sulfuric acid, or trifluoroacetic anhydride, very markedly increase the overall formation of polymer, but they do so by shifting the equilibrium in the direction of polycondensation rather than by a catalytic influence on the elementary process of chain propagation. As most polycondensation reactions are carried out at rather elevated temperatures (200° C or higher), it is necessary to employ acids and bases of very low volatility, such as antimony (III) oxide, Sb_2O_3, lead dioxide, PbO_2, calcium hydride, CaH_2, or potassium hydroxide, KOH.

PROPERTIES AND USES OF POLYMERS

Mechanical strength of polymers. The most important property of organic polymers, as compared with ordinary organic substances, is that they exhibit considerable mechanical strength in the solid state. Hence polymers are used to make fibres, films, plastics, rubbers, coatings, and adhesives of commercially valuable properties. The degree to which favourable mechanical properties are exhibited depends upon several factors, the interaction of which determines the most appropriate use of a given polymer and characterizes it as a typical material to form a fibre, plastic, or coating.

Degree of polymerization. One decisive factor for mechanical resistance is the degree of polymerization, or the

molecular weight, of the material under consideration. Extensive experiments with many polymers have shown that for each polymer there exists a certain critical molecular weight below which the material shows only poor mechanical strength. Above this critical value, mechanical strength is rapidly developed with increasing molecular weight up to a second level, above which the increase of mechanical resistance with increasing molecular weight becomes less pronounced. An industrially useful material must have, therefore, a certain molecular-weight value above which only a diminishing return of strength is gained. As a matter of safety, it is advisable to choose a molecular weight well above this point, but it has been found that materials with too high a degree of polymerization exhibit exorbitant viscosities in solution or in the molten state, which render such important processes as filtration, spinning, casting, and molding unduly difficult.

Optimum molecular weight

A proper compromise between easy processing ability and desirable ultimate properties must therefore be established by choosing an optimum molecular-weight range in each individual case.

Intermolecular forces. Another important factor for the development of characteristic mechanical properties is the magnitude of the intermolecular forces between individual macromolecules in a given material, as well as the structural regularity of the macromolecules themselves. If the intermolecular attraction is small and the chains are difficult to fit laterally into a lattice-like arrangement, then at a particular temperature and stress material that has been stretched shows a distinct tendency to return to a relaxed state in which the macromolecules are again curled rather than laterally ordered. Such behaviour is typical of rubbers (elastomers). On the other hand, if the molecular cohesion is strong and the fine structure of the chains provides for easy lateral fitting into lattice-like aggregates, a state of substantial crystallinity is favoured and the material is a typical fibre. In intermediate cases, in which the forces are moderate and the geometry of the chains is not very favourable for crystallization, the behaviour of the material will depend greatly upon external conditions such as temperature and pressure. Such systems are typical plastics.

These qualitative considerations show that rubbers, plastics, and fibres are not intrinsically different materials. Their differences are rather a matter of degree and result from the combined effect of the intermolecular forces between the long chains and the general tendency of the chains themselves to curl and fold, which leads to a mixture of crystallized and disordered portions in a given sample of the material. In general, it can be said that under given conditions, such as temperature and external forces applied to the sample, the tendency to crystallize is brought about by two different factors, which to a certain extent conflict with each other:

Intermolecular forces versus molecular geometry

1. Forces between the individual macromolecules: if these forces are strong, then at ordinary temperatures they chiefly determine the behaviour of the material, and it can be expected to behave like a hard plastic or like a typical fibre. This condition appears to be true for cellulose, certain proteins, nylon, polyesters, and polyacrylics.

2. The microgeometry of the molecular chains themselves: If the chains fit easily into a crystal-like lattice, as polyethylene, nylon, and certain other substances do, the material crystallizes under the influence of comparatively weak forces and hence, in general, has a tendency to appear more fibre-like than would be expected if the intermolecular forces alone were considered. On the other hand, materials with bulky and irregular macromolecular chains do not crystallize even if the intermolecular forces are quite strong. These are soft plastics and elastomers, and they behave more like rubber than would be expected on the basis of the intermolecular forces alone.

Commercially important polymers. From the practical point of view, classification and application of organic polymers is dominated by the raw materials (monomers) from which they are derived, because the monomeric units are responsible not only for the intermolecular forces and the structure of the individual polymer molecules but, in most cases, also for the cost of the final product.

Polyhydrocarbons. Chemically the simplest class of commercial polymers is the polyhydrocarbons. These are very widely used and cover the entire range from very soft and resilient rubbers, through plastics of all kinds, to strong, tough, and high-melting fibres. Considering all varieties and all applications, it can be estimated that in 1970 about 10,000,000 tons of polyhydrocarbons were produced and used commercially worldwide.

The most important commercial hydrocarbon polymer is polyethylene, which exists in two types: a lower density material, which is made by high-pressure polymerization, and a high-density type, which is made with the aid of special catalysts at normal pressure. Both are processed by various molding, extrusion, and casting techniques and are widely used to produce such products as trash cans, pails, containers for milk and most household liquids, shopping bags, and wrapping films for many dry goods. Polypropylene is somewhat stiffer and has a higher melting point and a more brilliant and transparent appearance. It is used for the same purposes as polyethylene but also, because of its higher melting point, as a fibre for carpets, upholstery, drapings, and, mixed with wool or acrylic fibres, for blankets. Polystyrene is brilliantly transparent and excellently moldable, but it has a somewhat lower softening point and it is more likely to swell in organic solvents than polyethylene or polypropylene. It is widely used for many household goods, as well as toys, pens, pencils, and decorative molded items. These three polyhydrocarbons all have relatively regular, easily orientable molecular chains, which can be readily brought into laterally ordered bundles resembling a crystal-like structure. They are used, therefore, as plastics and fibres, in spite of the fact that the intermolecular forces between the hydrocarbon chains are low. Other important polyhydrocarbons, however, with more bulky chains, which show more resistance to lateral order, have the properties of a typical rubber. Natural rubber—*cis*-polyisoprene—is the classical representative of these substances. Others are the principle synthetic elastomers, such as polybutadiene and copolymers of butadiene or isoprene with styrene and with each other. It is interesting that random copolymers of ethylene and propylene are also typical elastomers, because the irregular sequence of the two monomers along the chain reduces their capacity for the formation of laterally ordered semicrystalline domains.

Uses of polyethylene, polypropylene, and polystyrene

Chlorinated and cyanated polyhydrocarbons. Commercially important classes of polymers are the chlorinated and cyanated polyhydrocarbons. In these, the presence of a chlorine atom or cyano-group increases intermolecular attraction and has the consequence that regularly built chains of these materials behave like fibres or plastics. Outstanding examples are the successful synthetic fibres made of polyvinylidene chloride, polyvinyl chloride, and polyacrylonitrile. If irregularity is introduced into the molecular chains by copolymerization or by the use of bulky monomers, elastomeric materials are obtained. Examples are neoprene—a polychloroprene rubber—and the copolymers of butadiene with acrylonitrile, which form a large and important class of synthetic elastomers.

Uses of polyvinyl chlorides and polyacrylonitrile

Polyesters. Intermolecular forces between adjacent macromolecular chains can also be increased by the introduction of an ester bond into the backbone of the chain; this addition leads to the large and important family of polyesters. If the chains are regularly built and easy to align, typical fibre-forming polymers are obtained, such as polyethylene glycol terephthalate, which is today one of the most successful synthetic fibres. Polyesters with less regular chains form a large variety of plastics that are reversibly softening and behave like typical thermoplastics; such polyesters can be cross-linked and thereby made into hard, insoluble, and non-melting thermoset materials.

Polyamides. Still larger intermolecular forces are obtained when an amide bond is introduced into the back-

Uses of nylons

bone of linear macromolecules, producing the large and important family of polyamides, or nylons. These have the distinction of being superior fibre-forming materials, and in the late 1930s they initiated the introduction of synthetic fibres into the textile industry. Polyamides with reduced chain regularity produce excellent plastics, which are used in molding and extrusion processes. Polyacrylic compositions excel by their weather resistance, scratch resistance, high gloss, and capacity to accommodate pigments and other fillers. As a consequence, they represent an extremely successful class of materials for synthetic paints and coatings, widely used on products ranging from furniture to automobiles and airplanes.

Other polymers. Other polymers of some practical importance are: the polyurethanes as rubbers, foams, and adhesives; the polyfluorocarbons and the silicones because of their exceptional chemical inertness; the epoxy resins as coatings and adhesives; and several linear macromolecules composed of aromatic rings, because of their useful behaviour at temperatures as high as 600° C.

BIBLIOGRAPHY. Detailed information on this subject may be found in the multivolume *Encyclopedia of Polymer Science and Technology*, ed. by H.F. MARK, N.G. GAYLORD, and N.M. BIKALES (1964-). Polymorphism, Biological

Variation occurs in all species of living things and may be manifested in any character that the organism displays. It may be classified as genetic or nongenetic; *i.e.*, variation may be determined by genetic differences or by differences in the circumstances under which individuals live and are able to adapt. In a few characters, such as the blood groups, the differences are wholly genetic in origin, and no external influence can change them. Most characters, however, show both genetically and environmentally determined variation simultaneously. Furthermore, variation arising from genetic causes cannot be distinguished by inspection from that determined by environment. Thus an animal may be small because of the genes it has received or because it is undernourished.

Distinction between discontinuous and continuous variation

Genetic variation can be classified as discontinuous or continuous. In principle, discontinuous and continuous variation have the same genetic basis; discontinuous variation is usually controlled by unit genetic determiners (alleles) of one gene or a cluster of genes. The many genetic effects displayed by continuous variation, on the other hand, result from the cumulative effects of many genes, each exerting small but similar effects.

A discontinuous variation divides the individuals of a population into two or more sharply distinct forms. If the frequency of both forms is too high to be explained by mutation, the population showing the variation is said to be polymorphic. The most obvious example of a discontinuous variation is the separation of most higher organisms into males and females; another is the human blood types. In continuous variation, on the other hand, the individuals do not fall into sharp classes but are almost imperceptibly graded between wide extremes. This type of variation is found in virtually all characters of all populations and, if it is determined chiefly by heredity, can be altered relatively rapidly by selection. A familiar example is the smooth graduation of height among individuals of human populations.

A character may show both discontinuous and continuous variation within a population. Thus a human population, while showing continuous variation in height among its normal members, may simultaneously include sharply distinct dwarf or giant individuals.

General features. *Nongenetic variation.* Although the adaptive modifications in the effects of genes (phenotype) within a population that are commonly known as nongenetic variation do not involve genetic changes, the ability of a given species to produce several phenotypes is under genetic control.

Several types of nongenetic variation occur. One type occurs in adults of animal species that undergo seasonal changes in phenotype; *e.g.*, the plumage of certain birds and the fur of some mammals change colour with the season. The effects of physical environment, a type of nongenetic variation, are particularly pronounced in plants; *e.g.*, soil, amount of sunlight, and other factors can affect a plant's appearance. The phenotype of some freshwater fishes is dependent upon certain physical and chemical properties of the water they inhabit—e.g., temperature, acidity. The formation of genetically identical but morphologically different castes among social insects such as ants and bees is regulated by the nutrition of the larvae and other environmental conditions. Similarly, among a few species of Lepidoptera—*e.g.*, the European butterfly *Araschnia levana* and the African butterfly *Precis sesamus*—temperature or moisture differences may give rise to highly dissimilar spring and summer forms or dry- and wet-season forms.

Genetic variation. Because no two individuals are genetically identical in sexually reproducing species, genetic variation is important with regard to variations of the phenotype. Thus, almost any feature, be it morphological, physiological, or cytological, may vary. When the differences among individuals within a population can be divided into several classes based on the presence of certain characters, the variation, called polymorphism, is frequently controlled by one gene; however, the genetic requirements for polymorphism may be met by the segregation of a gene, a super-gene (a section of a chromosome containing more than one gene and acting as a unit), or a specialized pair of chromosomes.

A definition of genetic polymorphism

The nature of polymorphism. Genetic polymorphism, found throughout the animal and plant kingdoms, has been defined by the British zoologist E.B. Ford as

> the occurrence together in the same locality of two or more discontinuous forms of a species in such proportions that the rarest of them cannot be maintained merely by recurrent mutation.

Polymorphism provides variation within a species and may better its chances for survival. Characteristics within a species that may be polymorphic include colour, sexual features, blood groups, and chromosomal variations.

Two conditions that can lead to an increase in the relative frequency of a gene cannot lead to a permanent, or balanced, polymorphism. In one condition, the appearance of the gene (*A*, for example) increases through mutation at the expense of its alternative state, or allele (*a*), which is its less dominant counterpart. If the new gene has a harmful effect, it will be eliminated each time it appears. Should the new gene possess some advantage, however, it may eventually become dominant and may spread in the population, so reducing the alternative allele to the status of a rare mutant and thus extinguishing the variation. In the other condition, which occurs only rarely, a new gene of neutral survival value appears; such a gene is able to spread through a population only in a random way, and the process occurs so slowly that the delicate balance required for neutrality is upset by genetic and environmental changes.

A balanced, or permanent, polymorphism can arise in two ways. One is by frequency-dependent selection; the rarer gene of a pair is at a disadvantage when present in a high frequency, but subject to positive selection when at a low frequency. The other is heterozygous advantage, which is described below.

The significance of the heterozygous condition. The usual basis for ensuring a permanent polymorphism is one in which the best-adapted individuals are heterozygous—*i.e.*, with respect to one or more gene pairs they contain different genes, in contrast to homozygotes, who contain similar genes of a pair. The colour polymorphism of the marine crustacean *Tisbe reticulata* and of the fly *Drosophila polymorpha* both involve heterozygotes whose viability is superior to that of the homozygotes.

Origins of heterozygous advantage

A heterozygous advantage, which tends to arise automatically as a gene becomes an asset and spreads through a population, can originate in either of two ways. In one, a commonly occurring type of mutant gene, the so-called recessive semi-lethal gene, is responsible for a trait that is fatal or highly unfavourable to mature development of an individual. Since the harmful effect is recessive, it is not manifest unless the gene is homozygous for the trait. Because the other homozygote is less advantageous than the heterozygote, the latter becomes the superior genotype; *i.e.*, the presence of both the recessive gene and the dominant gene is superior to that of the two dominant or the two recessive genes. The second way by which heterozygous advantage can arise involves the multiple effects of genes; some of these effects are an asset to the organism, and others are harmful. In addition, advantageous qualities tend to become dominant and disadvantageous ones recessive. The heterozygote, as a consequence, eventually possesses advantages only; the two homozygotes, on the other hand, will have some advantages and some disadvantages. Apparently, heterozygous advantage tends to evolve as a gene spreads through a population, and, as a result, the polymorphism to which it gives rise becomes common.

Although polymorphism is generally associated with heterozygous advantage, this advantage is not a necessary outcome of the heterozygous state but evolves as indicated above. In studies of chromosome inversion (reversal of gene order) in *Drosophila pseudoobscura*, it has been found that the heterozygotes have an advantage over both homozygous states in the same population unless the parents come from localities far removed from each other. That is, the advantage of the heterozygote is not intrinsic but exists where it can evolve. The evolution of heterozygous advantage has been demonstrated in studies of a black form of the moth *Biston betularia* in London. Before 1906 there was no evidence of heterozygous superiority of the black form. In the succeeding 50 years, however, heterozygous advantage gradually evolved.

The maintenance of polymorphism. Genetic polymorphism may be controlled by either a gene or a super-gene. A specifically adapted chromosome or chromosomal segment may function as a control for polymorphism, as do the sex chromosomes.

The concept of a super-gene may be explained by using mimicry as an example of the numerous and very different characteristics often involved in adaptations of organisms. In this case, all of the genes controlling features such as colour pattern, shape, habit, and viability segregate as a group. The once-separate genes have been brought together by advantageous linkage and crossing-over (mutual exchange of equivalent loci between chromosomes) to produce a tightly packed unit of several genes sufficiently near each other on the chromosome that they segregate together. The controlling element in polymorphism is commonly such a super-gene.

In addition to segregation, a super-gene may be maintained as an inversion; that is, a region of a chromosome in which the order of the genes is reversed. In this case, crossing-over cannot occur if the region of the inversion is heterozygous because the alleles are no longer opposite their counterparts. All of the genes in such a region thus continue to be held together as a super-gene.

Types of polymorphism. *Colour.* In a snail species, *Cepaea nemoralis*, common to Britain and Europe, the shell colour may be yellow (greenish when the animal is within), pink, or brown. Shell-colour variations are controlled by genes at one locus on a chromosome. In addition, the shell may either be bandless or marked with one to five dark bands. The presence and number of bands is determined by multiple alleles—*i.e.*, two or more alternative factors with the same chromosomal locus and with an effect on the same genetic character. The two loci, for shell colour and banding, form one super-gene. Although the loci normally are so close as to appear inseparable, crossing-over has been shown to occur between them. The greenish or yellow shells predominate in grasses of lowland areas; brown shells are most common on the leafless floor of beech-tree groves. The unbanded shell is more common on a uniform background such as short turf; banded types predominate in the diversified conditions provided by mixed herbage. The difference in the relative proportions of such forms varies from 20 to 40 percent between populations of different habitats.

The snails are preyed upon by various birds, especially the song thrush, and by other animals. The song thrush carries the snails to stones and breaks open the shells. Evidence provided by accumulated shells reveals that predation is not random; *i.e.*, the snails with better natural camouflage are less likely to be eaten. In each locality, therefore, relatively larger numbers of the types least appropriate to the background are eliminated; the populations, however, do not become uniform, because the genes that influence colour pattern in *Cepaea* also affect its physiology, and they favour the heterozygote, thus maintaining the polymorphism; the relative numbers of the different colours, however, are determined by predation. Similar phenomena demonstrating the selective control of polymorphism in other snails with variously coloured and banded shells have been observed in Africa, islands of the South Pacific, and other regions.

Instances of colour polymorphism

Another striking instance of colour polymorphism has been mentioned previously, the industrial melanism, or "blackness," of certain Lepidoptera. Over 100 species of moths have acquired black forms in the industrial areas of Britain since the mid-19th century. Similar changes are also occurring in continental Europe and in North America. This colour difference is genetically controlled; the black form is almost always dominant and in some areas comprises 95 percent of the population of certain species. In all populations affected, however, a small proportion of the pale form persists as a result of heterozygous advantage, which tends to increase the proportion; a polymorphism is thus established.

All of the species involved in industrial melanism rest upon such surfaces as tree trunks, rocks, and fences with no apparent attempt at self-concealment. These forms are selectively eliminated by insectivorous (insect-eating) birds, which tend to destroy the insects that are the least camouflaged—*e.g.*, black forms on pale lichen-covered bark in rural districts and pale forms on soot-begrimed trees in industrial regions. Two conditions thus affect the survival of the moths—a heterozygous advantage that ensures polymorphism and selective elimination by birds.

The appearance of black moths in presumably rural areas may in fact be the harbinger of environmental pollution there. The effectiveness of man's efforts to minimize atmospheric pollution is indicated by the fact that a significant reduction in the proportion of melanic moths has gradually taken place where anti-smoke regulations have been introduced.

Polymorphism in Batesian mimicry

Mimetic. In mimicry of the Batesian type, harmless or palatable species mimic formidable or nauseous ones. In Müllerian mimicry, in which formidable or nauseous species resemble one another, uniformity tends to develop both within and between distinctly marked and warningly coloured species. One encounter with an unpalatable prey should thus have a widespread influence on a predator. Thus polymorphism is generally restricted to mimicry of the Batesian type.

Batesian mimicry may involve general features other than colour pattern. In butterflies, for example, shape, scent, or motion may be mimicked. The "deceiver" is often only the female. Striking similarities may be involved, with disguises so convincing that the insects themselves may be deceived—a male butterfly sometimes chasing a female of the wrong species. Such mimetic forms, controlled genetically by the segregation of genes

or super-genes, have evolved gradually, through selection; *i.e.*, the gene complex is favoured that evokes the appropriate deception most efficiently. The sudden appearance of one gene by mutation may give rise to a more convincing copy in districts in which the species serving as a model is present than in those in which the model is absent because the effects of a gene can be modified by selection acting on the gene-complex.

Polymorphic mimicry appears to provide the essentials for a condition of diversity; for, as a mimic becomes more common relative to its model—by means of the advantage of similarity—the advantage eventually is converted into a disadvantage because a colour pattern, which originally was a warning, comes to be associated by predators with something edible rather than inedible, thus favouring diversity of the mimic. Inherent in the situation is another condition capable of producing polymorphism, for the heterozygotes are superior in viability to the homozygotes. Such a situation illustrates the almost requisite evolution of heterozygous advantage in polymorphism (see also MIMICRY).

Behavioral. The brood parasitism of cuckoos is illustrative of polymorphism in behaviour. Different female cuckoos can lay eggs of differing appearance. These they introduce into the nests of appropriate species. There is an advantage, indeed a necessity, for a good copy since most host species will eject from the nest an egg that differs noticeably from their own. In fact, different females of one cuckoo species (*Hierococcyx sparveroides* of India) can lay eggs that differ in both colour and size in order to match those of two distinct host species.

The cuckoo, it seems, is able to choose the nests of correct species by means of behavioral patterns implanted at an early age; *i.e.*, the adult cuckoo is apparently attracted to a host species by sights and sounds encountered very early in life. Each female lays one type of egg, but she shows no tendency to mate with a male that is genetically appropriate in enabling her to lay a specific type of egg, nor does she show a tendency to have only one mate. The genes for egg colour pattern in cuckoos have apparently become transferred from the autosomal chromosomes (chromosomes other than sex chromosomes) to the Y-chromosome (the chromosome for female sex), which in birds, unlike mammals, is transmitted through the female line.

Polymorphism in behaviour, then, can be genetically controlled, as is the mimicry of butterflies and the early conditioning of cuckoos.

Chromosomal inversions in *Drosophila*

Chromosomal. Another aspect of polymorphism involves chromosomal inversions acting as super-genes. Such rearrangements of genetic material, which are known in the fly *Drosophila*, have been examined in the third chromosome of *D. pseudoobscura* and *D. persimilis*. All such inversions observed in *Drosophila* give rise only to physiological effects (*i.e.*, cryptic variation); the individuals thus look alike, and the polymorphism is detectable only by examining the giant chromosomes in the salivary glands of the immature flies (larvae). The occurrence of the polymorphism is controlled by selection, the heterozygotes having an advantage over either homozygote. The advantages and disadvantages of the different chromosomal inversions ensure that the frequencies of their occurrence correspond to environmental changes.

The frequency of occurrence of so-called standard chromosomes undergoes a seasonal cycle in *Drosophila pseudoobscura*. In one California locality, for example, the frequency of the standard chromosomes regularly decreases from about 53 percent in March to about 28 percent in June. The process is reversed in the hot summer period up to late August until the proportion characteristic of early spring is again reached. Some powerful selection mechanism is able to bring about these seasonal adjustments in a few generations, since *D. pseudoobscura* passes through only six to eight generations per year at the locality studied.

The chromosomal polymorphism of *D. pseudoobscura* provides an instance of recent evolution. The so-called Pikes Peak gene arrangement in this insect has always been common in Texas but was rare in California before 1946. Until then, only four instances of it had been encountered in some 20,000 chromosomes. By 1970, 8 percent of *D. pseudoobscura* in California carried the Pikes Peak gene arrangement. The change is perhaps caused by the evolution of some new gene complex favouring this gene arrangement.

Blood group. Cryptic variation in human blood groups provide further examples of polymorphism. The variation is maintained by a balance of selective advantages and disadvantages.

Several blood groups are known to be controlled by genes, and it may be assumed that the groups have evolved heterozygous advantage. In the O, A, B, AB series for which individuals are commonly typed, heterozygous advantage has not yet been fully demonstrated for the A and B types because the heterozygotes are not yet distinguishable. In matings between individuals who are both of the AB type, however, A, B, and AB genotypes can be distinguished among the offspring. In such cases, an excess of the AB group has been clearly established; it is achieved because prenatal mortality eliminates the homozygotes.

In view of the selective balance involved in the human blood groups, it has been possible to predict susceptibility differences between individuals of different groups to various medical disorders. For example, persons with blood type O are about 35 percent more likely to develop duodenal ulcers than are those of other blood types.

The study of protein radiation by means of electrophoresis (the migration of substances in an electric field) makes possible the observation of differences in the nature of the amino acid components of the proteins. The genetic loci that control amino acid variation of the proteins can also be distinguished. About 40 percent or more of the diversity observed is polymorphic. Studies indicate that many genetic loci are polymorphic in animals and in plants.

This type of protein variation generally produces only cryptic effects; but, since the genes have multiple effects, it may be expected that protein variation is sometimes associated with overt characteristics. These may indeed contribute to its persistence; it has been shown, for instance, that there is a correlation between protein variation and habit in a colony of eider ducks, *Somateria mollissima*, in Scotland. One of the egg-albumen protein types is significantly more common among the migrant ducks than the nonmigrant ducks in the colony.

Development of polymorphism. Particular genes may become an asset and spread through the population—sometimes promoting a balance of selective agents and leading to polymorphism—before the evolution of heterozygous advantage. This may be seen in the colour and banding of snails and in mimicry, both of which are themselves capable of maintaining diversity. A further example is polymorphism for colour pattern in the moth *Panaxis dominula* in a marsh near Oxford. The polymorphism is controlled by a pair of genes in which the two homozygotes and the heterozygote are visibly distinguishable. The female moths of each state prefer to mate with males of one of the other types, although the males show no such inclination. Because competition exists among the males, who are able to pair with a number of females, the rare forms are favoured, thus leading to diversity and establishing polymorphism. No trace of heterozygous advantage has thus far evolved in this case—probably because the polymorphism has developed relatively recently.

Polymorphism for colour pattern in *Panaxis dominula*

Control of the breeding system is an important factor in the development of polymorphism. Such control is exemplified in plants by heterostyly, a condition common in the Primulaceae (primrose family). In heterostyly, now recognized as a super-gene involving as many as seven loci, the respective positions of the male and female parts of the flower are transferred. Either the anthers (the pollen-bearing tips of the male part of the flower) are high and the stigma (the elevated tip of the female part of the flower) low—hence difficult for pollen-transporting insects to reach—or the positions are reversed. These types of primrose, the "thrum" and "pin," respectively, are

polymorphic and appear in approximately equal numbers in populations of the species affected. As pointed out by Charles Darwin, heterostyly makes easier the transfer of pollen by insects between plants with unlike types of flowers, thus favouring outbreeding, or the mating of unlike individuals, while a physiological mechanism ensures sterility when crossing between similar types does takes place. Conversely, a crossover within the supergene ensures that the male and female parts are formed at the same height (homostyly) and favours self-fertilization. Plants with the heterostyle-homostyle mechanism can thus vary between outbreeding with relative variability and inbreeding with relative uniformity to suit the ecological situation.

The relationship between polymorphic and multifactorial variation is important. In the latter, numbers of genes having small, similar, and cumulative effects operate, as in the genetic component of human height. This may allow a change to develop more easily than in the case of polymorphism, since most of the genes concerned in multifactorial variation are generally scattered in the normal population. This distinction occurs in the development of resistance to warfarin, a rodent poison. Such resistance is multifactorial in the mouse (*Mus musculus*); in the rat (*Rattus norvegicus*) it is caused by a single gene.

Polynesian Cultures

Polynesia is the name used to cover a huge triangular area of the east-central Pacific. A triangle, each side of which is approximately 4,500 miles in length, it has its apex at the Hawaiian Islands and its western and eastern base angles at New Zealand and Easter Island, respectively. (See OCEANIC PEOPLES AND CULTURES for a map of the area.)

The basis for grouping the islands together is not their form and structure from a geographical point of view, for there is a good deal of physical diversity among the islands of the Polynesian group. They are grouped together because they are (in a few cases, *were*) inhabited by a people sharing a common basic cultural, linguistic, and racial heritage—the Polynesians. Although this heritage shows a measure of variation from one island culture to another, the underlying similarities are so marked and evident that the cultural relationship between the peoples of these far-flung islands is clear even to observers who have no training in anthropology.

This article will deal for the most part with traditional aspects of Polynesian society before the coming of the Europeans. The effects of this development are discussed in the concluding section.

THE PHYSICAL ENVIRONMENT

The physical environment of the islands of the Polynesian triangle is not as favourable for human habitation as it might at first seem and certainly presented difficulties when the ancestors of the Polynesians entered the area from the west, well before the turn of the Christian Era. The islands were apparently devoid of much that was needed for human habitation. Most of the food and useful plants and all of the domestic fowl and animals had to be transported by the Polynesian settlers themselves. Since that time, the physical environment has continued to exert a marked influence on the nature and extent of the evolution of Polynesian cultures by virtue of the constraints and opportunities that it provides.

Three Polynesian island types

There are essentially three main types of islands in the Polynesian triangle, each of which offers a different set of potentials and limitations to the inhabitants: coral atolls, "high," or volcanic, islands, and makatea islands.

The islands of the Tuamotu Archipelago are examples of coral atolls, each of which consists of a string of irregularly shaped and low-lying islets fringed by a reef, surrounding a central lagoon that may be as much as 20 to 30 miles (30 to 50 kilometres) in diameter. Endowed with a rich sea and shore fauna, atolls are generally impoverished in terms of land vegetation, lacking soil for planting and water.

High, or volcanic, islands (the Hawaiian Islands, the Samoan Islands, and Tahiti, for example) are volcanic in origin, produced by outflows of lava along faults and other lines of weakness in the sea floor in relatively recent geologic times. These islands display rugged terrain with remnants of extinct volcanic features, such as craters and volcanic plugs, and some live volcanoes. There is ample depth of soil for agriculture and abundant groundwater. The mountains of many of the volcanic islands are high enough to trap and hold rain clouds, resulting in good precipitation and lush vegetation. Usually, a series of vegetation zones can be identified on such islands as one proceeds from the beach uphill and inland to the island's central plateau.

Makatea islands (Makatea Island; Aitutaki in the Cooks, for example) are coral atolls that have been raised, wholly or in part, exposing the coral rock of the atoll high above the sea. Such islands generally have rugged surfaces and steep edges due to the differential erosion of the coral rock by wave, wind, and water. Soil may have developed in pits and hollows upon such surfaces, giving makatea islands a generally richer and more profuse vegetation than coral atolls.

New Zealand is unique in this grouping, for it is the only island in Polynesia of continental origin. It is actually an outpost island of the ancient continent of Australasia, which has been in formation since the Cambrian Period (*i.e.*, since at least 500,000,000 years ago). It has a wide range of environments, including high mountain ranges and glaciers, hot springs, lakes, dense forests, great rivers, and rolling grasslands. New Zealand also had the only indigenous terrestrial food animal of any real significance in Polynesia: the large, ostrich-like birds known to the New Zealand Maori as moa. This bird, a major resource for the early Polynesian settlers of New Zealand, was ultimately rendered extinct by the growing Maori population. New Zealand's uniqueness in Polynesia in terms of its geological history is enhanced by virtue of its position well outside the southernmost limit of the tropical climate zone. The differing climate, flora, and fauna of the New Zealand islands led to the development of the very distinct Maori version of Polynesian culture.

Climatic variations

The Polynesian triangle, lying astride the Equator, includes both tropical and nontropical climates. In the tropical section, the apex of the triangle lies in the northwest trade winds, while the southeast trade winds blow through the base of the triangle approximately 70 percent of the year, bringing rainfall to the southern and eastern coasts of the high islands particularly. For approximately 30 percent of the year northwest winds take over in the Southern Hemisphere. These winds, appearing at roughly the same time each year, played an extremely important part in Polynesian voyaging, for they enabled Polynesian mariners to sail eastward more easily. Much of tropical Polynesia lies in the area of heaviest rainfall in the Pacific, a zone having from 80 to 160 inches of rain per year.

This helped the early settlers considerably in establishing their native agricultural and useful plants. The doldrum region, with its high temperature and humidity and low wind speeds, cuts across the triangle in an east–west direction, presenting what must have been a somewhat imposing barrier to north–south travel with aboriginal vessels.

CULTURE PATTERNS

General characteristics. The popular image of polynesian culture is one of an almost blissfully simple and easy way of life, devoid of harsh extremes of any type, played out on islands of great beauty and natural abundance—in short, the exact opposite of much of Western culture. But the image, a product of popular literature and the motion-picture industry, is wide of the mark. Polynesian culture is both complex and highly specialized, and it abounds with extremes of all types.

The principal characteristic of Polynesian culture is its effective adaptation to the ocean environment in which it has flourished: no other culture of which there is record has ever so successfully mastered the sea. This mastery did not extend merely to the technology involved in ship building, to the techniques of navigation, and to other obvious nautical aspects of the culture but permeated social organization, religion, sexual behaviour, food production, and every other facet of the culture. The Polynesians could not only sail the seas, but socially they could cope with the human problems of shipwreck, split families, and the sudden loss of large portions of the social group. The food plants upon which they existed were all capable of withstanding long sea voyages, and their domestic animals were also easily portable. In short, the culture was well equipped to handle the numerous hazards that it had to face in the beautiful but actually quite hostile Pacific environment.

Polynesian conservatism

Another important characteristic of Polynesian culture is its high degree of conservatism and traditional orientation and the rather detailed structuring that places every man in a well-defined relationship to his society and to the universe.

The conservatism of Polynesian cultures is apparent even in a rapid examination of Polynesian materials from islands separated by hundreds or thousands of miles, whose populations were separated from the common Polynesian stock two or three millennia in the past. The similarity between such items as stone adzes and fish hooks is most remarkable. The same is true for kinship terms, plant names, and much of the rest of the technical vocabulary of the cultures, as well as for art motifs and medical preparations. A profound reverence for the past as embodied in the ornate and voluminous genealogies, chants, legends, songs, and spells that are passed down and elaborated through the generations provides a further illustration of this conservative tendency. The reason for this retentive nature of the culture is likely to be found in its successful adaptation to the Pacific island environment. There was no need to alter a technology or a social system so capable of coping with problems likely to be encountered.

The traditions of Polynesian culture provided a definition of a man's relation to his society and to all of nature. The creation myths told of the origin of the world, setting forth the order of precedence of Earth, sky, and sea and all the phenomena thereof, including man and woman. The genealogies fixed a man tightly into the typically aristocratic Polynesian social order. Other legends interpreted natural phenomena that were beyond his power to explain, while historical accounts often described, with varying amounts of mythological embroidery, the migrations of his people before they arrived at the island on which they were located, their adventures on the way, and the development of the culture following settlement.

The Polynesian was unusually well oriented, as would be expected in a nautical culture, to the entirety of nature. Their languages abound with terminology for stars, currents, winds, land forms, and directions; they are also unusual in their possession of a large number of grammatical elements indicating, for example, direction of motion implied by verbs, including movement toward or away from the speaker, relative positions of objects with reference to the speaker, and direction of movement along a seashore–inland axis.

It is one of the interesting contrasts of Polynesian culture that a way of life that displayed such a thoroughly realistic and practical exploitation of its environment at the same time exhibited a profound interest in the supernatural. This interest was directly related to the general interest in systematization and structure, the supernatural being for the Polynesian another portion of reality, albeit less manageable, that had to be structured and coped with.

Violence and cruelty were ever-present elements of Polynesian culture before and after contact with the Europeans. This is reflected strongly in Polynesian oral literature and in all aspects of life. Custom controlled and repressed direct physical expression of aggression within the kin group and the tribe up to a point, but there were definite limits beyond which only violence could restore status or assuage injured pride. Punishments for transgressing rules of behaviour toward chiefs and high priests or for violating various rituals incorporated ritual sacrifice and cannibalism as major features. Intertribal warfare was extremely common, particularly when population pressure had built up and land and resources were limited.

Perhaps the most publicized, and accordingly overrated, aspect of Polynesian culture is its sensuality: as in many other aspects of life, the Polynesians generally took a very direct, realistic, and quite physical approach to gratification of the senses. But there was no abnormal focus or concentration on any aspect of sensual gratification such as is seen in many other cultures where, for example, eating, drinking, or sex have become culturally important out of all proportion to their real significance and have consequently been the object of great cultural elaboration. This lack of elaboration in the areas of sensual gratification may be due in part to limitations imposed by the environment. The flora of Polynesia did not, for example, provide a very good basis for elaboration of cuisine, as the number of edible plants was rather restricted, and there was a dearth of spices. In general, however, this balanced approach to sensual gratification seems to be just another reflection of the Polynesian straightforward approach to the world. Polynesian culture, for example, is generally thought to have been characterized by extreme sexual promiscuity, but such is not the case. Definite restrictions were placed on sexual behaviour, though the limits of acceptable behaviour were indeed wider than in many other cultures of the world. Children were permitted freedom of sexual expression; from puberty on, sexual activity was strongly encouraged, limited only by incest restrictions (which were not stringent) and considerations of social prestige. Parents would become concerned if daughters were not sought after for sexual favours, and premarital pregnancy only enhanced a girl's attractiveness. Public intercourse was common during religious festivals and crisis rite ceremonies. There was, however, no pathological elaboration of sex for its own sake. Polynesian art, for example, is strikingly devoid of sexual content. There are occasional references made to sexual activity in native Polynesian oral literature, but many of these have to do with creative acts of the Polynesian gods, for the Polynesians saw the process of the creation of the universe as having taken place in a manner similar to human procreation. There is no corpus of Polynesian literature analogous to pornography. Sexual activity was an important part of certain religious ceremonies, but this was performed as a magical technique to promote general fertility rather than as an end in itself.

Sexual mores

Economic systems. *Settlement patterns and housing.* Two major settlement patterns were present in Polynesia prior to European contact: the hamlet and the village. Their origin and development may depend to a large extent on geographical factors, such as the distribution of food-crop resources, on defense considerations, and on social organization.

The hamlet settlement pattern was often found in the

larger volcanic islands, where food resources were diversified and scattered over the range of environmental zones that developed on such islands. A typical hamlet settlement pattern was often found in the Marquesas Islands. There, in prehistoric times as at present, the population spread over the floors and up the sides of the deep and narrow Marquesan valleys in clusters of perhaps four to five houses, often with gardens, taro patches, coconut trees, and breadfruit clustered in the immediate vicinity. The Marquesan houses were built on rectangular platforms, the height and composition of which depended on the prestige of the owner. Individuals of lower status might have a simple paved rectangle no more than a few inches high, while warriors, priest, or chiefs might live in houses perched on platforms seven to eight feet (about two metres) high and containing stones of several tons in weight. The house itself was built on a kind of a step running across the rear of the platform. Composed of a lashed and fitted wooden framework and with a thatched roof, the typical house was open all the way across the front and had square ends. The roof sloped from the high ridgepole directly to the platform floor in the rear. Inside, a polished coconut log often ran the length of the house, serving as a kind of community pillow. The floors were covered with mats, shredded leaves, or bark. Belongings were suspended in bundles from the rafters. Most of the household activity took place on the "veranda," or unroofed front portion of the platform, which was paved with smooth basalt stones from stream beds. Houses of chiefs and other high status individuals often made use of cut stone slabs for decorating the platform. Many also had rectangular pits in the platforms for storing fermenting breadfruit paste (an important delicacy) and small caches in which were interred the carefully cleaned and packaged bones of important family members.

Among the clusters of houses in each major valley section was a large rectangular ceremonial plaza, or *tohua*, which served as the focal point for all tribal or subtribal ceremonies, as well as a point for daily social gatherings. This complex of structures, often 600 feet (200 metres) or more in length, was generally built upon a huge artificial terrace carved out of a slope. Surrounding the plaza atop the terrace were the houses of the tribal chiefs and priests, temples and other sacred structures, and long sheds for spectators, At one end was usually found a temple with a sacred banyan tree in which were suspended the packaged bones of the illustrious dead of the tribe.

In Samoa, on the other hand, the village settlement pattern was followed after AD 1000 or so. There, fortified villages, consisting of 30 or more houses arranged in a network of paths, grew up along the coast. The houses at the time of European contact were built on oval mounds faced with rough stone slabs, although earlier houses had been built on rectangular platforms much like those of the Marquesas. The typical Samoan house was and is today a large shedlike structure without walls, oval in floor plan, with a beehive-shaped, thatched roof supported by a series of stout wooden pillars. Rolled mats along the eaves were let down to protect the inhabitants from sun, rain, or the night air. These houses, arranged in orderly fashion along the paths and sunken roadways that crosscut the villages, were surrounded by a fortification wall of stone or by wooden palisades.

Maori fortified villages

The Maori of New Zealand constructed large and impressive fortified villages (*pa*), surpassing those of all other Polynesian cultures. These forts were protected by ditches, palisades, trenches, and terraces. The interiors were partitioned off by additional defensive works so as to facilitate battle even after the outer defenses had been penetrated by an enemy assault. The houses within were of timber, rectangular in plan and generally dug a foot or so into the earth surface.

Other, unfortified Maori villages consisted of loose collections of houses arranged around a level area where ceremonies and meetings might take place. Forts were usually constructed in the vicinity of such villages for the use of inhabitants in time of war.

Production and technology. The Polynesians were above all mariners, but among the many seafaring peoples of the world they were quite unusual, for, far from having a disdain for the land and all that it involves, they were capable and devoted to horticulture and arboriculture.

The sea provided most of the protein in the Polynesian diet. Fishing was carried on not only on an individual basis, with spear, line, or net, but on a group basis with large numbers of men spreading and drawing in huge nets in bays or lagoons or driving fish toward shore, where they could be captured in nets held in shallow water. In some Polynesian societies (Marquesas and Samoa, for example) there were specialists who directed the mass fishing efforts and the elaborate religious rituals that went along with them. Sea mammals (porpoises and whales) were also taken, the former often being driven into shore by means of large, well-organized drives: when a school of porpoises was sighted in a bay, a fleet of canoes would seal off the bay entrance, and crew members would leap into the water carrying stones in their hands, which they beat together as they swam slowly toward shore. The sounds terrified the porpoises, and they beached themselves in a frenzy.

The Polynesian fisherman's exploits were not, however, confined to coastal waters, for he was just as much at home on the high seas. The waters around their island homes were explored for miles in all directions. The Easter Islanders, for example, used to travel to Sala y Gomez reef to fish—a journey of some 300 miles (500 kilometres). Good fishing places were located by reference to land bodies if visible or just by dead reckoning. Line fishing to depths of 90 feet was not uncommon to take the grouper. School tuna were taken in large quantities on the high seas by means of shiny pearl shell lures with bone points. The flesh of sharks and rays were delicacies.

Mollusks and crustaceans were important as food, and mollusks also provided the shells from which a wide variety of tools and ornaments were made. Clams, cowries, and various snails and conches were collected, generally by women and children, along the reefs or shorelines and in the shallows. Shrimps were netted with fine nets, while lobsters were collected by men who dove and pried their spiny prey loose from underwater crannies. The octopus was lured from its hiding place by an ingenious lure made of leopard cowrie shells. Various types of seaweeds and algae were also collected and were highly prized for their salty taste. There was, in short, nothing edible in the sea that was not food for the Polynesians.

Horticultural practices

Gardens and groves produced the staples of the Polynesian diet and most of the condiments. The major native Polynesian crops were yams, sweet potatoes, taro, breadfruit, bananas, sugarcane, coconuts, and chestnuts. These crops achieved different levels of importance in various Polynesian societies, depending on cultural factors and environmental conditions. The Hawaiians, for example, relied heavily on taro, building extensive irrigation systems to grow the variety that requires muddy soil and planting the "dry" variety in the uplands. Breadfruit was not of great importance in Hawaii, however. In the Marquesas and Tahiti, on the other hand, breadfruit was the major staple, although taro was by no means neglected. In these islands breadfruit was allowed to become overripe and was then beaten into a pulp and stored in large, well-drained pits in the ground, in neat hibiscus-leaf bundles. The breadfruit paste thus stored would ferment but remain edible and nutritious for years, its sour taste being highly prized for imparting flavour to the rather bland fresh breadfruit paste.

In the subtropical climate of Easter Island and in temperate New Zealand, the most important Polynesian food plants could not survive. On Easter Island, for example, the coconut did not survive, although legends maintain that germinating coconuts were brought by the earliest settlers. This deprived the Easter Islanders not only of a variety of condiments and a rich vitamin source but also of the leaves that were used elsewhere in Polynesia for thatch and baskets and of string, for most fishing line and netting in tropical Polynesia is made of plaited coconut-husk fibres, called *nape*. In New Zealand it was not only the coconut but also breadfruit, yams, and bananas that

did not survive. The radically different flora and fauna of New Zealand, however, offered new foods to replace, at least partially, those that it would not support.

Not only the coconut but most food plants in Polynesia also provided materials for other purposes. The breadfruit furnished wood for the hulls of dugout canoes, and the milky sap of the fruit itself was used in caulking the gaps between the planks of larger canoes. The black mud of the taro patches was used to stain wood and stone carvings. The pandanus fruit was highly prized as a kind of chewing gum, as well as a major component of floral necklaces and headpieces, to which it contributed its strong and pleasant colour. Pandanus leaves, when bleached, became the raw material for fine mats. The candlenut was used for torches; its oil was a cathartic, and its wood furnished certain canoe parts.

Polynesian technology can be circumscribed by five words: wood, stone, vegetable fibre, shell, and bone. The canoes, houses, domestic utensils, weapons, religious sculpture, and a host of other incidental tools were fashioned from wood with stone or shell adzes, stone-flake knives, files made of coral, sea urchin, or rough stone, and drills of bone, stone, or shells, Fine carving was done with stone, shell, or animal teeth, particularly those of rats or sharks. Stone, generally fine-grained basalt, was the hardest material available to the Polynesians and was used to produce a variety of adzes, the production of which was a demanding task in itself, for many broke at some point short of completion.

The absence of metal for use in attaching or clamping wooden parts posed no obstacle to Polynesian construction. Wooden components were skillfully fitted together and lashed with cordage made of various types of vegetable fibre, such as hibiscus bark, pandanus-leaf fibre, coconut fibre, or banyan bark. Huge double canoes 100 to 150 feet (30 to 45 metres) in length, for example, were built of numerous small wooden components all held together only by fitting and lashing, yet they were able to withstand the pounding of wind and wave for thousands of miles.

Vegetable material also furnished a major source of clothing in the form of the beaten bark (*tapa*) of the paper mulberry tree or the banyan. This material was beaten out into small sheets that could then be assembled to produce loincloths, capes, skirts, and headdresses. Bark cloth was decorated by painting and water marking and by attaching feathers, shells, teeth, and other ornaments. Fine mats were also used as apparel in western Polynesia.

Home furnishings also consisted mainly of vegetable material in the form of mats for sleeping and sitting, as well as for protection from the weather, and of baskets for holding personal belongings and food. Coconut shells and bottle gourds provided handy, durable containers for various items.

Pottery

Pottery was in use in western Polynesia at the time of European contacts. Its presence was originally thought to be a result of Fijian influence, but archaeological evidence now shows that pottery was in use before the Christian Era in the Marquesas Islands, at the extreme eastern edge of Polynesia, but subsequently it disappeared from the technology. This disappearance is easy to account for if one reflects on the lengthy and involved process required to produce a pot that was actually quite fragile, when there were durable natural containers (coconut shells and gourds) around in abundance and when wooden bowls of great durability could be produced for only a little more effort than that involved in making a pot.

Craft organizations are an interesting aspect of Polynesian culture. These organizations provided for the training of specialists in tasks requiring special knowledge and higher levels of manual skills—canoe construction, wood carving, and adz making, for example, as well as complicated operations, such as fishing and tattooing. When specialist groups existed, they were usually designated by name and would ply their craft for pay in the form of goods and services, as well as support for the period of their service.

Property and exchange systems. Personal property was a well-developed concept in primitive Polynesia. Each individual, regardless of rank, had his own tools, small canoes, clothing, ornaments, trophies, weapons, and other items and was generally free to dispose of them as he wished. Other types of property, however, were owned by kinship or residence groups in common and used for the common good. These included items too large to be produced or managed by a single man alone, such as a large double canoe or a fishing net several hundred feet in length, as well as facilities and land intended directly for community use, such as a tribal ceremonial ground, a refuge fortification, or a large breadfruit paste storage pit.

Land-holding practices

The matter of ownership of land and the means of production is complicated and varies among Polynesian cultures depending on the type of social organization that they developed. In Polynesian societies of the more traditional type, land was vested in a corporate kinship group. Among the Maori this corporate kin group, known as the *hapu*, usually inhabited one or a few villages located in close proximity to each other. The land of the *hapu* was viewed as being symbolic of the *hapu* chief's sanctity and power and as almost a literal extension of his body. Yet, the land was apportioned out to the various family groups within the *hapu* and worked by them. The chief, regardless of his prestige (stemming from a close family tie to the tribe's mythological ancestors), could not evict a family of nonproducers or in any way cut them off from their source of livelihood. He could invoke supernatural powers in the form of a curse of a ritual prohibition, but expropriation was quite uncommon. In return for this essentially inalienable right to his land, the good Maori was expected to provide certain quantities of produce for the chief on various occasions and also for the chief of the next highest element in Maori social organization, the *iwi*, which was composed of several *hapu*. If his offerings were not of sufficient size and quality, the Maori risked punishment and possibly even death in extreme cases but not expropriation. If the food offered was acceptable, however, the offeror would be assured of an appropriate amount of food of other types in return, demonstrating the chief's desire to live up to his own obligations.

A number of Polynesian societies were essentially similar to the Maori in their land-holding practices, including the Tikopia, Pukapuka, Futuna, and Uvea; but in others, evolutionary changes in social organization began to exert pressure on the basic land-holding kinship group (as exemplified by the Maori *hapu*), which seems to have been the basic building block of Polynesian society. As a result, the kinship group ultimately lost control of all rights to land, surrendering it to increasingly powerful and autocratic chiefs. Thus, in Hawaii, perhaps the most sociopolitically evolved of all the Polynesian societies, there was a large mass of completely landless commoners dwelling in territorial districts, each of which ran from the seashore to the island's centre, thus including a segment of each of the island's ecological zones. Each of these districts was ruled by a chief, somewhat like a lord in medieval Europe, who was responsible to the paramount chief of the island for supervising, among other things, the production of that district. The district chief or the paramount chief was free to shift at will the population of commoners within the district, regardless of their kin affiliation, although the chief and nobles themselves still relied heavily on their own kinship affiliations and prerogative. The district chief saw to the production of each household in his district and could evict the unlucky farmer who failed to meet his quota. Both he and the paramount chief could also make a variety of arbitrary demands from which the commoners had little or no protection, except to leave the district and submit to the authority of another district chief. The commoners were responsible for producing certain specified quantities of food at certain times, which was collected and passed up to the district chiefs and ultimately to the paramount chief. At that level, certain types of food reserved for chiefs only would be set aside, and a redistribution of the food would take place, with portions flowing back down the same channels that had been used to collect the

Economic redistribution in Hawaii

food in the first place. Kinship groupings, consisting of all individuals related through both male and female lines, still existed to be sure, but their main functions seem to have been to serve as a channel for low-level exchange of food and other commodities and to assist in the organization of the massive food collections held periodically throughout the year for the nobility.

The Polynesian system of exchange of goods and services may be summarized by two terms: redistribution and reciprocity, both already mentioned in connection with the discussion of the land-holding systems. The redistributive system was essentially a vertical system with goods moving up from the lower strata of the society to the chiefs and other high-ranking persons and then being apportioned and redistributed, so that all would share in more equal fashion in the productivity of every kinship group or region. This system involved a complex, shifting web of reciprocal obligations, which is very much at the heart of Polynesian culture, even today. Goods and services rendered, even if not requested, necessarily give rise to an obligation for a return in kind. There were no markets in Polynesian cultures, nor was there any standard medium of exchange. All exchange was in the form of barter, often under the general supervision of some senior family or kin-group member. Thus, for example, a portion of the fish catches made on a minor fishing expedition by coastal residents would be passed inland to residents at central villages, who might return dry taro for the fish at some fixed ratio of units of taro to units of fish. The services of any of the numerous specialists in Polynesian cultures (tattooists, fishermen, wood-carvers, for example) was also paid for by barter, usually over and above the cost of the specialist's keep during his period of service. Early European visitors to Polynesia who were able to analyze the importance of reciprocal exchange and put it to their own use generally fared quite well among the Polynesians, although they sometimes found themselves overwhelmed by the increasing size of the obligations they had undertaken. Capt. David Porter, United States Navy, for example, in 1813 won the friendship of the chief of Taiohae, Nuku Hiva, with a gift of sperm whales' teeth, but within a few months found himself fighting a tribal war essentially on behalf of the same chief, in order to live up to his obligations.

Social structures. *Local and territorial organization.* The two major types of settlement in Polynesian cultures —hamlet and village—were bound together by a web of kinship and territorial ties of varying degrees of importance.

There were two main and probably related types of kinship-based descent groups prevalent in Polynesian society. By far the most common and perhaps the most like the ancestral form of Polynesian social organization was the "ramage" type, in which the whole society might be represented in the form of a multibranched tree. There was a senior line of descent, in which descent passed from firstborn son to firstborn son and was traceable back to the mythological past. Branches off this main line were founded by junior sons, and these branches in turn produced further branches. Because the main line was the direct line to the gods and therefore carried the maximum traditional prestige and sanctity, it followed that each of the branches was ranked in terms of its proximity to the main line, and each individual in each branch could presumably place himself in a prestige-ranking scale relative to other members of his household settlement and kin group.

The various levels of the branches off of the main line assumed different levels of importance in various Polynesian societies. In New Zealand, for example, four levels were recognized: (1) the *waka* were a group of people descended on both maternal and paternal sides (male preferred) from the crew of one of the original canoes in the traditional Maori migration to New Zealand. They occupied a given territory and had a chief who functioned only in times of crisis and members who recognized their common tradition and interest. (2) The *iwi* were component parts of the *waka* but were made up of individuals tracing descent from a single occupant of one of the canoes, through either maternal or paternal line (again, the male line was the prestige line). The *iwi* had a chief and was a more tightly knit kinship group occupying a defined section of land within the *waka* territory. (3) The *hapu*, a component unit of the *iwi*, was the principal Maori descent group, consisting of all descendents of a given ancestor, usually sited in a particular village, and controlling the farming land around the village. The *hapu* also had a chief who was responsible for all economic and civil affairs. (4) The *whanau*, or households of the *hapu*, formed the lowest unit within Maori society and usually consisted of three to four generations.

Each of the hierarchical kinship segments just mentioned could be ranked relative to the others, with the exception of the *iwi*. The *hapu* could all be ranked within any given *iwi* on the basis of their chiefs' ancestry. Within the *waka*, each *iwi* could also be ranked in terms of the distance of its founding ancestor from the chief of the canoe.

This form of hierarchical branching-descent-group organization with territorial overtones was found in most Polynesian societies, with appropriate variations for local environmental conditions and cultural history.

Descent-line kinship groups

The other major form of kinship-based descent group found in Polynesia is that known as the "descent line." Descent-line organization appears to be the result of a breakdown in genealogical ties between the lower levels of a ramage organization. The descent line in Samoa, for example, consists of a group of people tracing descent in the male line from a commom mythical ancestor. This group was known as a *sa*. There was no concern for genealogical relationship of one descent line to another, nor was there any concern for ranking based on distance from or proximity to any particular male line of descent. What were passed down through the descent line were titles, each of which had rank and prestige attached to it. Each descent line held a number of these titles, which enabled it to participate in certain ways in the village council (*fono*). A number of descent lines were represented in each village council, and each descent line was spread through a number of villages in a given area. Within a given village, the senior title, determined by mythological connections, gave its holder the position of chief.

A characteristic of the descent-line system is its flexibility. Depending so heavily on myth and tradition for validation of status and title, it was only natural that ambitious titleholders could advance the prestige of their titles at the expense of others by various kinds of prestige behaviour, such as displays of wealth and power. The traditions governing title seniority could then be judiciously tampered with to produce the realignment that would allow the advance in status to occur. New descent lines might also be founded with similar "rewriting" of oral tradition.

Family and kinship patterns. The typical Polynesian family was an "extended" patrilocal patrilineal family—*i.e.*, a family consisting of more members than just parents and their children, living close to the senior male's people, and tracing descent through the male line. It consisted of a senior male and two to three generations of his male descendants and their children. Adoption, a very common custom in Polynesia, introduced additional children into the extended family, and these children behaved toward their adopted parents and siblings as they would toward their own. The flexibility of Polynesian social customs was such, however, that there were many variations on this patrilocal theme within and among Polynesian societies, depending on local conditions. There were also variations in lineality. In Tahiti and elsewhere, for example, inheritance could pass through females, if no male heirs were available. In other societies, more distant, collateral relatives and even slaves might be included in a household.

The basic Polynesian kinship pattern is essentially a very simple one: it distinguishes among generations, as might be expected in a society so strongly oriented on tradition and genealogy. There are sets of terms for: grandparents generation, distinguishing by sex only; par-

ents generation, in which parents are distinguished from various categories of aunt and uncles; members of a person's own generation, in which the terms permit identification by sex, relative age, and sometimes marital potential (marriage of certain cousin categories is preferred in some Polynesian societies); and, finally, for children, in which age and sex are again distinguished.

In general, the kinship terminologies in use in the various societies in eastern and marginal Polynesia are relatively simpler than those in the west.

Stratification. The tendency toward social stratification is perhaps inherent in Polynesian society, with its great interest in and emphasis on status and the indicators and prerogatives thereof. There seems to have been a process of social evolution occurring in Polynesia that tended to be somewhat unidirectional, leading toward more sharply defined differences in status and development of social classes that were clearly defined in terms of rights, duties, behaviour, and general life style.

The chief in ancient Polynesian society was the person of highest status, yet he was regarded by his people and generally conducted himself as merely "first among equals." In most of the more traditional of the societies, the chief could not appropriate the land of his followers, nor did he appear to be too interested in increasing his own group's holdings at the expense of neighbouring groups. In terms of his clothing and behaviour, there was little to distinguish him from other males. Nevertheless, he was the repository of sacred power for the group, a symbol of its tie with the past, and the vehicle whereby this tie would be perpetuated for coming generations. Even in the traditional Polynesian societies, however, it was possible for a man to rise in prestige by various achievements; by giving gifts, holding feasts, or displaying military prowess, for example. These activities seem to have contained the seed of change in the traditional social order.

Breakdown of traditional social order in certain Polynesian societies

There was a group of Polynesian societies in which the more traditional social order when breaking down gave way to one in which chiefs and other high status individuals no longer held office on the traditional genealogical basis but by virtue of having taken it, often by force, or as a result of some act that raised their prestige higher than that of the actual chief. In these societies the chiefs behaved more autocratically and set themselves off from the rest of the population by various kinds of privileges and behaviour. Changes in leadership were frequent, and kinship groups were split internally and reorganized in the course of internecine wars. Finally, out of this dynamic social situation emerged the most socially and politically advanced Polynesian societies (Hawaii, Tahiti, Tonga), with clear-cut social stratification and concentration of all power at the apex of the social pyramid—the paramount chief—below whom were several levels of nobility usually selected on genealogical relationship to the chiefly line. The paramount chiefs and upper classes had absolute powers over the commoners, inflicting cruel physical punishments, such as human sacrifice, for all manner of affronts to their dignities (touching a chief's shadow, for example). Warfare was frequent, well organized, and marked by acts of great cruelty. Religious and political powers were closely linked, with religious concepts and the gods themselves mirroring the cruelty and viciousness of the societies that had produced them.

Socialization and education. The Polynesian child was and is today generally born into a large and warm family environment. Even before the child can walk, it is turned over for care to the other children of the household (siblings, cousins), who generally associate in a kind of amorphous play group with children of other families. It is in this context that the Polynesian child receives a great deal of its socialization, first carried piggyback by an older sister and then running with a crowd. A particularly warm relationship exists between a child and its grandparents, often taking the form of rather gross bantering but providing the vehicle for inculcation of traditional love, technical training, and even sexual advice.

There was little by way of formal education in Polynesian society, except for the training in special crafts and skills, such as canoe making or tattooing, and the sacred academies for training the priest-bards who were the repositories of the society's traditions, mythology, and genealogies.

Rites of passage

Rites of passage varied in type and importance from society to society, but there were several that were generally held throughout Polynesia. The birth of a child was a matter of a great significance, particularly if the child happened to be a firstborn son of a high-status lineage. Various procedures were called for to announce the birth to the community, to the ancestors, and to the gods, and to care for the welfare (both physical and supernatural) of the infant and mother by application of medical and magical techniques.

Circumcision was a major gateway in the male life cycle and was appropriately marked by elaborate rituals, which increased in importance with the status of the male. Polynesians generally have an unusual abhorrence of the uncircumcised, to the extent that in some societies it was believed such people would automatically go to a very unpleasant netherworld after death. Although no such rite involving mutilation of any sort is reported for girls, some societies, such as the Marquesas, had orgiastic ceremonies in which adolescent girls made a more or less public debut, in a sexual sense.

There were other milestones in life that were marked with ceremonies in Polynesian cultures, such as the formal presentation of a royal heir, the completion of a tattooing operation or ear piercing in a high-status child, and the formal investiture of a priest or chief. The observances of these milestones were marked with a variety of rituals, quite often including human sacrifice, wanton killing of members of the population who might happen into the path of the ceremonial party, or members of the party who might make mistakes in performance of the rituals.

Death, the terminal milestone, was universally celebrated with extravagant behaviour, increasing in extravagance in direct proportion to the status of the deceased. In many societies these ceremonies were marked by violence, with mourners mutilating themselves and others, and the seemingly inevitable human sacrifices, obtained from within the social group or without. Feasts were also common, as was orgiastic behaviour. The extravagance of funeral rites was surpassed, in some societies, by ceremonies to deify a departed chief or priest. These went on for prolonged periods, involving prodigious feasting and drinking, violence, and sexuality.

Belief and aesthetic systems. *Religion and magic.* Religion and magic pervaded all aspects of Polynesian culture. All things, animate and inanimate, were believed to be endowed to a greater or lesser degree with *mana*, or sacred supernatural power. This power could be nullified by various human actions. Polynesian chiefs had great *mana*, so great, in fact, that in some islands if a commoner touched the chief's shadow the injury to the chief's *mana* could only be compensated by the death of the commoner. In many Polynesian cultures even today, it is still considered to be in very poor taste to step over a person's legs, pass one's hand over a person's head, or stand with one's head higher than that of a person of high rank. These actions are believed to sap a person's *mana*, rendering him profane.

It was not only people who had *mana*, however, but buildings, stones, tools, canoes, and all things. Polynesian life was loaded down with an often-bewildering variety of complicated rules designed to prevent damage to the *mana* inherent in various things. Groves, trees, temples, or tracts of land were considered sacred and could not be entered by ordinary people because they were pervaded by the *mana* of a high-status person or god. If anyone inadvertently stepped over a tool left on the ground, it was thus rendered profane and would often be discarded. Women were not permitted in canoes under normal conditions in the Marquesas because their presence defiled the canoe. In many societies, men preparing for war or for any other hazardous or demanding undertaking had to avoid the company of women, eat certain foods only, and often go into seclusion so as to protect their powers from

defilement. Some chants and songs were so sacred that every syllable had to be pronounced correctly. The penalty for major violations of these *tapu*, or prohibitions, was often death, swiftly executed and gruesome. Violations of lesser *tapu*, such as trespassing in a sacred grove or disturbing the bones of the dead, were visited with supernatural punishment in the form of illness, bad luck, or debilitation.

Mana was not the only problem that the Polynesian had to live with, however. The universe, in their beliefs, was peopled with spiritual beings of various types, many of whom were malevolent. In addition, there was a host of gods of various degrees of importance, ranging from the great gods of the Polynesian pantheon, such as Tangaroa, Tu, and Lono, to strictly local gods who were deified priests or chiefs of great renown. All of these gods had to be worshipped in their own way, the most important by full-time priests, of highest status, those of lesser importance by part-time priests. Worship of the gods involved sacrifices (including humans), chants and recitations, feasting (often with great prodigality), sexual orgies (to promote fertility), and elaborate rituals, often preceded by long fasting and abstinence.

Magic flourished in Polynesian society, with everyone practicing various rituals for success in love, war, planting, fishing, or just to bring misfortune to rivals. There were also magical specialists who could be resorted to when the problem at hand was too big and complicated to be solvable by ordinary magic. Such magical practices have survived in Polynesian cultures right down to the present time.

Abolition of *tapu* restrictions in Hawaii, 1819

The numerous restrictions and demands placed upon the average Polynesian by religion and the supernatural were in many cases seen as oppressive by the Polynesians themselves, and, in one case, the whole system was simply abolished. This occurred in Hawaii in 1819, when the young king, Kamehameha II, assisted by the high priest, his adviser, and other leaders of the court, publicly and intentionally broke the main food and eating *tapu* at a festival, after which the high priest desecrated the images of the gods and burned the temple. While many factors played a part in the prelude to this dramatic act (not the least of which was the presence of Europeans and the desires of the royal women to be free from the burden of *tapu*, which hit them the hardest), the principal factor motivating Kamehameha II seems to have been a real impatience and frustration at an increasingly constricting system that provided little obvious benefit in return for the great inconvenience. Although no other islands in Polynesia followed the Hawaiian example, there is evidence that the religious system was viewed as extremely frustrating in many other Polynesian cultures.

Artistic endeavour. Polynesian art was highly developed and brilliant, but little of what is known to have existed has survived down to the present day. This is mainly due to the perishability of much of the material (bark cloth, basketry, featherwork) and the dispersion of such items that took place during the era of European contact, when such items were bartered with European ship captains, soldiers, and collectors for firearms, liquor, iron tools, or various trinkets.

Each Polynesian society developed its own particular area of artistic endeavour—monumental stone sculpture on Easter Island and the Marquesas; highly decorated bark cloth in western Polynesia; fine mats in Tonga. In this development, a vocabulary of art motifs, styles, and artistic principles was elaborated, which also differ somewhat from culture to culture. There are, nevertheless, certain types of motifs that are widely distributed in Polynesia. There are, for example, a number of small geometric decorative elements, such as a toothed pattern or units of diagonally sloping lines, that are found in most cultures in many media. Stylized floral and animal elements are also widely distributed. In eastern and marginal Polynesia, an anthropomorphic figure and an often grotesque anthropomorphic face with bulging eyes and protruding tongue are prominent in all types of plastic art, as well as in tattooing.

Architecture as an art form was developed everywhere in Polynesia, but only the ruined stone structures of the eastern Polynesian islands remain to bear witness to the Polynesians' very considerable architectural skill. The stone temples of the Society Islands, Easter Island, and the Marquesas demonstrate the skill of the architects and masons. Even in their ruined state, many of these structures display striking proportions and design, clever use of stones of different colours, shapes, and textures and the evidence of sound combination of practical engineering with artistic objectives.

Architecture

EUROPEAN CONTACT AND ITS CONSEQUENCES

Integrating and disintegrating factors. The history of Polynesian culture since European contact is in many respects a sad repetition of what happened in all other parts of the world when a primitive society, well-adjusted to its own environment, was suddenly confronted with a vastly superior technology.

A number of factors internal to Polynesian culture had, in a sense, rendered it quite vulnerable to outside influences of a certain type. The political instability of the more evolved Polynesian societies, with social mobility gained by breaking down kinship ties and pushing aside traditional leadership, was a major weakness. The constant warfare that had developed as a concomitant of this political instability or as a result of overpopulation on some of the smaller islands in many cases crippled the economics of whole sections of a society, destroying cultural goods that had been produced at great cost, as well as constituting a serious chronic drain on the population. The emphasis on conspicuous consumption in lavish feasts and ceremonies caused a further drain on the economy, with huge quantities of food being consumed or wasted without heed for long-term needs.

Another series of vulnerabilities were in the area of health. Certainly, the Polynesians were not free from disease, but they had long been isolated from continental diseases by miles of cleansing sea and had thus developed no immunity to many types of disease then prevalent in other parts of the world. Certain of their customs, such as their relative sexual permissiveness, the practice of having the kava beverage prepared by mastication, and their affinity for this intoxicant, also predisposed them to difficulties in dealing with the health problems of advanced Western cultures.

On the other hand, some Polynesian societies were quite large and well-established systems with productive economies. The very flexibility and productivity that permitted the quest for prestige also enabled them to survive severe shocks, and their almost Oriental reverence of cultural tradition was a strong cohesive element.

The external factor that destroyed so many Polynesian societies and wrought such drastic changes in those that have survived was very simply Europeans and European culture. Their presence was a catalyst that set in action a chain of events that is still continuing to this day. Before colonization ever took place, whalers and other mariners were calling at many of the Polynesian islands to provision and refit. In the course of these calls, venereal and communicable childhood diseases were introduced, with often appalling results. Desire for the simplest products of European technology, such as nails, led many Polynesian societies to strip themselves of needed supplies in order to purchase the articles. Firearms, once introduced in quantity, only exacerbated the social and political instability, as did the colonies of European deserters and beachcombers who quickly formed on many islands.

Superior knowledge of firearms and tactics often made the Europeans indispensable allies of hard-driving warrior chiefs. Active missionary work began quite early, leading to systematic and almost total destruction of several cultures (in Magareva and the Marquesas, for example) and resulting in major alterations in most. Many missionary-introduced measures may have been beneficial; some, such as the puritanical insistence on full European style clothing for both sexes, were quite deleterious for health, and the stringent measures taken to segregate the sexes at all times led to an unhealthy psychological atmosphere regarding sexual activity. Full European

clothing was unsuitable for people accustomed to near or complete nudity: the heavy fabrics impeded respiration, raised body temperature, trapped bacteria, and caused chills when soaked with rain or perspiration.

Benefits of European contact

The European presence was not totally negative in its impact, however, for when the initial shocks of contact and colonization were past, European influence could often result in a stabilization of the social and political situation, with a concomitant diversion of resources and energies to more socially useful ends. (An exception was the Marquesas, where the French used Christianized Marquesans in combat against their still-pagan compatriots, further inflaming old tribal animosities.) Further, European presence often brought with it excellent medical assistance to stamp out health problems and correct certain customs and practices not conducive to health, such as the disdain for latrines displayed in some Polynesian societies.

Current cultural conditions. In the early 1970s, after nearly two centuries of heavy European contact, Polynesia is a patchwork quilt of cultural evolution. Southeastern Polynesia, particularly that part under French rule, is still very much between two worlds. The old ways are definitely gone, and so far, no good substitute has been provided by the ruling power. Conditions throughout much of the area are very spartan, and life is quite bleak. Tahiti, and particularly its sole town, Papeete, has been the beneficiary of a recent boom as a result of a rapid but rather badly handled tourist expansion and the use of the island as a staging area for the French nuclear test range, located some distance to the south, at Mururoa. This influx of foreigners has led to the development of a variety of "native culture," seasoned and packaged for tourist consumption. It can be seen everywhere in Papeete, in souvenir stores, art shops, and nightclub floor shows. In Tahiti, European conveniences such as motor bikes, pressure stoves and lanterns, radios, and television sets are common at all levels of society, and automobile use has increased dramatically in the last 15 years. European clothing, jewelry, and cosmetics are almost universal. One must go far from the town and off the main road to find anything representative of the indigenous culture.

Hawaii today represents what Tahiti will probably look like some years in the future, after land developers, the tourist industry, and industrialization have run their course. The 50th state of the U.S. still has a strong native Polynesian substratum in its culture, evident in language, the arts, dress, and customs. This substratum has been influenced, however, by a succession of waves of immigrants to the islands—including several European nationalities as well as Japanese, Chinese, and Filipinos—and, most recently, by organized crime, based apparently in the U.S. The result has been a strong "Orientalization" of much that was basically Polynesian. Definite attempts are being made to preserve and foster the Polynesian cultural heritage, including courses in universities and public schools in the Hawaiian language and the study of Polynesian cultures.

New Zealand, a member of the British Commonwealth, was far better endowed than its Polynesian compatriots with natural resources and has, in consequence, attained a reasonable degree of self-sufficiency as a political unit. The Maori play an important role in New Zealand culture as individuals, but the majority of them are in the lower income brackets, working in agricultural or livestock work in the country or in manual labour in the cities. Urbanization has caused social problems for the Maori, resembling those encountered in any area when the original proprietors of the land suddenly find themselves a minority, but social welfare programs of various types are being undertaken to better equip the Maori for his role in society.

The recent drive for independence consuming small colonies throughout the world has also hit Polynesia; Western Samoa (formerly a New Zealand protectorate), and Tonga (an independent kingdom under British advisorship) having decided to become totally independent in recent years. These societies have managed to retain the largest share of their native culture intact, including, in Tonga, the whole traditional political system. While cars, aircraft, and television have also invaded, the majority of the population live in traditional houses, wear modified traditional dress, and carry on many aspects of their subsistence activities, as did their forebears centuries ago.

Polynesia is thus being torn in many directions, one part standing on the threshold of the 21st century with the rest of the Western world, another still trying to recover its identity and purpose after the long period of colonization, which was largely destructive of its traditional ways. Meanwhile, still another segment is attempting to find a different path by maintaining much of its traditional culture and at the same time accepting some of the very new ways that are available to it.

BIBLIOGRAPHY. There is a wealth of published information on Polynesia, but much of it is to be found in the monograph series of the Bernice D. Bishop Museum, Honolulu, Hawaii, and in the publications of the *Journal of the Polynesian Society*, Wellington, New Zealand. Neither series is widely available. Many major works dealing with the area were published long ago, in very limited editions, and are not available in many libraries. PETER H. BUCK, *Vikings of the Sunrise* (1938), is quite dated but still provides an excellent introduction to Polynesian culture. No better survey presently exists. A fascinating account of Polynesian cultures as seen through the eyes of one of the greatest European explorers of the 18th century may be found in the Hakluyt Society's edition of the *Journals of Captain James Cook*, 4 vol. (1955–67). DAVID MALO, a courtier in the Court of Kamehameha I, published an interesting account of pre-European-contact customs in *Hawaiian* (1898; Eng. trans., *Hawaiian Antiquities*, 2nd ed., 1951). RAYMOND W. FIRTH has provided impressively detailed accounts of life on Tikopi, a Polynesian "outlier," in *We, the Tikopia* (1936) and in *Tikopia Ritual and Belief* (1967). The same author has also published on Maori social organization and economics in *Primitive Polynesian Economy* (1939). MARGARET MEAD, *Coming of Age in Samoa* (1928, reprinted many times), discusses the maturation process in the context of that Western Polynesian culture. BENGT DANIELSSON in *Den lyckliga ön* (1951; Eng. trans., *The Happy Island*, 1956), describes life, both past and present, on a Tuamotu atoll in French Polynesia. ALFRED METRAUX'S *classic L'Ile de Pâqueo* (1941; Eng. trans., *Easter Island*, rev. ed., 1957), presents a highly readable and nonsensational account of the aboriginal culture of that island based on research conducted there in the 1930s. Two recent summaries of Polynesian social organization from radically differing viewpoints are M.D. SAHLINS, *Social Stratification in Polynesia* (1958); and I. GOLDMAN, *Ancient Polynesian Society* (1970). The latter is encyclopaedic, summarizing data on archaeology, linguistics, and physical anthropology, and presenting summary portraits of 18 Polynesian societies representing the entire spectrum of social organization. It also has a very lengthy bibliography to guide further reading. R.C. SUGGS, *Marquesan Sexual Behavior* (1966), is the only book-length treatment of sex in a Polynesian society. Marshall discusses Mangaian sexual behaviour based on previously unpublished data in *Human Sexual Behavior*, ed. by D.S. MARSHALL and R.C. SUGGS (1970). Discussions of Polynesian art in the context of Oceanian art as a whole are found in A. BUHLERS, *Art of the South Sea Islands* (1960); J. GUIART, *Arts of the South Pacific* (1963); and P.J. WINGERT, *Art of the South Pacific Islands* (1953).

(R.C.Su.)

Polytheism

Polytheism, the belief in many gods, characterizes virtually all religions other than Judaism, Christianity, and Islām, which share a common tradition of monotheism, the belief in one God. Sometimes above the many gods a religion will have a supreme creator and focus of devotion, as in certain phases of Hinduism (there is also the tendency to identify the many gods as so many aspects of the Supreme Being); sometimes the gods are considered as less important than some higher goal, state, or saviour, as in Buddhism; sometimes one god will prove more dominant than the others without attaining overall supremacy, as Zeus in Greek religion. Typically, polytheistic cultures include belief in many demonic and ghostly forces in addition to the gods, and some supernatural beings will be malevolent; even in monotheistic religions there can be belief in many demons, as in New Testament Christianity.

Nature of polytheism. In the course of analyzing and recording various beliefs connected with the gods, historians of religions have used certain categories to identify different attitudes toward the gods. Thus, in the latter part of the 19th century, the terms henotheism and kathenotheism were used to refer to the exalting of a particular god as exclusively the highest within the framework of a particular hymn or ritual; *e.g.*, in the Vedic hymns (the ancient sacred texts of India). This process often consisted in loading other gods' attributes on the selected focus of worship. Within the framework of another part of the same ritual tradition, another god may be selected as supreme focus. Kathenotheism literally means belief in one god at a time. The term monolatry has a connected but different sense; it refers to the worship of one god as supreme and sole object of the worship of a group while not denying the existence of deities belonging to other groups. The term henotheism is also used to cover this case, or more generally to mean belief in the supremacy of a single god without denying others. This seems to have been the situation for a period in ancient Israel in regard to the cult of Yahweh.

Categories of attitudes toward the gods

The term animism has been applied to a belief in many *animae* ("spirits") and is often used rather crudely to characterize so-called primitive religions. In evolutionary hypotheses about the development of religion that were particularly fashionable among Western scholars in the latter half of the 19th century, animism was regarded as a stage in which the forces around man were less personalized than in the polytheistic stage. In actual instances of religious belief, however, no such scheme is possible: personal and impersonal aspects of divine forces are interwoven; *e.g.*, Agni, the fire god of the Ṛgveda (the foremost collection of Vedic hymns), is not only personified as an object of worship but is also the mysterious force within the sacrificial fire.

Belief in many divine beings, who typically have to be worshipped or, if malevolent, warded off with appropriate rituals, has been widespread in human cultures. Though a single evolutionary process cannot be postulated, there has been a drift in various traditions toward the unification of sacred forces under a single head, which, in a number of nonliterate "primal" societies, has become embedded in a supreme being. Sometimes this being is a *deus otiosus* (an "indifferent god"), regarded as having withdrawn from immediate concern with men and thought of sometimes as too exalted for men to petition. This observation led Wilhelm Schmidt, an Austrian anthropologist, to postulate in the early 20th century an *Urmonotheismus*, or "original monotheism," which later became overlaid by polytheism. Like all other theories of religious origins, this theory is speculative and unverifiable. More promising are attempts by sociologists and social anthropologists to penetrate to the uses and significance of the gods in particular societies.

Besides the drift toward some unification, there have been other tendencies in human culture that entail a rather sophisticated approach to mythological material—*e.g.*, giving the gods psychological significance, as in the works of the Greek dramatists Aeschylus and Euripides and similarly, but from a diverse angle, in Buddhism. At the popular level there has been, for instance, the reinterpretation of the gods as Christian saints, as in Mexican Catholicism. A fully articulate theory, however, of the ways in which polytheism serves symbolic, social, and other functions in human culture requires clarification of the role of myth, a much debated topic in contemporary anthropology and comparative religion.

Forms of polytheistic powers, gods, and demons. *Natural forces and objects.* A widespread phenomenon in religions is the identification of natural forces and objects as divinities. It is convenient to classify them as celestial, atmospheric, and earthly. This classification itself is explicitly recognized in Indo-Aryan religion: Sūrya, the sun god, is celestial; Indra, associated with storms, rain, and battles, is atmospheric; and Agni, the fire god, operates primarily at the earthly level. Sky gods, however, tend to take on atmospheric roles; *e.g.*, Zeus's use of lightning as his thunderbolt.

Celestial, atmospheric, and earthly gods

In the earliest cultural levels, in which hunting and then pastoralism and agriculture are clearly vital, religion exhibits these identifications in rites connected with fertility. The sun's vitality is seen in the cyclical effects of causing things to grow and wither. Moreover, because of its dominance of the world, the sun is often seen as all-knowing, and thus sky gods of various cultures tend to be highly powerful and knowledgeable, if also sometimes rather remote. The sky is also often associated with creation. By contrast the moon is rarely of the same importance (though in Ur, a city of ancient southern Babylonia, the moon god Sin was supreme). The role of the sky god in ensuring food and in providing light and warmth, over against the chaotic effects of darkness, was a theme of various myths of the cosmic drama and was one main reason for the connection in mythic thought between creation and light.

Heavenly divinities have also been influential in the development of astrology, which assigns a special significance to stars and planets. In the Middle East astrology was important but was weakened by monotheism; and in Indian culture it came to be deeply woven into the fabric of both Hinduism and Buddhism. Astrology was influential in the Greco-Roman world and in the astral religion attached to Gnosticism (dualistic sects that emphasized salvation through esoteric knowledge) and other cults of the early Christian Era. Astrology was also elaborated in Central America, for instance in Aztec religion.

Gods of the sky become especially powerful when they take on an atmospheric guise. The association of gods such as Zeus and Indra with storm, as well as with fertility-bearing rain, makes their connection with warfare fairly natural; thus, Indra is the most perfect example of an Indo-Aryan warrior. Many societies, however, have had separate gods of war. The ambivalence of atmospheric deities is paralleled in female counterparts who are both creative and destructive. The combination of sky and earth and the joining of differing cosmic forces are sometimes represented in the *hieros gamos* ("sacred marriage"); *e.g.*, between Apsu and Tiamat in Mesopotamia, Śiva and Śakti in India, and Gaea and Uranus in Greece. The forces of water and fire are particularly significant in bridging the gap between the earthly and heavenly realms. Fire is manifested not only in the hearth but also in lightning and the sun; water is sometimes connected with the moon. Thus, earthly fire and water can also be seen at work higher in the cosmos.

Important in the development of fertility religion were the "dying and rising" gods, such as Adonis, Attis, Osiris, and Tammuz. Their cults had a new life in the mystery cults of the Greco-Roman world, where the original agricultural significance of the rites was transformed into more personal and psychological terms.

On earth, besides the divine mother out of whose womb plant life has its birth, there are a host of divinities connected with agricultural and pastoral life. In addition, sacred significance is often attached to features of the particular environment in which a given group finds itself. Thus, sacred mountains, such as Olympus in Greece, have their resident deities; a river, such as the Ganges (Ganga), may be divinized. Underground rivers have special significance in connecting with the underworld, or nether regions, which can be important as the place of repose of the dead but also as the matrix for the re-creation of life. Geographical locations can also have cosmic significance; *e.g.*, Delphi, Greece, was known as the navel of the earth. Further, many cultures have gods and goddesses associated with the sea.

Vegetation. In a number of cultures trees are seen as a primordial form of vegetation and have a symbolic connection both with heaven and earth; sometimes they are held to contain spirits, as the *yakṣa*s of Indian tradition. Particular sorts of trees, such as the *aśvattha*, or pipal (sacred fig), are held in special veneration. Among plant deities, however, probably the most important are those connected with cultivated plants, such as maize in Central America and the vine in the Mediterranean world. Notable is the cult of Dionysus, the ecstatic wine

Plants and animals as divine forces

god who became one of the most influential objects of devotion in the classical period. The vine linked agriculture and ecstasy. The connection between vegetation and dying and rising gods has already been noted; to some extent such motifs were carried over into Christianity in the notion that the cross was the tree both of death and of new life. One of the most obvious modern survivals in the West of vegetation cults is the use at the winter solstice of mistletoe, symbolizing fertility and continued life.

Animal and human forms. Just as plants can be seen as divine forces, so can types or species of animals. For instance, the cult of the snake is widespread and is especially important in the Indian tradition. The serpent is vital in the Old Testament story of Adam and Eve and appears in the Babylonian *Epic of Gilgamesh* as one who knows the secret of rejuvenation. The snake has a fertility aspect because of its possible phallic significance and because it lives in holes in the life-giving earth. The cult of the monkey is important in India, having its essence in the figure of Hanumān, half monkey and half human. It is possible that such theriomorphic cults (in which gods are represented by various animal forms) have been assisted by rituals in which priests wear masks representing the relevant divinities, a practice that may in turn explain the hybrid half-human form. Examples of the wide variety of animal and living forms in which gods appear include Huitzlipochtli (hummingbird; Aztec); Cipactli (alligator; Aztec); Viṣṇu's avatars, or incarnations (fish, tortoise, boar, man-lion; Hindu); the Rainbow Snake (Australian Aboriginal); Cernunnos (stag god with antlers; Celtic religion); Nandi (bull; Hindu). A figure partly in animal guise found in Les Trois-Frères cave at Ariège, France, may represent a complex lord of the beasts analogous to the supposed Śiva (the destroyer and re-creator in Hindu mythology) figure found at sites in the Indus Valley; while a bird-man figure at Lascaux, France, may depict a priestly representation of a divine being. Thus, theriomorphism seems to have a very ancient pattern. In brief, various cultures have taken existing species in their environment and woven them into the pantheon—partly because of their essential dependence on the animals and partly for other reasons, such as similarities between animal forms and other sacred forces (*e.g.*, the analogy of the lion to the force behind kingship).

Gods as human and men as divine

Because man can enter into living relationship with the supernatural beings that surround and dominate his life, it has always been natural to model the gods as human beings. Such anthropomorphism is most evident in the Greek tradition, in which the Homeric gods are brilliantly and unashamedly human in their passions and thoughts. The human model has been assisted by the representation of the gods in art; for a statue is not just a symbolic representation of a god but often his place of presence and influence. Thus, in a number of cultures, the images are treated as replete with divinity.

Just as gods can be human in character, so men can be conceived as divine, either by becoming identified with deities (*e.g.*, through descent) or by displaying appropriate power. Thus, divine kingship was a not uncommon feature of the ancient Middle East; it was also found in the Roman world, when the emperors were divinized, and in Japan and China, where the emperor was son of heaven. Culture heroes and other significant humans could be elevated to semidivine status or more; *e.g.*, Kuan Ti and other heroes in the Chinese tradition, Rāma and Kṛṣṇa (Krishna) in India. Strictly, the succession of sages known as buddhas and tīrthaṅkaras in the Buddhist and Jain traditions, respectively, were not conceived as divine but came to be objects of a cult. In the Mahāyāna (Greater Vehicle), celestial buddhas and *bodhisattvas* (those vowed to become buddhas) came to be profoundly important for devotional religion; from a functional point of view, the Mahāyāna has operated as a polytheistic system, united, however, under an overarching doctrine of emptiness, or the void (*śūnya*), according to which all things are said to be empty of the characteristics assigned to them. The Theravāda (Way of the Elders) accepted the principle that virtuous followers of the Buddha could be translated in the next life to a heavenly existence in which they would have godlike status (an impermanent status, however, for gods share the universal transitoriness of all living beings), but such gods were scarcely the objects of a cult.

Functional deities. In addition to the various forces operating in nature, various social and other functions are divinized. Thus, the god Brahmā in the Vedic tradition, besides being creator, contains and expresses in personal form the power implicit in the Brahmin class. Again, there are gods of healing, such as Asclepius in Greece, and of seafaring, agriculture, and so on. The most elaborate reflection of human concerns is, perhaps, to be found in the later Taoist pantheon, which provided a heavenly counterpart to the Chinese Imperial court. In a number of societies gods of war, such as Mars (ancient Rome) and Skanda (India); gods of learning, such as Sarasvatī (India); and gods of love, such as Aphrodite (Greece) and Kāma (India), have been important. Even such abstractions as the directions (north, south, east, and west) have been divinized. The fact that these varied entities and relationships have been taken as gods is, perhaps, partly the result of the mythic style of thinking, in which distinctions between natural forces and social conventions are not clearly perceived.

Of special importance regarding human affairs are the gods concerned with death and judgment after death, such as Osiris in ancient Egypt, Yama in India, Hades in Greece, and Hel in pre-Christian Scandinavian religion. There are also gods associated with cemeteries and more generally with patterns of the disposal of the dead.

Supernatural forces

The various gods must be seen against the background of a whole host of spirits, demons, and other supernatural forces prevalent in the environment of pastoral and agricultural communities. Among entities hostile to man are the antigods, very often older gods, such as the Titans in Greece, who have been displaced by later deities or gods worshipped by a people conquered by a new dominant folk. The warfare between the old and new can be woven into dramatic myths of the fight between good and evil. This is well brought out in the major myth of the Orphic writings: Zeus's son Dionysus-Zagreus was killed and eaten by the Titans, who in turn were destroyed, burned up by Zeus's lightning flash. Man is made of the ashes, and therefore he is a compound of divinity and Titanic evil. Purification from this evil brings redemption and release from the round of reincarnation. Sometimes, however, the ambivalence of good and evil is built into the same deity, so that creation and destruction and good and evil are seen as complementing one another.

Types of polytheism. *Greco-Roman religion.* By the time of the establishment of the Roman Empire, the Greek tradition was already exerting considerable influence on the Roman, to the extent that once relatively independent traditions became somewhat fused. Equations between gods were freely made: Zeus became Jupiter, Aphrodite became Venus, and so on. Originally Roman *pietas* (sense of duty to the gods) was a good deal less personalized than the relationship to the anthropomorphic gods of the Homeric pantheon and was directed at spirits called *numina*. In addition, the various philosophical systems, such as Epicureanism and Stoicism, provided a more systematic cosmology and sense of man's destiny than traditional polytheism. Influential in the Hellenistic period were mystery cults—such as those of Isis, Cybele, Mithra, and Demeter—which catered more to personal concerns with salvation than did the official and civic cults. Under the mid-4th-century emperor Julian, a last vigorous attempt was made to revive paganism and to restore the cult of the gods over against the widespread grip of Christianity.

Germanic, Scandinavian, Celtic, and Slavic mythologies. The sources for a reconstruction of northern European religion are far better than those for the south Germanic peoples, but there were evidently similarities between the religions. The three main Scandinavian gods were Odin, Thor, and Freyr: Odin (or Wodan) had great magical power and wisdom and was called Allfather; Thor (or Donar) was the warrior god; and Freyr

was the god of fertility. It is possible that these gods are a reflection of the tripartite division of Indo-European society—priest, warrior, and cultivator. Among other deities, Balder, the dying god who was killed by a mistletoe branch, had a poignant charm. Nordic mythology also carries with it a sense of final doom of the gods, looking to the point when the world will be burned up, before its eventual re-creation.

The pattern of Celtic cults is not easy to decipher because of lack of written records; but the stag-headed god Cernunnos was highly significant in iconography. There was also a variety of ancestral gods and goddesses, including a "great mother" of the type found in fertility cults of the ancient Middle East. Celtic religion had a special reverence for water in such forms as pools and rivers.

The Slavic religions of eastern Europe and Russia are likewise imperfectly known, but they involved worship of a high god who is both a creator and an atmospheric force. Another important figure was the war god Svantovit. Finno-Ugrian pre-Christian religion bears some resemblance to the Scandinavian, possibly indicating some mutual influences, while Baltic cults are of Indo-European type.

Political considerations in Egypt

Egypt and the Middle East. The Egyptian pantheon evolved into a complex form; many deities were theriomorphic but were presided over by such great gods as Re, the sun god, and Nut, the sky goddess. Re's transformation as Horus, with a hawk's head, was connected with the Osiris legend. The pharaoh was identified with him as the "living Horus." Despite the attempt of Akhenaton, pharaoh in the 14th century BC, to exalt Aton as the single god, the Egyptian cult remained essentially polytheistic but highly articulated. With the domination of Egypt by the Ptolemies about ten centuries later, the worship of Sarapis, a hybrid Greco-Egyptian deity, was instituted as a means of binding together the two groups.

Though in Egypt the cause of the rise and fall of gods was partially the political struggles between the major city-states, the Sumerian religion was much less affected by such "earthly" considerations. An, the god of heaven, remained supreme, and such deities as the water god Enki and the air god Enlil were prominent. In Babylon, partly the successor state of Sumer, the most vital god was Marduk, creator of the world and of mankind, and victor over the primeval Tiamat, or chaos, who all but absorbed the older surrounding gods. His story is recounted in the epic *Enuma elish* ("When on High"). In Assyrian religion Marduk was in effect replaced by Ashur; and Ishtar, the mother goddess, was also important. In general, it can be said that Middle Eastern religion stemmed from early Sumerian and Egyptian sources and that the latter eventually had some effect on Hellenistic religion.

Early Indo-Iranian religions. For almost a millennium close relations existed between the Vedic and Iranian religions—from before the time of the Iranian prophet Zoroaster, who reformed the ancient religion in the late 7th and early 6th centuries BC, back to the time of the Vedic religion of the Aryans, who invaded India about 1500 BC. Zoroaster, in his reforms, succeeded in excising the many gods, some of whom were subsumed as qualities of the supreme Ahura Mazdā. The rich pantheon of the Vedic hymns developed into the world of classical Hindu mythology, which was fed by streams other than the Aryan.

Classical and modern Hinduism. Certain gods of no great importance in the Vedic tradition came to dominate classical Hinduism, above all Śiva and Viṣṇu. The latter was associated with belief in *avatāra*, or incarnation. Most male gods in the Hindu pantheon also came to be represented with a female consort, symbolizing the *śakti*, or creative power of the deity. The increasing elaboration of Hindu cults as different groups were absorbed into a systematized social fabric has led to the estimate of as many as 33,000,000 Hindu gods. It has been common practice for devotees to select the form under which the divine is worshipped, and such a deity is called the *iṣṭadevatā*. Most Hindus are inclined to interpret the many gods as being symbols of the one divine reality.

Buddhism. Buddhism's tolerance of popular cults, provided that the main essentials of the faith are maintained, means that in most Buddhist cultures several gods are worshipped. In Mahāyāna Buddhism, increased devotion to the Buddha became elaborated as a belief in many celestial beings, notably Amitābha and Avalokiteśvara (Kwannon), who were, however, in essence all unified in the absolute (*śūnya*, the void). In Tibet, a synthesis between the indigenous religion and Buddhism was established. The most notable feature of this form of Buddhism, known as Vajrayāna (Vehicle of the Thunderbolt), was the use of divine forms to symbolize the various factors of existence, such as the different elements making up human personality.

Far Eastern religions. In ancient China the cult of Heaven and ancestor worship were elements woven into the system of Confucianism. Numerous lesser deities were worshipped in popular Chinese practice, and the dividing lines between Confucianism, religious Taoism, and Buddhism were hard to draw. In Taoism, an elaborate pantheon was evolved, modelled in part on the Imperial bureaucracy, and was presided over by the Jade Emperor (Yü-Huang). Other deities included atmospheric gods, gods of locality, and functional gods (of wealth, literature, agriculture, and so on). The Taoist gods were in part a response to the richness of Mahāyāna myth, with its cults of celestial buddhas and *bodhisattvas*.

The Taoist pantheon

The religions practiced in China influenced Japanese culture, which took over some main elements of Confucianism and Buddhism, that interacted with the indigenous polytheistic religion, Shintō (Way of the Gods). The divinities of Shintō tend to be connected with natural forces and localities; the most important deity is Amaterasu, who is the sun goddess and divine ancestress of the emperor.

Religions of ancient Meso-America. The Aztec culture, successor of earlier civilizations, together with the associated Maya culture, laid great emphasis on astronomical observation and on a complex religious calendar. Important were the high god Ometecuhtli, the morning star Quetzalcóatl, and the various legends woven round Tezcatlipoca, patron of warriors, who in the form of Huitzlipochtli was patron of the Aztec nation. Inca religion also possessed a high god, Viracocha; a number of the most important deities were associated with celestial bodies, notably the sun, patron of the Incas. Both in Central and South America, the fertility aspects of deities were also emphasized.

Modern ethnic religions in Africa and elsewhere. In some areas, such as much of Africa and Oceania, the indigenous religions are ethnic or tribal; each group has its own particular tradition. These traditions have been affected considerably by the impact of Christian missions and Western technology. Clearly there is no single pattern of belief, though certain patterns do recur in some of the cultures, such as belief in a high god, totemism (characterized by recognition of a relationship between certain human groups and particular classes of animal, plant, or inanimate object in nature), spirit possession, and so on. In various respects there are matches between myth and social organization that are likewise quite varied. Anthropologists, however, are far from a consensus on the role and origin of the gods.

Polytheism in its wider relations. Polytheism can bear various relationships to other beliefs. It can be incompatible with some forms of theism, as in the Semitic religions; it can coexist with theism, as in Vaiṣṇavism; it can exist at a lower level of understanding, ultimately to be transcended, as in Mahāyāna Buddhism; it can exist as a tolerated adjunct to belief in transcendental liberation, as in Theravāda Buddhism.

BIBLIOGRAPHY. S.G.F. BRANDON (ed.), *A Dictionary of Comparative Religion* (1970), contains articles on the various gods and also on theories, and these have bibliographical sections. A useful compendium is the *Larousse Encyclopedia of Mythology* (1959). One example of the numerous recent anthropological literature is G.E. SWANSON, *The Birth of the Gods: The Origin of Primitive Beliefs* (1960).

(N.Sm.)

Pombal, Marquês de

Virtual ruler of Portugal from 1750 to 1777, remembered for both his ruthless exercise of his despotic powers and his reforms, Sebastião José de Carvalho e Mello (known for most of his life as Sebastião de Carvalho) was born in Lisbon on May 13, 1699.

Pombal, engraving by João S. Carpinetti, 1759.
By courtesy of the Biblioteca Nacional, Madrid

His father, Manuel de Carvalho e Ataíde, had served in the army as a cavalry captain and had been a nobleman of the royal house. He died relatively young, and Sebastião's mother remarried. Sebastião's uncle, Paulo de Carvalho, a professor at the Universidade de Coimbra, enrolled his nephew in that institution. But Sebastião abandoned his studies to enlist in the army, in which he reached the humble rank of corporal. Disillusioned with the army, he quit and dedicated himself to the study of history and law, and was later admitted, at the age of 34, to the Academia Real da História Portuguesa.

In 1733 he married Teresa Maria de Noronha e Almada, a widow, niece of the Conde de Arcos. They moved to the village of Soure, near Coimbra, where he had property. There he dedicated himself to his studies and to agriculture. In 1738 he returned to Lisbon. His uncle, who was professor at the Universidade de Coimbra, archpriest of the patriarchal see, and a person of political influence, recommended him to João da Mota, prime minister for King John V, who appointed him Portuguese ambassador to England. His wife, due to poor health, was unable to accompany him; she died in 1739.

Appointment as ambassador to England

His diplomatic career opened wider political horizons for him. He distinguished himself by the zeal with which he conducted several negotiations. And, for the seven years he stayed in London, Carvalho carefully studied the English in their political, social, and economic aspects.

After returning to Lisbon in 1745, Carvalho was immediately appointed ambassador plenipotentiary to Vienna, with the mission of serving as mediator in the solution of a serious quarrel between the Holy Roman empress Maria Teresa and the Vatican. The probabilities of success were very slight, but he overcame all obstacles, winning the sympathy of the Empress and the love of Eleonora von Daun, daughter of the Graf von Daun, whom he married in December 1745. The Austrian climate was bad for his health, however, and he submitted his resignation and returned to Lisbon at the end of 1749.

As King John V did not like him, Carvalho's progress was temporarily halted. But soon after the King's death on July 31, 1750, he was called by Queen Maria Ana, the widow, of whom he was a favourite, and was appointed to one of the royal councils. The heir to the throne, Prince Joseph, on being crowned king, made him a minister, along with two other favourites. He soon came to dominate Portuguese politics and the new monarch gave him a free hand. Thus began what may be termed the reign of the Marquês de Pombal.

Carvalho instituted domestic administrative reforms and succeeded in elevating Portugal's prestige in external politics. He granted England privileges that entitled it to receive large amounts of gold in exchange for manufactured articles. On the other hand, he stimulated national industry, forbidding the exportation of certain raw materials and developing the manufacture of silk, woolens, ceramics, and glass. Aiming at the development of commerce in the Orient, he founded a company for trade with India, similar to England's but which, however, was unsuccessful. But he was successful in another, similar enterprise—the Companhia do Grão-Pará—aimed at stimulating trade with Brazil.

His reforming activity was interrupted by a catastrophe, the earthquake of November 1, 1755. Two-thirds of Lisbon was reduced to rubble. Carvalho mobilized troops, obtained supplies, and had shelters and hospitals improvised. The day after the catastrophe, he was already outlining ideas for reconstruction. With architect Eugénio dos Santos' plans, old medieval Lisbon was changed into one of the most beautiful European cities.

Carvalho's firm and effective handling of the crisis enhanced his prestige and strengthened even further his position with the King. But his ascendancy had from the beginning created envy and animosity among two very powerful and influential groups: the high nobility and the Society of Jesus. On the night of September 3, 1758, an unsuccessful attempt was made on the King's life. This served as a pretext for Carvalho to rid himself of his enemies among the nobility and Jesuits, whom he accused of conspiracy. The court, influenced by him, attributed the crime to the Duque de Aveiro and to other members of the Távora family. On January 13, 1759, they were tortured to death. Carvalho then began persecuting members of the Society of Jesus. Almost all were deported to Rome, but some were imprisoned, along with many noblemen confined without proof of guilt.

Sebastião de Carvalho's power had become absolute. He was created conde de Oeiras in 1759 and continued to enact reforms, including the reform of university education, the initiation of commercial education, the creation of trading companies, and the reorganization of the army. In September 1769, the King conferred on him the title of Marquês de Pombal.

Fall from power

With the death of King Joseph on February 24, 1777, however, all the Marquês' power vanished. Under the new queen, Maria I, political prisoners were freed, and Pombal was accused of having abused his powers. He was found guilty by a judicial tribunal that subjected him to severe interrogation from October 1779 to January 1780. Queen Maria then banished him from Lisbon, and he retired to Pombal, where he died on May 8, 1782.

(M.J.D.)

Pompadour, Madame de

Jeanne-Antoinette Poisson, marquise de Pompadour, held for nearly 20 years the important position of *maîtresse en titre* (officially recognized mistress) to the French king Louis XV. The future Madame de Pompadour was born in Paris on December 29, 1721.

Early years

Her parents were on the fringes of a class gaining in importance, speculators in the world of finance. Some of these people made immense fortunes, but many ended in the gutter if not in prison. Her father, François Poisson, involved in a black-market scandal, had to flee the coun-

try in 1725—his beautiful wife and two small children were then looked after by a more fortunate colleague, Le Normant de Tournehem. Both children were clever, and the girl was fascinating; she was educated to be the wife of a rich man. In those days rich men, even if they came from a low class, were interested in art and literature, and they expected their wives to share these interests. By the time Mademoiselle Poisson was of an age to marry, she could hold her own in any society and had made friends with many distinguished men, including Voltaire. Le Normant de Tournehem arranged a match for her with his own nephew, Charles-Guillaume Le Normant d'Étioles, a rising young man; they had a little girl, Alexandrine. Madame d'Étioles became a shining star of Parisian society and was admired by the King himself. In 1744 Louis XV's young mistress, the Duchesse de Châteauroux, died suddenly. She was soon replaced by Madame d'Étioles, who obtained a legal separation from her husband and was created marquise de Pompadour.

Nineteenth-century historians thought that Madame de Pompadour had complete ascendancy over Louis XV. These post-Revolution writers were concerned with portraying the Bourbon monarchs as poor creatures; it is now generally admitted that Louis XV was a much more able man than he has been painted. Shy and introspective, he had difficulty in communicating with people whom he did not know well. Madame de Pompadour acted as his private secretary; but although she gave the orders, the decisions were made by the King.

She began her reign at Versailles modestly. She was lodged in a few rooms under the roof; she set out to make herself agreeable to all those who counted for anything in the palace, beginning with Queen Marie (Maria Leszczyńska). Marie could hardly have been a more unsuitable wife for the handsome, artistic, sensual, and pleasure-loving Louis XV. Older than he, she was dowdy, stupid, and interested only in religion. After giving birth to an heir to the throne, she let the King understand that she had no wish to go on sleeping with him. Louis XV has a bad reputation as a husband, but few men ever had a better excuse for taking mistresses.

After five romantic years in her attic, Madame de Pompadour moved downstairs to a regal apartment. Louis XV now began to take other mistresses, but Madame de Pompadour was more firmly established than ever before; favours, promotions, and privileges could be obtained only through her good offices.

Her artistic and political collaboration with Louis

Her collaboration with the King was twofold, artistic and political. The artistic side was wholly successful. On her suggestion, her brother was appointed director of the King's buildings and created marquis de Marigny; the brother, the sister, and Louis XV, working in perfect harmony, planned and built the École Militaire and the Place Louis XV (now the Place de la Concorde) in Paris, most of the palace of Compiègne, the Petit Trianon Palace at Versailles, a new wing at the palace of Fontainebleau, and the exquisite Château de Bellevue, as well as many pavilions and summer houses. He and his mistress patronized all forms of decorative art: painters, sculptors, cabinetmakers, and craftsmen worked under the royal eye; the famous porcelain factory was built at Sèvres. Madame de Pompadour's 20 years of power marked the very apogee of taste in France. The protector of most of the authors and the editor of the *Encyclopédie*, she would have liked to do for literature what she did for the arts, but the King had no literary interests and disliked the intellectuals whom he knew.

The political collaboration between the King and his mistress was much less successful than the artistic, mainly because the French politicians and generals of the day were of such poor calibre. The Duc de Choiseul, by far the ablest of the ministers, was Madame de Pompadour's protégé. He was brought in to implement the famous Reversal of Alliances, which allied France with its old enemy Austria against the German Protestant principalities. This was a statesmanlike conception, but it was unpopular and led to the Seven Years' War, disastrous to France. Frederick the Great crushed the huge, incompetently led French and Austrian armies, while the English were driving the French out of Canada. All these defeats were laid at the door of Madame de Pompadour. She fell a prey to melancholy, and soon after the end of the war she died, on April 15, 1764, probably of cancer of the lung, in her apartment at Versailles. One of her last actions was to get Louis XV's support for the revision of the Calas case, a gross miscarriage of justice in which Voltaire was interested. Voltaire said of her:

> I mourn her out of gratitude. . . . Born sincere, she loved the King for himself; she had righteousness in her soul and justice in her heart; all this is not to be met with every day.

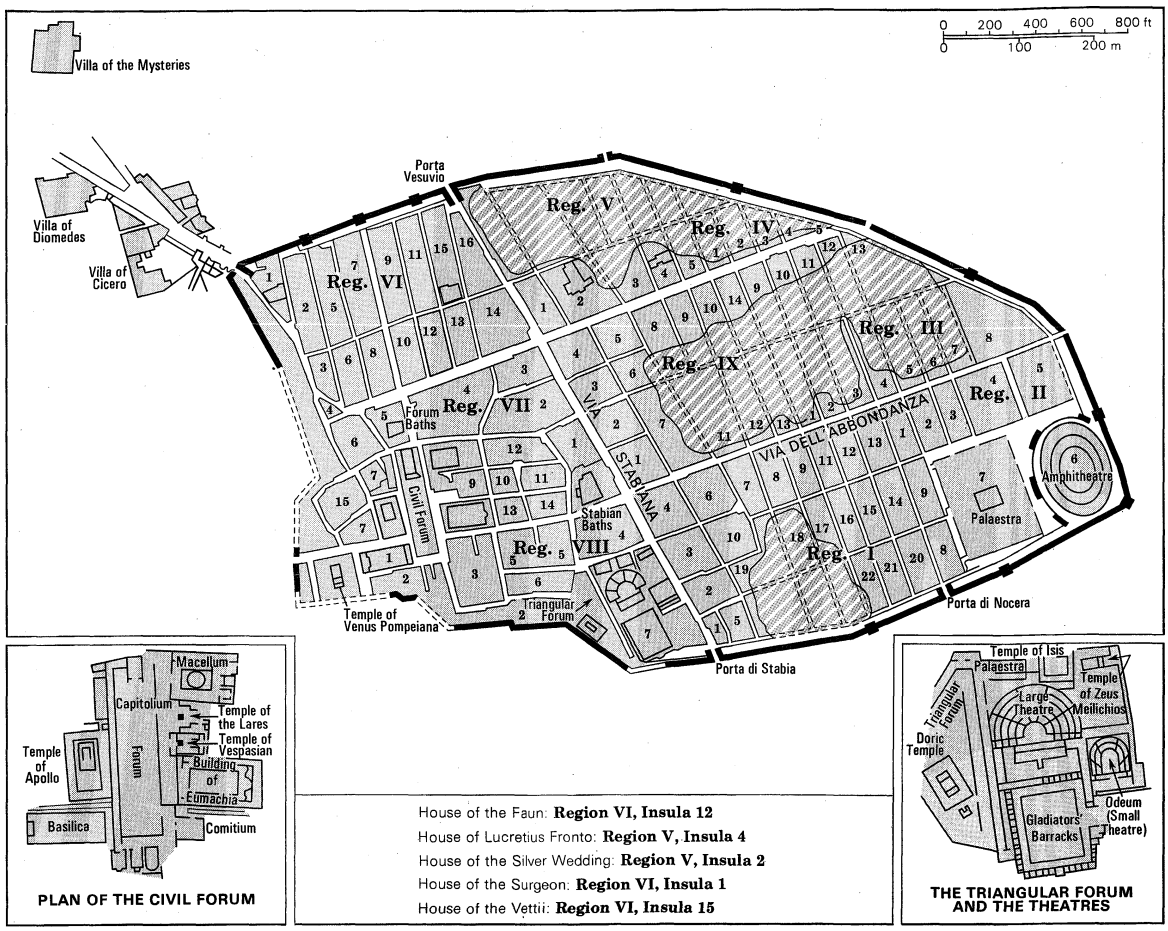
Pompeii and Herculaneum

The ancient cities of Pompeii and Herculaneum, situated in the fertile Campanian plain of Italy southeast of Naples, 14 miles (23 kilometres) and five miles (eight kilometres) respectively, owe their fame to their sudden destruction by Vesuvius in AD 79. Their origins are obscured by legend, and few events in their history are preserved in the writings of the ancient authors. But the archaeological evidence derived from the excavation of these cities and numerous villas in the adjacent area is an invaluable source of information about a great many aspects of life in the Greco-Roman world.

History. It seems certain that Pompeii, Herculaneum, and Stabiae were first settled by the Oscans, who were descendants of the Neolithic inhabitants of Campania. Archaeological evidence indicates that the Oscan village of Pompeii, strategically located near the mouth of the Sarnus River, soon came under the influence of the cultured Greeks who had settled across the bay in the 8th century BC. Greek influence was challenged, however, when the Etruscans came into Campania in the 7th century. The Etruscans' influence remained strong until their sea power was destroyed by King Hieron I of Syracuse in a naval battle off Cumae, in 474 BC. A second period of Greek hegemony followed.



Then, toward the end of the 5th century, the warlike Samnites, an Italic tribe, conquered Campania, and Pompeii, Herculaneum, and Stabiae became Samnite towns. Coinage suggests that a century later the city of Nuceria was the head of a league to which Pompeii, Herculaneum, and Stabiae may have belonged.

Conquest by Rome

Pompeii is first mentioned in history in 310 BC, when, during the Second Samnite War, a Roman fleet landed at the Sarnus port of Pompeii and from there made an unsuccessful attack on Nuceria. At the end of the Samnite Wars, Campania became a part of the Roman confederation, and the cities became "allies" of Rome. But they were not completely subjugated and romanized until the time of the Social War (the war of the *socii*, or "allies"). Pompeii joined the Italians in their revolt against Rome in this war and was besieged by the Roman general Lucius Cornelius Sulla in 89 BC. After the war, Pompeii, along with the rest of Italy south of the Po, received Roman citizenship. As a punishment for Pompeii's part in the war, a colony of Roman veterans was established there under Publius Sulla, the nephew of the Roman general. After initial difficulties, Pompeians and colonists seem to have adjusted with a minumum of friction. Whether Herculaneum had such a colony is not known. Latin now replaced Oscan as the official language of both towns, and they soon became romanized in institutions, architecture, and culture. Stabiae was destroyed and its territory given to Nuceria.

A riot in the amphitheatre at Pompeii between the Pompeians and the Nucerians, in AD 59, is reported by the Roman historian Tacitus. An earthquake in AD 62 did great damage in both Pompeii and Herculaneum. The cities had not yet recovered from this catastrophe when final destruction overcame them 17 years later.

Vesuvius erupted on August 24, AD 79. A vivid eyewit-

Plan of Pompeii.

Eruption of Vesuvius

ness report is preserved in two letters written by Pliny the Younger to Tacitus, who had inquired about the death of Pliny the Elder, commander of the Roman fleet at Misenum. Pliny the Elder had died at Stabiae while trying to rescue friends. When the eruption ceased on the second day, Pompeii was covered with lapilli (volcanic debris) and ashes to a depth of 19 to 23 feet (six to seven metres). The villas at Stabiae, at a greater distance from Vesuvius, did not have as deep a covering. At Herculaneum the avalanche of volcanic materials carried along by torrents of water hardened into a kind of mud-lava that penetrated everywhere and covered the city up to a depth of 65 feet (20 metres). Excavation there is thus much more difficult, but the tufa-like covering preserved the city and made it inaccessible to plunderers.

History of excavations. The ruins at Pompeii were first discovered late in the 16th century by the architect Domenico Fontana, who tunnelled under the hill known as La Cività to build a water channel to bring water from the Sarno River to the town of Torre Annunziata.

Excavation of the buried cities began first at Herculaneum, in 1709, during Austrian occupation. When the workmen of an Austrian officer, the Comte d'Elbeuf, sank a shaft that reached the theatre among the finds were three marble statues of young women, which eventually found their way to Augustus III of Poland, who took them to Dresden. There they fired the imagination of his daughter, Maria Amalia, who became the wife of King Charles IV of Naples (later Charles III of Spain). In 1738 Charles began excavations at Herculaneum. Work did not begin at Pompeii until 1748, and in 1763 an inscription (*rei publicae Pompeianorum*) was found that identified the site as Pompeii.

Excavations have continued intermittently until the present. Earlier digging was haphazard and often irresponsible; excavators were primarily treasure seekers, hunting for imposing buildings or museum objects. Haphazard digging was brought to a stop in 1860, when the Italian archaeologist Giuseppe Fiorelli became director of the excavations. Areas lying between excavated sites were cleared and carefully documented. Pompeii was divided into nine Regions; the insulae (blocks) in each Region were numbered, and each door on the street was given a number so that each house could be conveniently located by three numbers (see plan). Fiorelli also developed the technique of making casts of bodies by pouring cement into the hollows formed in the volcanic ash when the bodies disintegrated. This technique is also used to make casts of ancient doors, furniture, and roots.

Systematic excavations

In 1951, after the interruption caused by World War II, intensive excavation was resumed under Amedeo Maiuri, who was in charge of the excavations from 1924 to 1961. Large areas to the south of the Via dell'Abbondanza in Regions I and II were uncovered, and the debris piled outside the city walls was cleared away. This revealed the Porta (Gate) di Nocera and an impressive stretch of cemetery lining each side of the road leading from the gate to Nuceria. By the early 1970s, about three-fourths of the city had been excavated.

At Herculaneum excavation was carried on by means of shafts and underground tunnelling until 1765. In this way the theatre, the so-called Basilica, and the Villa of the Papyri on the outskirts of town (named from a library of Greek papyri found there) were explored and a tentative plan of the city was made. Many magnificent paintings and statues were uncovered. In 1828 excavation in the open was begun, but because of the hardness of the fill and because the modern town of Resina is built over part of the ancient town, the work has been carried on intermittently, and only four insulae have been completely excavated, along with parts of four others. The regular plan of the city, laid out on a grid system, indicates Greek influence. The public buildings that have been uncovered include two baths, an unusually large palaestra (sports

Edwin Smith

ground), and the recently discovered Shrine of the Augustales, which was dedicated to the emperor cult and is located on the partially excavated Forum. Among the most luxurious homes are the House of the Stags and the House of the Mosaic Atrium, both with terraces overlooking the bay. At the opposite extreme is the Casa a Graticcio, named from its cheap construction. Its small apartments opened on a common courtyard.

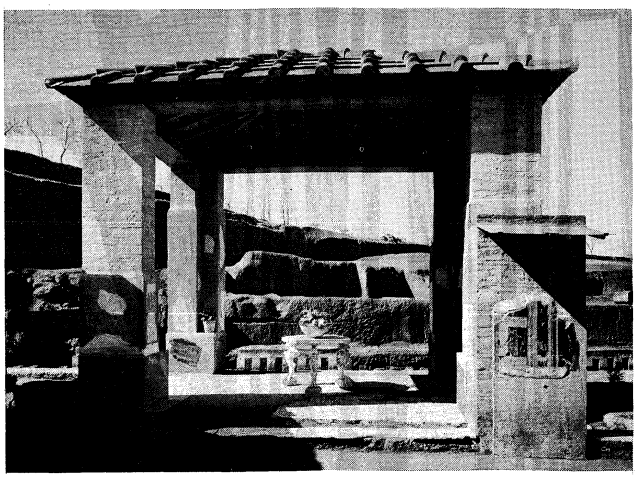
In the vicinity of Stabia and Gragnano, excavations initiated by Charles IV discovered 12 villas between 1749 and 1782. Work was not resumed again until the present century, and it is still in progress. The Villa of San Marco, with its two large peristyle gardens and bath, is the best preserved. Other villas have been found near Gragnano, in the vicinity of Pompeii, and at nearby Scafati, Domicella, Torre Annunziata, and on the lower slopes of Vesuvius near Boscoreale and Boscotrecase. Many of these villas were reburied after excavation, but a few can be seen, notably the Villa of the Mysteries.

Description of the remains. The city of Pompeii was shaped irregularly because of the prehistoric lava flow on which it was built. Excavations indicate that the southwestern part of the town was the oldest, but scholars are not agreed as to the stages by which the walls were expanded, or by whom. The walls are two miles (three kilometres) in circumference, and they enclose an area of about 155 acres. They were probably given their final boundaries after the Samnites took over Pompeii, but there is evidence of Greek influence. Seven city gates have been excavated. The chief street running in a southeast–northwest direction was the Via Stabiana; it connected the Porta Vesuvio (144 feet [44 metres] above sea level), in the highest part of the city, with the Porta di Stabia (26 feet [eight metres]), in the lowest part of town. Through this gate came traffic from the Sarnus River and Stabiae. This street was crossed by two other main streets, the Via dell' Abbondanza and the Via di Nola.

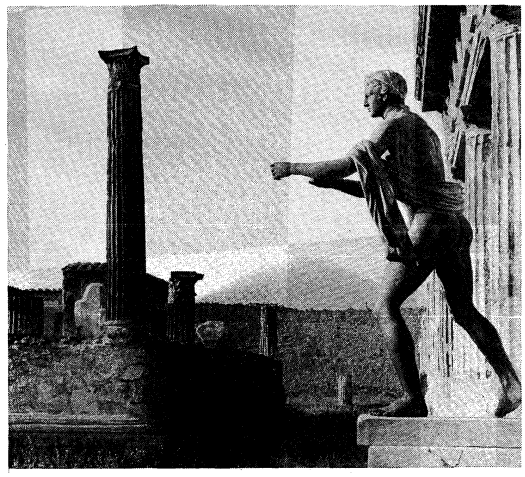
The public buildings at Pompeii are for the most part grouped in three areas: the Forum (elevation 110 feet [34 metres]), located in the large level area on the southwest; the Triangular Forum (82 feet [25 metres]), standing on a height at the edge of the south wall overlooking the bay; and the Amphitheatre and Palaestra, in the east.

The Forum was the centre of the religious, economic, and municipal life; it was a large rectangular area surrounded by a two-storied colonnaded portico. Dominating the Forum on the north was the temple dedicated to the Capitoline triad of deities: Jupiter, Juno, and Minerva. To the east was the Macellum, or large provision market; to the south the small sanctuary of the city Lares (guardian deities), built after the earthquake in AD 62, the Temple of Vespasian, and the imposing headquarters of the woollen industry, erected by the wealthy patroness Eumachia. Opposite the Capitolium on the south end of the Forum were the meeting place of the city council and the offices of the magistrates of the city. The large basilica, with its main room surrounded on four sides by a corridor, is the most architecturally significant building in the city and of considerable importance in studying the origin and development of the Christian basilica. It served as a covered exchange and as a place for the administration of justice. To the west was the Temple of Venus Pompeiana, patron deity of Pompeii. Across from the basilica was the Temple of Apollo, one of the oldest in the city. Subsoil excavations here give evidence for Greek and Etruscan influence.

The Triangular Forum is the site of the Doric Temple, the oldest temple in the city. Between the third and the first centuries, a theatre, a palaestra, and a small covered theatre were built to the east of the Triangular Forum. The temples of Zeus Meilichius and of Isis, and the old Samnite palaestra were nearby. In the east corner of Pompeii was the Amphitheatre; the oldest so far known, it was built after the Roman colony was established at Pompeii. To the west a large palaestra was built to replace the old Samnite palaestra. Baths were scattered throughout the town: the Stabian Baths (which date before the Roman period), the Forum Baths, the Central Baths—still under construction at the time of the eruption—and many baths in luxurious private homes.



But more significant than the public buildings, which have been excavated at other sites, are the hundreds of private homes. These are unique, for only at Pompeii is it possible to trace the history of domestic architecture for at least four centuries. The earliest houses date from the First Samnite period (4th–3rd centuries BC). The House of the Surgeon is the best known example of the early atrium house built during this period.



Importance of private homes

The most luxurious houses were built during the Second Samnite Period (200–80 BC), when increased trade and cultural contacts resulted in the introduction of Hellenistic refinements. The House of the Faun occupies an entire city block, has two *atria* (chief rooms), four *triclinia* (dining rooms), and two large peristyle gardens. Its facade is built of fine-grained gray tufa from Nuceria, the chief building material of this period. The walls are decorated in the Incrustation, or First Pompeian style of painting, which imitates marble-veneered walls by means of painted stucco. The famous Alexander the Great mosaic found in the House of the Faun is probably a copy of a lost Hellenistic painting. Many of the houses from this period were decorated with elaborate floor mosaics. The House of the Silver Wedding, with its imposing high-columned atrium, was also built during this period, but it underwent later alterations. The handsome banquet hall and the exedra, which served as a schoolroom for children of the family, were decorated in the Second Pompeian, or Architectural, style, which was popular from 80 BC to AD 14.

The large number of houses built during the Samnite period made it necessary to build fewer houses in the Roman period. Those that were built were usually less imposing, with lower *atria,* but with more elaborate decoration. The House of Lucretius Fronto is a small but elegant house of the Roman Imperial period. The tablinum (master's office) is decorated in especially fine Third Pompeian, or Egyptianizing, style, usually dated from the early empire to the earthquake. The House of the Vettii is typical of the homes of the prosperous merchant class of the Roman period. Some of its rooms are decorated in the Fourth Pompeian, or Ornamental, style.

The atrium-peristyle house, with its handsome paintings, elegant furniture, beautiful gardens with fountains and bronze and marble sculptures, is not as typical as has generally been supposed. There are also numerous small homes throughout the city, many of them shop-houses. Excavators now preserve as completely as possible all aspects of ancient life. The homes of the humble have as much to tell us as those of the wealthy. Roofs, second stories, and balconies can now be restored.

Excavated buildings.

Influence on European culture. The discoveries at these sites had a profound influence on European taste. News of the excavations kindled a wave of enthusiasm for antiquity that spread throughout Europe. The laudatory pronouncements of the eminent German classicist Johann Joachim Winckelmann, who made his first trip to Naples in 1755, and the etchings of Giambattista Piranesi did much to popularize the excavations. Naples, Pompeii, and Herculaneum became important stops on the European Grand Tour made by English visitors, who found an enthusiastic guide and a well-informed amateur archaeologist in Sir William Hamilton, ambassador to the Naples court from 1764 to 1800, and a captivating hostess in his second wife, Lady Emma Hamilton.

Artists, architects, potters, and even furniture makers drew much inspiration from Pompeii and Herculaneum. Contemporary painted interiors were inspired by the frescoed walls found in the excavations. The stucco work popularized in England by the 18th-century architects Robert and James Adam used the same motifs. The famed potter Josiah Wedgwood changed the style of his work and named his factory "Etruria," sharing the mistaken belief that Pompeii and Herculaneum were Etruscan. In France, the Louis XVI style incorporated Pompeian motifs, and the apartment of Louis's queen, Marie-Antoinette, at Fontainebleau was decorated in this style, which became popular throughout Europe. Jacques-Louis David and his student Jean-Auguste-Dominique Ingres drew inspiration for their paintings from the excavations. Indeed, the Neoclassic style stimulated by the discoveries at Pompeii and Herculaneum completely replaced the Rococo and became the artistic style of the French Revolution and of the Napoleonic period.

Importance as historical source. The extent of these archaeological sites makes them of the greatest importance, for they provide a unique source of information about so many aspects of social, economic, religious, and political life of the ancient world. The many well-preserved house shrines give a hitherto unexpected picture of the vitality of religion in the family. The bakeries, complete with mills, kneading machines, and ovens, some still containing loaves of bread, show how this staple of everyday life was produced. Numerous fulleries (wool processing and cleaning plants) make it possible to study this important industry. The shops of the sculptor, toolmaker, gem cutter; the *garum* (fish sauce) and the lamp factories; and the many wine and food shops document other aspects of ancient life. Pompeii was a busy port town that exported wine, *garum*, woollen products, and perfume throughout the Mediterranean. Merchants and tradesmen found food and lodging in the taverns, restaurants, and inns located near the city gates and the Forum. Some were quite attractive and served food to guests who reclined in the garden; in the cheaper places the rooms were small and dark, and customers sat on stools.

Everyday life

Inscriptions provide further information. They include monumental inscriptions on public buildings, tombs, and statue bases; the business transactions recorded in the famous wax tablets of the banker Lucius Caecilius Jucundus; announcements of gladiatorial combats; and many election notices, echoes of hotly fought contests. Preserved in the graffiti are accounts, lists of market days, the exchanges of lovers, quotations from Virgil, and even the scratched alphabets of children. Epigraphical and archaeological evidence makes it possible to study the stratification of society and learn more of the freedmen, slaves, small businessmen, and aristocrats of the ancient Roman world.

Further, Pompeii offers the best opportunity for the study of city planning and land use in an ancient city. Recent excavations have revealed an unexpected amount of open land. The large insula across from the Amphitheatre was not the "Foro Boario" (Cattle Market), as has been long supposed, but a vineyard. Many vineyards, fruit trees, and gardens have been found, indicating less intensive land use and a smaller population than has been thought.

Unfortunately, the excavations are constantly endangered by the ravages of weather and destructive vegetation. Of first importance is the preservation, restoration, and study of the valuable evidence already uncovered before it is lost forever.

Pompey the Great

In the desperate struggle for power in the late Roman Republic, Gnaeus Pompeius Magnus (anglicized Pompey) stands as one of the greatest statesmen and generals

of the age. His campaigns in Africa, Spain, Asia Minor, and the Mediterranean were conducted with a thoroughness and efficiency that marked his entire career. His reorganization of Rome's eastern frontier regions lasted with few changes for five centuries. He lacked the genius of his great rival Julius Caesar, but to admirers of the republic he represents the bulwark of the conservative nobility against Caesar's towering ambitions.

By courtesy of Ny Carlsberg Glyptotek, Copenhagen

Pompey, bust *c.* 60–50 BC. In the Ny Carlsberg Glyptotek, Copenhagen.

Early career. Pompey was born in Rome on September 29, 106 BC. He belonged to the senatorial nobility, although his family first achieved the office of consulship only in 141. Fluent in Greek and a lifelong and intimate friend of Greek literati, he must have had the normal education of a young Roman nobleman; but his early experience on the staff of his father, Pompeius Strabo (consul in 89), did much to form his character, develop his military capacities, and arouse his political ambition. The family possessed lands in Picenum, in eastern Italy, and a numerous body of clients, which Strabo greatly enlarged in the year of his consulship. In a civil war (88–87) between the rival generals Lucius Sulla and Gaius Marius, Strabo defied Sulla and favoured the Marians and a fellow general, Cinna (see ROME, HISTORY OF).

Support of Sulla

But, after his father's death, Pompey detached himself from the Marians. A report that he was "missing" in Cinna's army, when it was embarking for the Balkans to deal with Sulla, led to the lynching of Cinna by his troops (84). Pompey's part in this mutiny is unclear; he next appears with three legions recruited in Picenum, joining Sulla as an independent ally in the campaign to recover Rome and Italy from the Marians (83). Sulla made ample use of his youthful ally's military abilities. Pompey married Sulla's stepdaughter, Aemilia, pregnant from her former husband, only to see her die soon after in childbed. On Sulla's orders the Senate gave Pompey the job of recovering Sicily and Africa from the Marians—a task he completed in two lightning campaigns (82–81). Pompey ruthlessly executed Marian leaders who had surrendered to him. To his enemies he was Sulla's teenage butcher; to the troops he was "Imperator" and "Magnus." From Africa Pompey demanded that a triumph be given him in Rome; he refused to disband his army and appeared at the gates of Rome, obliging Sulla to yield to his demand. After Sulla's abdication, Pompey supported the renegade Sullan Marcus Lepidus for the consulship of 78. Once in office Lepidus attempted revolution, and Pompey promptly joined the forces of law and order against him. The rising crushed, however, Pompey refused to disband his army, which he used to bring pressure on the Senate to send him with proconsular power to join Metellus Pius in Spain against the Marian leader Sertorius.

Campaigns in Spain

The reconquest of Spain taxed Pompey's military skill and strained his own and the state's resources to the utmost. In the end it was he, not Metellus, who imposed on Spain a settlement reflecting and promoting his own political aims. His policy was one of reconciliation and rehabilitation. His personal authority and patronage now covered Spain, southern Gaul, and northern Italy. Unlike Metellus, Pompey took his army back to Italy with him, ostensibly to assist in putting down a slave revolt led by Spartacus but, in reality, to secure a triumph and election to the consulship for 70. The nobles whom Sulla had restored to power had proved to be more corrupt and incompetent than ever. Pompey promised reforms at home and abroad, especially the restoration of the power of the tribunes, elected officials who protected popular rights by initiating legislation. A bargain was struck with his rival Marcus Licinius Crassus, the two were jointly elected consuls, and Pompey was given another triumph. The uneasy partners cooperated in sweeping away the more important of Sulla's reactionary laws.

Reorganization of the East. Although the nobles were to continue to dominate the consular elections in most years, the real sources of power henceforth lay outside of Italy. Extraordinary commands would have to be created if Rome was to recover control of the sea from the pirates and bring peace to the eastern provinces, threatened by Mithradates VI of Pontus, a kingdom in eastern Anatolia. It was Pompey who benefited most from the restoration of tribunician initiative. After his consulship, he waited in Rome while rival nobles undermined the position of Lucius Licinius Lucullus, who was campaigning against Mithradates in Anatolia, and made halfhearted attempts to deal with the pirates. Finally, in 67, the tribune Aulus Gabinius forced a bill through the popular assembly empowering Pompey to settle the pirate problem, and Pompey cleared the sea in three months (67).

Pompey was still in the East, resettling pirates as peaceful farmers, when in Rome another tribune, Gaius Manilius, carried through, against weakened opposition, a bill appointing Pompey to the command against Mithradates, with full powers to make war and peace and to organize the whole Roman East (66). Pompey displaced Lucullus and lost no time defeating Mithradates in Asia Minor. With the death of Mithradates in 63, Pompey's hands were free to plan the consolidation of the eastern provinces and frontier kingdoms. For 6,000 talents he set up King Tigranes in Armenia as a friend and ally of Rome —and as his own protégé. Pompey rejected the Parthian king's request to recognize the Euphrates as the limit of Roman control and extended the Roman chain of protectorates to include Colchis, on the Black Sea, and the states south of the Caucasus, Iberia and Albania. In Anatolia, he created the new provinces of Bithynia-Pontus and Cilicia. He annexed Syria and left Judaea as a dependent, diminished temple state. The organization of the East remains Pompey's greatest achievement. His sound appreciation of the geographical and political factors involved enabled him to impose an overall settlement that was to form the basis of the defensive frontier system and was to last, with few important changes, for over 500 years.

Defeat of Mithradates

Pompey's power and prestige were at their height in December 62, when he landed at Brundisium (Brindisi) and dismissed the army, whose continued loyalty he had ensured by lavish gifts from his spoils of war. His third triumph (61) trumpeted the grandeur of his achievement. The following decade was the period of his ascendancy in Italy, an ascendancy that was to be eroded through Caesar's growing military power and gradual capture of Pompey's worldwide *clientelae*, from the power base he, in turn, created in north Italy and Gaul. Pompey's inveterate enemies in Rome were the Optimates, the inner ring of nobles, not Crassus or Caesar, who had merely tried to steal the limelight in Pompey's absence and to manoeuvre into a better position for bargaining with their former political ally. The nobles mean-

Pompey's political enemies

while had gradually reasserted their dominance in Rome and hampered attempts to alleviate the condition of Italy and the Roman populace. Once back in Italy, Pompey avoided siding with popular elements against the Optimates. He was no revolutionary. He wanted all classes to recognize him as first citizen, available for further large-scale services to the state. He had divorced his third wife, Mucia, and now proposed to ally himself by marriage to the party of the young senatorial leader Marcus Porcius Cato the Younger. But the nobles were closing their ranks against him, and his offer was rebuffed. Lucullus and others were determined to prevent the *en bloc* ratification of Pompey's eastern settlement and to reject his demand for land for his veterans. Pompey turned to Cicero and sought his help, in vain.

The First Triumvirate. Help only came when Casear returned from his governorship in Spain, prepared to give up a triumph if he could secure election to the consulship for 59. Pompey, Crassus, and Caesar formed the unofficial and at first secret First Triumvirate (mid-61). It was to become more than a mere election compact. It would strain all the resources of the triumvirs to wrest one consulship from the Optimates; their continued solidarity was essential if they were to secure what Caesar gained for them in 59. Caesar, for his part, wanted a long-term command. He was Pompey's pupil in this. Pompey, who now married Caesar's daughter, Julia, saw Caesar as his necessary instrument. Caesar, once consul (January 59), immediately forced through a land bill and, shortly after, another appropriating public lands in Campania. Once he had secured a five-year command in Illyria (on the Adriatic coast) and Gaul he could be relied on to take off a large proportion of Pompey's discharged troops and give them further opportunities for profitable employment. The year saw a continuous battle with the enemies of the triumvirs. Caesar's obstructive consular colleague, Marcus Calpurnius Bibulus, did his best to undermine the validity of Caesar's legislation, which included the ratification of Pompey's eastern settlement. Pompey was forced to give open approval to Caesar's violent, unconstitutional methods. To bolster the triumviral cause in his absence, Caesar persuaded Pompey to support the election to the tribunate of Publius Clodius, a personal enemy of Cicero. Cato was silenced by being sent on an honourable and lucrative mission to annex Cyprus. In his tribunate (58) Clodius first carried out the policy of triumvirs. The consuls were induced to block attempts to rescind Caesar's measures by the bribe of lucrative provincial commands. Clodius, aided by gangs of street thugs, passed a law forcing Cicero into exile, and Pompey, ashamed of his failure to help Cicero, could only confess that his hands were tied. But Clodius saw his tribunate as an opportunity that would never recur. Using the violence of his street gangs and bribing voters with free corn, Clodius used his legislative initiative to acquire power and wealth, but only by cutting into Pompey's monopoly of patronage in the East. Pompey at once began to work for Cicero's return, to have him as a counterweight against Clodius. At first Clodius' gangs hustled Pompey off the streets and besieged him in his own house. Extreme Optimates joined Clodius in baiting Pompey, but moderate senators rallied to him. Caesar consented to the recall of Cicero, who returned late in 57 committed to support Pompey. The Optimates and Clodius continued their opposition but had to consent to the passage of a law through the Senate assigning Pompey the task of organising Rome's grain supply (57). Pompey's enemies were brought to heel by the threat of a more extreme tribunician proposal to give Pompey the supreme military powers they suspected him of desiring.

Opposition to Clodius

Pompey solved the problem of Rome's grain supply with his usual efficiency, but the nobles kept up their opposition. The year 56 was a critical one for the triumvirs. The nobles concocted religious impediments to prevent the dispatch of Pompey on a military mission to Egypt, while Clodius contrived to persuade Pompey that Crassus had designs on his life. An attempt was made to suspend Caesar's law for the distribution of Campanian land.

Alarmed at Pompey's suspicions and truculence, Crassus set off to meet Caesar at Ravenna, and Caesar in turn came to the limit of his province at Luca to meet Pompey. The Luca conference (56) prepared the ground for the next phase of triumviral cooperation: Pompey and Crassus were to secure election to the consulship for 55, for they, too, wanted five-year commands in the provinces, while Caesar's command was to be renewed for another five years. The three secured their ends by violence and corruption after a prolonged struggle in Rome. Early in 55 Pompey and Crassus were at last elected consuls, with most of the lesser magistracies going to their supporters. Caesar obtained the extension of his command, while Pompey and Crassus received commands in Spain and Syria, respectively. Pompey could stay on in Italy and govern his provinces by deputies. His ascendancy was now more pronounced than ever. It was then that he dedicated a great new theatre in Rome. Laws were passed in Caesar's interest, allowing him the expectation of a second consulship after the regular ten-year interval. Clodius was made to come to heel, the power of the political clubs in Rome was broken, and the functioning of the courts improved.

The conference at Luca

But the triumvirate was coming to an end. The death of Julia (54) destroyed the strongest bond between Pompey and Caesar, and Crassus suffered disastrous defeat and death in Mesopotamia. The triumvirate existed no longer; but Pompey as yet showed no inclination to break with Caesar, whose greatest victories in Gaul were yet to come.

Civil war. Meanwhile, from outside the walls of Rome, Pompey watched the anarchy in the city becoming daily more intolerable. He was prepared to wait without committing himself until the Optimates found an alliance with him unavoidable. He refused further offers from Caesar of a marriage alliance. There was talk in Rome as early as 54 of a dictatorship for Pompey. Street violence made it impossible to hold the elections. In January 52 Clodius was killed by armed followers of Titus Annius Milo, whose candidacy for the consulship was being bitterly opposed by both Pompey and Clodius. Now both factions exploded into even greater violence. The senate house was burnt down by the mob. With no senior magistrates in office the Senate had to call on Pompey to restore order. It was the hour he had waited for. He speedily summoned troops from Italy. The nobles would not have him as dictator; they thought it safer to appoint him sole consul. Though Pompey now chose the Optimate alliance, he continued to profess loyalty to the old bond with Caesar. He could now impose his will on the Optimates, defeating their efforts to engineer Milo's acquittal.

Pompey's legislation of 52 reveals his genuine interest in reform and the duplicity of his conduct towards Caesar. He reformed procedure in the courts and produced a panel of respectable jurors. A severe law against bribery at elections was made retrospective to 70 and, for all Pompey's protests, was rightly taken by Caesar's friends as aimed at him. Another useful law enforced a five-year interval between tenure of magistracies in Rome and assumption of provincial commands. But this law and another, which, in one of its clauses, prohibited candidature in absence, effectively destroyed the ground of Caesar's expectation (based on earlier legislation and an understanding with Pompey) that he should become designated consul, and so safe from prosecution, before he had to disband his army in Gaul. Several attempts were made in the years 51 and 50 to recall Caesar before the expiration of his second term in Gaul. They were frustrated by the growing assertiveness of Caesar's faction and agents in Rome. Pompey, for all his growing fear and suspicion of Caesar's power and ambitions, did not come out openly against Caesar until late in 51, when he suddenly made clear his intentions. He declared that he would not consider the suggestion that Caesar should become designated consul while still in command of his army. His proposals for a compromise date for Caesar's recall were unacceptable to Caesar whose sole, but effective, resource now was to use the wealth he had accumulated in Gaul to buy men who could obstruct his enemies

Break with Caesar

in the Senate, in particular Gaius Scribonius Curio, tribune in 50, who eventually induced the Senate to vote for a simultaneous surrender of their provinces and armies by both Pompey and Caesar. When war came, the Senate and even the nobles were evenly divided as between Caesar and Pompey. The consulars—that is, those who had held the rank of consul—were solidly for Pompey, although they saw him simply as the lesser evil. Late in 50 the consul Gaius Marcellus, failing to induce the Senate to declare Caesar a public enemy, visited Pompey with the consuls designate and placed a sword in his hands. Pompey accepted their invitation to raise an army and defend the state. Caesar continued to offer compromise solutions while preparing to strike. On January 7, 49, the Senate finally decreed a state of war. Four days later Caesar crossed the Rubicon.

Pompey's strategic plan, unpopular but sound, was to abandon Rome and Italy to Caesar and rely on his command of the sea and the resources of the East to starve out the Caesarians in Italy and overcome his rival; but he did not have the disciplined loyalty and full cooperation of his Optimate allies, and Caesar's swift advance southward only just failed to prevent his withdrawal from Italy. Across the Adriatic at Dyrrhachium the wisdom of Pompey's strategy became clear, even to Cicero. Caesar, after a hazardous crossing in pursuit, found himself cut off from his base in Italy by sea and facing superior land forces. But Pompey eventually had to abandon his naval blockade of the rest of Caesar's forces in Brundisium and failed to prevent their crossing to join Caesar. Caesar's army was repulsed in an assault on Pompey's camp at Dyrrhachium and, failing a quick decision in the West, he was obliged to move eastwards into Thessaly. Pompey followed and joined forces with the Senate's army there under Scipio, rendering Caesar's position intolerable. But at this juncture Pompey, under pressure from his Optimate allies, decided for battle, a sensible enough decision, if his opponent had not been a commander of genius.

Defeat at Pharsalus

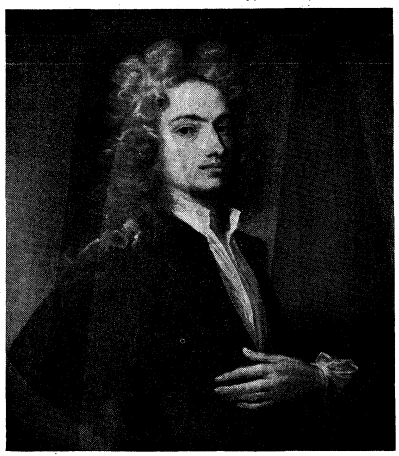
Pompey suffered a disastrous defeat on the plain of Pharsalus (48); it was his first major reverse in battle, and it shattered his morale. He fled from his camp as the enemy stormed it and made his way to the coast. His supporters were to rally and involve Caesar in strenuous fighting in Africa, Spain, and the East for three more years; but Pompey did not live to play a part in this struggle. Hurried on by Caesar's rapid pursuit, hesitating to seek Parthian help, he lost contact with his own fleet. He moved on southward to Cilicia and Cyprus and thence, despairing of raising fresh forces, towards Egypt. He decided to land at Pelusium and seek the assistance of Ptolemy, his former client. The King marched down to the coast, ostensibly to welcome him; but he and his counsellors had chosen not to risk offending the victorious Caesar. Pompey's small squadron lay offshore while Pompey, bidding farewell to his wife Cornelia, complied with an insidious invitation to enter with several companions a small boat sent to bring him to land. As he prepared to step ashore he was treacherously struck down and killed (September 28, 48 BC). The Egyptians cut off his head and left the corpse to be cremated and given funeral rites by a faithful retainer. A simple mound by the sea marked the spot.

Assessment. Pompey's great name cast a lasting shadow. His end inspired some of Lucan's finest verses. In the empire he acquired official respectability, and the greatness of his achievement was fully appreciated by such writers as the elder Pliny and Plutarch. Tacitus, writing in the 1st century AD, echoed harsher judgments of Pompey's near contemporary, Sallust. But there are few clear-headed or unbiased accounts of Pompey by his own contemporaries. Caesar would have his readers believe that he wrote of Pompey more in sorrow than in anger; his propaganda was discreet and subtly damaging to his rival's reputation. Cicero's veering, day-to-day judgments of Pompey reveal his inability to see clearly through the distorting medium of his own vanity. The inflated eulogies of Pompey in Cicero's speeches are punctured by his persistent sniping at him in his letters. Yet he looked up to him for leadership and, in the moment of decision, joined him. Modern scholars have been slow to reach a balanced judgment. To the 19th-century German historians Theodore Mommsen and Wilhelm Drumann, Pompey was merely a blundering foil to Caesar, magnified by circumstances. Eduard Meyer, providing in the early 20th century a corrective to Mommsen's Caesar worship, saw Pompey in his later years as the forerunner of Augustus. The German scholar Matthias Gelzer in the mid-20th century has stressed the early influence of Pompeius Strabo. Sulla's example, too, was an all-important determinant in Pompey's career. But he was neither a revolutionary nor a reactionary, willing to wreck the fabric of the commonwealth for the advantage of self or class. He expected a voluntary acceptance of his primacy but was to discover that the methods he had used to get his commands had permanently alienated the dominant nobility. So year after year he had to play a passive role, covertly intriguing or waiting for successive occasions to arise that would force them to accept his leadership. Some thought his waiting game duplicity, others, sheer political incompetence. He was an ineffective politician, not from any incapacity for intrigue or ruthless action but from lack of candour and consistency in speech and action. He saw the need for basic solutions to the formidable problems presented by the rapid expansion of the empire, but his talents were suited not for the elucidation and determining of ends but for the deployment of means. In domestic affairs his preference was for constructive compromise and reforms of a kind that fitted into and gave additional momentum to the slowly evolving process of adaptation of Roman city-state institutions to the needs of a large empire. The crisis of state and empire demanded more drastic remedies than he was able to envisage or willing to apply.

Comparison with Caesar

As a military leader, he fell short of real greatness, lacking Caesar's genius, his dynamism and panache, and his geniality in personal relationships. He was circumspect and thorough—the perfect administrator. His vision of empire was no narrower than Caesar's. Like many a more recent imperialist, he was satisfied with the ideal of efficient and clean-handed administration and justice, and many of his contemporaries believed that he went far to achieve that aim in his own practice. Pompey, by far the wealthiest man of his age, invested his millions prudently; his landed estates were distributed throughout Italy in manageable units. For all the extravagance of his triumphal shows and the inexcusable heartlessness of the contests in slaughter with which he entertained the populace, he was a plain living man, friend and admirer of the Stoic Panaetius.

His third wife, Mucia, bore him two sons, Gnaeus and Sextus, and a daughter, Pompeia, before he divorced her for infidelity (62). Julia was the wife he loved most dearly; Cornelia outlived him and mourned his death.



BIBLIOGRAPHY. Of ancient sources PLUTARCH'S *Lives* (of Pompey and his Roman contemporaries) are invaluable; also the *Histories* of CASSIUS DIO (Book 36–42); APPIAN'S *Civil Wars*, I and II; and CAESAR'S *Civil War*; but Cicero's speeches and letters throw most light on Pompey's role in the public life of his day. For background to his career, see *The Cambridge Ancient History*, vol. 9 (1932); or more briefly, RONALD SYME, *The Roman Revolution*, ch. 2–5 (1939), a masterly analysis. MOMMSEN did scant justice to Pompey in his *Roman History*, Book 5, now partly superseded by more recent scholarship. W. DRUMANN and P. GROEBE, *Geschichte Roms*, 2nd ed., vol. 4, pp. 332–561 (1908), is a well-documented historical biography, as is the more recent survey by F. MILTNER in *Pauly-Wissowa Realencyclopädie*, vol. 21, col. 2062–2211 (1952). The title of EDUARD MEYER, *Caesars Monarchie und das Principat des Pompejus* (1918), indicates the thesis of that classic work and its limitations. MATTHIAS GELZER, *Pompeius*, 2nd ed. (1959), is a balanced and realistic political biography. JULES VAN OOTEGHEM, *Pompée le grand* (1954), breaks little new ground, but is useful for its overall coverage, its brief discussion of the iconography of Pompey, and its bibliography of articles on points of detail. See also, for Pompey's operations in the East, DAVID MAGIE, *Roman Rule in Asia Minor*, vol. 1, ch. 15–16 (1950); and, for the Civil War, THOMAS RICE HOLMES, *The Roman Republic and the Founder of the Empire*, vol. 3, ch. 14–19 (1923).

(E.W.G.)

Pope, Alexander

The Augustan age in English literature produced no greater satirical poetry than that of Alexander Pope. He became renowned for his translations of Homer and for his biting rebuttals to the criticism of numerous literary enemies, but is best remembered today for his mock-epic poem *The Rape of the Lock* and *The Dunciad* and for his satires in imitation of Horace. Pope was born in Lombard Street, London, on May 21, 1688. His father, a wholesale linen merchant, retired from business in the year of his son's birth and in 1700 went to live at Binfield in Windsor Forest. The Popes were Roman Catholics, and at Binfield they came to know several neighbouring Catholic families who were to play an important part in the poet's life. Pope's religion procured him some lifelong friends, notably the wealthy squire John Caryll (who persuaded him to write *The Rape of the Lock*, on an incident involving Caryll's relatives) and Martha Blount, to whom Pope addressed some of the most memorable of his poems—the satire on women, entitled "Of the Characters of Women," "To Mrs. M.B. on Her Birthday," and "An Epistle to Miss Blount with the Works of Voiture"—and to whom he bequeathed most of his property. But his religion also precluded him from a formal course of education; he was trained at home by Catholic priests for a short time and attended Catholic schools at Twyford, near Winchester, and at Hyde Park Corner, London, but he was mainly self-educated. He was a precocious boy, eagerly reading Latin, Greek, French, and Italian, which he managed to teach himself, and an incessant scribbler, turning out verse upon verse in imitation of the poets he read. The best of these early writings are the "Ode on Solitude" and a paraphrase of St. Thomas à Kempis, both of which he claimed to have written at the age of 12. But perhaps in later life he believed himself to have been more precocious than he was.

Early works. Windsor Forest was near enough to London to permit Pope's frequent visits there. He early grew acquainted with former members of Dryden's circle, notably William Wycherley, William Walsh, and Henry Cromwell, the recipients of his earliest surviving letters, which are devoted to a somewhat mannered discussion of the art of poetry. By 1705 his "Pastorals" were in draft and were circulating among the best literary judges of the day. In 1706 Jacob Tonson, the leading publisher of poetry, had solicited their publication, and they took the place of honour in his *Poetical Miscellanies* in 1709.

Pope's physical disabilities

This early emergence of a man of letters may have been assisted by Pope's poor physique. As a result of too much study, so he thought, he acquired a curvature of the spine and some tubercular infection, probably Pott's disease, that limited his growth and seriously impaired his health. His full-grown height was four feet six inches; but the grace of his profile and fullness of his eye attracted numerous painters (such as Sir Godfrey Kneller and Charles Jervas) and sculptors (such as John Michael Rysbrack and Louis-François Roubillac), who transmitted his likeness in such variety as to make his iconography more extensive than that of any other English writer perhaps to the present day. He was a lifelong sufferer from headaches, and his deformity made him abnormally sensitive to physical and mental pain; and though he was able to ride a horse and delighted in travel, he was inevitably precluded from much normal physical activity, and his energetic, fastidious mind was largely directed to reading and writing.

When the "Pastorals" were published, Pope was already at work on a poem, in an equally well-established tradition, on the art of writing. This was *An Essay on Criticism*, published in 1711. Its brilliantly polished epigrams (*e.g.*, "A little learning is a dangerous thing," "To err is human, to forgive, divine," and "For fools rush in where angels fear to tread"), which have become part of the proverbial heritage of the language, are readily traced to their sources in Horace, Quintilian, Boileau, and other critics, ancient and modern, in verse and prose; but the charge that the poem is derivative, so often made in the past, takes insufficient account of Pope's success in harmonizing a century of conflict in critical thinking and in showing how nature may best be mirrored in art.

Essay on Criticism

The well-deserved success of the *Essay on Criticism* brought Pope a wider circle of friends, notably Richard Steele and Joseph Addison, who were then collaborating in *The Spectator*. To this journal Pope contributed the most original of his pastorals, "The Messiah" (1712), and perhaps other papers in prose. He was clearly influenced by its policy of correcting public morals by witty admonishment and in this vein wrote the first version of his mock-epic, *The Rape of the Lock* (two cantos, 1712; five cantos, 1714), to reconcile two Catholic families. A young man in one family had stolen a lock of hair from a young lady in the other. Pope treated the dispute that followed as though it were comparable with the mighty quarrel between Greeks and Trojans, which had been Homer's theme. Telling the story with all the pomp and circumstance of epic made not only the participants in the quarrel but also the society in which they lived seem ridiculous. Though it was a society where

Publication of *The Rape of the Lock*

> . . . Britain's statesmen oft the fall foredoom
> Of foreign tyrants, and of nymphs at home;

as if one occupation concerned them as much as the other; and though in such a society a young lady might do equally ill to

> . . . Stain her honour, or her new brocade;
> Forget her pray'rs, or miss a masquerade;

Pope managed also to suggest what genuine attractions existed amid the foppery and glitter. He acknowledged how false the sense of values was that paid so much attention to external appearance but ridicule and rebuke slide imperceptibly into admiration and tender affection as the heroine, Belinda, is conveyed along the Thames to Hampton Court, the scene of the "rape":

> But now secure the painted vessel glides,
> The sunbeams trembling on the floating tides:
> While melting music steals upon the sky,
> And soften'd sounds along the waters die;
> Smooth flow the waves, the zephyrs gently play,
> Belinda smil'd, and all the world was gay.

A comparable blend of seemingly incompatible responses—love and hate, bawdiness and decorum, admiration and ridicule—is to be found in all Pope's later satires.

Pope had also been at work for several years on "Windsor-Forest." In this poem, completed and published in 1713, he proceeded, as Virgil had done, from the pastoral vein to the georgic and celebrated the rule of Queen Anne as the Latin poet had celebrated the rule of Augustus. By choosing for its background a region so rich in historical associations, he was enabled to prophesy the greater glories of a regenerate and peaceful society.

In another early poem, "Eloisa to Abelard," Pope borrowed the form of Ovid's "heroic epistle" (in which an abandoned lady addresses her lover) and showed imaginative skill in conveying the struggle between sexual passion and dedication to a life of celibacy.

Translation of Homer. These poems, with "Verses to the Memory of an Unfortunate Lady" (modelled on the elegies of Ovid and Tibullus), some translations from the classics, and a few shorter pieces, were collected in the first volume of Pope's *Works* in 1717. This is a volume of experiments in various poetical kinds; it might almost be called a volume of juvenilia. When it was published, he was already far advanced with the greatest labour of his life, his verse translation of Homer. He had announced his intentions in October 1713 and had published the first volume, containing the *Iliad*, Books I–IV, in 1715. The *Iliad* was completed in six volumes in 1720. The work of translating the *Odyssey* (vol. i–iii, 1725; vol. iv and v, 1726) was shared with William Broome, who had contributed notes to the *Iliad*, and Elijah Fenton. The labour had been great, but so were the rewards. By the two translations Pope cleared about £10,000 and was able to claim that, thanks to Homer, he could ". . . live and thrive/Indebted to no Prince or Peer alive."

The merits of Pope's Homer lie less in the accuracy of translation and in correct representation of the spirit of the original than in the achievement of a heroic poem as his contemporaries understood it; a poem Virgilian in its dignity, moral purpose, and pictorial splendour, yet one that consistently kept Homer in view and alluded to him throughout. Pope offered his readers the *Iliad* and the *Odyssey* as he felt sure Homer would have written them had he lived in early 18th-century England. In Dr. Johnson's estimate, he achieved "the noblest version"—*i.e.*, translation—"of poetry which the world has ever seen."

The Homer quarrel

Political considerations had affected the success of the translation. As a Roman Catholic his affiliations were Tory rather than Whig; and though he retained the friendship of such Whigs as William Congreve, Nicholas Rowe, and Charles Jervas the painter, his ties with Steele and Addison grew looser owing to the political animosity at the end of Queen Anne's reign, and he found new and lasting friends in Tory circles—Swift, John Gay, John Arbuthnot, Thomas Parnell, the Earl of Oxford, and Viscount Bolingbroke. With the first five he was associated (1713–14) in the Scriblerus Club to write joint satires on pedantry, later to mature as *Peri Bathouse, Or the Art of Sinking in Poetry* (1728) and the "Memoirs of Martinus Scriblerus" (1741); and these were the men who encouraged his translation of Homer. The Whigs, who associated with Addison at Button's Coffee-House, put up a rival translator in Thomas Tickell, who published his version of *Iliad,* Book I, two days after Pope's. Addison preferred Tickell's manifestly inferior version; his praise increased the resentment Pope already felt owing to a series of slights and misunderstandings; and when Pope heard gossip of further malice on Addison's part, he sent him a satirical view of his character, published later as the character of Atticus, the insincere arbiter of literary taste in the "Epistle to Dr. Arbuthnot" (1735), but with the most topical couplet omitted:

> Who when two wits on rival themes contest,
> Approves them both, but likes the worst the best.

The stages in this famous quarrel and the partial reconciliation that followed remain obstinately obscure; but Pope's subsequent praise of Addison in the verse epistle first published in Addison's *Works* (1721) and in the "Epistle to Augustus" (1737) is generous and genuine.

"The Dunciad." Even before the Homer quarrel, Pope had found that the life of a wit was a perpetual warfare. There were few years when either his person or his poems were not objects of attacks from the critic John Dennis, the notorious bookseller Edmund Curll, the historian John Oldmixon, and other writers of lesser fame. The climax was reached over his edition of Shakespeare. He had emended the plays, in the spirit of a literary editor, to accord with contemporary taste (1725); but his practice was exposed by the scholar Lewis Theobald in *Shakespeare Restored* (1726). Though Pope had ignored some of these attacks, he had replied to others with squibs in prose and verse. But he now attempted to make an end of the opposition, and to defend his standards, which he aligned with the standards of civilized society, in the mock-epic, *The Dunciad* (1728). Theobald was represented in it as the Goddess of Dullness' favourite son, a suitable hero for those leaden times; and others who had given offense were preserved like flies in amber. Pope dispatches his victims with such sensuousness of verse and imagery that the reader is forced to admit that if there is petulance here, as has often been claimed, it is, to parody Wordsworth, petulance recollected in tranquillity. Pope reissued the poem in 1729 with an elaborate mock-commentary of prefaces, notes, appendixes, indexes, and errata; this burlesque of pedantry whimsically suggested that *The Dunciad* had fallen a victim to the spirit of the times and been edited by a dunce.

Pope's edition of Shakespeare

His life at Twickenham. Pope and his parents had moved from Binfield to Chiswick in 1716. There his father died (1717), and in 1719 he and his mother rented a villa on the Thames at Twickenham, at that time a small country town where several Londoners had retired to live in rustic seclusion. This was to be Pope's home for the remainder of his life. There he entertained with studied modesty such friends as Swift (who returned from Ireland in 1726 and stayed with Pope while seeing to the publication of *Gulliver's Travels*), Bolingbroke, Oxford, and Jonathan Richardson the painter, regaling them with gudgeons and flounders from the Thames at his door and with figs and walnuts from the little garden that he took such pains to design and cultivate. The famous grotto, which provided a tunnel under the main highway and formed a study, ornamented with rare minerals, is all that now survives of this domain. Pope kept his own boatman to row him downstream on his frequent visits to London, and his own coach to take him on his customary round of summer visits to country houses: the Duke of Argyll's at Adderbury, Lord Bathurst's at Cirencester, Lord Cobham's at Stowe, Ralph Allen's at Prior Park, Bath, and Lord Peterborough's at Southampton. These friends were all enthusiastic gardeners, and it was Pope's pleasure to advise and superintend the laying out of their grounds on the best contemporary principles, formulated in his "Epistle to the Right Honourable Richard Earl of Burlington" (1731). This poem, one of the most characteristic works of his maturity, is a rambling discussion in the manner of Horace on false taste in architecture and design, with some suggestions for the worthier employment of a nobleman's wealth.

Pope's plan for the *Essay on Man*

Pope now began to contemplate a new work on the relations of man, nature, and society. This was evidently to be such another grand organization of human experience and intuition as Milton had attempted in the 17th century, and Wordsworth was to attempt in the 19th; but he was destined never to complete it. He told Joseph Spence that the following lines, later incorporated in the *Essay on Man,* would have conveyed its dominant tone and interest:

> Laugh where we must, be candid where we can;
> But vindicate the ways of God to man.

An Essay on Man (1733–34) was intended as the introductory book discussing the grand design. The poem has often been charged with shallowness and philosophical inconsistency. There is indeed little that is original in the thought, almost all of which can be traced in the work of the great thinkers of Western civilization. It is not strictly an argumentative poem as much as a discourse or extended monologue delivered by the poet to a friendly auditor. As becomes a good conversationalist, he alters his mood from time to time, now grave, now gay, colloquial at one moment, formal at another, now affirmative, now quizzical. He deliberately prefers the middle flight to the sublime; but within that range he uses all the arts of diction and versification, the charm of imagery, and variation of rhythm to effect his persuasion. Subordinate themes were treated in greater detail in "Of the Use of Riches, An Epistle to Bathurst" (1732), "An Epistle to Cobham, Of the knowledge and characters of men" (1733), and "Of The Characters of Women: an Epistle to a Lady" (1735). He was deflected from this "system of ethics in the Horatian way" by the renewed need for self-defense. The character of Timon, an ostentatious nobleman in the "Epistle to Burlington," was reported to represent the

Duke of Chandos, who had generously subscribed to Pope's Homer. Though the report was malicious, it was plausible enough to rouse Pope's apprehensions. This attack and others of a like nature drove him to consider his position as satirist. He chose to adapt for his own defense the first satire of Horace's second book, where the ethics of satire are propounded, and after discussing the question in correspondence with Dr. John Arbuthnot, he addressed to him an epistle in verse (1735), one of the finest of his later poems, in which were incorporated fragments written over several years. His case was the satirist's traditional case, that depravity in public morals had roused him to stigmatize outstanding offenders beyond the reach of the law, concealing the names of some and representing others as types, that he was innocent of personal rancour and habitually forbearing under attack.

Imitations of Horace

The success of his "First Satire Of the Second Book Of Horace, Imitated" (1733) led to the publication (1734–38) of ten more of these paraphrases of Horatian themes adapted to the contemporary social and political scene. Pope's poems followed Horace's satires and epistles sufficiently closely for him to print the Latin on facing pages with the English; but whoever chose to make the comparison would notice a continuous enrichment of the original by parenthetic thrusts and compliments, as well as by the freshness of the imagery. Thus Horace declares that he is a peace-loving fellow, "but he who provokes me (better not touch me, I cry) will weep for it and be well-known in song throughout the city"; while Pope, in following him, not only glances at the King's first minister, Sir Robert Walpole, and his French counterpart, Cardinal Fleury (at that time both anxious for peace), but enlivens the whole passage:

> Peace is my dear delight—not Fleury's more:
> But touch me, and no Minister so sore,
> Whoe'er offends, at some unlucky time
> Slides into verses, and hitches in a rhyme,
> Sacred to ridicule his whole life long,
> And the sad burden of some merry song.

The series was concluded with two dialogues in verse, republished as the "Epilogue to the Satires" (1738), where, as in the "Epistle to Dr. Arbuthnot," Pope ingeniously combined a defense of his own career and character with a restatement of the satirist's traditional apology. These imitations and dialogues show Pope at his easiest and most genial in manner. In them he directed his attack upon the materialistic standards of the commercially minded Whigs in power and upon the corrupting effect of money, while restating and illustrating the old Horatian standards of serene and temperate living. His anxiety about prevailing standards was shown once more in his last completed work, *The New Dunciad* (1742), reprinted as the fourth book of a revised *Dunciad* (1743), in which Theobald was replaced as hero by Colley Cibber, the poet laureate and actor-manager, who had not only given more recent cause of offense but seemed a more appropriate representative of the degenerate standards of the age. In *Dunciad*, Book IV, the Philistine culture of the city of London was seen to overtake the court and seat of government at Westminster, and the poem ends in a magnificent but baleful prophecy of anarchy. He had begun work on *Brutus*, an epic poem in blank verse, and on a revision of his poems for a new edition, but neither was complete on his death at Twickenham on May 30, 1744.

The New Dunciad

Assessment. In the "Epistle to Dr. Arbuthnot" and the "Imitations of Horace," Pope had presented himself to his readers as he would have them see him. He supplemented this defense of his character by editing a selection of his letters. To publish them himself seemed an offense against modesty; he therefore arranged for copies to be placed in the hands of Curll, the bookseller whose taste for piratical publication ensured that a "surreptitious" edition would be produced. The stratagem succeeded (1735) and enabled Pope to complain that he was injured in his reputation and must bring out a correct and authentic edition (1737). Other stratagems were required to secure the publication of his letters to Swift (1741) without his open connivance. Collation of the printed texts with such manuscripts as have survived shows that Pope published a text not substantially different from that which his correspondents read, though he felt himself free to repair his syntax and to readdress a few letters from correspondents who had kept many to correspondents who had kept none. These and his many other surviving letters reveal him at first as a young man labouring successfully to be a wit in the Restoration manner, but show him later in a more sympathetic light as a dutiful son, a kind and thoughtful friend, a well-bred host, a disinterested critic of society, warm in wishes for his country's good, patient under attack, a man of plain living, high thinking, and unimpeachable integrity. Not every critic of Pope has been able to accept this picture; his friendliest critics could wish that he had been less accustomed to equivocation and devious dealings; but when allowances have been made for this and for the too relentless pursuit of some who had injured him—Lady Mary Wortley Montagu, for example, though why Pope came to hate this famous bluestocking for whom he had once expressed a gallant admiration is still obscure—the picture obtained from the letters is convincing, though somewhat conscious in its pose. The picture is paralleled in the later poems, where Pope frequently describes himself as a model of modest, honourable, contented living, a survival of old Roman simplicity in an age of degenerate taste.

Personality and reputation

Pope's favourite, but not invariable, metre was the ten-syllable, iambic pentameter, rhyming ("heroic") couplet. He handled it with increasing skill and adapted it to such varied purposes as the epigrammatic summary of the *Essay on Criticism*, the pathos of "Verses to the Memory of an Unfortunate Lady," the mock-heroic of *The Rape of the Lock*, the discursive tones of the *Essay on Man*, the rapid narrative of the Homer translation, and the Miltonic sublime of the conclusion of *The Dunciad*. But his greatest triumphs of versification are found in the "Epilogue to the Satires," where he moves easily from witty, spirited dialogue to noble and elevated declamation, and in the "Epistle to Dr. Arbuthnot," which opens with a scene of domestic irritation suitably conveyed in broken rhythm:

> Shut, shut the door, good John! fatigu'd, I said:
> Tie up the knocker, say I'm sick, I'm dead.
> The Dog-star rages! nay 'tis past a doubt,
> All Bedlam, or Parnassus, is let out:
> Fire in each eye, and papers in each hand,
> They rave, recite, and madden round the land;

and closes with a deliberately chosen contrast of domestic calm, which the poet may be said to have deserved and won during the course of the poem:

> Me, let the tender office long engage
> To rock the cradle of reposing age,
> With lenient arts extend a mother's breath,
> Make languor smile, and smooth the bed of death,
> Explore the thought, explain the asking eye,
> And keep a while one parent from the sky!

His command of diction is no less happily adapted to his theme and to the type of poem, and the range of his imagery is remarkably wide. He has been thought defective in imaginative power, but this opinion cannot be sustained in view of the invention and organizing ability shown notably in *The Rape of the Lock* and *The Dunciad*. His standing as a poet was recognized not only at home. He was the first English poet to enjoy contemporary fame in France and Italy and throughout the Continent, and to see translations of his poems into modern as well as ancient languages. Soon after his death different standards began to prevail; but even when his stock was at its lowest, in the 19th century, he found such champions for his poetry as Byron, Lamb, and William Hazlitt, and, for his letters, as Thackeray. In the 20th century he has long been restored to the esteem, if not to the pre-eminence, he enjoyed in his lifetime.

MAJOR WORKS

VERSE: *An Essay On Criticism* (1711); *The Rape of the Lock* (1712; 2nd enlarged version, 1714); "Windsor-Forest" (1713); "Ode for Musick (on St. Cecilia's Day)" (1713); "Verses to the Memory of an Unfortunate Lady" and "Eloisa to Abelard" (published in a collected works, 1717); translations from *The Iliad Of Homer*, 6 vol. (1715–20), and

The Odyssey of Homer, 5 vol. (1725–26); *The Dunciad*, 3 books (1728), *The Dunciad Variorum* (1729); *The New Dunciad* (Book iv, 1742); the *Dunciad* (complete, 4 books, 1743); "Moral Essays" (1731–35); "An Epistle to Dr. Arbuthnot" (dated 1735).

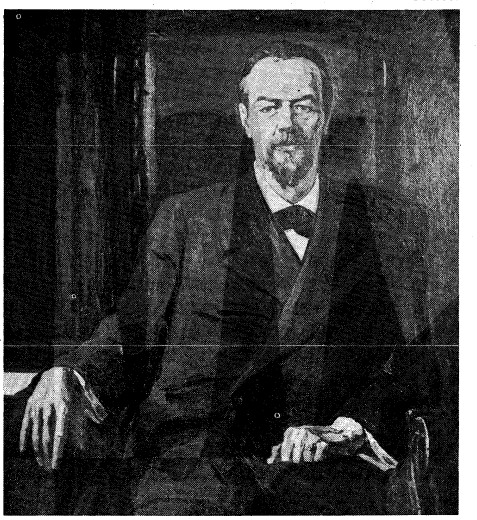
PROSE: *The Works of Mr. Alexander Pope, In Prose* (vol. 1, 1737; vol. 2, 1741); prefaces to *The Iliad* (1715), *The Odyssey* (1725), Shakespeare (1725); *Mr. Pope's Literary Correspondence* (1735–37).

BIBLIOGRAPHY. The standard bibliography of Pope's own writings is R.H. GRIFFITH, *Alexander Pope: A Bibliography*, 2 vol. (1922–27). A valuable list of modern studies of the poet and his works is contained in J.E. TOBIN, *Alexander Pope: A List of Critical Studies Published from 1895 to 1944* (1945); and in C.L. LOPEZ, *Alexander Pope: An Annotated Bibliography, 1945–67* (1970). J.V. GUERINOT, *Pamphlet Attacks on Alexander Pope, 1711–1744: A Descriptive Bibliography* (1969), gives a memorable account, with quotations, of the kinds of hostility that the poet's actions and his meteoric success generated among the lesser writers of his time and so has biographical and critical as well as bibliographical value.

Letters and manuscripts: Pope's letters from his boyhood to his death (1704–44) may be consulted in the edition of his *Correspondence* by GEORGE SHERBURN, 5 vol. (1956). Several of his poetical manuscripts have been published in facsimile, with transcript and editorial commentary: *Windsor Forest*, ed. by R.M. SCHMITZ (1952); the *Epistle to Bathurst*, ed. by E.R. WASSERMAN (1960); *An Essay on Criticism*, ed. by R.M. SCHMITZ (1962); *An Essay on Man*, ed. by MAYNARD MACK (1962). A census of the surviving poetical manuscripts is contained in JOHN BUTT, "Pope's Poetical Manuscripts," *Proceedings of the British Academy*, 40:23–39 (1954).

Editions and selections: Pope published the first collected edition of his poems in 1717, adding a second volume of poems in 1735, a volume of letters in 1737, and a volume of further letters and miscellaneous prose in 1741. After 1734 not a year passed until his death without some earlier writings being reissued, so great was the demand. The standard edition of the poems today is the Twickenham Edition, general editor, JOHN BUTT, 11 vol. (1939–67). There is a one-volume version of the complete text of the first six volumes with selected notes, ed. by JOHN BUTT (1963). *The Prose Works of Alexander Pope*, vol. 1, *The Earlier Works, 1711–20*, ed. by NORMAN AULT, was published in 1936 (reprinted 1968); vol. 2 is now in preparation. Two of his most important prose works have been edited and published separately: *The Memoirs of Martinus Scriblerus*, by CHARLES KERBY-MILLER (1950, reprinted 1966); and *The Art of Sinking in Poetry (Peri Bathous)*, by E.L. STEEVES (1952).

Biography: The best of the early biographies was that of DR. JOHNSON, in his *Lives of the English Poets* (1781); he had access to the most important primary document (apart from Pope's letters), JOSEPH SPENCE'S *Anecdotes* of his conversations with Pope and others, which was eventually published, ed. by S.W. SINGER (1820); a much fuller edition from the manuscripts, by J.M. OSBORN, appeared in 1966. New facts were gathered by ROBERT CARRUTHERS in his *Memoir of Pope*, 2 vol. (1853; rev. ed., 1857); by C.W. DILKE, whose papers, mainly on the authenticity of Pope's letters, were published as *The Papers of a Critic*, 2 vol. (1875); and by NORMAN AULT in *New Light on Pope* (1949). The standard biography so far as it goes (1727) is GEORGE SHERBURN, *The Early Career of Alexander Pope* (1934, reprinted 1969), which may be supplemented for Pope's life at Twickenham by MAYNARD MACK, *The Garden and the City: Retirement and Politics in the Later Poetry of Pope, 1731–1743* (1969).



Criticism: The first substantial study of Pope's poetry was by JOSEPH WARTON in *An Essay on the Writings and Genius of Pope*, 2 vol. (1756–82; 4th corrected ed. reprinted 1970). Of 20th-century assessments, the most important are GEOFFREY TILLOTSON, *On the Poetry of Pope*, rev. ed. (1950), and *Pope and Human Nature* (1958); and R.A. BROWER, *Alexander Pope: The Poetry of Allusion* (1959). Of many shorter studies the most rewarding are by GEORGE SHERBURN, "Pope at Work," in *Essays on the Eighteenth Century Presented to David Nichol Smith* (1945); and by MAYNARD MACK, "Wit and Poetry and Pope: Some Observations on His Imagery," in *Pope and His Contemporaries: Essays Presented to George Sherburn* (1949), and "The Muse of Satire," *Yale Review*, 41:80–92 (1951). On specific poems the following studies are helpful: E.N. HOOKER, "Pope on Wit: *The Essay on Criticism*," in *The Seventeenth Century: Studies by R.F. Jones and Others* (1951); D.M. KNIGHT, *Pope and the Heroic Tradition* (1951), on the *Iliad*; A.L. WILLIAMS, *Pope's Dunciad* (1955); ROBERT W. ROGERS, *The Major Satires of Alexander Pope* (1955); T.R. EDWARDS, JR., *This Dark Estate: A Reading of Pope* (1963), mainly on the satires and epistles; PETER DIXON, *The World of Pope's Satires* (1968). There is a useful reprint of critical studies entitled *Essential Articles for the Study of Alexander Pope*, ed. by MAYNARD MACK (1964, rev. and enl. 1968).

(J.E.Bu.)

Popov, Aleksandr Stepanovich

A Russian physicist and electrical engineer who is remembered for his pioneering investigation of electromagnetic waves and acclaimed in the Soviet Union as the inventor of radio, Popov in 1895 devised equipment to receive electromagnetic (wireless or radio) waves sent out by giant electric sparks forming lightning flashes; this detector thus preceded the first patent taken out by the Italian physicist Guglielmo Marconi in June 1896 for the transmission and reception of signals by means of wireless (radio) telegraphy.

Sovfoto

Popov, painting by P.D. Korin (1892–1967).

Early years and education

Aleksandr Stepanovich Popov was born on March 16 (March 4, old style), 1859, at Bogoslavsky, Perm, a mining village in the Ural Mountains of Russia, where his father was a priest. He received his early education in an ecclesiastical seminary school and planned to enter the priesthood. But in 1877 his interests changed to mathematics and he entered St. Petersburg University, from which he was graduated with distinction in 1883. Joining the teaching faculty of the university, he lectured in mathematics and physics in preparation for a professorship.

Popov's main interest soon changed to electrical engineering, however; and because Russia in that period lacked colleges that taught the subject, he became an instructor at the Russian Navy's Torpedo School at Kronstadt (presently Kronshtadt), near St. Petersburg (presently Leningrad) where students were trained to take charge of electrical equipment on warships. Popov took advantage of the school's library, which was stocked with foreign books and periodicals, and also of its well-equipped laboratory to follow scientific developments abroad and carry out experiments. Recognizing the importance of Heinrich Hertz' discovery of electromagnetic waves in Germany, Popov began to work on methods of receiving them over long distances.

Popov constructed an apparatus that could register atmospheric electrical disturbances and, in July 1895, installed it at the meteorological observatory of the Institute of Forestry in St. Petersburg. In a paper published a few months later, Popov suggested that such an apparatus could be used for the reception of signals from a man-made source of oscillations, provided a sufficient power source became available. Later, in March 1896, he appeared before the St. Petersburg Physical Society and demonstrated the transmission of Hertzian waves—as they were then termed—between different parts of the St.

Petersburg University buildings. There is evidence to suggest that on that occasion the words "Heinrich Hertz" were transmitted in Morse code and that the aural signals received were transcribed on a blackboard by the society's president, who was the chairman of the meeting.

During the academic year 1895–96 at the Torpedo School, however, Popov became interested in setting up experiments on Röntgen rays (X-rays), which had just been discovered. Therefore, he discontinued for a time the further development of his lightning, or thunderstorm, detector. During the summer of 1896, Popov worked as electrical engineer in charge of the power plant at the annual fair in Nizhnii Novgorod (presently Gorky) where the demonstration of his storm detector won him a prize. He then read the first newspaper accounts of Marconi's demonstrations in September 1896. It seems clear that neither Marconi nor Popov was aware of the close similarity between their experiments.

Similarity between Popov's and Marconi's experiments

The news of Marconi's work, as disclosed in his patent of June 1896, aroused Popov to fresh activity. Working in conjunction with the Russian Navy, he effected ship-to-shore communication over a distance of six miles (ten kilometres) by 1898. The distance was increased to about 30 miles (50 kilometres) by the end of the following year, during which he had also visited wireless stations in operation in France and Germany.

Popov was given remarkably little support by the Russian government until 50 years later, when national attitudes and enthusiasms had changed and on May 7, 1945, the Bolshoi Theatre was packed with a distinguished audience to celebrate the 50th anniversary of the "invention of the radio" by A.S. Popov. On the stage sat scientists, marshals, admirals, commissars, leaders of the Communist Party, and Popov's daughter. It was announced that in the future, the 7th of May would be celebrated as the day of the radio.

Although it is agreed that Popov's experimental work in connection with Hertzian waves is deserving of recognition, it has not been generally accepted that radio communication was actually invented by Popov. Thus, while it is true that historical research has brought to light indirect evidence that Popov demonstrated the transmission of intelligible signals in March 1896, there is comparable evidence that Marconi demonstrated the transmission of intelligible signals at an even earlier date, though not before an audience of scientists.

In 1901 Popov returned to St. Petersburg as a professor at the electrotechnical institute, of which he was later elected director. He died on January 13 (December 31, 1905, O.S.), 1906.

BIBLIOGRAPHY. CHARLES SUSSKIND, "Popov and the Beginnings of Radiotelegraphy," *Proc. Inst. Radio Engrs.*, 50:2036–2047 (1962), a comprehensive and critical review of the early days of wireless communication, with special reference to the Soviet claim that Popov invented radio; R.L. SMITH-ROSE, "Marconi, Popov, and the Dawn of Radiocommunication," *Electronics and Power*, 10:76–79 (1964), a review of the claims of the two pioneers, G. Marconi and A.S. Popov, with an assessment of credits as the founders of practical radio communications.

(R.L.S.-R.)

Popular Dance

The term popular dance refers to dance performed in public or in private solely for the enjoyment of the dancers. Such dance requires no audience nor any special occasion. Its movements are usually simple, but they are sometimes complex in rhythm. It is at times described as social dance, although that term may also embrace folk dances, which are social in function and the forms of which are ancestral to many popular dances. A detailed coverage of these traditional dances may be found in the article FOLK DANCE. In strictest definition, popular dance developed entirely within the West until, in the 20th century, its forms were carried around the world.

CHARACTERISTICS OF POPULAR DANCE

Unlike folk dance, popular dance is neither ritual nor functional, although it has developed or borrowed from traditional sources and may be danced on occasions that were once a part of folk rites. Unlike ballet and other theatrical forms of dance, popular dance requires no strict physical or mental discipline. Its movements usually require little or no training, nor do they express mood, emotion, or action. From the 13th to the 18th century, however, many popular dances originated in court ballrooms, where niceties of behaviour and of dress were, like the dances themselves, subject to rules of the dancing masters. These dances required much training and practice, and dance was an important part of the education of the young nobles.

Bases. The bases of popular dance are numerous. First, popular dance helps to fulfill the need for identity with communal activities. Second, it is related to courting, in which the male displays his ability to move his partner in harmony with himself. In much social dance the male role is dominant, the female that of a follower. Third, some popular dancing, especially before the 20th century, was to celebrate such events as weddings, harvests, or merely the end of a working day.

Change. The forms of popular dance are susceptible to change from many sources. The migration of the performers or the adoption of a dance by a different nation or social class may subject it to new social situations and political institutions. The process of urbanization, the broadening of education, and the ease of communication not only altered traditional forms but also disseminated new dances rapidly. The primary vehicle for change in popular dance, however, always has been youth.

Youth always has tended to rebel against the dancing masters, whose insistence on correctness and uniformity of execution are contrary to the spontaneous responses to rhythm sought by the young. The teaching of these dancing masters led to concentration on performance, to a kind of studied dance that became largely an entertainment for onlookers. Since popular dance has always been, at base, for the participants, demands for correctness of performance rather than enjoyment caused youth continually to seek less conventionalized forms, often from among the dances of another nation or social group.

Music. Unlike the ritual dancer, who guides the music or actually supplies it, the ballroom dancer follows the music. The timing of dance rhythms has varied as fashions have changed or as wars and political upheavals have altered the structure of society. No matter how the rhythms may be beaten out, the dancers have always responded to the lilt of the melody with moving feet and body until they are caught up in the spirit of the dance.

HISTORY OF POPULAR DANCE

The concept "popular dance" cannot properly be applied to most of the dancing of prehistoric or ancient societies, even in the West, because of the ritual elements that pervaded it. Even the Greek Dionysiac dancing at the grape harvest and the Roman floralia at the advent of spring were essentially ritual, despite their popular and orgiastic nature. There was some secular dancing in Greece, but its forms and its festivities placed it in the tradition of the folk dance. Some of these dances persisted into the 20th century and spawned such other dances as the Provençal farandole and the Catalan sardana. A dance of sacrificial ritual survived as a dance by men in Greek seaport taverns. The Cornish Furry Dance, a flower dance, is believed to be descended from the Roman floralia. In ancient Greece, as in later centuries, dance had a place in educating youth. Plato's dictum "dance begets a healthy mind in a healthy body" was echoed by the Greek slave Lucian to his Roman masters. The Romans, however, contributed little to dance and tended to regard it with disfavour.

The dances of the early Middle Ages were often thinly disguised pre-Christian forms that included animal dances, fertility rites, and the like. The church countenanced dancing on social occasions because this popular means of celebrating could not be ignored, but it tried to eradicate the pagan elements.

Early court dances. The court dance, from which the ballroom dance was to develop, evolved about the 13th

century from the common chain and circle dances of the townsfolk and peasants. These traditional dances were consciously changed by such mentors as the troubadours, who imposed codes of courtly behaviour onto the dances.

Chivalry in dancing

These dances followed the codes by emphasizing the strength of the male and the delicacy of the lady. They contained elaborate displays of courtesy between the sexes and indicated the order of social precedence, from the lord and his lady to the squires and ladies-in-waiting. In addition, the dances accommodated the robust peasant steps to the court costumes, with their greater weight and ornament. The "Lay of Robin and Marion" (1285) mentions such new dances as the carole, a solemn stepping in triple time in which ladies and gentlemen, standing alternately hand in hand, circled about gracefully; and the stately courtesia, in which the couples interrupted their slow procession to express their affections through a stylized sequence of mimetic gestures. Such dances usually were accompanied by religious songs of grave tone and measure suited to the slow, gliding steps and the gentle rise and fall of the bodies. A musical setting for the 109th Psalm, of folk origin, was a favourite tune for these dances.

The troubadours may be considered the first of the dancing masters, who subsequently became an institution of importance in the development of the court and, later, the ballroom dance. The earliest of these masters were fiddlers and men of considerable learning. They would frequently accompany their young pupils when the latter married into foreign courts. Such travels made the dancing masters instrumental in the spread of dance forms across Europe, from court to court, as well as in regularizing dance and social decorum. They also made social dancing into an entertainment for spectators, eventually transforming it into staged dances.

In 1416, Domenico di Piacenza, dancing master to the ruling Este family of Ferrara in Italy, wrote the first known treatise on social dance. It indicated that a definite technique had been established for upper class social dance. Originated at the courts of Provence in southeastern France, it was penetrating into the Spanish, English, and other European courts. The caroles and the courtesia were gradually giving place to the branles and *basses danses*. These were similar in quality but were often danced to especially written secular tunes that gave them a livelier movement.

From 1500 to 1650. The period in dance from 1500 to 1650 has been called the "age of the galliard," but this lively couple dance, or jig, with its *cinq pas* ("five steps"), or "sink-a-pace" as Shakespeare called it, was by no means the only quick dance to be performed by the aristocracy. By 1500 youthful courtiers had revolted against the solemn caroles and branles. They again sought change later in the century after the pavane, a slow, procession-like dance from Padua, and the Spanish sarabande, requiring elegant pointing of the toes, were introduced at court. It became fashionable to follow these slow steppings with a faster "after dance." The galliard was the first of these. It included the mimed gestures of courtship that had been eliminated from the slower dances, and its more complex hops and capers allowed the male dancers to show off their agility.

With the increased amount of court entertainment, social dance became more varied, particularly in France after the Fêtes of Bayonne in 1565, staged by the former queen, Catherine de Médicis. At this fete, groups of dancers from various provinces introduced a host of folk dances to the court. Among them were the bourrée from Auvergne, the courante from Périgord, the volta from Provence, and the gavotte and the rigaudon from Dauphiné. The bourrée, with its neatly executed steps, later became the most popular court dance, and the courante was a favourite with Louis XIV (1643–1715). The vigorous volta, in which the male lifted his partner off the floor and swung her, shocked the Spanish ambassador to England when he saw it danced by Elizabeth I, who wore skirts shorter than most noble ladies. The gavotte, one of the first dances in which the feet were lifted from the floor, remained popular for three centuries.

New peasant dances

These dances became popular in the courts only after dancing masters evolved techniques that enabled the nobles to perform the rapid and intricate steps with ease and dignity and to display the graceful turnings of their legs or wrists. These subtleties were the marks of ladies and gentlemen aware of the figure they were cutting in society. The book *Orchésographie* (1588) by Thoinot Arbeau (pseudonym of Jehan Tabourot) was an important record of contemporary dances. In it, Arbeau insisted that the dancer pay greater attention to the display of his figure, manner, and style than to his enjoyment of the dance.

From 1650 to 1750. In 1653 the *branle du Poitou* was introduced at the French court under the name "minuet." This dance, of folk origin, became the most popular of aristocratic social dances at European courts until the French Revolution in 1789. It often was revived until the beginning of the 20th century. Characterized by its tiny steps (*pas menus*), it had many different forms, every dancing master altering or adding to the figures made, the exact placing of the feet, the angle of the partners' bodies in relation to each other, and other details. The minuet allowed the couples, who no longer held hands as in the earlier caroles and branles, to woo one another with their glances.

Minuet

From the accession of Louis XIV in 1643 until just before the beginning of the Revolution in 1789, the fashionable dances of the French court dominated aristocratic ballrooms in western Europe. But in England another kind of group dance became a permanent part of popular dance. These English "country dances," derived from traditional folk sources, were arranged by John Playford and published as *The English Dancing-Master*, first in 1651 and in 17 subsequent expanded editions in the following 80 years. Dances for social occasions always had been easily exchanged between court and common people in England. Contemporary accounts of the dances at the Elizabethan court and of the masques by John Milton, Ben Jonson, and others, as well as numerous references in Shakespearean plays, show the country dances and the various jigs taking their place alongside the fashionable French court dances.

Dance democratized

These country dances served the purposes of the middle-class-dominated Commonwealth government in the 1650s. Its puritanical ethic tolerated dancing, provided it was seemly and showed good manners and style. The steps were simple and patterns were intricate and "occupied the mind." The dancers constantly changed partners, giving no occasion for flirtatious behaviour. Everyone stood equal in circular, square, or longways sets, and as many as wished could join in. Moreover, because such dances belonged to tradition and to all classes, a person could step more easily from one rank of society to another without having to be groomed by some foreign dancing master, whose artificialities frequently annoyed Englishmen. These country dances, notably the Scottish and Irish reels and jigs, had already been taken by emigrants to the various colonies, where they continue to be practiced. Many underwent sea changes and came to be known as square dances.

After the Restoration of the English monarchy in 1660, the country dances retained their popularity, both at court and in the lower class dance halls that began to spring up in cities. These dances became popular also on the Continent, where they were introduced at the French court in 1710. They found favour quickly among the aristocracy, and, under the name contredanses, they were enlivened with steps from minuets, bourrées, and courantes. The popularity of these dances was due in large measure to the ease with which they could be learned.

The English public dance halls originated at spas, after the Restoration, as entertainments for the upper and middle class patrons who were "taking the waters." Soon they had spread into the cities and across the Channel. Among these were such dance halls and "pleasure gardens" as the Parthenon, Vauxhall, Ranelagh, Mrs. Cornelys', and Almacks, all in London. Their dances were derived from traditional or court dances, but their popularity lay in the rousing tunes played by military or town bands. The

musicians made up for any lack of finesse by the robust beat and the lilt of their music. By 1789 Paris alone had 684 public ballrooms. They offered one avenue of youthful escape and allowed the court to maintain its decorum.

The dancing masters who ran these commercial ballrooms assumed the old court title master of ceremonies. As such, they introduced couples to one another and directed each dance, often calling out the steps and figures to be performed. But when the French dancing masters elaborated their contredanses and developed the cotillons, their insistence on formal behaviour and technical precision once again made aristocratic youth look elsewhere for entertainment.

From 1750 to 1900. The allemande, a lively, turning couple dance of German origin, had become the most popular dance at open-air balls and fetes by 1760. It required skill, for the man turned his woman under his arm as they progressed around the ballroom. It was soon popular in aristocratic society, for practically alone among couple dances it allowed partners to keep close contact throughout.

The allemande did not retain its ascendancy long, however, for an exciting new dance began to appear in public ballrooms before the French Revolution. Mozart was one of the first to note the growing popularity of the Austrian Ländler, also known as the Deutsche. It was based on a simple, traditional courtship dance in which the man strutted around the woman like a mountain cock at the mating season. To music in $\frac{2}{4}$ time, the couple spun around in each other's arms with a step and hop. Such steps could not be danced on a slippery ballroom floor nor in the dress of the day, so Austrian musicians gradu-

Waltz

ally smoothed out the lively tunes into a swift, lilting $\frac{3}{4}$ measure. Thus the waltz swept into the people's dance halls and was taken up by aristocratic society.

At the Napoleonic court there was an attempt to emulate the grandeur and dignity of the court of Louis XIV by giving pride of place to the more formal figure dances. The quadrille became a favourite in fashionable society of the empire, particularly in the more expensive ballrooms. It provided an excellent opportunity for displays of skill. But once the waltzes of the Strauss family and of other Viennese composers became known throughout western Europe, this swirling dance became queen of the ballroom and remained so into the 20th century.

In 1840 the polka, a lively peasant dance from Bohemia with a bouncing, turning step and strongly rhythmic measure, began to rival the waltz in European ballrooms. It was followed by the even faster and simpler galop in 1845, but neither could surpass the waltz. Goethe's description of the hero of his novel *The Sorrows of Young Werther* (1774) dancing with his beloved suggests the intoxicating quality of that dance:

> And never have I moved so lightly. I was no longer a human being. To hold the adorable creature in one's arms and fly round with her like the wind so that everything around us fades away.

The ballrooms of England were among the last to succumb to the waltz. True to tradition, English dancers preferred the older group dances, and at first the middle classes eagerly adopted the cotillons and quadrilles. These in turn, were replaced by the lancers, a quadrille which contained familiar figures from traditional English dances and Scottish and Irish reels. But by the end of the 19th century, with the number of public ballrooms growing even larger, the waltz had become the dance for all.

The 20th century. Dance forms had always moved between social classes with relative ease. In the 20th century differences in dance styles related to the "who" and "where" of performance were virtually eliminated. So-called pop music from phonograph records or the radio and the examples of dance stars performing on the stage, television, and film became available to nearly everyone. These conditions produced at first a uniformity of dances across society. The Official Board of Ballroom Dancing, an association of dance teachers, was founded in England in 1929 to standardize dance techniques and regulate dance competitions. At the same time, social dance, now rightly called popular dance, increasingly defied regimentation. Dancers, especially the young, found improvised steps and patterns preferable to following prescribed routines. In seeking different forms of expression they embraced new dances, quickly exhausted their interest in them, and discarded them for even newer forms. The popular dance became a phenomenon in rapid flux.

A major innovation was the lead taken by the Americas in providing dances to the world. The main sources were the dances of the American Negro, largely by way of the stage, and of Latin America. The latter dances were based on a blend of indigenous and Iberian music and rhythmic elements brought from Africa. The first major break with the older European forms came in 1910 with the arrival of the tango in North American and European ballrooms. It became extremely popular in middle and upper class European ballrooms when managers of hotels and other gathering places began to stage their "tango teas." At these, the dance was first demonstrated by a professional couple, then danced by the clientele, who enjoyed its new hesitant rhythm and seemingly daring steps. The dance could be mastered fairly easily. It provided an excuse, as had the waltz, for close contact with a single partner.

Latin-American dance

An even more powerful beat began to sound through ballrooms at about the same time. Jazz musicians of the U.S., South America, and the Caribbean gradually brought the sound of their spirituals and "blues," with their syncopated rhythms and improvised playing, into the world of social dance. The original fox-trot was devised by a dancer-comedian, Harry Fox, for the Ziegfeld Follies revue in 1913. The unique syncopation of its music, and the simplicity of its steps, immediately aroused the audience's enthusiasm. Its potentialities were quickly recognized by ballroom-dance teachers, and it spread rapidly before the outbreak of World War I in 1914. The steps were gradually standardized, largely by the famous U.S. dance team of Vernon and Irene Castle, and the fox-trot remained popular for many years.

Throughout World War I the popularity of jazz increased in Europe, especially through the influence of American soldiers. When peace came in 1918, American films, musicals, and revues, as well as dancers and bandsmen, found engagements throughout Europe. The fox-trot, the Boston (a variety of waltz), and the one-step (a fast fox-trot) required little training. But others demanded the services of dancing masters before they became popular or were even countenanced in European ballrooms; *e.g.*, the shimmy of 1923, with its shaking body; the Charleston of 1925, with its wildly flailing legs; and the black bottom and the blues of 1926, the former with its distinctively twisted contortions and the latter with its close embraces.

These dances, too, had originated with the American Negro. They had been given theatrical form without losing their spontaneity. The musicians and dancers used the printed music or the prescribed steps only as the starting point for the improvisation that gave individuality to their performances. Such individuality had no place, however, in English and other European ballrooms. There, decorous behaviour was still expected, and many dancers were still too self-conscious to break into spontaneous movement. The jazz dances were therefore swept aside by new Cuban rhythms, exemplified by a craze for the rumba in 1930. After some sophistication and regularization, the rumba, like the tango before it, was introduced in public ballrooms by exhibition dancers, who then gave the floor to the spectators.

In the early 1930s some dance halls attempted to revive group dancing to counter the decline of the ballroom as a social meeting place. In these dances a number of couples performed a popular dance while following carefully prescribed patterns over the floor, much in the manner of a corps de ballet. But the idea found favour only among expert dancers, leading to the "formation dancing" performed in ballrooms or on the screen by professionals. The man in the street had no wish to be regimented in this way.

The tradition of the dancing master continued, however,

especially in Europe, where he acted as master of ceremonies at dance halls or in hotel ballrooms. Many of the masters developed large and fashionable followings. In the early decades of the century, many dancing studios sprang up in cities in the U.S. and in England, but they made little headway on the Continent. The heads of such studios eventually persuaded local authorities to license and regulate all dancing sessions and thus give their ballrooms a more respectable status in their communities.

The English style

The so-called English style of the Official Board of Ballroom Dancing became ascendant with the first international match, between English and Danish dancers, in 1934. It was recognizable for its elegance, grace, and comparative simplicity. Wherever dancers, teachers, and managers felt that the formal techniques of ballroom dancing were the only things that mattered, it became an accepted standard and was used by trained dancers in the major dance halls of the five continents. National and international competitions were fierce, and the ballroom championship of the world was highly prized. But such dancing, like formation dancing, can no longer be considered popular dance.

Dancers seeking enjoyment rather than the regimentation of the average ballroom took new pleasure in the Lambeth walk, introduced in England in 1937. Originated by the comedian Lupino Lane in his popular musical *Me and My Girl*, it rapidly became popular throughout the British Isles. It was little more than a parade with mimetic passages and friendly, even familiar, gestures that allowed the couple to do more than hold each other sedately. Moreover, the music had all the elements of old London street songs. This friendly familiarity first endeared it to cockney Londoners, then to their mates in the armed forces, and finally to foreigners living in the British Isles during World War II. Three similar cockney dances, "boomps-a-daisy," "under the spreading chestnut tree," and the "hokey-cokey," the last based on a children's game, also became popular.

Just before World War II, in 1939, the jitterbug found its way across the Atlantic. A favourite in the U.S. during the 1930s, it featured improvised spins, twists, lifts, and other athletic interchanges between the youthful partners. It evolved also into the less acrobatic "swing" and "jive" characteristic of the "era of the big bands." True jazz dance, from which jitterbug was derived, was repugnant to European dance-hall managers, because of its unrestrained and improvised movements. Another feature of the 1930s in the U.S. was the dance marathon, in which couples competed for prize money by trying to outlast all others in nonstop dancing. Threats to dance halls that they would lose their licenses kept the phenomenon out of Europe.

Dance in wartime

World War II led to the final breakdown in class distinctions within popular dance. It also weakened the hold that the dancing master and the ballroom manager had exerted on social dancing since the first Provençal troubadours demanded propriety in the performance of caroles. In Germany all social dance was prohibited, as it had been in World War I, but in England dance became a release for persons living under stress, often in cramped underground shelters. A tune blared out of a radio often broke tensions and brought on spontaneous dancing. In such circumstances, dance became again a communal activity.

Since World War II. After 1945, popular dance became increasingly without, and perhaps without need of, aesthetic theory or formal technique. The dances were learned by direct observation of other dancers on the dance floor or on stage, film, or television. As if in revolt against the restrictions of the war as well as of social dancing, youth asserted its own ideas in the dance halls, discothèques, cafés, and wherever else they joined in social activities. They improvised as the music or their spirits moved them. They had danced like that during the war and thus they continued to dance—to the deep-throated Negro singers, to the crooners whispering into their microphones, or to the throbbing beat of electric guitars. Whether it was jive, rock 'n' roll, the twist, the frug, or any other newly fashionable dance, and whether the musicians were some of the dozens of "rock" or "pop" groups or folk singers with their songs of protest, the dancers sought eagerly for new ways to enjoy themselves, to forget their troubles. The flashing stroboscopic lights in many of the teen-age dance halls appeared to freeze their writhing forms in space and time.

DIFFUSION OF EUROPEAN POPULAR DANCE

Influence of colonization and conquest

Beginning with the voyages of exploration and colonization in the 16th and 17th centuries, popular dances found their way from Europe to other parts of the globe. The emigrants from the British Isles to North America, South Africa, and Australia brought their country dances to those areas. These dances often contained elements from other nations as well. In South Africa, for example, the country dances and reels exhibited both the English love of pattern and the Dutch feature of stamping the feet. The do-si-do (dos-à-dos, "back to back") pattern of the North American square dance clearly showed a French influence.

The influence of the Spanish explorers and conquistadors was everywhere evident in Latin America, where the mixture of European, Amerindian, African, and Asian cultures spawned the tangos, sambas, congas, and other popular dances of the 20th century. Mexico and Brazil offer striking examples of the mixtures of peoples and dances. The Mexican Indians were overwhelmed by Spanish, who brought with them not only African but also Asian slaves, from the Philippines and Malaya. With them came the syncopated rhythms that were to make Latin-America dances so popular. In the 1860s came the French armies, led by Archduke Maximilian of Austria. From the early 16th century until the revolution of 1911, Mexico was continually infiltrated by popular tunes and dances from different European countries. First came the Spanish zarabanda and later the fandango. Later, opera became the rage of the Spanish-French upper classes; and the waltzes, mazurkas, and polkas acquired a Spanish flavour and were given fresh colour and new African and Asiatic rhythmic elements.

Brazil offered a similar picture. The case of the samba indicates how the shifting and intermingling of races produced different results. In northern Brazil, *samba* was the place where social dances were—and still are—held. Until recently, these were waltzes, polkas, and fox-trots. In Bahia, in east central Brazil, the *samba* was a communal round dance performed at carnival time with a soloist turning and leaping in the centre of the circle. In the northwest the "samba" was a type of unsyncopated tune in $\frac{2}{4}$ time. In Rio de Janeiro, the popular ballroom *samba* made its debut in 1917 as a reckless couple dance.

Effects of technology

During the 20th century, the phonograph, the motion picture, the radio, and the television set made the latest Western rhythms the property of the world, nearly as familiar in Japan, Africa, India, or the Philippines, as in London and New York. The traveller from the West encountered familiar tunes and saw the same shuffling, shaking, and stepping that he had known at home. He was not, as he might have been a century earlier, an outsider to the fashionable local dances. The transistor radio became a status symbol for many persons in more primitive areas of the globe. Its sounds, together with other elements of Western civilization, weakened the hold of indigenous dances, which as the 20th century progressed, were in danger of becoming museum pieces in many areas.

BIBLIOGRAPHY. *The Dancing Times* (monthly), and *The Ballroom Dancing Times* (monthly), contain articles on all types of social dances at all periods, as well as articles by expert teachers on all past and present forms of social dance; *Journal of the International Folk Music Council* (annual), contains articles on the relation between folk and popular dance, the development of contemporary popular dance, and the relation of popular dance to its music; P.J.S. RICHARDSON, *A History of Ballroom Dancing, 1910–45* (1946); and CURT SACHS, *Eine Weltgeschichte des Tanzes* (1933; Eng. trans., *A World History of Dance*, 1938, reprinted 1963), both give comprehensive surveys of all types of social dance.

(Jo. L.)

Popular Literature

The term popular literature has several connotations: it may mean literature intended for the masses, or literature that finds favour with large numbers of people, or it may be a literature of the people. The types may overlap, or they may remain distinct. Thus, "popular literature" can describe ballads, verse, tales realistic and picaresque, romances and confessions, jest books and chapbooks, westerns and thrillers, science fiction and fantasy literature, allegory and satire, emblem books, strip cartoons, comics, and even picture postcards; it may be applied to pamphlets and certain kinds of journalism; and it encompasses a whole range of dramatic literature, from monologue and comic turn to full-length play.

Many of the terms used in discussing popular literature, such as people, folk, and culture, carry widely differing and even conflicting implications. A broad discussion of such concepts as they relate to all the arts will be found in the article PRIMITIVE, FOLK, AND PRIMITIVE ARTS. This article will treat the subject of popular literature primarily as it relates to other forms of literature and only in general terms, since any attempt to present a comprehensive detailing of its outcroppings would prove endless. An analogous article is FOLK LITERATURE. Many of the literary forms most commonly associated with popular literature, such as detective stories, gothic romances, science fiction, and "best sellers" are discussed at some length in the article NOVEL; and there is also some discussion of other genres of popular literature in the articles SHORT STORY; and LITERATURE, NONFICTIONAL PROSE. Discussion of what is popular in other arts may be found in the articles POPULAR THEATRE and POPULAR MUSIC.

Articles on the history of literature, such as LITERATURE, WESTERN; and LITERATURE, EAST ASIAN; and articles on the arts of various peoples, such as SOUTH ASIAN PEOPLES, ARTS OF; and AFRICAN PEOPLES, ARTS OF, also discuss popular literature.

THE DEVELOPMENT OF POPULAR LITERATURE

Modest in achievement though so much of it is, popular literature can boast that the origins of journalism and the novel are to be found in it. A vast number of tales and romances of a popular nature were published in Great Britain before 1740, the date Richardson's *Pamela* appeared, and the date used by many critics to mark the beginning of the English novel.

Before some of the attempts to define popular literature are described, it might be useful to examine examples from one particular cultural context—that of English literature—which have proved to be popular or which have been said by scholars with different interests to be expressions of popular culture. The examples and the evaluations are not comprehensive and are not intended to be typical. They may, however, illustrate how differently understood is the expression popular literature and warn against taking too uncritically the generalizations about it.

With the advent of printing, literary popularity of a new magnitude became possible. Early evidence of the extent of such popularity is usually incomplete: the number of copies printed of 16th-century books is not known and often whole editions are lost. Thomas Deloney's tale, *Jacke of Newberie*, was evidently published in some ten or a dozen editions between 1597 and 1637, but no copies of the earlier editions have survived. Deloney's popularity extended beyond his own age, for there were at least another half-dozen editions of *Jacke of Newberie* in the later 17th century, and his *The Gentle Craft* was even more popular, if the number of surviving editions is an indication of the number printed. Furthermore, it was turned into a play by Thomas Dekker a year or two after it first appeared and it survived in chapbook form in the 18th century.

Sermons, chapbooks, and broadsides

Even more popular in Shakespeare's time were the sermon and such moral tales as Richard Bernard's *The Isle of Man* (of which 16 editions are recorded up to 1683). The appetite for sermons, at least in towns, seems to have been insatiable. There are at least 128 known editions of the works of Henry, or "silver-tongued," Smith in various combinations, published between 1589 and 1637; and 128 editions of the works of the Puritan preacher William Perkins (1558–1602) are recorded before 1640. The equivalent editions of Shakespeare for this period number about 90, Marlowe 31, and Spenser 19. "Popular" may justly be associated with Smith and Perkins in ways other than that assessed by counting editions. Sermons were more than instruments of the salvation of mankind; they were the chief source of political information and political ideas for most Englishmen, and their "popular" significance in prerevolutionary England is considerable.

Another source for the history of popular literature is the chapbook, a wood-block illustrated pamphlet of tales, tracts, and rhymes circulated by peddlers in the 18th century. A rival to the chapbook would be the broadside ballad. The variety of subjects of broadsides was considerable. Subjects might be topical, political, or loyal; they might deal with calamities—shipwrecks, fires, or even the collapse of a building; but those that sold in largest numbers in the early 19th century (as many as 2,500,000 copies of a single broadside are reported) were those issued by James Catnach and John Pitts that reported trials and executions.

Although figures for the sale of broadsides in the early 19th century—and thereafter those for the novels of Dickens and Mrs. Henry Wood, and, outstandingly, Harriet Beecher Stowe's *Uncle Tom's Cabin*—are impressive evidence of this kind of popularity, the 19th century is even more significant in terms of popular literature for the birth of popular journalism. Though the origins of the popular press go back to the pamphleteers of the 16th century, it was the success of *Tit-Bits*, launched in 1881, and the *Daily Mail*, in 1896, that ushered in what has come to be called the "post Northcliffe" era of mass culture, after one of the most influential newspaper publishers, Viscount Northcliffe (1865–1922). Television now plays an even more significant part in popular journalism than the newspaper.

Popular journalism

This highly selective—and almost arbitrary—list of what has proved popular in terms of sales, or of what has been described by scholars as being of the people, or influenced by them, over the centuries, will indicate how varied is the range of literature which can be described as popular. It will be apparent how loosely the term is used and how broad, and unsure, generalizations about popular literature are likely to be.

FUNCTIONS AND EFFECTS

Popular literature can be approached theoretically in two sharply distinct ways. It can be thought of as deriving *from* the people, or it can be thought of as directed *at* them—with greater or lesser degrees of conscious calculation on the part of its originators. Those who attempt to define the first approach are likely to insist on the importance of the oral tradition. This tradition does not exclude the work of known authors, but it does require that it be refashioned by the community in order to make it a part of the culture of that community.

In discussions of this kind of popular literature, class and community distinctions are important for some scholars. Folk literature may be seen to be associated with agricultural communities or it may be rather more broadly defined as being associated with all the lower classes.

Popular literature, it has been suggested, is designed to entertain; it is immediate and demands spontaneous response. High, or elite literature, in contrast, is said to be formal and composed, an art for contemplation and *intended* to endure. It has also been argued that high literature may be judged by its ability to disturb and challenge, whereas the popular arts confirm known experience and values, seeking to reassure. This is an extremely useful distinction, but it attracts two comments.

Contrast with elite literature

Though there is no doubt that much contemporary critical evaluation regards highly the capacity to disturb and to challenge, this is nevertheless a limited approach. It fails, for example, to assign much merit to the capacity to delight (and to create delight without being trivial is,

perhaps, more difficult to achieve—and much more difficult to explain—than to challenge or disturb), and it disregards certain aspects of the expression of individuality and independence through language. Popular literature *can* give delight without being trivial and in its use of language, in, say, the absurd and the bad pun, its cultural contribution may be significant and lasting, awkward though it may be to assess in terms of high art.

Second, though it may do so infrequently, popular literature can disturb and challenge. This can be experienced in some of the earliest English dramatic literature that has roots in the community (as in the Crucifixion plays, which are a remarkable mixture of pathos and farce), in some ballads and music-hall songs and acts, and even in film and television comedy. When popular art is accepted by critics of high art, however, it is elevated hierarchically—it becomes work attributed, say, to the "Wakefield Master" or is lifted above the mass, as was the English music-hall art of Dan Leno (1860–1904) by Max Beerbohm, or the works of such detective story writers as Dashiell Hammett in America or Georges Simenon in France were by a variety of critics.

In Germany in the 1930s, then in America, and later in Britain, attention has been paid to the way in which popular literature has been affected—some would say corrupted—by mass media: newspapers, films, radio, and television. Many people express concern at the situation in which nations of the Western world find themselves in this respect. Alongside the fear of the corrupting effect of the mass media is an awareness of the progressive alienation of elite art from popular art. Yet the situation is not, perhaps, quite so desperate, nor so completely distinct as it may seem to modern man, confronted as he has been by three new media—films, radio, and television—in the space of half a century. Furthermore, the alienation of popular and high art forms is not uniform, and in some areas, this trend is being reversed.

Changing contexts of popularity. Elizabethan drama has been called a "popular form" not so much because it was a drama of the streets but because the plays had a *substructure* of the popular in works of high seriousness and in their use of popular attitudes and forms (such as revenge tragedy). It should be noted that "popular" is being used here in both of its principal meanings: popular *of* the people and popular *with* the people.

There are undoubtedly close links between popular dramatic forms and the plays of Shakespeare and many of his contemporaries. That these plays were popular in that they reflected attitudes popularly held, and that they enjoyed wide esteem is well established. But it is also clear that such plays are no longer "popular" either *of* the people or *with* the people. Full houses for Shakespeare in seasons at Stratford-on-Avon are not a true indication of either kind of popularity, and his contemporaries never fare as well.

Although their work has not fallen into the virtual oblivion suffered by the sermons of Smith or Perkins, it has nevertheless become representative of high art. Furthermore, the popular elements of the writing of these dramatists have to be searched out by scholars.

Thus, what was popular (in both major senses) in those dramatists has become, for today, something different, and much else that was popular—whether sermons or pamphlets or plays—can hardly be said to excite the attention of anyone but the specialist scholar. What was popular in the Elizabethan period, a modern scholar's understanding of what then was popular, and the response of a modern popular audience to such works are by no means coincidental.

The "threat" of popular literature. Those who are most sensitive to the high cultural tradition tend to see a threat to it from the popular arts of their own time, especially from the popular arts involving mass media: mass journalism, film, radio, and television. It is difficult to understand the effects of the new media while fully exposed to their innovations. Objective evaluations are complicated by inherited traditions of high culture, fears for their survival, the difficulty of detecting popular traditions in the new media, and perhaps, too, elements of Puritanism. Above all, it is impossible to predict how the human intellect and spirit will respond to these new media. Grounds for optimism may be found in the human response to the advent of printing, a challenge in its time no less remarkable than those occurring in the 20th century.

In the study of popular literature, the present is felt much more sharply than even the recent past. False comparisons with this past can easily result from this sensitive awareness of the present. Popular literature presents a much more difficult problem than any form of high art, which is, by its very nature, selective. In popular literature, some estimate of the whole, the mass, must be made. This presents physical difficulties and there must then arise the inadequacy and inaccuracy of data.

FORMS AND TECHNIQUES

It may seem to a modern scholar, studying the new media of the 20th century, that there has been a sudden shift from popular art to mass art and that this has led to depersonalization and the destruction of style. Mass art, in this use of the term, is not simply the art conveyed to a large audience through one of the mass communications media, but rather an art that is distinct from popular art in its relation to its audience. Popular art is seen as retaining the vital link between artist and audience that folk culture enjoys but mass culture relinquishes. Both appeal to large audiences, but the popular writer respects both his art and his audience, whereas the maker of mass art is ruled by his audience, which he is anxious to please—no matter how. The popular writer knows his audience as he knows himself. Although he may use a mass medium, he still expresses something essential to his own nature, and from the depth of this nature he brings up memories and feelings to which his audience, being of the same background as he, can respond.

Mass and popular art

That much of the literature fabricated for the mass media of today is depersonalized and lacks style is undeniable: but so, of course, was much of the literature created for large audiences of preceding generations (see, for example, the description of serial writing in Charles Manby Smith's *The Working Man's Way in the World*, 1853). Again, it is impossible to conclude with certainty that the proportion of mediocre writers to genuine artists is higher in the mass art of today than in the popular arts of the 19th century.

The romance probably has the longest and fullest tradition in popular fiction, extending from the early Middle Ages to the present. It is found in verse, prose, and dramatic forms. In popular literature, though it shows countless differences, its mainspring is some kind of forbidden love. The censure may apply in the world outside but not in the fictional world (this is notably so in pornographic literature, which frequently depicts societies freed from civil, and sometimes physical, restrictions and limitations). The censure also can be represented in the story, directly or indirectly; it may be legal or religious, or very frequently social (a class barrier, for example). A characteristic of such romance is that even when it appears to be realistic, it presents a world from which certain normal restrictions are removed.

Another principal kind of fiction is the realistic tale. Though the terms suggest a general difference between the worlds of romance and realism, it should not be assumed that realism necessarily reproduces the actualities of real existence, however carefully verisimilitude may be suggested. It is not actuality with which writers of popular realistic literature are chiefly concerned, still less with "real" issues or "real" relationships. Their aim (though there are exceptions), like that of the writers of popular romance, is to provide their readers with wish fulfillments, and in this respect it can be hard to differentiate between the two kinds.

Of the many other forms favoured by popular literature, fantasy is one of the most significant. Fantasy literature can be conceived of as an extension of the romance except that love is not the object of the inhibition. Utopian literature and science fiction are the two most obvious forms of fantasy writing and the latter is particularly intriguing in this context for two reasons. In the first

place, though its worlds may not be our known world, it is often at pains to be "realistic" within its own fantasy—for example, the careful, as well as imaginative, use of technological paraphernalia by the pioneer French science fiction writer Jules Verne. Secondly, while being in most of its manifestations a popular literary form normally disregarded by critics of high literature, it makes use of archetypal myths and gives expression to deep-seated urges and fears, which relate it not only to the popular subconscious but also to high art. The Soviet novelist Yevgeny Zamyatin, for example, using the science-fiction form in his novel *We* (1924), expressed fears of totalitarianism so effectively that he was forced to leave the U.S.S.R.

Values espoused. The prime aim of the writer of popular literature is immediate entertainment, and, in this, the tradition is as limited and as worthy as is the ancient craft of which it is a part: storytelling. The most serious criticism of popular literature (indeed, of all literature) concerned primarily with immediate effect—with wish-fulfillment—is not that its "literary standard" may be low, or its ideas stereotyped, but that its representation of human relationships and the values it espouses are false. The more seemingly in accord with verisimilitude it is, the more will its readers be encouraged to make unreal demands on life and the more frustrated may they become if their expectations are disappointed. Though this would seem to be true of most, if not all, products of formula literature, it ought to be borne in mind that most literature is mediocre or worse and that these criticisms can also be levelled at literature that is intended to be sophisticated, profound, complex, and enduring.

Attitudes toward love and sex

Nowhere is the difference between popular and high literature more striking in the latter half of the 20th century than in fiction dealing with relations between the sexes. Avant-garde literature and the fiction that gains critical recognition from the serious literary journals reflect an attitude to sexual relationships generally in accord with what has come to be termed the permissive society: frank, open, uninhibited. Yet at the same time there is a steady output of the novel and short story devoted to romantic love. Here, the standard set—the code of behaviour—not only is different at all points from that espoused in high literature, and *seemingly* acceptable in daily life itself, but has at no time come very near to actuality. In this genre (if two manifestations so utterly different can be comprehended in a genre) there is virtually no interaction between high and low, unless it be for the occasional parody of the popular by the high.

Qualities beyond literary analysis. On close verbal analysis of what is said and the way it is said, almost all popular literature will seem inferior to high literature. In its manipulation of words, in sophistication and complexity, in the use of irony, and so on, high literature will respond more readily and more satisfyingly to analytical techniques. It is apparent, however, that some popular literature, which is unresponsive to analysis of this kind, is not without artistic and human virtues. This is true of some folk poetry, of some ballads, and, of some of the tradition of nonsense and the absurd in music-hall entertainment. This last tradition fostered imagination and verbal delight when high literary art was concerned with realism and naturalism, and its significance is far greater than what is judged to be its literary merit. In English literature, especially popular literature, the irrational has played an important role: its expression of nonsense is tantamount on occasion to a poetical faculty of a kind quite distinct from that found on the Continent. This quality is also unresponsive to the kind of literary criticism appropriate to high literature.

Criticism and the bad pun

In its inability to deal with the bad pun, the inadequacy of such criticism can be seen to be particularly acute. The frequent use of the bad pun by the greatest of all English writers, Shakespeare, makes it difficult to dismiss out of hand. The delight afforded to those of all classes by the bad pun cannot be explained in high literary terms. It may be that this play on words, and the distortion of language that is frequently involved, is a means whereby individuality is expressed, due order and the rational are subverted, and personal independence asserted, while at the same time—in the response it evokes—a sense of community is shared. Though the bad pun cannot be accounted for in the terms of high art, its cultural importance (in the anthropological sense), and its popularity—transcending class distinctions—are of great significance.

The paradox of the bad pun epitomizes some of the peculiarities and problems posed by popular literature. Thus, although by high-literary standards the language of popular literature is often weak, analysis appropriate to high literature may not reveal its essential qualities, and what is different is not necessarily inferior.

INFLUENCE ON FORMAL LITERATURE

As significant as the differences between the characteristics of popular and high literary forms are the ways in which high forms develop from popular beginnings. The influence of the popular on the high is familiar enough in music but less obvious in literature.

Popular into high literature

One of the most interesting characteristics of certain popular genres of the 20th century has been the way in which they have shown signs of developing higher literary forms. Western novels, for example, have been largely third- and fourth-rate, but the works of such writers as Walter van Tilburg Clark and A.B. Guthrie are something more than "popular entertainment." More subtle has been the indirect effect on dramatists, such as Arthur Miller in America, and the Australian Ray Lawler, of that cliché of the Western, the isolation and independence of the frontier hero; both writers have used it, switching their locales not merely superficially to the city, but to the frontiers of national attitudes to life.

Without question, the clearest, though not necessarily the most significant, evidence for the growth of a high art form out of the popular is to be found in science fiction. The origins of science fiction, if the term is interpreted broadly, go back many centuries and the names of men of high ability have been associated with the literature of fantastic voyages and Utopian worlds. Nevertheless, it can be shown that in the form in which science fiction has proved so immensely successful in the 20th century, its sources are truly popular—of the people. Modern science fiction has sprung from the passionate enthusiasm of its fans, who exerted strong influence on the editors of science-fiction periodicals to ensure that the literature developed as its readers—its participants, indeed—wished. The way in which ordinary readers in this way played a part in the development of science fiction suggests that the concept of popular literature as being no more than a shadowy imitation of high art is not inevitably true.

Although the literature of science fiction may seem at first homogeneous, it is not only diversified but quite strikingly reflects the cultures supporting it. Thus, American science fiction is much concerned with what has been called the breaking of a culture (seeking new worlds in which man can develop further owing to the decline foreseen in Earth's civilization), while British science fiction is dominated by impending disaster.

The influence of popular art on high art can be seen most clearly in dramatic literature. It is a commonplace that popular drama has burlesqued the greatest art (Shakespeare, for example, by innumerable television comedy writers), and a little less obvious that popular elements have been used by serious creative writers (John Osborne's use of the music hall in *The Entertainer*). But the influence of popular drama on legitimate drama goes much deeper and further.

An examination of two of the most persistent dramatic traditions—the comic monologue and the two-man comic turn—tell much about this influence. The two occur in the earliest English drama, they are much in evidence in the plays of Shakespeare and his contemporaries, and they are to be found in the popular tradition up to the present. What distinguishes these forms from drama, in which disbelief must be suspended, is their continuous breaking of the continuity of the audience's involvement. In drama in which disbelief must be suspended, an actor who forgets his lines embarrasses his audience and the

integrity of the play-world is broken. In popular drama, the performer can use such an error as a source of comedy; furthermore, the effect is not to break the dramatic world but, paradoxically, to involve the audience in the performer's world more fully and more willingly. There are, too, differences between the relationship of the actor to his role in the two kinds of drama. The actor is involved in a legitimate role: he takes a part. In popular drama, the performer stands apart, retaining his own personality.

Many forces combined to separate the high and popular dramatic forms. In post-World War II English drama, however, they were reunited in the work of such playwrights as Harold Pinter and Samuel Beckett. What is so fascinating about this new relationship is that it makes intellectual use of popular dramatic material and forms as well as the popular dramatic relationship of performer to audience.

BIBLIOGRAPHY. The number of books and articles on popular literature and the mass arts is vast. The selection below will serve only as an introduction. Most of the books listed contain bibliographies and these should also be consulted. Volume 4 of the *New Cambridge Bibliography of English Literature* (forthcoming), contains a fairly lengthy selection of titles on the cultural debate, mass communications, reading and readership, journalism and the press, popular genres, content analysis, and the relations of literature to film, radio, and television, for the period 1900–50. Many of the studies included are very recent and some have implications for earlier centuries. HELMUT BONHEIM (ed.), *The English Novel Before Richardson* (1971), is a useful checklist of texts and criticism.

The best introduction to the common reader is R.D. ALTICK, *The English Common Reader* (1957), containing an extensive bibliography. Q.D. LEAVIS, *Fiction and the Reading Public* (1932), should also be consulted. RAYMOND WILLIAMS, *Culture and Society 1780–1950* (1958), and his *Long Revolution* (1961), are illuminating discussions of the interrelation of artistic and social developments. Undoubtedly the most stimulating and most moving account of popular culture is RICHARD HOGGART, *The Uses of Literacy* (1957). CHRISTOPHER PULLING, *They Were Singing* (1952), not only gives a good account of the music hall, but relates it in a significant way to the social life of the 19th and early 20th centuries. *The Popular Arts* (1964), by STUART HALL and PADDY WHANNELL is a pioneering critical study of the mass media; it is significant not only for what it says but for its attempt to stimulate further discussion by means of a series of projects intended for use in schools and adult education centres. S.L. BETHELL, *Shakespeare and the Popular Dramatic Tradition* (1944), is essential reading for an understanding of the relationship of popular and high dramatic art forms. It served as the starting point for P. DAVISON, "Contemporary Drama and Popular Dramatic Forms," in *Aspects of Drama* (1965). GEORGE ORWELL, *Collected Essays,* 4 vol. (1968), brings together much that has influenced later writers on popular literature in England; P. DAVISON, *Songs of the British Music Hall* (1971), gives words and music of 50 songs, with individual and general critical and social comment.

Five collections of readings are of special interest: B. ROSENBERG and D.M. WHITE (eds.), *Mass Culture: The Popular Arts in America* (1957); E. LARRABEE and R. MEYERSOHN (eds.), *Mass Leisure* (1958); D. THOMPSON (ed.), *Discrimination and Popular Culture* (1964); N.F. CANTOR and M.S. WERTHMAN (eds.), *The History of Popular Culture* (1968); and JEREMY TUNSTALL (ed.), *Media Sociology* (1970).

Finally reference should be made to those centres specializing in the popular arts which issue communications from time to time: The Centre for Contemporary Cultural Studies, University of Birmingham; the Centre for Mass Communication Research, University of Leicester; L'institut de littérature et de technique artistiques de masse, Bordeaux; and the Popular Culture Association (which publishes the *Journal of Popular Culture*), at Bowling Green University, Ohio.

(P.H.D.)

Popular Music

Popular music is music inhabiting the broad domain that lies between folk music and fine art music. It is a domain with no clearly defined frontiers, and at one extreme it merges into folk music; at the other, into art music. But for the most part, the distinction between folk, popular, and fine art music is clear enough.

In general, popular music—unlike folk music proper—is produced by professionals and mainly in the towns. At the same time—unlike fine art music—it is in many cases diffused by oral means. In some important examples, such as Spanish flamenco, central European gypsy music, and a great deal of jazz, it flourished without the aid of print. These three considerations, professionalism, urbanism, and the relative degree of its oral transmission, have for centuries affected the nature of popular music in many parts of eastern and western Europe, North and South America, and much of Asia. After the mid-20th century, with the global expansion and dominance of Western music from Los Angeles to Laos, from Prague to Peking, a worldwide uniformity of popular music began to be apparent, derived in large part from U.S. models.

EARLY HISTORY

Antiquity to the Middle Ages. In antiquity another layer of music was interposed between the music of the peasantry and that of the upper classes. Cities such as Rome and Alexandria attracted Greek minstrels, Syrian dancers, Negro musicians, singers from the Italian countryside, and former slaves or smallholders who made a living by providing music for the urban crowds at circuses or in theatres, in processions or dances. The phenomenon of the popular "hit" song, spreading from the theatre into the streets, was already familiar in Roman times. The Roman writer Suetonius reports that when Galba was made emperor in AD 68, the entire audience in a theatre roared out a song in vogue at that moment, satirizing Galba's avarice.

When, in 6th-century Europe, the by then degenerate theatre of antiquity finally disappeared during the barbarian invasions, dispossessed professional musicians were driven afoot to mingle with the bards of various peoples —Teutonic, Celtic, Slav—in that miscellaneous body of entertainers who haunted the towns and thoroughfares of the Middle Ages. Before long, a general European popular music idiom began to show itself, in which the national differences between music of Spanish, Italian, German, and Polish origin, for example, were to some extent masked by a stylization that resulted from the cosmopolitanism of the professional musicians' calling—but to some extent only. It is true that the popular performances of medieval Europe were far more "international" in character than those of folk music, which often varied enormously in style from country to country and even from province to province. Yet there were characteristic differences between the analogous melody forms and utterances of such varieties of poet-musician as the northern French trouvères, Provençal troubadours, German minnesingers, Spanish juglares, and English minstrels. A 14th-century proverb of French origin indicates the manner of popular singing among various nations: "The French sing, the English carol, the Spaniards wail, the Germans howl, the Italians bleat." In the high and late Middle Ages, popular music covered a wide social and artistic range. Minstrels might be of the court or the tavern, they might be large landowners or beggars, wandering scholars or illiterates, virtuosos or strummers. The repertory ranged from aristocratic hero ballads through lyrical songs, courtly or crude, to rustic dance tunes. Musicians' earnings varied as widely as their grades, and the wealthy troubadours were as scornful of the ragged jongleurs (French minstrels) as minnesingers and meistersingers were of the itinerant *Spielleute* of the German countryside and back streets. The fortunes of popular musicians in the Middle Ages were subject to the same ups and downs as those experienced by the star performers today. Thus the talented jongleur Bernart de Ventadour (flourished late 12th century), a baker's son, attained the courtly rank of troubadour and entered the aristocracy; on the other hand, his contemporary, the equally gifted Raimbaut de Vaqueyras, a dispossessed nobleman, sank down into the ranks of the juglares, playing and singing on fairgrounds and in market squares.

National differences

International traffic in popular music, exemplified in modern times in the worldwide spread of jazz and rock 'n' roll, was already foreshadowed in the Middle Ages by

itinerant professional musicians who might wander anywhere within a territory bounded by Edinburgh (Scotland); Santiago de Compostela (Spain); Cyprus; and Tallinn (Estonia) on the Baltic. Paris-based minstrels would operate in France between Roncesvalles and Metz; German musicians based in Nürnberg might be in Cracow (Poland) for the summer and in Verona (Italy) for the winter. French, Italian, Spanish, and Portuguese minstrels were frequent guests in England. In the towns on the Adriatic coast, Serbian, Greek, and Croatian musicians played alongside instrumentalists from the German principalities and from Transylvania (Romania). French popular musicians, settled in the Hungarian wine-growing districts, accompanied the annual Tokay caravans through Slovakia and across the Carpathians into central Poland. All these musicians exchanged melodies, musical ideas, and instrumental techniques.

Near Eastern influence

Nor was the influence of the Near East unimportant. Urban popular music of Arabic-Persian origin was early spread over parts of southwest Europe by the Moors in Spain, southern France, and southern Italy. From this culture came the short-necked lute with bent-back pegbox, the instrument now popularly associated with medieval minstrels. Later, with the Turkish invasions and occupations, music of similar provenance was spread among occupational musicians in the towns of southeast Europe, notably Bulgaria, Romania, Serbia, Bosnia, and Albania. It was carried, mainly by gypsy professional entertainers, into Central Europe, where it mingled with the local musical stock to create the peculiar, hybrid, semi-Oriental kind of popular music of which, in the 18th century, Mozart availed himself in his *alla turca* (Turkish-style) compositions.

The Renaissance. As feudalism merged into early capitalism (in western Europe in the 15th and 16th centuries, later elsewhere), popular musicians became more settled, and generally only those in the lowest reaches of the profession remained itinerant. An active traffic between town and country culture became the normal condition of popular song. Some of the agents of this process were amateur composers among the rural middle class, making formalized arrangements of folk tunes; domestic servants bringing village music into towns and taking town music back into the villages with them; fairground and marketplace singers; street showmen; booth-theatre actors; peddlers of cheap songbooks and broadsides (from the 16th century onward).

Various institutions helped in the formation of popular-music idioms. In England, from Tudor times, the municipalities employed "town waits," instrumentalists who combined the functions of perambulating night watchmen and town bandsmen. They played for official visits, for the mayor on market days, and for summer-evening concerts from the guildhall roof or a roadside scaffolding. In Coventry, for instance, they also played softly at various corners of the city five days a week between midnight and 4 AM, for the reassurance of citizens. Their repertory consisted mainly of adapted folk melodies, humble amateur compositions, popular dance tunes, theatre music, and marches. In France, from the time of François Villon and Rabelais onward—*i.e.*, from the early 15th to the mid-16th century—popular city cabarets were putting into circulation a large number of songs, sentimental, satirical, or comic, most of which enjoyed only a brief vogue, though some proved lasting.

An even more powerful source of popular music was the secular theatre that established itself firmly in France, Spain, and Italy during the 15th and 16th centuries. The theatres performed short plays, often four pieces in an evening, acted usually on open platforms of a movable kind by companies consisting partly of professionals and partly of amateurs, including women and at times children. Many of these plays began and ended with a song, in the manner of an overture-finale frame, and most of them were punctuated with chansons, villancicos, and villanelle during the course of the action. Some of the actors played instruments and at times would perform pieces from the regular minstrel repertory, in the absence of music especially written for the theatre.

In Germany, where, following the Reformation, printed music, the popular choral movement, and the activities of educated amateur musicians, parsons, and schoolmasters worked with especially powerful effect on lower class music making, a vast amount of folk song was transformed into popular song by the imposition of the conventions and usages of art music. This was accomplished by simplifying rhythms, converting old modes into modern scales, tidying up the structure of melodies, and encouraging a standard kind of voice production. A characteristic institution of the early capitalist period in Germany was that of the meistersingers—mostly small merchants, artisans, and tradesmen—who assembled, usually in the guildhall on Sunday afternoons, to practice their new often homemade songs that belonged firmly to the realm of popular music, being neither folk song nor fine-art compositions.

The Baroque. In 17th-century England, the powerful expansion of bourgeois ways of life and manners of thought was accompanied by a flourishing of urban popular music that became equally as important as folk music and art music. Significant landmarks were the extremely successful publication of John Playford's *The English Dancing-Master*, a collection of contredanse tunes, many of them based on popular song and ballad airs, that ran into 17 editions between 1650 and 1728, and Henry Playford's *Wit and Mirth. An Antidote against Melancholy*, published in 1682, gained great fame when it was re-edited in 1699 with the subtitle of *Pills to Purge Melancholy*. Rather unjustly, Thomas D'Urfey (*c.* 1653–1723) gets the most credit for this collection of popular songs, serious or saucy, of aristocratic, bourgeois, or lower class, origin. New volumes were added over the years and reprintings constantly ordered. By 1720, the work had grown to six volumes and contained more than 1,000 songs, giving a wide view of the popular music of the time in parlour and kitchen, tavern, and pleasure garden.

Influence of British pleasure gardens

The pleasure gardens that sprang up, notably during the 18th century, in the cities and spas, or watering-places, gave an important stimulus to popular music through their evening entertainments. Thousands of songs were written specifically for performance in these places and, at least from the middle of the century, were profusely printed on leaflets or in books. In London, between 1769 and the early years of the 19th century, at least one, sometimes two or three, books of Vauxhall Gardens songs were published annually, as were songs from Marylebone Gardens. One composer, James Hook, wrote more than 2,000 songs mainly for the "gardens crowd," and another, Charles Dibdin, wrote nearly 1,000; several other composers were scarcely less diligent. A comparable flood of lyrical popular music flowed at a slightly later time from the beer-garden entertainments of the German and Austrian towns.

Meanwhile, in most of the larger towns of 18th-century continental Europe, popular comedies with music could be seen in the puppet and marionette tents and on the fairground or back-street stages, often with stereotyped figures derived from the Italian *commedia dell'arte*, such as Pantaloon, Harlequin, and Pulcinella. A report from 1711 tells that at the fairs of Saint-Germain and Saint-Laurent in Paris (held on the respective saints' days), the theatre audiences habitually joined with the actors in singing the favourite songs of the day; the actors had only to sing the opening bars of the song, and the audience knew the rest.

Ballad opera

Later in the century, when the French royal opera forbade actors to sing in the popular theatres on grounds of its exclusive privilege for such performance, the actors would cause a scroll to unfurl each time they came to a song, the instrumentalists would introduce the melody, and the entire audience would roar out the song, reading the words from the scroll. Usually, in this kind of performance, the text was more important than the music, which more often than not was derived or adapted from well-known tunes, similar to the ballad opera. Probably the most important of the ballad operas and one that had great effect internationally was *The Beggar's Opera*, by John Gay, an aggressively satirical piece and a

huge favourite with the populace. It was first staged in 1728 and was an immediate success; within a few years it had been played on countless stages in England, Ireland, and Scotland. In 1733 it was performed in Jamaica and in 1750, in Paris and New York. Its triumph encouraged others. By the end of 1729 London had seen 15 ballad operas and by 1733, 70. Some 700 popular tunes were used in these works, with librettos sometimes written by hack writers, sometimes by such eminent literary men as Jonathan Swift, Henry Fielding, and Richard Sheridan. In later years, this form of light Baroque lyrical theatre was to have considerable influence on continental popular music, notably in Germany.

The French Revolution. The years of the French Revolution comprise a singular period in the history of popular music. Admired singers would set up their little platforms in the squares or near the bridges of Paris to amuse the public by singing topical songs. In many parts of the city the audiences were so large that coach-and-wagon traffic was seriously hindered, and the municipal authorities were at length obliged to provide special vantage points where the singers might perform. During the height of revolutionary enthusiasm there was hardly a gathering of any kind where patriotic, satirical, or general popular song was not heard. In his compendious work, *Les Hymns et chansons de la Révolution* (1904), the musicographer of the French Revolution, Constant Pierre, reports:

Political songs

> For a certain period the theatres were literally invaded and treated as an annexe of the public highway; the audiences displayed their opinions by themselves singing songs of political tendency or by demanding performances, there and then, of their preferred ditties.

Singing invaded the National Convention itself, with one deputation after another announcing its revolutionary fervour and then singing its favourite song to the accompaniment of drums and other instruments brought along for the purpose. Deputies had the habit of standing up in the Convention and intoning lengthy ballads written on some topical point or other until, at last, in March 1794, Georges Danton, a prominent revolutionary leader, proposed a resolution "That henceforth this platform hears nothing but reason in prose." The motion was carried, and from then on singers were rarely heard in the Convention hall, unless by invitation. The course of the torrent of revolutionary popular songs is not without interest. In 1789 a mere 100 songs on political or social themes were published. In the enthusiasms of 1793 the number rose to 590, and the next year, 701 such songs were issued. With the reaction that set in after the execution of the revolutionary leader Robespierre, the numbers declined steeply. Only 137 new songs on topical themes were issued in 1795; and by the end of the century the flow of directly political songs had to all intents ceased. This example serves to remind that popular music is far more sensitive to the important moments of history than either fine-art music or folk music, at least in the Western tradition. Thus, the American Revolution and the Civil War both produced a flood of popular songs but only a few occasional pieces for the concert hall, while—contrary to general belief—the reflection of these events in folk song proper was minimal.

19TH AND 20TH CENTURIES

The 19th century. The period of industrial capitalism saw the greatest spread of specifically popular music. The growth of large towns meant bigger audiences, which, in turn, gave rise to an entertainment industry of vast scope; at first in Europe, later in the Americas, and then in Africa and Asia. Conditions favouring an oral culture weakened, and the immense mass of working people evolved away from self-made folk song toward the products of music hall, dance hall, and popular theatre.

Particularly in the early part of the 19th century in western and central Europe and the Americas, popular social song developed enormously in all its forms—sentimental, patriotic, comic, satirical. The remarkable evidence of the democratization on musical life, after the period of the French Revolution and with the growth of the industrial proletariat, was the appearance of the British music hall, which was to have an even more decisive influence on the trends of popular music than the cabarets of Paris or the operetta theatres of Vienna. The music halls first sprang up in the big industrial cities as workingmen's beer halls with entertainment. Gradually, during the second half of the 19th century, the entertainment became more important than the drinking, and the beer halls evolved into theatres-with-a-bar, providing shows that largely consisted of humorous, satirical, or sentimentally emotional songs, mainly of lower class life. In the earlier years of the 19th century, visiting entertainers from the British music halls were instrumental in stimulating the American entertainment industry that in a later time, in the domain of popular music as in other fields, was to become the dominant influence throughout the world.

Music halls

During the whole of the 19th century the process by which music "from below" in the social scale is taken over and formalized by educated composers for the benefit of a middle and even upper class audience was vigorously under way. Out of the topical songs and festive dances (the carmagnole, for example) of the French Revolution emerged the tradition of Parisian cabaret song and such boisterous gallops as the can-can. Describing these songs and dances as he experienced them in lower class city dives, the German poet Heinrich Heine wrote:

> They make fun not only of sexual relations but of bourgeois relations too, and of everything else that seems good and fair . . . patriotism, faith, belief, family relations, heroism and godliness in every shape and form.

This originally proletarian satirical tradition was transformed to provide the basis for the lively bourgeois operettas of Jacques Offenbach, Hervé, Charles Lecocq, and others.

Also powerful in its effect on the popular musical theatre was the less mordant, more sentimental Viennese tradition represented by the younger Johann Strauss and by Franz von Suppé. This tradition had derived much from the *Liedertafel* (sociable-song) movement of popular harmony-singing clubs and from waltz music that had grown out of the Ländler dances of the Austrian and Bavarian peasantry put into evening dress and performed amid the glitter of high bourgeois candelabra. This style even invaded the realm of fine-art music and reached its peak in Richard Strauss's opera *Der Rosenkavalier*.

Even in the less developed parts of Europe and in Central and South America, popular music was expanding and undergoing transformation. In Spain, flamenco music was growing away from its folk origins, becoming progressively more showy and exotic in the cabarets and small theatres that sprang up around the middle of the century, notably in the Andalusian seaports. In Lisbon, the fado developed in much the same way. About the same time in the Balkans, the emancipation of serfs and the weakening of the Turks' grip meant that many private orchestras belonging to nobles and officials—playing an orientally tinged music—were broken up. This released a flood of popular instrumentalists seeking employment in the restaurants and night spots of the towns and cities. The result was the stylized, urbanized idiom loosely called "gypsy music," in which—as with flamenco—the exotic aspects were often exaggerated to satisfy the customers.

In Latin America the great developments in popular music were in the domain of the dance. Fashionable travellers from Europe brought to Havana, Rio de Janeiro, Buenos Aires, and Lima the minuets, gavottes, schottisches, polkas, and waltzes of Paris and Vienna. In the upper class ballrooms, these dances would be performed as received, but as they seeped down to the lower classes—which, from the Caribbean to Brazil, were mainly comprised of Negroes and mulattoes—the dances and the music accompanying them became altered with the choreography, melody, and rhythm current among the working people, producing the rumbas, sambas, and congas that were later to invade the ballrooms and dance halls of North America and Europe and were to have great influence on urban popular music over some parts of Africa.

"Black" minstrel shows

In the United States, an important development toward the middle of the 19th century was the emergence of the blackface minstrel shows, with white performers disguised as Negroes presenting mainly a burlesque of Negro song and humour. Touring groups, such as Daniel Emmett's Virginia Minstrels, who made their debut in 1843, and the Christy Minstrels, who followed shortly after, gave widespread currency to a vast number of popular songs, some of which are still sung. Companies such as these, as well as the growing number of vaudeville theatres in the U.S. towns, promoted on a vast scale the compositions of such songwriters as Stephen Foster, the composer of "Oh! Susanna" and "Old Folks at Home"; Henry Clay Work (1832–84), who wrote "Marching Through Georgia" and "The Year of Jubilo"; and George F. Root, whose best known songs are "The Battle Cry of Freedom" and "Tramp, Tramp, Tramp." A more peripheral but ultimately influential development was the emergence of a stratum of rural musicians who became entertainers with medicine shows and on the country-town vaudeville circuits, playing a stylized music of folklore origin. It was these minstrels who laid the foundations for the powerful hillbilly "industry" and its subsequent analogues, country and western and bluegrass in the mid-20th century.

The 20th century. *Operetta and musical comedy.* In the early years of the 20th century, the upper, more genteel reaches of popular music were still dominated by European operetta and opéra bouffe (French light opera). This tradition, characterized by Jacques Offenbach and even more by Johann Strauss the Younger, was prolonged in the 20th century by such composers as the American Victor Herbert, who wrote some 40 operettas including *Babes in Toyland* (1903) and *Naughty Marietta* (1910). Prominent among Herbert's rivals were Rudolf Friml, born in Prague in 1879, and the Hungarian-born Sigmund Romberg (1887–1951), both of whom had emigrated to the United States in the early years of the century. Among Friml's greatest successes were *Rose Marie* (1924) and *The Vagabond King* (1925). Romberg is best remembered for *The Student Prince* (1924) and *The Desert Song* (1926).

Transformation into the "musical"

At the same time that these talented composers were producing their European-style works—sweetly lyrical, making heavy use of waltz time, and in the main presenting unrealistic and exotic subjects—a new kind of musical play known as musical comedy or just "musical," was emerging in the United States. It is a genre that is somewhat brash in character, with breezy rhythms, usually offering scenes of American life in relatively realistic terms. Representatives of this vigorous trend were Jerome Kern, whose *Show Boat* became a classic; and George Gershwin, who had a brilliant run of successes from *Lady Be Good* (1924) to the quasi-opera *Porgy and Bess* (1935). The boisterous folkways of the American frontier provided two outstanding successes in Richard Rodgers' and Oscar Hammerstein's *Oklahoma!* (1943) and Irving Berlin's *Annie Get Your Gun* (1946). More sophisticated and silken were the works of the composer-lyricist Cole Porter, whose urbane musical comedies skillfully combined the traditions of New York, Paris, and Vienna. Leonard Bernstein's *West Side Story* (1957) was a continuation of the tradition of realistic American urban musical comedy, begun in the opening years of the century by the vaudeville performer George M. Cohan, with such works as *Little Johnny Jones.*

Throughout the first half of the 20th century and to an ever increasing degree, the popular music of the cities and towns in a great part of the Western world (and ultimately, beyond) was nourished mainly from the United States, with songs from the musical shows and other lyrical pieces composed by such well-known musicians as those named above. Although most of these compositions, following the common fate of much commercial popular music, proved brittle and ephemeral, certain of them have lingered on over the years to become standard songs in the popular repertory.

Jazz. Most of the creations of the musical-comedy composers leaned heavily on the conventions of "serious" music for their idiom and the manner of their performance. Nevertheless, as the half-century progressed, they were more and more influenced by the world of jazz. Indeed, the most powerful development in the field of popular music in the 20th century has been the emergence of jazz as a commercially viable entertainment for a public of the broadest social range. Jazz developed first of all as a synthesis of European ballroom dance music (via ragtime), brass-band music, and the songs of black labourers (especially folk blues) and—to a less extent—white workers. It became such a powerful trend in mass music because conditions in post-slavery America favoured a synthesis of black African and white European music, attractive through its exotic colouring and informal atmosphere. Moreover, the growing drift of country workers into urban areas meant that a new current began to flow into the culture of the cities, always avid for novelty. At the same time, from the beginning of the 20th century the most propitious economic and technical conditions developed in America for the marketing of this new music, for adapting it to suit the tastes of various layers of society, and for stimulating its mass production, dissemination, and global export.

Ragtime and blues

Significantly, the first kind of jazz to make an impact on the broad popular music market was precisely the genre lying closest to conventional "serious" music, namely ragtime. The ragtime composers were mostly Negro pianists trained in European music, often men of considerable artistic pretensions. The structures of ragtime derived largely from French or American light-music models rather mechanically infused with syncopations from Negro tradition. Prominent among ragtime composers were Scott Joplin and James P. Johnson. With its basically conventional idiom, ragtime was easily absorbed into the mainstream of commercial popular music, and by 1900 Tin Pan Alley—the professional purveyors of U.S. popular music—had taken it over. As early as 1899, a writer in *Musical Record* forecast "Ragtime will find its way into the works of some great genius and will thereafter be canonized," as if he foresaw Debussy's "Gollywog's Cakewalk" and Stravinsky's "Ragtime."

Only a few years later a deeper, more spontaneous and folk-rooted component of jazz, the blues, entered the popular music market by way of professional women performers on the music-hall stage. The pioneer blues singer "Ma Rainey" (Gertrude Pridgett) obtained her first engagements in 1902, and subsequently, in company with such singers as Bessie Smith and Bertha Hill, established a bold, expressive, essentially professional style that some call "classic blues." Eventually, however, in diluted and polished forms, with its realistic passions replaced by the poetry of bourgeois dreams, the blues was adapted for general show-business exploitation, whether in the most expensive night clubs or in the cheapest suburban dance halls. For all that, it was the lyrical dance music of small jazz bands rather than the piano rags or vocal blues that attracted the attention of large-scale commercial promoters. After 1910, as jazz music and jazz musicians moved northward from such centres as New Orleans to the large cities such as Chicago, Kansas City, and New York, elements of jazz flowed easily and to an increasing extent, into the "sweet" popular music that was the dominant product of the entertainment industry. Prominent among Negro composers who profited from the discoveries and inventions of a great army of nameless jazzmen, black or white, is Duke Ellington (1899–), whose compositions over the last half century have moved progressively closer to the realm of "serious" music. As far as the mainstream of popular music is concerned, the vitalizing effect of jazz was most felt on the standard popular lyrical song, with its 32-bar AABA chorus, the great mainstay of the 20th-century light-music industry.

It should be recognized that jazz is not a single category but a whole sphere of popular music, ranging from light salon music (Glenn Miller), "big band" dance music (Count Basie), popular symphonic (certain works of Gershwin and Ellington), to a kind of chamber music (Modern Jazz Quartet) or even to a form of musical Dadaism (Charles Mingus).

Folk- and jazz-derived styles. Jazz was not the only music coming up "from below" to mingle with and ultimately to affect the direction taken by popular music in the 20th century. Just as, in the lowland South, the rapid industrialization of the post-World War I period in the United States had resulted in the emergence of the predominantly Negro hybrid music called "jazz," so in the upland South—primarily in the Appalachian and Ozark Mountain regions—similar factors produced the predominantly white hybrid music called "hillbilly."

"Country music"

For much of the 20th century this music played but small part on the general scene of popular music. Shortly after World War I a number of the newly established U.S. country radio stations began to draw on the growing tradition of hillbilly musicians, interspersing local advertising with brief musical interludes provided, often free, by performers appearing in the neighbourhood. By 1924 it was realized that there was even a Northern market for this music; the first successful Barn-Dance program was established on WLS Chicago, mainly using country musicians from Kentucky. Around the same time the recording industry began to interest itself in the music, intending to issue discs mostly for sale in rural crossroads stores. To their surprise, they soon found there was some national demand, at first modest, for the product. Unlike jazz, which was based chiefly on wind instruments, hillbilly music relied on strings. Instruments such as violin, guitar, and banjo had become widely available in rural areas through urban contact and mail-order houses and were found to be relatively cheap, easy to combine in ensemble, and well-suited for a repertory that had grown to a large extent out of folk-fiddle music.

By the 1930s the place of "country music" was consolidated in the mainstream of popular music. The repertory of performers of "country music" represented a jumble of music deriving from folk-dance tunes, white adaptations of Negro blues, the sacred songs of fundamentalist Protestant sects contrasted with lyrics of drink and violence, ballad-like accounts of railroad disasters and hard times in the cotton mills, and, above all, a range of songs of commercialized pathos treating of dying mothers, orphaned children, bereft lovers, and lonely men far from home. During World War II "country music" expanded enormously through intense promotion by the popular entertainment industry, probably because the strong nostalgic bias of the music was particularly appealing during a time of wide-scale shifts of population into urban industrial plants and the armed forces.

By the mid-1950s, two contrasting styles of "country music" had become dominant: on the one hand, the Southeastern tradition had hardened into the impetuous "bluegrass" forms, giving prominence to a virtuoso five-string banjo style (perfected from North Carolina folk tradition by Earl Scruggs). On the other hand, the Southwestern tradition, less folkloric, more pliant, happily accepted elements from a metronomic, jazz-influenced city Negro blues backed by a heavy thumping bass (called "rhythm and blues"), and from this amalgam, rock 'n' roll emerged.

During the 1950s, the growth of a profitable market among adolescents, combined with the invention of electronic instruments allowing the easy production of a powerful and impetuous sound, stimulated the enormous diffusion of rock 'n' roll music, which relies largely on amplification for its exciting effects and which proved irresistible to many young people throughout the world. Subsequent modifications of "pop" music have retained the metronomic quality present in the music of Elvis Presley and later rock 'n' roll performers, but have also reinforced its blues ingredient. Rather paradoxically, what was originally an intensely American kind of popular music was to find some of its most characteristic modifications and its greatest commercial successes in England with such performers as the Rolling Stones and most notably and influentially with the four young men who comprised the group known worldwide as the Beatles.

Toward the end of the 1960s, a new force began to enter the world of professional popular music, coming mainly from the white middle class, particularly the more libertarian fringes of the intelligentsia. This music was derived in large measure from a parody of the blues, with the old Negro slum preoccupation transposed into bourgeois terms, complaining of spiritual rather than material deprivation and commenting, at times frenetically, on the general dilemmas of the world rather than on personal domestic tragedies. In its various nuances such as folk, acid, and hard rock, this form of music, sometimes called "Progressive Pop," existed successfully alongside the more conventional popular music, at times approaching the aleatory fragmentation characteristic of some present-day "serious" music.

Urban blues and "soul" music

Concurrently, the folk-rooted blues tradition persisted in the cities, reflecting the culture of the Negro ghetto-dweller, yet appealing also to audiences beyond the ghetto. The older city blues evolved into the urban blues style, marked by freer vocal phrasing and, often, larger, more electronically amplified ensembles; and, through urban blues, into "soul" music, which fuses blues with jazz and gospel music influences.

Initially formed mainly in the south and west of Europe, Western popular music has gradually spread throughout the entire world, at first to the ends of Europe, then to the colonized Americas, then to the cities of the Orient, and now into the maize and paddy fields and even the jungles of peoples who had hitherto remained primitive. The rise of the United States to a position of economic and political power accelerated the process by which Western popular music replaces the proper musical arts of Asians, Africans, and other peoples, a process already begun with the weakening of tribal and feudal traditions and the introduction of formal education through Western colonialism. Missions, schools, trade, radio, films, development aid projects, have all played a part in encouraging a taste for Western popular music. At the same time, throughout the Communist world, sovietization carried the more formal idioms of popular European music across a vast area of the globe, acclimatizing it by means of political rather than commercial propaganda.

Throughout the Communist world, popular music has become mainly identified—at least officially—with stylized folk music performed in a diluted manner, while in the Western world and throughout the sphere of Western influence, jazz music has seemed progressively to shrink into an intellectually rarefied atmosphere, replaced in the affections of the younger mass audiences by the emotional and musical simplifications of rock 'n' roll and its successors. Musical comedy, in theatre and in motion pictures, was still vital in the 1970s, but salon music was fading. For the global intrusion of Western popular music, the Orient extracted a mild revenge, with the introduction in the 1970s of one or two Eastern instruments (such as the sitar) and a few tentative Oriental intonations into popular instrumental ensembles of both the U.S. and Europe.

BIBLIOGRAPHY

General works: WATER WIORA, *Die vier Weltalter der Musik* (1961; Eng. trans., *The Four Ages of Music*, 1965), a concise and penetrating account of the evolution of music through four great periods—prehistory, antiquity, the growth of Western music, and the era of global industry—that sets the development of popular music clearly within the framework of general musical culture; REGINALD NETTEL, *Seven Centuries of Popular Song* (1956), a social history of English popular (as distinct from folk) song from the Middle Ages to the era of ballroom jazz (handy for the layman); S.G. SPAETH, *A History of Popular Music in America* (1948), a broad panorama of popular songs and the musical theatre from colonial times to the mid-20th century.

Specialized works: WALTER SALMEN, *Der fahrende Musiker im europäischen Mittelalter* (1960), a comprehensive social-historical study of the way of life of itinerant professional minstrels throughout Europe in the late Middle Ages, with a musicological account of their vocal and instrumental repertory—the best account of this important and little-understood class of popular musicians; C.M. SIMPSON, *The British Broadside Ballad and Its Music* (1966), a monumental reference work that relates some thousands of broadsides from the mid-16th to the early 18th century to the 500-odd

tunes for which they were designed; ANDRE HODEIR, *Hommes et problèmes du jazz* (1954; Eng. trans., *Jazz: Its Evolution and Essence*, 1956), an analytical work for the musically educated—brilliant, if a little overbalanced toward the modernist viewpoint; M.W. STEARNS, *The Story of Jazz* (1956, reprinted 1970), a serious study, regarded by some informed critics as the only history of jazz worthy of the name; B.C. MALONE, *Country Music U.S.A.* (1968), a broad-based account of the development of white rural professional music from its humble origins to its present state as large-scale commercial entertainment; CHARLES GILLETT, *The Sound of the City* (1970), an exhaustive survey and acute analysis of the emergence and growth of rock 'n' roll, and the consequent global changes in commercial popular music.

(A.L.Ll.)

Popular Theatre

To engage in an act of theatre, a living performer does not need a specially designed building nor elaborate equipment nor a written text nor a high artistic aim; all he needs is a place, a time, an audience, and himself. Performers in music hall, vaudeville, burlesque, follies, revue, extravaganza, circus and sideshow, musical comedy, and the like are as much a part of the theatre as those who appear in what is sometimes—rather grandly—called the "legitimate," "high," or "artistic" theatre. The singers, dancers, comedians, clowns, puppeteers, jugglers, acrobats, conjurers, ventriloquists, and others who make up their number refer to their profession as show business, or "show biz," and their unashamed intention is to please and astonish their audiences by the display of some special visual, vocal, or physical skill. They provide what the director Sir Tyrone Guthrie called the "theatre of delight," and they are part of a popular theatre that has at times itself been of the highest importance in the history of world theatre, reaching its peaks in the theatre of ancient Greece, in that of Renaissance England and Spain, and in the commedia dell'arte tradition of 16th- to 18th-century Italy. Outside the West, the Japanese Kabuki theatre, various kinds of puppetry throughout Asia, and certain other forms of Oriental dance or of dance-drama are examples of popular theatre that also achieve the status of high art. The present article considers popular theatre in terms of its impulse to generate exuberance and joy, the nature of its audiences, and its capacity for change; it then examines the basic ingredients of most popular theatre and concludes with a section on its internal continuity and its impact on other kinds of theatre. Popular theatre is set within the larger context of theatre art in the article THEATRICAL PRODUCTION, and its history side-by-side with "high" theatre is sketched in the article THEATRE, WESTERN and in general articles on the arts of other cultures. Its ability to transform sometimes crude facilities into a theatre is noted in the article THEATRES AND STAGES. For other general information, see THEATRE, ART OF. For more detailed articles on certain forms relevant to popular theatre, see CIRCUS; COMMEDIA DELL'ARTE; MIME AND PANTOMIME; MUSIC, THEATRICAL; PAGEANT AND PARADE; and PUPPETRY.

The people of "show biz"

SCOPE AND CHARACTER

Popular theatre adheres to the core of theatrical tradition in three crucial ways. First, it involves performances by one group of persons for another; second, it demands that the performers acquire at least a minimum of skills relevant to their activities on stage; and third, it usually follows an agreed-upon sequence and reaches a set conclusion. The last of these factors eliminates athletic or sporting events, which otherwise are skilled performances—a kind of "theatre of improvisation" or chance. With the almost certain outcome of the bullfight, however, an approximation of ceremony is achieved. (Religious ceremony may involve all three of the conditions, though a close analysis of the relation between religion and art will distinguish performance from ceremony, as well as the impulse to create a work of art from the impulse to worship.)

The notion of popular theatre should also be examined with reference to its basic impulses, its audiences, and its proclivity to change. Popular theatre has almost always involved an expression of physical pleasure and exuberance—indeed, of joy—that can be distinguished from the pleasure of the intellect or spirit. The harvest songs of praise and thanksgiving from which a primitive "theatrical" activity emerged were, among other things, expressions of joy that physical labours were finished and that physical needs were provided for. With regard to the makeup of its audience, popular theatre, in general, continues to be as broadly based as the theatres of Shakespeare or Classical Athens. Peasants doubtless used to watch the jugglers and comedians at a local fair in order to find momentary release from their toil, much as the intellectual today finds recreation in the circus or in the basement café, with its guitarists and folk singers. In the matter of change, fashion and taste prevail here as elsewhere in the arts: such forms as music hall, burlesque, and vaudeville have largely been replaced by various kinds of nightclub and television entertainment. Another kind of change occurs when a popular form is transformed into a more sophisticated brand of entertainment, less appealing to a broad public. The once widely popular art of the mime has been brought to a brilliant polish by such practitioners as Marcel Marceau in France, yet its audience has become restricted to a relatively small coterie. Puppetry, often a joy to persons of all ages, is now almost exclusively a children's entertainment in the West. On the other hand, the musical comedy, as it is understood in the mid-20th century, has drawn upon a long tradition of song, dance, and narrative to emerge as an art form in its own right while yet retaining its popularity and drawing its audience from a broad cross section of society (although the costliness of its presentation and the consequently high admission prices often exclude less affluent patrons).

Expressions of exuberance and joy

THE INGREDIENTS OF POPULAR THEATRE

Throughout its history popular theatre has made use of physicality and music as direct means of communication. The two are not always distinct; the movements of the dance, for example, are both physically and musically expressive.

The physical element. The physical element in popular theatre most often presents itself through eroticism, through distortion, or through the acrobatic.

Eroticism. The pre-theatrical ceremonies, characterized by excess, that accompanied spring and harvest festivals appear to have influenced the development of comedy in Classical Greece, where indecency and lewdness were integral parts of comic performances. In Roman times, the highly popular mime made such play of gross indecency that after the triumph of Christianity in the West during the 5th century AD this and all other forms of theatrical activity were officially banned. Theatrical traditions, however, were kept alive by itinerant bands of players, whose repertories undoubtedly made use of eroticism, though probably in humorous form. It was probably also eroticism, disguised as temporary lunacy, that was responsible for the dance manias that sometimes seized entire communities during the Middle Ages; and, as sentiment, it certainly pervaded the cult of chivalry and informed the songs of the troubadours and other wandering minstrels. Court entertainments in the 15th and 16th centuries, which evolved into ballet, tried to achieve in living form the idealized image of the human body that was represented in ancient Greco-Roman statuary. But the general direction taken by ballet tended away from the erotic. In spite of the glorification of the ballerina throughout the 19th century and the introduction of erotic themes in modern ballet, the form has virtually desexualized dance or else has taken sexuality into a rarefied realm outside that of popular theatre.

Influence of Greek spring and harvest festivals

It is the female figure in rhythmic motion, however, that has epitomized the erotic element from earliest times. In the 19th century, female dancing became an essential ingredient of popular theatre in four similar manifestations: revue, vaudeville, music hall, and burlesque. The first two, almost identical in form, go back in spirit to medieval France: the revue to street fairs, during which the past year was reviewed in satiric song and skit;

Revue, vaudeville, music hall, and burlesque

vaudeville to similar sources that, in the 18th century, were adapted to accompany the production of short pantomime plays by itinerant players. Revue and vaudeville had as many variants as there were companies performing them; their many offshoots tended either toward greater vulgarity or else toward greater refinement. Whereas the revue became most closely associated with France (though it provided the model for the "follies" type of show in most Western countries), vaudeville became most associated with the United States, in which it passed from a condition of low repute in the early 19th century to that of respectable family entertainment.

In England, the traditional music hall was virtually identical with vaudeville, originating in the "music annex" of working class alehouses but becoming standard fare for all classes of society. All three forms generally offered a variety of short pieces—sentimental and patriotic songs, dances of all kinds, comedians, humorous or pathetic skits, magicians and jugglers, tightrope walkers, and other acrobats. In burlesque, however, there was an insistent emphasis on the female dancer, and in the 1920s striptease became part of the entertainment.

Distortion. The gross deformity of a malformed body has often been used as a source of entertainment: theatrical wonder resides in the body itself rather than in anything it may do. People flock to such sights, perhaps as a means of alleviating their personal sorrows through a reminder of the greater misfortunes of others.

Fascination with deformity has a long history, social as well as theatrical. Primitive societies might either destroy or deify their defectives; barbarian people of odd appearance were herded along, strangely garbed, in the triumphal processions of the ancient world; dwarfish or humpbacked jesters, whether clever or dull-witted, provided kings with entertainment or served as butts for derision; genetic or birth defects resulted in people being called "village idiots" or in their being exhibited in circuses and sideshows; and the humour of "differentness" is still exploited by comedians who caricature, for example, a foreign accent or ethnic cliché. At the fullest artistic exploitation of distortion, Shakespeare often made his fools speak with greater understanding or compassion than did their masters.

Humour itself may be a distortion of reality—sometimes crude, as in the pratfall and the slapstick, sometimes kindly, as in the satires of a revue sketch, and sometimes corrosive, as in the barbed mockery of a modern-day "stand-up comic." Although at times humour reaches so far past the physical that it attains the sophistication of wit, it retains a basically physical impact. Its effect—earthy, ribald laughter—has been sought in all kinds of theatre, no matter how "serious," while the greatest playwrights have been able to blend the humorous and the serious in their reflection of life.

Use of the mask

On another level, distortion has served to generalize, to wipe out what is particular to the individual personality and to substitute a universal face that can be funny, pathetic, tragic, or anything else. The mask is the traditional means: wearing it, the performer is depersonalized, his character more obviously seen as symbolic. The Greek tragic and comic actor, the ancient mime, the Nō actor in Japan, the Harlequin and Columbine and Capitano of the commedia dell'arte all used the mask to diminish themselves and to extend their significance. Perhaps the ultimate mask is that of the puppet, where the individual is abandoned altogether. Sometimes a performer, playing in the popular tradition, adopts a private mask of such universal significance that the gap between popular theatre and high art is bridged. Outstanding examples in this connection are Charlie Chaplin's Little Tramp and Buster Keaton's deadpan mask of Everyman.

The acrobatic. The West seems to have lost almost all touch with the experience of magic, especially that of the shaman, the prophet-priest-medicine man whose intense and disciplined training allowed him to mediate between the people of his tribe and the mysterious, invisible forces of nature and who was also a physical and spiritual healer. His skills probably included almost the entire repertory of a modern circus. Many qualities invested in him survive in the West in a fragmented form. All artists, to a greater or lesser degree, follow a regimen such as that of the shaman, disciplining body and mind to the unique demands of their art, and all art may be said to reveal characteristics of the old magic: it excites wonder. Ballet dancers, opera singers, and musicians must keep their various instruments in fine tune, and actors must keep alive the openness that allows many voices to speak through them.

Nowhere, however, is there a greater and more conscious attempt to transcend the limits of the body, to attain an ever more astonishing level of accomplishment than in the art or craft of the acrobat, whether he is a juggler, a tumbler, a trapeze or high-wire artist, a knife thrower, an equestrian, an ice skater, or even a magician-prestidigitator. The shaman, whose maskings and whirlings were a precursor of drama and dance, was not, of course, a performer in the theatrical sense. Nor were his actions and feats carried out as demonstrations of prowess, as ends in themselves. Yet, in the desire to perform an act far beyond the reach of the average person or at least to create the appearance of stretching the human body beyond its capacities into some unknown new area, the acrobat and the prestidigitator retain some small element of the shaman's magical powers of casting spells. Like the shaman, the acrobat must punish his body to attain his skill, and his concentration must be absolute; for one inexpert move or one flicker of inattention can destroy him. And the drumbeats of the shaman to get the attention of the gods might be compared, in their effect on their human audience, to the drum rolls that intensify the suspense surrounding the acrobat's preparation for his next astounding feat of skill and daring.

Such displays of physical skill have been a mainstay of theatre from its earliest days, though they have been granted little esteem as artistic endeavour. With the demise of vaudeville and the music hall, they have retreated to the circus, the sideshow of the carnival or county fair, the ice show, and the television studio.

The importance of music. Few experiences in the theatre can equal the uncomplicated and unabashed enjoyment of "singing along" with the entertainer, whether in a crowded taproom with only an upright piano or in a gilded auditorium with a large orchestra. Indeed, there is little else that can encourage interaction between audience and performers as can music, the very presence of which tends to remove any pretense of realism, thereby joining performer and viewer even more closely in a shared event. Apart from its occasional function as a background accompanying other skills, music in the popular theatre has been employed chiefly in various kinds of musical-dramatic performances, from which today's musical comedy has evolved; in song-and-dance routines characteristic especially of the minstrel show and of vaudeville and its relatives; and in the stage singing and instrumental playing of cabaret, jazz, country-western, folk, rock 'n roll, and other "pop" performers who have gained favour at various times in the 20th century.

The effect of music

Musical drama. Musical comedy, as it is known today in the West, has had no straight line of development but has emerged from a wide variety of musical, dramatic, and dance styles. The use of relatively simple ballads to reinforce the narrative or dramatic structure of a play was known to the Elizabethan dramatists and was very popular during the early 18th century in works like John Gay's *The Beggar's Opera*. The tradition of Viennese operetta and that of the English comic operas of Gilbert and Sullivan was exploited in the United States in the early 20th century and Americanized in the musicals of Jerome Kern and others. *Oklahoma!*, in 1943, saw the introduction of balletic dancing and a tighter unity of song, dance, humour, and narrative, while in the late 1950s a more serious vein began to appear in such works as *West Side Story* (1957), *Man of La Mancha* (1965), *Hair* (1968), and *Company* (1970).

Song and dance. The entertainer known as a "hoofer," who could satisfy an audience by executing a good song-and-dance routine, was thought especially important in vaudeville and the music hall and on the showboats

that carried live entertainment down the rivers of the U.S. Middle West and South during the 19th century. Also in demand were sentimental and patriotic singers, including much-loved personalities such as Yvette Guilbert and Maurice Chevalier in France; Florrie Forde, Sir Harry Lauder, and Marie Lloyd in Britain; and George M. Cohan and Al Jolson in the United States. The work of such performers is inextricably linked with the history of show business in the late 19th and early 20th centuries, when entertainment became big business. In these decades, with improved communications in most Western nations, professional entertainment became widely available, most of it under the control of a few great theatrical empires that were created around 1900. London, Paris, New York, and other centres became the hubs from which variety and dramatic companies toured provincial theatres. Internecine warfare was practiced to control both talent and theatres: finally, one circuit tottered, then another, until the motion-picture industry began to grow, restricting the living theatre to urban areas.

The heyday of show business

Songs and instruments. "Pop" singer-guitarists and nightclub crooners are part of "show biz"—the latest in a line of singing entertainers that stretches back for centuries to the balladeer. Remnants of very ancient ballad traditions still exist, mainly in isolated regions of less industrialized nations. The urbanized West, however, has received watered-down versions of the old or musical materials manufactured to order (and to formula) through a commercial and competitive branch of show business once known as "Tin Pan Alley."

The advent of the phonograph and its major allies, radio and the jukebox, has increased demand for this kind of popular theatre in live form. In a small town, it is easier to bring together a number of players and a singer than to gather the diverse talents needed for a vaudeville show or a play, and such a group has an assured appeal, especially among the young. The modern balladeers, however much their art may fall short of the epics of Homer or the lyrics of the troubadours, continue to sing of love and peace as their ancestors sang tales of tribal wars, heroes, and heroes' loves. The erotic is often brought into play here, as, sometimes, is humour, while not infrequently the listeners respond with dance—as in those pretheatrical tribal ceremonies when performer and audience were one.

CONTINUITIES AND IMPACTS

Remnants of the popular theatre. Throughout much of the West and in other regions of the world in which Western (especially U.S.) influences have been strong, traditions and instances of live theatre seem to be on the wane despite public and private efforts to inject new life onto its stages. The traditional face-to-face confrontation of performer and audience has generated spontaneity and joy, however shopworn the materials. But the sweeping technological advances of the 20th century have altered, in a few decades, the centuries-old traditions of popular theatre. Circuses and ice shows may visit large cities once or twice a year; a vigorous puppet theatre may help to enliven the arts in a few areas of the world; various entertainments in cabarets, clubs, discotheques, and theatres still may be quite widely available. But the overwhelming proportion of what was the live popular theatre, both physical and musical, now comprises a major part of television's grist. Whether audiences and performers experience the same spontaneity and joy is doubtful. No matter how physically rambunctious, suggestive, or broadly satirical television may aspire to be, it remains hobbled by various kinds of censorship in ways the live theatre outside the family living room rarely was.

Popular theatre as the grist of television

Popular and literary theatre. Of the countless thousands of performers who have worked in the theatre, the great majority have done so only to make a living or to satisfy some personal drive to showmanship. Their displays of acting, singing, or acrobatics that have been given today must be repeated tomorrow. Before the arrival of film, only the playwright could survive in anything more than reputation. Popular theatre, with little or no literary base, has had to rely on tradition passed from one generation of performers and audiences to the next.

In his book *The Empty Space*, English director Peter Brook has linked popular theatre with what he calls the "Rough" theatre, saying of it that in the many forms it has taken there has been one constant factor:

> . . . a roughness. Salt, sweat, noise, smell: the theatre that's not in a theatre, the theatre on carts, on wagons, on trestles, audiences standing, drinking, sitting round tables, audiences joining in, answering back: theatre in back rooms, upstairs rooms, barns; the one-night stands, the torn sheets pinned up across the hall, the battered screen to conceal the quick changes—that one generic term, *theatre*, covers all this. . . .

Brook relates it to the freedom of Shakespeare's theatre, and contrasts it, by implication, with the respectable sterility that stifles much of today's legitimate theatre (which he dubs "deadly"). The "Rough" theatre, however, has consistently given refreshment and inspiration to the more "serious" theatre with which it exists side-by-side. In the present century, for example, such a director as Joan Littlewood in England has made uninhibited use of its sometimes vulgar but always vigorous current, borrowing its immediacy and excitement. Toward the end of his life Bertolt Brecht in Germany urged that the theatre must rediscover its naivety: his work had already borne witness to his point of view. The small and deliberately tinny orchestra that accompanied his *Threepenny Opera*, for example, was reminiscent of the limitations that a small cabaret might impose, and the format of this and many other of his works had much in common with a series of loosely linked vaudeville skits. Brecht's theory of dramatic alienation, formulated with the aim of forcing his audience into an objective analysis of the drama, owes a good deal of inspiration to fairground entrepreneurs, whose frank and unabashed methods of presentation are far removed from the comfortable theatre of illusion, where audiences are encouraged to sink back into a world of make-believe and think it "real." The clown and the jester of popular theatre, too, their comic images and antics turned to grimly serious purpose in the works of such playwrights as Samuel Beckett and Eugène Ionesco, still play a significant part in modern dramatic theatre, just as they did in the plays of Shakespeare and of Molière.

BIBLIOGRAPHY. Since popular theatre as discussed in this article is not a generally recognized genre, no critical study has been applied to the area as a whole; the closest is ABEL GREEN and JOE LAURIE, JR., *Show Biz* (1951, reprinted 1971), the story of show business in the United States for most of the 20th century as seen through the eyes of the industry's "bible," the weekly newspaper *Variety*. M. WILLSON DISHER has written extensively on aspects of popular theatre, especially *Music Hall Parade* (1938), *Blood and Thunder: Mid-Victorian Melodrama and Its Origins* (1949), and *Pleasures of London* (1950). ENID WELSFORD, *The Fool: His Social and Literary History* (1935); and DOUGLAS GILBERT, *American Vaudeville* (1940), remain valuable. *The Journal of Popular Culture* (quarterly) is a rich resource. Numerous motion pictures have probed into facets of show business; especially perceptive are *The Blue Angel* (German, 1930) and *The Entertainer* (English, 1960). Books containing more general discussions include MARTIN ESSLIN, *The Theatre of the Absurd*, rev. ed. (1968); PETER BROOK, *The Empty Space* (1968); and THEODORE ROSZAK, *The Making of a Counter Culture* (1969), especially ch. 8, "Eyes of Flesh, Eyes of Fire."

(G.W.W.)

Population

Any population, whether human or animal, constitutes a collection of elements modified by increases (births and immigrations) and losses (deaths and emigrations). A "natural" human population—that is, one that is unable to cope with death by means of efficient therapeutic methods or with birth by means of birth control and that is restricted to one geographical area—will find itself in approximately the same position as an animal population. Such a population will be unable to expand beyond a certain total; a herbivorous population, for example, will be roughly limited by the annual growth of grass. For purposes of illustration, it is helpful to consider a population, originally small, living in a restricted natural environment. Such a population increases because of its

multiplying powers, its birthrate being superior to its deathrate; at a certain stage it reaches a degree of saturation (lack of food, water, or other necessities) that results in an increase of deathrate, often accompanied by a decline in the birthrate; at some point the population reaches its position of equilibrium within the environment and it fluctuates in the neighbourhood of this maximum under the effect of the seasons (heat, humidity, and so forth), of diseases, or of other tribulations that may temporarily afflict it.

This "natural" balance can be lastingly modified, either through a change in the environment or through a change in the species. The environment may improve or deteriorate, mainly under the influence of the climate. The species may become better adapted to the natural environment, with a resulting increase in its maximum number; however, if such progress allows the species to consume its own capital (for example, by exterminating the prey upon which it lives) the results may be fatal.

Fertility

In addition to the conditions for natural balance other factors affect human populations. Some of these involve *fertility*—*i.e.*, the actual frequency of births in a population—as distinguished from *fecundity*, or a population's ability to bear children. (In French and other Latin languages, demographers tend to reverse the meanings of these terms—*fécondité* meaning "fertility" and *fertilité* meaning "fecundity.") It has been estimated that if all of the couples in any given population were to reproduce from puberty through the woman's menopause at an approximately natural rate, the population would multiply about six times every generation. The reasons that the human species has never actually achieved this rate of multiplication, however, are the following: (1) a fraction of the population does not marry or procreate; (2) not all males and females couple upon reaching puberty; (3) some couples are separated by death or by some other cause; and (4) the new generations are reduced in number by death before all of them, in turn, reach puberty or the age of procreation. In a natural population this last factor alone is enough to decrease the rate by more than half.

It is not easy to separate completely the biological and sociological factors listed above and to imagine a population that might use its powers of fecundity to the full. Theoretically, the only system allowing such total use might be a kind of human stud farm. In actual fact, random or promiscuous mating does exist among certain populations, but always in conjunction with very poor hygienic conditions that compensate for its generative advantages. Practically speaking, the matrimonial system that puts the multiplying powers of the human species to the best use is usually thought to be monogamy; a clear historical illustration of this is given by the French Canadians who, within three centuries, increased from some 3,000 initial inhabitants to several million.

Mortality

Another important determinant of population is mortality, or frequency of death, as it relates to average life-spans. In a human population that does not suffer from chronic excessive hunger or from overwhelming disasters but does exist under conditions of poor hygiene and inefficient therapies, the average life-span of an individual is some 25 or 30 years. In addition to this more or less natural mortality experience, human beings also experience an accidental super-deathrate, which may stem from disasters of nature (floods, changes of climate, etc.) but more generally appears under three conditions: acute famine, epidemics (from exterior sources), and wars or massacres. These three scourges can, in fact, be found to interlock, with war often provoking a state of famine, an epidemic spreading more easily among an undernourished population, and so on.

Finally, it is a fact that human populations are not merely arithmetical totals. They are characterized by variations in total numbers and also by changes in structure, including changes in the distribution of ages, occupations, and various qualitative, physical, and intellectual attributes (such as average or predominant height, weight, blood types, colour, nationality, intelligence, and level of education).

I. History of population

PREMODERN AGES

Until the contemporary period, the total population of the globe throughout millennia in general experienced a slow increase in numbers, with occasional, sudden periods of regression in numbers, in most cases following such phenomena as wars, epidemics, and famines.

Among primitive cultures and in ancient civilizations fertility was usually honoured, probably for the very reason that life is opposed to inevitable and yet so dreaded death. This feeling, which today is still strong among certain rural populations, nevertheless yielded to other considerations in the Greek republics. Ancient Greece was the first known, and relatively well-assessed example of a population that declined for reasons other than catastrophes—namely, because the culture favoured the family practice of having few children and, in fact, even favoured celibacy. The politician and historian Polybius actually denounced the decline of procreation in Greece, considering it tantamount to suicide.

That the concept of birth control existed in the earliest days of the Roman Empire seems evident in the fact that the emperor Augustus instituted laws to encourage marriage and, above all, childbearing. Although no proof exists, birth control, along with other Roman influences, may have spread throughout the empire beyond Rome. In any case, if the imperial population had been governed by natural multiplication, it should, in four centuries, have increased so sharply as to swarm out beyond the borders or, at least, to have densely populated the existing territories of the empire. But it did not, for there was a shortage of men to face the barbarians, themselves undoubtedly relatively few in number. Even the recurrent and widespread plagues, particularly from AD 166 to 180, do not satisfactorily explain the shortage.

Another ancient country, China, whose demographic history remains to be written, seems to have been densely populated from very early times; overpopulation was commonly deplored by ancient Chinese writers.

From the fall of the Roman Empire to medieval times, Europe was beset by massive invasions and by vast disorder and destruction, and populations tended to decline. Beginning with the 9th century, however, a certain degree of human stabilization and some signs of progress may be observed in Europe. These became more evident in the course of the 11th century and are almost certainly confirmed by the Crusades, which could not have been undertaken by sparse populations. The 14th century, on the other hand, was a time of severe crisis, which stemmed from famines and wars and particularly from the Black Death, the plague that ravaged all of Europe from 1347 to 1351 and resulted in a mortality varying in the different regions between one-eighth and two-thirds of the population; on an average it may possibly have killed off as much as one-third of the population. After some increase in population during the 15th century there ensued an uneven period, a time of bloody wars and the beginnings of emigration away from Europe. On the American continent the demographic contribution of the white man was at first often more than offset by the decline of the native populations, which were subject to decimation and massacres, new diseases introduced by Europeans, and expulsion from their homes and customary means of livelihood. As contacts with the other parts of the world became more frequent, Africa was revealed as a half empty continent and Asia as a teeming mass of human beings.

The 17th century was marked by two important additions to knowledge: in 1662, one John Graunt established the first genuine table of mortality, and various other authors estimated the world population (a Dutch scholar, Isaac Vossius, suggested a figure of 545 million).

THE MODERN ERA

The first demographic revolution

In the 17th century all populations, even those of western Europe, could, from a demographic point of view, still be described as "natural." Medical knowledge had made great strides in anatomy and physiology, but not in therapy, and the efficiency of antimortality techniques as a

whole was negligible. At the same time, contraceptive practices, as well as being inefficient, were reserved for so small a fraction of society (prostitutes and the aristocracy) that they had no influence upon global statistics. The normal annual deathrate reached 30 to 35 per 1,000, and the birthrate approximately 35 to 40, limited by partial or total celibacy. Thus from the earliest days of mankind, its biological conditions had scarcely changed.

This was the period that witnessed the start of a far-reaching transformation—known as the demographic revolution—which was to modify the life and reproduction of the species, thanks to a significant decline in both the deathrate and the birthrate. This transformation would have two phases, first among the advanced countries, and later throughout the rest of the world.

Decline of the deathrate in the West

Changes in the Western world to the 1930s. In the course of the second half of the 18th century, with such innovations as smallpox inoculation and vaccination, therapy became more efficient. A slight decline in the deathrate had occurred even earlier, however, as a result of improved hygienic conditions and, possibly, of improved food supplies. Furthermore, the super-deathrate from acute famine and epidemics virtually disappeared during the 18th century in western Europe because of agricultural advances, international trade that improved the availability of all resources, and better hygienic defenses (the famine of 1847 in Ireland was atypical). It was also in the course of the 18th century that epidemics of the plague ceased in western Europe, though they persisted for long periods of time in the less developed countries—as did cholera, which persisted even in Europe until the middle of the 19th century.

The decline of the normal deathrate became notable toward the end of the 19th century, after Louis Pasteur's experiments and the discovery of various vaccines; but it was a phenomenon still restricted to developed countries. On the eve of World War I, expectation of life was over 50 years in the most advanced countries.

Although the decline of the birthrate started in France at about the same time as the decline of the deathrate (because of the spread of contraceptive practices, particularly the use of the condom and coitus interruptus), the decline was experienced only much later in the rest of western Europe. In England the birthrate did not begin to decline before about 1875. Because of this time lag of nearly a century between the decline in the birthrate and that of the deathrate, Europe's population increased at a tempo hitherto unknown, at least over any long period of time and over such a vast area. The natural rate of increase of 1 percent was frequently exceeded. Even with the heavy emigrations to the Americas between 1801 and 1901, populations increased from 11,000,000 to 38,000,000 in the U.K., for instance, and from 25,000,000 to 56,000,000 in Germany.

Decline of the birthrate in the West

After 1875 the decline of the birthrate became more pronounced and spread to all the developed countries. A few typical rates are shown in Table 1. Birthrates reached their lowest levels in the course of the 1930s. Generations no longer provided their own successors, and there was already being advanced the theory of a permanent decline of the Western races. The decline was accentuated by the economic depression.

Table 1: Annual Births per 1,000 Inhabitants

	France	U.K.	Germany	U.S.
c. 1880	24.6	33.9	38.0	36.0
c. 1900	21.4	28.5	35.0	30.1
1911–13	18.8	26.3	28.0	27.0
1933	16.2	19.8	16.7	16.5

In the developed countries the falling birthrate caused a significant aging of the population. The proportion of sexagenarians rose to about 10 percent, as compared with 6 percent in the 18th century.

In the rest of the world there was no demographic revolution; the birthrate remained in the neighbourhood of the natural level and the deathrate declined only slightly.

Table 2: Pre-World War II Annual Birthrates and Deathrates per 1,000 Inhabitants

	birthrate	deathrate	natural increase
Africa	40	36	4
U.S., Canada	18	11	7
Latin America	42	24	18
Near East	42	33	9
Southern Asia	42	32	10
Japan	27	17	10
Far East	42	32	10
Southern Europe	23	16	7
Eastern Europe	33	22	11
Rest of Europe	17	12	5
Oceania	20	10	10
World total (*c.* 1939)	36	26	10

In Table 2 are shown regional approximations of the birthrates and deathrates per 1,000 inhabitants in 1939 on the eve of World War II.

The second demographic revolution

Changes after World War II. World War II and the years immediately following witnessed far-reaching changes: (1) The birthrate resumed an upward trend in the developed countries. The significance of the phenomenon lies in the fact that it constituted a change in a century-old trend, which earlier had been considered irreversible. (2) The deathrate underwent a sharp decline in the less developed countries. The antimortality techniques of advanced civilization significantly outstripped economic and birth-control techniques, because the most important of the former (such as water purification and vaccination) demand neither heavy capital investment nor much cooperation from the population. Though very uneven (depending on the countries involved) the deathrate at times has declined in major proportions; life expectancy sometimes reaches beyond 60; the deathrate falls often below 10 per 1,000, a lower rate than that of the developed countries because of the relative youth of the populations in the less developed countries.

Because births have remained at their traditional rates (or have sometimes even risen slightly because of the decline of puerperal mortality), the less developed countries have experienced a far more rapid population increase than did the European countries in the 19th century. The rate of 2 percent, previously unknown in history, is exceeded almost everywhere; many countries reach 3 percent (and even 3.5 percent in parts of Latin America). A rate of 2.5 percent represents a doubling of a population within one generation. A typical family, which in days gone by had five children, of whom two survived, may now have six, with four surviving.

Thus, the world, which until now had known two types of population—one traditional, young, highly fertile, but subject to a high deathrate, and the other modern, older, its birthrates and deathrates both low—is today experiencing a third type of population, young, endowed with both a high birthrate and a low deathrate. Such a condition if it lasted very long would result in earth's population being multiplied 32,000 times in only 500 years. Though present rates must, therefore, be considered temporary or transitory, just as Europe's population increases were temporary in the 19th century, the length of the transitional period can be of great importance.

Table 3: World Population Growth

year	population estimates
1000	340,000,000
1650	545,000,000
1800	907,000,000
1900	1,610,000,000
1950	2,509,000,000
1970	3,650,000,000

The aging process that had been affecting the developed nations for about a century continued after World War II, despite the upward trend of the birthrate. The proportion of sexagenarians in some developed countries is now over 17 percent and should continue to rise. The less

developed countries, on the other hand, have more or less retained their former age distributions, so that not only is their combined population two and a half times as great as that of the developed nations but also, with a more youthful population of procreative ages, their potential growth is accelerating. The less developed nations have three to three and a half times more people who have not passed out of the childbearing age.

Table 4: Present-day Age Distributions
(percent)

age groups	developed regions	less developed regions
0 to 14 years	27	42
15 to 64 years	63	55
65 years and over	10	3

It might also be noted that worldwide population distribution by sex never reveals more than minor variations. The approximate proportion of 105 boys born for every 100 girls (observed in all countries) is sooner or later corrected by a differential in their deathrates. Even when the balance between males and females is occasionally disturbed by wars or migration, it is gradually re-established by the rise of younger generations.

From a geographic point of view, the most striking 20th-century change in developed countries has been the migration from rural to urban areas as a result of the relative decrease in the need for labour in the primary sector of the economy (agriculture and fisheries) in favour of the secondary (industry) and tertiary (services) sectors. In the past 20 years, however, the less developed nations have also experienced shifts to urban areas.

Table 5: Rural-Urban Ratios
(percent)

	1950	1970
Developed regions		
Rural population	49	32
Urban population	51	68
Less developed regions		
Rural population	84	24.5
Urban population	16	75.5

Social characteristics of contemporary population. *Characteristics of modern fertility.* Standards of living and cultural traditions greatly influence fertility during the transition from a demographically primitive to a highly developed society. Birth control begins among the wealthy and the highly educated and in cities, but at a later stage it embraces all social classes and, among European countries, an opposite trend eventually may be observed: although the influence of urbanization generally keeps the birthrate low, prosperous couples in the cities again tend to have a larger number of children. In Table 6 are shown the number of children per 1,000 couples in West Germany in 1962, categorized by level of income and by the size of the community.

Birthrates among social classes and in cities

Table 6: West Germany, Number of Children per 1,000 Couples

income (Deutsche Marks)	townships of fewer than 3,000 inhabitants	towns of 3,000 to 50,000 inhabitants	cities of 500,000 inhabitants and over
Under 600	1,955	1,701	1,385
600 to 800	1,961	1,771	1,494
800 to 1,200	1,858	1,798	1,550
1,200 and over	1,944	1,882	1,630

Aside from noting the influence of urbanization, there has been insufficient exploration of various social factors influencing deliberate birth control. It is known, however, that housing conditions, for instance, seem to have different effects in the poor and the rich nations. Among a generally impoverished population, in which individuals live in overcrowded conditions, there is usually a rather high natural fertility, whereas in an economically developed population, unsatisfactory housing may well reduce the number of a family's children. It can also be noted that although traditional religions, such as Roman Catholicism, have not been powerful enough to put a stop to birth control and the reduction of the number of children born in wedlock (as influenced by economic and social evolution), they have been able to apply brakes to such reductions (as in Canada, Italy, and Spain). The fertility differential resulting from this braking effect has actually resulted in a change in the religious balance of certain countries—between the Catholics and Protestants in The Netherlands, for instance. When interpreting such statistics in terms of religion, however, it is important to keep in mind the fact that faiths are often linked with social status—the Protestants in Northern Ireland, for instance, enjoying higher social and economic status than the Catholics.

Characteristics of modern mortality. From the 18th century onward, writers have tried to assess the influence of professions and of social standing upon the deathrate. Although social-class inequality in the face of death has always existed, to the extent that the lower classes have been relatively undernourished, such inequality must have become even sharper during the 19th century, when a more efficient, though expensive, medical science began to afford the middle and upper classes a greater life expectancy. The deathrate was possibly twice as great among the lower classes. Today, however, this gap appears to be closing, at least in highly developed countries, because of improvements in housing and in the food available and because of the extension of medical care through welfare service. The disparities that persist in developed countries seem to be related more to levels of education than to levels of income. Nevertheless, poverty and malnutrition still plague various minority groups in such affluent countries as the United States.

Social class differences in mortality

In the underdeveloped world rampant death unquestionably still stalks the poor. A survey by the Food and Agricultural Organization of the United Nations in 1963 found that at least 60 percent of the people in less developed areas were undernourished and that half the world's people suffered from malnutrition. Also, although such large-scale preventive medicine as the Ceylonese eradication of malaria and other diseases have indeed made possible a startling decrease in the deathrate, the lack of adequate physicians, hospitals, and medical services under most welfare programs has reduced the possibilities of individual attention to the poor. Thus, class disparities in mortality seem to be still very much a part of the less developed countries.

There remains the question of whether or not, in the advanced countries at least, the drop in the deathrate that began in the 18th century is now nearing its end. Opinions on whether or not man's life-span can continue to extend and, if so, how far, are widely divergent. The optimists (the Soviets especially) currently hold that longevity will still notably increase, though they recognize the present impossibility of assigning any precise limits to such growth. The majority of scholars and medical specialists in gerontology think otherwise, although they do not rule out the possibility of entirely new discoveries. For the time being it can be assumed that progress is being made in the struggle against specific diseases, cancer in particular, but that the slow attrition of the body, which begins at a very early age, has not decreased its tempo. At the present level of knowledge, the average extreme limit of age of the human species would seem to remain invariable at some 107 years, the deathrate increasing sharply with the latest years of life.

Characteristics of modern international migration. With the total absorption of all land areas by sovereign states and with the imposition of restrictions on immigration (and sometimes on emigration), the 20th century has added new characteristics to patterns of global migration. Although the free movement of individuals has always been impeded by poor health or ignorance, attachment to habitual sites, the costs and risks of migration, the availability of economic opportunities, and, to

New immigration restrictions

some extent, political barriers, these political barriers lately have assumed major importance. Although the sick, the physically handicapped, and the insane, for example, have always been hindered from migrating through a kind of process of natural selection, nations have now generally imposed a stricter process of physical selection, demanding that immigrants submit to medical examinations. Similarly, not only have the young always emigrated more willingly than the old but now most host countries flatly restrict the entry of old people. Host countries also usually specify occupational or economic conditions, often receiving migrants only from among those professions in which they find themselves shorthanded.

For countries of origin, emigration has generally served, in favourable terms, as a means of releasing population pressures, of extending influence overseas (as in the days of exploration and colonialism), and of providing economic and occupational opportunities. In unfavourable terms, it has occasionaly meant a "brain drain"—the loss of highly qualified individuals—which has often been very pernicious (as in France, when the Protestant Huguenots were expelled in the 17th century, or in Nazi Germany, from which many Jews and intellectuals fled when faced by persecution). The brain drain continues today, though more slowly and principally in the direction of countries already highly advanced industrially and professionally. But emigration can scarcely any longer solve the pressures of population. In the heavily populated areas of the underdeveloped world, the sheer magnitude of population and the force of natural increase exclude the possibility that international migration can be a major factor in raising levels of living, at least for the foreseeable future. Only in a few countries pressured by moderate overpopulation, principally in southern Europe, can emigration still relieve demographic problems.

For the host country, immigration under current conditions of restriction can be advantageous. Screening applicants at the point of entry permits a country to improve its own professional profile (and ultimately actually reduce unemployment). The country also profits by the arrival of mature men, who have reached their fullest "value" and whose upbringing and education it has not had to pay for. Restrictive policies also avoid the problems of having to assimilate large numbers of people of culturally different backgrounds.

Characteristics of modern internal migration. The most important migrations within the boundaries of individual states have been those from rural areas to the cities. Throughout history, the rural exodus has been due largely to demographic factors (for a long time the deathrate was higher in the cities, and later on, the birthrate was higher in the country). Today the rural exodus in advanced countries is mainly the result of technological progress: fewer men are required to till the soil and operate the productive machinery of modern agriculture, and more men, conversely, are demanded by the urban systems of industrial production, distribution, and management. Even in less technologically developed countries, the considerable increase in total population has resulted in an overflow of the surplus from the overpopulated rural regions toward the cities. (The reverse pattern of movement from urban to rural areas, incidentally, is rare and not always spontaneous. The government of the People's Republic of China, for instance, has on different occasions forced a return to the land.)

But the rural exodus is not the only variety of internal migration. With improvements in transportation, communication, power sources, and various distributional techniques, manufacturing and service industries need no longer be concentrated in urban areas. Furthermore, there is often the lure of lower taxes in nonurban areas. Thus there is evidence of some dispersion of population or at least the possibility of such dispersion. One or the chief reasons why industries—and, with them, populations—have not dispersed as much as they could is that these populations generally resist moving from the traditional centres of urban culture.

II. Population beliefs, theories, and policies

PREMODERN BELIEFS

Pronatalism among the ancients

From the earliest times when men first began to live together in groups, they were faced by problems of numbers. To help ensure their own survival most ancient peoples and civilizations fostered fertility cults and showed lively concern for the numbers of their descendants. Ancestors were honoured; sterility was considered a curse. The laws of Manu in Hindu mythology, for instance, stressed the holy duties of matrimony and paternity, just as did the Persian Zoroaster and his followers. On the other hand, Confucius was aware of overpopulation in northern China and may have been the first known writer to express the concept of an "optimum population." Various later Chinese writers expressed alarm over, or warned against, overpopulation.

The first legislators of ancient Greece—in particular, the legendary Spartan Lycurgus—were concerned with population levels, as were the philosophers Hippodamus (second half of the 5th century BC) and, particularly, Plato (*c.* 428–348/47 BC), who actually conceived of a republic whose members were to be kept at an optimum number (5,040 citizens) by means of birth control. The Romans, on the other hand—troubled by a falling birthrate and primarily concerned with national power—were, generally speaking, pronatalists. Many wrote about it, and the emperor Augustus promulgated laws encouraging marriage and childbearing.

Although Judaism had been guided by the injunction "Be fruitful and multiply," Christianity in its early days (from St. Paul to St. Augustine) attached little importance to population increases and, in fact, actually extolled celibacy. Later, Thomistic Christianity was to manifest greater interest in prolific families and to oppose all birth-control practices. The parson of Chaucer's *Canterbury Tales*, for instance, scorned "adultery in marriage" ("avowtrie . . . betwixe a man and his wyf")— that is, putting pleasure in sex before the desire for procreation. Taken as a whole, Europeans in the Middle Ages were pronatalists, as were their antagonists, the Arab Muslims; the historian Ibn Khaldūn favoured dense populations and elaborated a complete economic, demographic, and political system for the life of empires.

BEGINNINGS OF MODERN POPULATION THEORY AND POLICY

Population theories involve the effort to explain the lives of populations in their economic, social, and political environments. They attempt to render historical trends and events intelligible and thus to provide a basis for qualitative judgments and policies. Although this kind of deliberate wedding of theory and policy occurred sporadically throughout previous history, it was not until early modern times, beginning in the 16th and 17th centuries, that theories of population and its control began to acquire the interest and importance that they have today.

Mercantilism. One of the earliest, most broadly based, and most widely accepted population theories was contained in mercantilism, a school of thought dominant from the 16th to the 18th centuries, which was pronatalist and more concerned with national (or royal) power than with the standards of living of the inhabitants. According to this most consistent doctrine, each nation should wish to have a large population, for a large population would provide a supply of labour, a market, and a source of soldiers for effecting expansionist policies.

When mercantilism began to decline rapidly in the 18th century, it was supplanted by a confusion of views. Not characterized by a uniformity of ideas, the 18th century was a period of uncertain groping for policies as the earliest elements of the Industrial Revolution began to emerge. The century nevertheless remained pronatalist on the conservative governmental level in Europe—the state's aim being to increase the power of the sovereign and the wealth of the governing classes. As Turmeau de La Morandière, a noted populationist, cynically wrote, "We must multiply the number of subjects and cattle."

Laissez-faire theory. Perhaps the major 18th-century school of thought touching on population questions was

physiocracy, often regarded as the first "scientific" school of economics. With it is associated the well-known phrase laissez-faire, which perhaps suggests the physiocrats' belief that the state should lift its vast complex of mercantilist rules and regulations and let nature take its course. The physiocrats did, however, recognize the fact of growing populations and urged private investments (such as in clearing forests for agriculture) in order to provide expanding employment. It is also notable that, although the physiocratic influence on Adam Smith has often been cited, Smith himself evinced little interest in population matters, beyond claiming that an increase in a nation's aggregate wealth fostered increases in population and that population growth generally contributed to overall human happiness (if not to every individual's happiness).

Laissez-faire attitudes toward population policy

Malthusianism. Although various authors in 17th- and 18-century Italy, Germany, and England had warned against the dangers of overpopulation, the first definite and thorough association of these problems with social issues occurred at the very end of the 18th century. The 19th century produced the long-drawn-out debate between the exponents of two conflicting dogmas, expounded by Thomas Malthus and by Karl Marx, about relations between population and economic conditions.

Malthus, who in 1798 published the first edition of *An Essay on the Principle of Population, as It affects the Future Improvement of Society, with Remarks on the Speculations of Mr Godwin, M. Condorcet, and other Writers*, held that the increase of population caused by "the attraction between the sexes" constantly tended to exceed the food supply and other means of sustenance. The population was always subject to the "positive checks" of famine, war, and disease. Each technological advance was absorbed by a consequent increase of population, thus preventing any rise in the general standard of living. Increases in production, in Malthus' view, could never equal much less exceed increases in population. He later modified this position, however, by suggesting that under some conditions population might be brought into a more favourable balance with production through a "preventive check"—the postponement or avoidance of marriage and procreative activity.

The French philosopher Marquis de Condorcet had suggested that fertility might be controlled within marriage. This solution was repudiated by Malthus not only on moral grounds but also for economic reasons, because he viewed large families (and the consequent poverty) as a necessary stimulus to economic activity. He indeed opposed certain welfare measures such as the English Poor Laws, which he viewed as futile and dangerous, and he repudiated the idea of improving the condition of mankind through changes in economic and social institutions. In general, he defended private property in such a fashion that he provoked violent reactions among outstanding contemporaries, such as the political philosopher William Godwin and particularly among the doctrinaire socialists of all schools—Robert Owen, Charles Fourier, Pierre-Joseph Proudhon, and Karl Marx. These men reproached him with trying to lay at the door of the poor the guilt or responsibility for their own indigence, which, they contended, was on the contrary the result of the selfishness of the rich. "There is only one man too many on this earth," wrote Proudhon, "and that is Mr. Malthus."

Marxism. Whereas Malthus—in the laissez-faire, classical tradition of economics—had opposed deliberate intervention or change in social and economic institutions, Marx viewed revolutionary changes in economic and social institutions as inevitable and as leading toward an ideal society. He violently attacked Malthusian theory. He equated overpopulation with actual or latent unemployment; he described relative overpopulation in this sense as essentially and purely a phenomenon of the capitalist system. In other words, Marx—and indeed most orthodox Marxists and communists up until very recent times—tended to deny the existence of overpopulation and asserted that what seemed to be overpopulation was actually capitalism's failure to provide adequate employment. If such a view now seems simplistic, it must be remembered that Marx was reacting not only against what he considered to be a vicious Malthusianism but also to the relatively less critical population conditions of his time. Life expectancy at birth in his day was scarcely over 40 years in Europe (as against 70 today), and the number of deaths between 0 and 20 years of age was 35 per 100 births (as against 5 per 100 today).

Marxist theory of seeming "overpopulation" and unemployment

Exponents of Marxist doctrine have generally viewed the control of population and changes in economic institutions as alternative and incompatible approaches to the advancement of levels of production and income. In fact, the later division of Marxists into socialists or social democrats on the one hand and communists or orthodox Marxists on the other contained, among other things, a disagreement over the question of population control. The social democrats (and also the anarchists) came out in favour of birth control by means of contraception or even abortion. The communists, faithful to Marx, interpreted this attitude as capitulation before the capitalist system. According to communists, a socialist state would be at all times capable of feeding its population, however large it might be. Even today, although they have modified their attitude, the socialist countries still basically pay homage to Marx's theory.

CONTEMPORARY TRENDS

Modern theories. Most 20th-century demographers and economists view population size and environmental resources, age distributions and social security, and the labour force and education (or the development of "human capital") all as complementary elements in arriving at population theories and policies. It is true that until recently the social aspects of population (or the "quality" of life, as perhaps undermined by crowding and pollution) have received less attention than the economic aspects, but it is also true that these have now come to be seen by some as possibly even more important. Because of the difficulties still existing in trying to measure such qualities, however, the discussion here will be limited largely to standards of living and collective or national considerations.

Optimum population. The term optimum population, introduced as a scientific concept early in the 20th century by a Swedish economist (though resting, of course, on very ancient ideas) and since then elaborated upon by demographers and economists in many countries, is based on the notion of the happy medium. Simply put, it may be said that, since states of overpopulation and underpopulation both exist, there must also be an intermediary position corresponding to an "optimum." In other words, in any given area or country at a given time, there must be a certain population size that provides the best welfare for the nation or people, as measured by some established goal. This level of population is somewhere between overpopulation and underpopulation.

The criteria of optimum population

The real problem begins in trying to apply criteria of social objectives. Without going into the evidence of economic marginal analysis and mathematical models, it is apparent, for instance, that a population size that ensures the highest per capita production (that is, the highest average standard of living) is lower than a population size that ensures the highest collective power. This explains why dictators or authoritarian governments, more concerned with power than with standards of living, are generally more pronatalist than are democracies, and it explains why in times of war or even of heavy collective expenditures, a country finds it in its interest to have a larger population than in normal times.

Also involved in a discussion of optimum population are concepts of a "minimal population" and a "maximal population." A minimal population refers to that number below which a group in a given environment cannot go and still survive in the long run. A minimum number of people is required for division of labour, a sustaining number of marital partners, and so forth. A maximal population refers to that number above which a group in a given environment cannot go. Its standard of living would be the lowest compatible with human life; the addition of further inhabitants would consequently result in a higher deathrate. In both minimal and maximal pop-

ulations the people live at a bare subsistence level, which obviously is not conducive to the enhancement of either individual welfare or national power.

Criticisms of optimum population

The theory of optimum population has been criticized, usually on the following counts:

(1) The theory is too static and could scarcely apply to any but a traditional agricultural population.

(2) An optimum population is difficult to determine; no scientifically achieved results are available. Historical examples, though, might possibly be adduced: after the Black Death in the 14th century, for instance, the inhabitants of certain regions in Great Britain and France enjoyed an improved standard of living and even a certain degree of emancipation from the authority of their overlords. This may suggest that the population before the plague had been higher than the economic optimum.

(3) The political application is unclear, even assuming precise and reliable assessments of what is optimum. If a government of a particular country of 30,000,000 inhabitants were to determine that its optimum population should be only 20,000,000, how does it go about reducing the figure by the necessary 10 million? Similarily, if the optimum assessment were 40 million, how could it reach this figure in a reasonable time even with the help of immigration? In both cases a time factor intervenes; theories involving a more dynamic approach seem, therefore, preferable.

The effect of economic and demographic investments

Population growth and demographic investments. When a country's population remains constant, an efficient distribution of economic investments should raise the national income by about 4.5 percent a year on the average (though varying from 7 percent down to zero from year to year); such a growth is normally attained in many countries. This growth rate, however, is no longer the best when the population increases or decreases. In such an event "demographic investments" must be taken into account—investments, that is, which keep the fewer or greater number of people at least at the same standard of living as before. When the population increases, for instance, new arable lands must be brought under cultivation, factories and housing must be built as well as new hospitals, schools, and so forth. These demographic investments are approximately proportional to—and sometimes even greater than—the increases in population. For housing alone, an increase of 1 percent in the population might absorb, in one year, as much as 1.5 or 2 percent of the national income. In general this type of analysis was well summarized in a 1954 statement made by the UN Secretariat:

> To sum up, population enters into the problem of achieving satisfactory standards of living in the underdeveloped countries in three principal ways. . . . First, their high birth rates create a heavy load of dependent children per adult. This makes it difficult to save enough over and above what is required for the support of the workers and their dependants, for needed investments in equipment for economic development. It also seriously complicates the problem of providing the children with the education that is essential for social and economic progress in the long run. This aspect of the population problem is common to all the under developed countries. . . . Second, falling death rates with high birth rates bring about a rapid increase of population. Large investments must be made to keep the growing numbers of workers equipped even with the same inadequate amounts of working equipment per man as they have had in the past. So the possibilities for investments which would improve the equipment and raise productivity per worker are diminished. This speeding up of population growth, aggravating the shortage of capital, is now taking place in very many underdeveloped countries, wherever successful public health campaigns have greatly reduced death rates. . . . Third, many of the under-developed countries have an excessive density of agricultural population in relation to the area of cultivated land. The average farmer has too little land to make a satisfactory living for himself and his family. Not all underdeveloped countries face this difficulty, but it exists in some which have large amounts of unused land, as well as in those where nearly all the cultivable land is fully occupied. At least some of the countries now suffering from acute agricultural over-population might be able to employ all their numbers to good advantage, and benefit in the long run from a substantially larger population, if they were better equipped to utilize the land resources which they possess, or if they could industrialize. But neither the necessary improvements of agriculture nor the development of industry can easily be accomplished, and the difficulties are increased by high birth rates and rapid population growth. . . . It appears that even in a country where population growth would be economically advantageous in the long run, economic progress will be hindered if the birth rate is so high and if the population grows so rapidly as to put an excessive strain on the economy. (From UN Dept. of Social Affairs, "The Determinants and Consequences of Population Trends," *Population Studies*, No. 17 [1953], and "Population Growth and the Standard of Living in Under-developed Countries," *Population Studies*, No. 20 [1954].)

The question of adequate food production

As reasonable as these predictions may sound, however, there are demographers and economists who insist that they have not been entirely borne out by events in the years since 1954. These scholars note that, although available capital has been far less than had been considered indispensable and although the rate of population growth has exceeded all forecasts, the average standard of living has, generally speaking, not fallen; it has in fact grown higher in most areas of living. The notable and, admittedly, vital exception involves the production of food, which has not kept pace with the population increase—falling so far short of doing so, particularly with respect to high-protein food, that some of the more pessimistic forecasters have begun to see the beginning of wide-spread, chronic famine sometime in the future, their estimates ranging from some 5 to 30 years from now. Optimists, on the other hand, are pointing to an acceleration of an already visible "green revolution," the development of higher yield, higher nutrient food that can accommodate larger populations.

In other areas of production, the pessimistic forecasts have not all proven true, and this divergence between theory and practice may be explained in several ways: (1) The theory rests on the assumption that the productive output of an additional inhabitant is nil without supplementary capital. This is not always true. Two individuals, working with the same initial capital, may frequently be more productive than one. (2) An increasing population seems to adapt more easily to various changes in social structure (such as geographic or professional distributions) that are required by technological progress and economic evolution. (3) Certain social conditions seem frequently to benefit from a certain population growth. A nation, for instance, whose deathrate is declining but which continues to produce a young population avoids the economic drawbacks of an aging population. Because such social factors as these are neither easily submitted to experimental study nor easily adapted to individual cases, they are all too often neglected by economists and demographers who elaborate theories of growth.

Optimum rate of population growth. In noting that many demographers believe that a steady increase in population can be more advantageous than a constancy or decline in population, one must further note that such demographers do put a limit on the rate of increase. A runaway population can drain all or most of a national income into demographic investments. Certain demographic investments can sometimes increase even faster than the population, as noted earlier with reference to housing—an annual increase of 1 percent in population demanding in some cases as much as a 1.5 or 2 percent increase in housing investments. As a result there has come to be formulated what is called an "optimum rate of growth" in population—that is, a rate ensuring the highest annual increase in the standard of living.

Though perhaps more easily determined than a static "optimum population," the optimum rate of growth is still difficult to pinpoint scientifically and it has critics among those who are convinced of the desirability of a stationary population. In any case, the figure most often cited, one reflecting the experience of western Europe, is an annual increase of 0.5 to 1 percent in population—an increase that seems to afford the best economic advantages at present, subject as it is, though, to future technological, social, or political changes.

The rate of increase of the population—including the rate of its short-term variation—may of course depend largely upon special circumstances: when national resources, for instance, are abundant and easily exploited, the increase in population is more readily accommodated. Similarly, some scholars believe that population increases are not as easily accommodated in developed countries where there is a high accumulation of capital per individual—the reason being that each new addition to the population, each new worker, must himself be afforded a very high measure of added investment in order to keep him up with his fellows and to avoid drawing everyone down. Scholars with this point of view thus consider that a less developed country can handle higher rates of population growth because it depends less on capital and more on labour. The argument against this point of view might appear to be that wealthy countries tend to save more; they have greater surpluses of income, which can be applied to additional units of population. In any case, one can readily see that the complex nature of the problems involved and the difficulties inherent in trying to isolate the population factor entail considerable uncertainties.

Composition of the labour force. In economics the term labour force denotes all those members of a population who are at work or are available for work; it embraces workers of all grades and occupations, and it extends to both those who are unemployed and those who are underemployed (that is, not employed to their fullest normal capacity).

Of primary concern are those in the labour force who are not sufficiently employed. Generally speaking, the less developed countries are marked chiefly by underemployment, usually resulting from the demographic condition of overpopulation in rural areas. Industrial countries, on the other hand, are often characterized chiefly by unemployment, resulting largely from faulty economic or social adaptations and not from overpopulation. All countries, however, industrialized or not, are subject to inconsistencies between their effective labour forces and their "desired labour population," which is the distribution of workers by occupational categories that is considered appropriate for a country if it is to respond fully to the demand for its different products and services. For various reasons—technological or social changes, inadequate development, misdirected manpower training, or whatever—there may be extended periods of unemployment in certain professions and a lack of manpower in others. The desired population in certain professional categories, in other words, is not reached and can only be corrected by such measures as training or retraining, migrations, or work connected with increased foreign trade.

The issue of a "desired labour population"

Outside the membership of the labour force are, among others, the very young and the very old—that is, those in the "inactive ages." The dividing line between the "active age" and the "inactive ages" naturally varies among cultures and can remain constant or vary even within a single society, depending on the influences of social and economic change. Social security plans are, of course, dependent on assessments of the inactive ages. In any case, a manual worker's economic value usually begins to decline at about the age of 40 to 45, and that is precisely the age over which most countries refuse immigrants, unless they are possessed of adequate capital.

Modern governmental policies. *Policies regarding fertility.* A pronatalist policy—one designed to increase the birthrate—may call upon many different means: the encouragement of marriages, family allowances, various methods of helping the family (schooling, health, housing, and so forth), tax abatements based upon the number of children, and propaganda. The effectiveness of such measures varies. For example, an intensive program of housing construction or a general raise in salaries may have no effect on the birthrate; whereas allocation of housing to a family upon the birth of a third child or family allowances granted to the second and third child seem to wield a far greater influence.

In modern times most such policies derived from demographic trends alluded to earlier. During the late 1920s and the 1930s, when birthrates were falling rapidly in Europe and North America, there was much alarm about "the retreat from parenthood"—reinforced in some countries by considerations of national security. Some economists, moreover, viewed the slackening of population growth as tending to cause economic stagnation and chronic unemployment. It was, in any case, apparent that demographic changes were increasing the proportion of aged persons in the population.

These considerations led nations to public policies that promoted the maintenance and growth of population. In France, concern about population trends, in conjunction with other interests, led in 1939 to a comprehensive system of family allowances and related measures, called the *Code de la Famille* (revised in 1946), whereby the government subsidized the cost of additional children in many French families. Some programs of financial aid to families with children have been adopted in most European and many non-European countries, including Canada. These programs are usually designed to serve various ends, and it is often difficult to say to what extent they express population policies. Moreover, most governments have been reluctant to authorize expenditures on a scale comparable to that accepted in France. It may also be noted that laws against the promotion or sale of contraceptives, as well as against abortion, are supported in some countries by demographic as well as religious considerations, and that such laws have the effect of pronatalism.

Before World War II, several countries had permitted complete freedom in the use of contraceptives (the Soviet Union had even authorized abortion), but none had aimed at the restriction of the birthrate as a check on population growth. After the war, Japan launched the first birth-control policy of modern times (in the Eugenic Protection Act of 1948), based upon contraception and abortion. From that date onward, a considerable number of countries adopted policies aimed at extending family planning and reducing the birthrate. By the beginning of 1970, for instance, 22 developing countries had instituted a national policy to promote planned parenthood—countries as diverse as India, Pakistan, Sri Lanka, Malaysia, South Korea, Taiwan, Turkey, Egypt, Tunisia, Morocco, Mauritius, Kenya, Honduras, Puerto Rico, and Chile. Their plans were administered either directly through public agencies or through public assistance to private agencies. And in addition to these countries with official programs, many other countries granted approval to privately sponsored programs of planned parenthood. Furthermore, the General Assembly of the United Nations in 1962 adopted a resolution calling attention to the importance of population problems, and the UN Economic and Social Council in 1965 voted to increase "the amount of technical assistance in population fields available to governments of developing countries upon their request." The World Health Organization in 1965 also gave limited approval to this principle.

Birth-control policies

The results of official national programs—notably, for instance, in India—were at first discouraging. The obstacles to changes in personal behaviour in a vast illiterate population dispersed in small villages are enormous. Subsequent events have provided grounds for greater optimism. Methods of organization and communication have been improved on the basis of early experimentation. Appropriation for such work was increased in India from 1,500,000 rupees in the first five-year plan (1951–56) to 265,000,000 in the third and 300,000,000 in the fourth plan (1966–71). Equally intensive programs have been inaugurated in some other countries.

Such countries as Sweden, Denmark, and the United Kingdom, and some states of the United States have legalized abortion under regulated conditions. The Soviet Union and most of the eastern European nations have legalized abortion and promote contraception, even though they have maintained that such measures are intended only for the welfare of individual families and are not influenced by economic considerations or a desire for population control. Moreover, the Communist regime in China has lately encouraged delayed marriage and the control

of births within marriage as a factor in achieving its economic objectives.

Leading Roman Catholic theologians have also recognized the serious economic and social consequences of the persistence of high fertility, in association with declining mortality, in nations with limited resources. Accepting the regulation of fertility as a family goal, they continue to insist that the means of achieving this goal must conform to approved moral principles (see also BIRTH CONTROL).

Policies regarding mortality. Although in principle all national policies aim at reducing the deathrate to the lowest point possible, in no country are the means adequate, for there is always a compromise more or less candidly expressed (if nowhere else than in the budget of expenditures), between efforts to achieve the highest possible degree of longevity and other aims. Even more thorny questions can arise, however, regarding the desirability of therapeutic abortions, euthanasia, and sterilization, for example.

Policies regarding migration. Although an immigration policy may have a demographic purpose, when it is a matter of peopling a sparsely populated territory (as in Australia and New Zealand) or when cultural or political reasons encourage it (as in Israel), such a policy more often has economic aims and acts selectively, if not exclusively, in giving priority to workers in certain professions or to certain nationalities.

The main host countries of immigration after World War II were Australia, New Zealand, the U.S., Canada, Argentina, Brazil, Venezuela, and Uruguay. Highest rates of net inflow existed in Australia and New Zealand; immigration was responsible for two-fifths of the increase of population in Australia. Migrants in the Americas were absorbed most readily by Canada and Venezuela, though in absolute numbers the U.S. still took by far the largest total. Jamaica lost nearly a quarter of its natural increase through emigration, while Mexico had a net outflow of 250,000 (mainly to the U.S.), which however, was only 3 percent of the natural increase.

One of the striking developments after 1945 was the influx of European and Indian populations into certain parts of Africa. In the Federation of Rhodesia and Nyasaland (later Rhodesia, Zambia, and Malawi) the number of Europeans increased from 105,000 to 274,000 between 1946 and 1957, and more than two-thirds of this was due to immigration. A similar process was at work in the Belgian Congo (later Zaire) and in Kenya, Tanganyika (Tanzania), and Uganda. Except in white-dominated countries such as Rhodesia and South Africa, however, such immigration tended to decline after the country had achieved independence.

Australia's "white Australia" policy, officially termed the "restrictive immigration policy," though somewhat liberalized after 1965 to permit the entry of some non-Europeans, remains perhaps the most noted current example of the exclusion of coloured peoples. In a world in which the volume and direction of migration have been heavily influenced by restrictions unfavourable to coloured peoples, however, some channels remained open, as shown by the immigration of Puerto Ricans to the U.S., and, until passage of the restrictive Commonwealth Immigration Bill in 1968, of West Indians to the U.K. In these cases the fact of common citizenship made possible a relatively large increase in the movement of coloured migrants into these countries.

Other policies. Although people often fail to recognize a "population policy" in their own country (other than the obvious one involved in restrictions on migration or in the stimulation or restraint of the birthrate), all countries are in fact governed by a great number of economic, social, fiscal, and tariff measures that together may exert a quantitative or qualitative influence upon the growth and movement of population, without necessarily having such a purpose. Without enumerating their effects, the possible influence of the following may be significant: (1) agricultural policies, involving conservation, land tenure, land allotment, and the like; (2) national defense policies involving inequalities with respect to the draft or the distribution of recruits by race or national origin; (3) general economic policies, regarding such things as full employment, economic development, housing, and the like; (4) educational policies, involving particularly the teaching of children of foreign immigrants; (5) general welfare policies, involving social security, social and health services, naturalization, delinquency control, and the like; and (6) labour policies, particularly those involving occupational training and the recruitment of temporary labour of foreign origin. Such a sampling suggests that the whole domestic policy of a country can be considered, from one perspective, a population policy.

III. Future prospects of population

POPULATION PROJECTIONS

Population growth in the future

In 1969, the UN extended its projections of world population to the year 2050, on the basis of three estimates, "low," "medium," and "high"—the medium being deemed the most likely. The results are indicated in Table 7.

Table 7: World Population Projections

year	"low" variant (000,000)	"medium" variant (000,000)	"high" variant (000,000)
1950	2,500	2,500	2,500
2000	5,400	6,100	7,000
2050	8,500	11,000	13,500

Source: *World Population Situation*, Note by the Secretary General of the UN November 1969.

For the first time the tempo of growth was seen to slow down; in the medium variant, for instance, the increase decelerates in half a century from 144 percent in 1950–2000 to 80 percent in 2000–2050. Projections for the future have been carried even further: there are estimates that the growth of world population could come to a stop in the year 2050 (a low estimate) or 2100 (a medium estimate) or 2200 (a high estimate). On the basis of such hypotheses (uncertain ones, to be sure), the number of inhabitants on the planet would level off and become stable at 8,500,000,000 in 2050 or 13,500,000,000 in 2100 or 30,000,000,000 in 2150. Whatever the nature of the hypothesis, however, growth will be uneven among the developed and less developed nations. Whereas present growth ratios are roughly 2:1, in the year 2000 they would become 3:1.

Table 8: Population Projections in Developed and Less Developed Nations

	1970	2000
Developed regions	1,082	1,441
Less developed regions	2,510	4,688
Total	3,592	6,129

The aging process in the future

With regard to age distributions, in 1980 the proportion of individuals *over* 65 years of age should still be only 4 percent in the less developed regions, as against 10 percent in the developed regions (13 percent in Europe). On the other hand, the proportion of individuals *under* 15 should be 39 percent in less developed countries, as against 25 percent in developed countries (23 percent in Europe). After 1980, and particularly during the course of the 21st century, the number of older people will grow, because the great numbers of young people in the less developed countries today will have a greater life expectancy. Whether the percentage of older persons increases depends upon the birthrate—that is, upon whether or not the number of young people increases as rapidly as the number of old. The likelihood is that there will be a significant aging process; the birthrate—and thus the number of young people—will go down. All the countries of the world will find themselves faced with larger numbers of old people whose productivity in modern economies is less desired. In the meantime, all countries and particularly the less developed countries will undergo

jolts and jars trying to adjust to the new distributions in ages. The course of population growth and distribution probably will be very chaotic in the course of the 21st century in most of the less developed countries.

The population implosion—the further concentration of peoples in urban areas—should continue unabated. In Table 9 the vast increase of the urban population of less developed regions is noted; this will have quadrupled in 40 years. The drop in the rural populations in the more developed regions is also observed.

Table 9: Urban-Rural Populations

		urban population	rural population	total
More developed regions	1960	502	352	854
	2000	1,010	280	1,440
Less developed regions	1960	490	1,647	2,137
	2000	2,030	2,740	4,675
World total	1960	992	1,999	2,991
	2000	3,090	3,020	6,110

PROBLEMS OF RAPID POPULATION GROWTH

The rapid increase of population in the less developed regions presents a far more serious problem than the population increase in 19th-century Europe for the following reasons: (1) the increase is far more rapid (2.5 to 3.5 percent instead of 1 percent); (2) it affects a far greater population; (3) it is not susceptible to any compensation in such migratory and economic outlets as Europe found in the New World and Australasia.

The increased speed in the spread of antimortality techniques has rapidly raised the question of how an ever greater number of human beings, multiplying without controls of any kind, are to be fed. Faced with this vast problem, observers separate into two camps: the pessimists, with their unfavourable and even tragic prognoses (such as general famine), and the optimists, confident that science and technology can overcome these difficulties. A second conflict of scholars, not far removed from the first, exists between the "economic developers" and the "birth controllers." The former group favours an absolute priority for economic and cultural development, which, they contend, cannot fail eventually to trigger a decrease in fertility. The latter group hopes to work for birth control at the family level to reduce national population burdens—burdens that they assume must be alleviated before economic development can successfully be undertaken.

A defensible conclusion with respect to the matter of economic priority, even from the strictly economic point of view is difficult to ascertain. The cost of contraceptives capable of preventing the birth of a child can be much lower than the cost of investments and consumer goods necessary for that child's economic life (housing, food, tools, etc.)—but only if the contraceptives are reasonably efficient. When their efficiency is virtually nil, as may be the case among indigent and ignorant populations, economic development yields greater profits.

The difficulties met by such populations in the use of contraceptives have led to the search for new methods, such as the more efficient oral contraceptive (the Pill) and intrauterine devices, but even these are not yet entirely satisfactory. What are needed, perhaps, are pills with longer term action and intrauterine devices less susceptible to expulsions and complications. Some countries have resorted to what are usually considered to be "radical" birth-control techniques including surgical sterilization (India and Puerto Rico) and abortion (Japan, Tunisia, and the Communist countries). What may yet prove to be a more efficient means of encouraging birth control, however, may involve instilling in adults a love and appreciation of children and persuading them that they can extend better care to a smaller number of children (see BIRTH CONTROL).

That birth control can succeed without new contraceptive practices is proved by the experience of some countries, particularly in the Far East, whose birthrates had declined even before the use of the Pill and intrauterine devices, and continue still to decline (see Table 10).

Table 10: Selected Countries—Births per 1,000 Inhabitants

	1956	1970
Singapore	44.4	23.0
Hong Kong	37.0	20.1
Taiwan (Formosa)	44.8	28.1
Mauritius	43.3	27.3

The alternative to a direct program of birth control—that is, a program giving priority to economic development—also involves frustrations. Even in a very sparsely populated country richly endowed with natural resources (Brazil, for example, or Zaire), overrapid growth of the population brings in its train an excessive need for demographic investments—that is, investments just to keep pace with the extra mouths to feed and bodies to clothe and shelter. Such quantitative investments reduce the availability of qualitative investments intended to raise the standard of living. Although it is always difficult to measure optimum growth, that point in most of the less developed countries seems to have already been passed (the figure of 2 percent per year might well be taken as an upper limit).

International political debates

International discussion of population growth has been marked by wavering opinions on the necessity for measures on birth control. In February 1947, at the first meeting of the United Nations Population Commission in New York, the representative of the Soviet Union strongly opposed any restriction on the birthrate, thus opposing the U.S. The representatives of Roman Catholic countries similarly opposed those of the Protestant countries. At this time and for many years to come, the less developed countries—with their age-old traditions regarding fertility and with their new thirst for power and prestige—also generally opposed family planning. By 1962, however, after some 15 years of debates, the position had changed radically. A vote in the UN General Assembly in that year somewhat surprisingly split the nations into roughly three equal groups—those for birth control, those against it, and the remainder abstaining from opinion. In favour of a restriction of births were many African and Asian countries (particularly the Arab States), a new persuasion that prompted a cautious abstention from the Soviet Union. Since 1962 the tide of nations favouring the limitation of births has steadily swelled, particularly in Asia.

The continuing diversity in votes and opinions reflects, in part obviously, the great diversity among countries with respect to deathrates, birthrates, and levels of economic development or potential. Purely global studies of population have therefore become almost pointless; future studies must bear increasingly on regions and even on individual countries. India, for instance, faces almost terrifying population pressures as related to area, intense poverty, and density of population (436 inhabitants per square mile). In 1965 a threatened famine, following on two poor harvests, was narrowly avoided. Birth control has thus become a matter of national public welfare. In sub-Saharan Africa, on the other hand, the problem of the immediate future is far less urgent although malnutrition is at times dramatic enough. In Latin America the demographic and economic characteristics vary widely from country to country—with a relatively fine show of achievement in a country like Mexico, as contrasted with the increasing poverty of ever-larger numbers in a country like Haiti. Everywhere in Latin America, however, the growth of the population is very rapid and tends to aggravate the problems of political stability. Generally speaking, whether or not predictions of the danger of a sudden general worldwide famine are accepted, serious local problems do remain unsolved, problems quite capable of provoking political complications.

Population, Biological

A population of animals is the number of individuals of a species living in a restricted area. The term restricted area raises difficulties because all the individuals of a species, or at least of a subspecies, may intermingle to some extent. In a small area, even one with natural boundaries such as a forest or a pond, there is usually some movement of animals in and out. Perhaps it is only on nearly inaccessible islands that a biologist can hope to study a complete, self-contained population of large animals, and this has rarely been done. He may, of course, enclose a self-contained population of small animals in his laboratory, but this seldom replicates a natural situation.

One may also speak of populations of plants. In a plant population, however, there are often great variations in individual size, so that the total number of plants present may be less significant than their combined weight or "biomass." There is a further difficulty in counting the numbers of a plant that reproduces asexually (vegetatively) and in which the new shoots remain joined to the original plant. One bramble bush (*Rubus*) may extend for several miles, and the dog's mercury (*Mercurialis perennis*) covering the floor of a whole wood may be, effectively, one individual.

Animal and plant populations tend to be stable—that is, their fluctuations are small compared with what would be theoretically possible if no limits were placed upon their increase. Only a relatively small number of species are either expanding in numbers or decreasing to extinction. Stability is possible only if numbers tend to rise when low and to fall when high, through the action of density-dependent factors. This article attempts to summarize what is known about the critical factors concerned.

Human populations are currently unstable. Primitive tribes were perhaps limited by the density-dependent effects of starvation, disease, and fighting. In the last century or two, however, human populations have not been effectively regulated but have been increasing to an unprecedented extent. This has come about because of improved food supplies and the eradication of diseases. But a population must eventually cease to increase. It can do so in one of two ways, either through higher mortality (from starvation, disease, or war) or lower natality. While a further increase in food supplies may be desirable on humanitarian grounds, it can at best provide only temporary alleviation.

This article is divided into the following sections and subsections:

I. The study of populations
Reasons for studying populations
Species studied
II. The characteristics of biological populations
Age, sex, and genetic differences
Age distribution
Sex distribution
Genetic differences
Numbers and density
Natality
Mortality
III. Changes in population characteristics
Growth of populations
Fluctuations in stable populations
Seasonal fluctuations in numbers
Irregular annual fluctuations
Density-dependent natality
Density-dependent mortality
Predator–prey oscillations
Movements
Migration
Emigration
Dispersion
Dispersal
IV. Interactions of populations
Interactions between members of a population
Cooperative behaviour
Competitive behaviour
Interactions between populations of different species
Competition among species
Negative direct interactions
Positive direct interactions

I. The study of populations

REASONS FOR STUDYING POPULATIONS

Perhaps the most important reason for studying animal populations is scientific curiosity. Animals are able to reproduce so rapidly that any species might conceivably overpopulate the world in a short space of time, but in fact this does not happen. All species remain far below the numbers that their reproductive rates would allow, and the reasons for this provide a scientific challenge. Linked with this problem are fascinating subsidiary questions, such as why some species remain scarce for years and then suddenly increase explosively, why a few species show regular fluctuations in their numbers, and why some species are always scarcer than others. These questions lead to such further questions as why some animals lay many more eggs, and some plants produce many more seeds, than others; why some species eat out their supplies while others do not; and why some species engage in mass movements while others do not.

Apart from its theoretical interest, population dynamics has important practical bearings. Entomologists have been concerned with reducing the numbers of various pests that destroy crops or commercial forests; often they do this by introducing natural enemies, for which knowledge is needed of how the numbers of a predatory species interact with those of its prey. Fisheries biologists have been concerned with raising the weight of fish brought to the market, for which knowledge is needed of the influence of fishing on the age distribution of the fish and of the complex interaction between their growth and reproduction rates and their food supplies. Conservationists seeking to preserve large herbivorous mammals have been concerned with the problem of whether or not, or at what rate, to destroy natural enemies.

Complex relationships involved in population study

It cannot be stressed too strongly that the answers to practical problems of this sort are often complex, and that detailed study may be needed if effective practical measures are to be developed. This is largely because an action effective for a short time may prove disastrous later on. Tourists in the game parks of East Africa have complained to authorities in the dry season that young lions (one of the main attractions) are starving and that the wardens ought to feed them. They fail to see that if the young lions were fed, more would be present to starve in subsequent years. In the early days of conservation in North America and South Africa, large carnivores were killed in order to increase the numbers of deer or antelope, only to have the latter outrun their food supplies and decline catastrophically through starvation. Again, the British government for many years paid a bounty to encourage farmers to shoot wood pigeons (*Columba palumbus*), which are a pest of agriculture, but this measure was ineffective because, although many birds were killed, shooting did not bring numbers below the limit set by starvation in late winter. In the early development of a fishing industry, the weight of fish brought to market increases with the efforts of the fishermen, but beyond a certain point the catches drastically decline because the fish can no longer replace their losses. In Fiji, a native leaf-mining beetle (*Promecotheca reichei*), which eats coconut leaves, did no economic harm because its numbers were held down by a native insect parasite. But a predatory mite, *Pediculoides ventricosus*, was accidentally introduced. This mite also preys on the beetle, destroying virtually all the larvae at one time but leaving the adults untouched. At this stage, both the mites and the native parasites find no further prey, so that they die in large numbers; the next generation of beetle larvae is virtually untouched and does serious harm to the coconuts. Hence, under some circumstances, the introduction of an enemy may greatly increase, rather than reduce, the numbers of its prey. The problem in Fiji was solved by the introduction of another species of parasitic insect. To give a final example, the scale insect *Icerya purchasi* did enormous damage to the California citrus orchards until its enemy, a ladybird beetle, Vedalia (Rodolia) *cardinalis*, was deliberately introduced, after which, for many years, the scale insect caused no appreciable harm. But the use of chemical insecticides against mosquitoes, near the citrus orchards, once again made the scale insect a pest, because, though the poison affected the scale insects, it had a much greater effect on the ladybugs.

The interactions between different species and the factors controlling their numbers are often subtle; immense care must be taken before introducing new animals or plants if the balance of nature is not to be disturbed in unexpected ways, many of which may be disadvantageous to man. Because such interactions, though vital, are often inconspicuous, the factors controlling numbers in existing situations may be hard to discover. The common European Saint-John's-wort, for example, was accidentally introduced to California, where it made huge areas of grass pastures unsuitable for livestock, to which it is harmful. The numbers of the plant were later controlled by the introduction of a small beetle (*Chrysolina quadrigemina*), and both plant and insect are now so scarce in California that, without knowledge of the very recent past, it would be extremely difficult to discover that the one controls the other. Again, it has been shown, through the recovery of marked songbirds, that about half the adults die each year; yet this huge mortality passes unnoticed, mainly because the dead bodies are so quickly removed by scavenging animals.

The human population problem

The fundamental principles of population dynamics apply as much to man as to other animals. Some economists have argued, for example, that the human population problem could be solved by bringing new areas, such as the Amazon forests or the seabed, into cultivation or by further improving the genetic strains of crops; but the study of animal populations makes it reasonably certain that the mere provision of extra food would lead to a further increase in human numbers unless other things were done. Even the simple point that, in a stable population, the birthrate and the death rate must be equal, tends to be overlooked with respect to mankind: efforts to reduce the death rate tend to ignore the fact that for stability it will be necessary to reduce the birthrate. It should be added, of course, that the population problem is more complex in man than in other animals, principally because of the interplay of biological and ethical principles. The populations of small songbirds are stable because death rates equal birth rates, and about half the adults die each year; but such a high mortality among humans would be considered appalling.

SPECIES STUDIED

Each species has advantages and disadvantages as a subject of population research. Most birds are diurnal; they

can be readily watched, whole populations can be marked individually, and nests can be found with comparative ease. On the other hand, dead birds vanish quickly, non-breeding adults are hard to detect, and individuals moving outside a study area may go unnoticed. The often-studied small rodents are very abundant, but they are mainly nocturnal, and it is hard to catch whole populations. Big mammals present great advantages in that they can more easily be caught for marking. Fish, like small rodents, cannot be observed, but large samples can be caught and marked, and like various large mammals, their ages can be determined by structural characteristics; further, much money is available for fisheries research. The chief advantage in the study of insects is that large samples can be killed without significantly affecting the population. In some instances, it is not necessary to kill the insects; *e.g.*, certain insect larvae, called parasitoids, feed on other insect tissues in such a manner that the latter is not killed until larval development is complete. In this case, the living larvae can be examined. Individual marking, however, is not normally practical, and there may be a stage in the life history that is hard to study. Almost any species of animal may, in fact, yield results of value to a skilled researcher: planarian flatworms have provided some of the best evidence for the limitation of numbers by food shortage.

A great practical difficulty in the study of natural populations has been that biologists tend to change their posts and move from one area to another. Most of the long-term field studies have been carried out at research institutes rather than by particular individuals, and chiefly on animals of economic importance.

II. The characteristics of biological populations

AGE, SEX, AND GENETIC DIFFERENCES

Populations consist of individuals of different ages, of two sexes, and of varying heredity.

Age distribution. In some animals, the young are similar to the adults except in size; they eat similar types of food and are subject to similar predators, so their numbers and those of the adults may interact with each other. But in other kinds, the young are extremely different in appearance, live in different habitats, eat different types of food, and are subject to different predators, so that adults and young have no direct influence on each other's survival.

In many small invertebrates, notably many insects, the eggs are laid in one short period of the year, hatch into larvae more or less synchronously, pupate synchronously, emerge as adults together, and die after breeding. Hence at any one time, almost all the population consists of animals of the same age, and the breeding stock of one year is derived wholly from eggs laid the previous year. The situation is slightly more complex in species that have a similar life history but raise two successive generations each year; or, alternatively, that take several years to raise one generation. Most sockeye salmon (*Oncorhynchus nerka*), for example, live for four years. Each individual breeds once and dies; its young move from freshwater to the sea to complete their growth and then return to breed. Thus the populations coming up the rivers of British Columbia in four successive years are nearly separate. The point has commercial importance because in some areas one of the annual populations in a four-year period is much larger than the other three, probably because the average chance of survival is greater for a young fish hatched in a peak year, when they are much more numerous—relative to the numbers of predators—than in other years. In the European eel (*Anguilla anguilla*), which also breeds only once in its life, the age of breeding is more variable; the young of this group leave English ponds for the sea at between five and 20 years of age, largely depending on how fast they have grown.

Age distribution in salmon populations

The age distribution (*i.e.*, the proportion of individuals in each age group) is much more complex in most other vertebrate animals and in some of the larger invertebrates. In these groups, most adults breed every year until they die, so that the breeding population at any one time consists of individuals of a mixture of ages. The age distribution in a bird population with a high annual mortality is shown in Figure 1. In certain other birds the proportion

From *Journal of Wildlife Management* (1940)

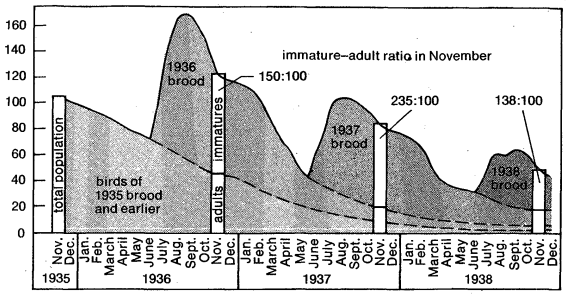

Figure 1: Age distribution of California quail (*Lophortyx californica*).

of younger individuals is much lower; there may be subadults, similar in appearance to adults, that do not breed. In most stable populations the age distribution remains relatively constant. But in certain fish and marine invertebrates, many more young are produced in some years than in others, and the predominance of a particular year class may persist for some years. A good example is the 1904 year class of herrings (*Clupea harengus*) in the North Sea that long outnumbered each of the later year classes, remaining predominant until 1919.

Various small plants, like various small animals, are annuals; they winter as seeds, breed once, and then die. Other species are biennials, and many more, including trees and bulbs, are perennials. Some large trees live much longer than any known animal—as long as several hundred or, in rare instances, 1,000 years.

Sex distribution. In most animals the male–female sex ratio is approximately equal. In various animals with an almost equal sex ratio at birth, one sex may become more common than the other later in life. In many monogamous birds, for instance, adult males are rather more common than adult females. This is probably because the females take the greater part, and in some species the whole part, in incubating and raising the young and thus are subject to heavier predation than the males. On the other hand, in polygynous birds (*i.e.*, those in which each male has several mates), breeding males are much scarcer than breeding females, perhaps in part because their exceptionally conspicuous plumage and behaviour patterns render them more subject to predation than the females. In one such species, the boat-tailed grackle (*Cassidix mexicanus*), the conspicuous males disappear faster than the less-conspicuous females in winter, perhaps through predation. Among humans, about 51 percent of all births are male, but in modern Western civilization, females survive slightly better than males, so that during adolescence the sex ratio becomes equal, and among adults there are slightly more women than men.

Variations in the sex ratio

In certain arthropods, notably aphids and water fleas, some generations consist solely of females that lay parthenogenetic eggs, which develop without fertilization by a male, though at other times of the year males are present and fertilize the eggs, which are of a different type. In another group of insects, the social hymenopterans (bees, wasps), most of the population consists of workers, which are sterile females. In various rotifers, only females are known. The sea worm (*Bonellia*) is first a microscopic male and later turns into a sizeable female, and a few other species also change their sex with age. Earthworms and snails, along with a few other animals, are hermaphrodites, with male and female organs on each individual. Hermaphroditism is, of course, common in flowering plants, both sets of organs usually being on the same flower. Asexual reproduction is common in plants, but in nearly all of them sexual reproduction is also the rule, and only a few species have dispensed with it entirely.

Genetic differences. In addition to the differences linked with sex, individuals of the same population differ somewhat in other genetic characteristics. These com-

prise the subject matter of population genetics, but it should be noted that the extent of genetic variation may vary with the state of the population; in particular, it may be unusually great in an expanding population because selection is temporarily lightened. When, for example, the fish *Bairdiella icistius* was introduced to the Salton Sea, California, it increased rapidly. In 1953 the population included many abnormal individuals, some blind, others with malformed jaws; a year later, when numbers had decreased, there were proportionately fewer abnormal individuals. Similarly, when the marsh fritillary butterfly (*Euphydryas aurinea*) greatly increased in the 1920s, for unknown reasons, in the north of England, there were unusual varieties in colour, pattern, and shape, but these had been absent when the population was small. Some researchers have argued that the regular population cycles discussed later in this article result from the production, in different years, of individuals of different genetic makeup; but there is no positive evidence for this, and it seems unlikely to be an important cause of cycles (though some genetic change is to be expected in populations that alternately increase and decrease in numbers on a big scale).

NUMBERS AND DENSITY

The numbers of large animals can often be counted directly, and in recent years aerial photography has been developed as a method for counting both big mammals and large birds. The numbers of various other animals have been assessed by capturing some of the population, marking and releasing them, and in a further series of captures finding the proportion of marked individuals in the new sample. Given large samples and random means of catching the animals, this "capture–recapture" method can provide accurate estimates of numbers. The results can be misleading, however, if the samples caught are biassed as to age or sex, particularly if this varies seasonally, and also if previous capture affects the chances of later capture—*e.g.*, if an animal learns to avoid being caught. In the case of some animals, including small but abundant species, total numbers are normally estimated from those counted in sample areas.

Estimates of numbers

Some animals are much more numerous than others. In general, large animals are sparser than small, because the larger the animal, the more food needed to sustain it; but there are so many exceptions that this generalization is of little use. Predators are much scarcer than their normal prey and are usually larger in size. Among the smallest existing populations are those of various land vertebrates on remote islands, though this is partly the result of destruction by man. Where man's destruction is checked, even a population of just over 20 individuals may persist, as shown by the conservation and recent small increase of the whooping crane (*Grus americana*) on the American mainland. The most numerous large animal in the world is man. It would be extremely hard to determine which is the most numerous small animal in the world.

The population density of a species typically varies in different parts of its range. Population biologists have tended to study animals where they are common—in the middle parts of their range and in optimal habitats—but their relation to their environment may be very different where they are sparse. In the few cases in which a population has been studied in two areas, it has been found that its density, natality, mortality, main predators, and even main foods may differ from one area to another. Most animal populations have inevitably been studied under conditions affected by man. This need not affect the validity of the general conclusions reached, but the proportionate importance of various factor influencing birthrates or death rates may be very different in man-modified and in natural habitats.

The equality between natality and mortality

Natality. The reproductive rate—in mammals the birthrate, in plants the rate of seed production—is the rate at which new individuals are produced. It should be distinguished from the recruitment rate, which is the rate at which new adults (not new eggs or new young) enter the breeding population. Most animal populations are not, on the average, either increasing or decreasing markedly, and in such populations the recruitment rate equals the adult mortality, while the natality or reproductive rate equals the total mortality of eggs, young, and adults.

Some biologists have argued that the equality between natality and mortality is an evolutionary mechanism to prevent overpopulation. This suggests that natality is smaller than it might otherwise be, particularly in long-lived animals. A different view holds that the implication of evolution by natural selection is that those hereditary types (genotypes) that leave most offspring must come to predominate over the rest. In other words, the reproductive rate of each species has been evolved through natural selection to correspond with that which gives rise to most surviving young per adult. This does not mean that each species must produce an immense number of eggs or young. In some this may, indeed, be the most efficient means of reproduction, but others are unable to form sufficient food reserves for many eggs, or cannot find food for a large family without serious risk to themselves, or need large food reserves for the young at hatching, and hence produce few (but often large) eggs or seeds. On this view, natality and mortality are roughly equal because mortality rises when the population is high.

Natality differs greatly in different kinds of animals. An oyster can probably lay 100,000,000 eggs during its life, and even so complex an animal as the cod *Gadus callarias* produces some 4,000,000. In contrast, an elephant matures late, has one offspring at a birth with an interval of several years between births, and may produce only five young in its life. Similarly, the number of seeds produced by a plant differs greatly in different species.

Birds. The average clutches of different species of birds vary from one to 15; the largest in a species that feeds its young is ten, in the blue tit *Parus caeruleus*. Clutch size is characteristic for each species and presumably depends on hereditary factors, although there are also phenotypic (nonhereditary) variations, the same individual laying clutches of different size under different conditions.

Egg numbers

In birds that feed their young, clutch size corresponds to the greatest number of young for which the parents can find enough food without serious risk to themselves. For instances, the European common swift *Apus apus* usually lays three eggs. If it is experimentally given four, then, as shown in Table 1, so many nestlings starve that each pair raises, on the average, fewer young than pairs starting with three. Hence, any tendency to lay a clutch of four will be eliminated by natural selection. Similarly, the most frequent clutch size in first broods of the European starling (*Sturnus vulgaris*) and the great tit (*Parus major*) corresponds with that brood size from which the most young survive; in these species, however, the young in larger broods do not starve in the nest, but leave it underweight and die soon afterward.

Table 1: Number of Young Raised by the European Common Swift Apus Apus

brood size	broods observed	number hatched	number fledged	proportion raised (percent)	number raised per brood
2	72	144	139	97	1.9
3	20	60	51	85	2.6
4	16	64	27	42	1.7

Source: Observations by C.M. Perrins at Oxford in the years 1958–61. Broods of four were not natural but were made up by adding newly hatched young from other broods, which does not disturb the parents. Some broods of two came from clutches of two, but others from clutches of three, either through failure of an egg to hatch or because a nestling was removed to make up a brood of four.

Many phenotypic variations in clutch size are adaptive. The Eurasian nutcracker (*Nucifraga caryocatactes*), which stores the food for its young the previous autumn, lays four after a good and three after a poor season for nuts. Various hawks and owls that prey on lemmings or voles lay unusually large clutches in the occasional years when their prey is extremely abundant. Regular seasonal variations in the clutch size of songbirds in north temper-

ate regions broadly fit the seasonal variations in the availability of their food. Individuals breeding for the first time lay slightly smaller clutches than older individuals and are also known to be rather less efficient at finding food. If such phenotypic adaptations were perfect, each species would always lay the clutch best suited to its circumstances, but this would require precise prediction of future feeding conditions for the young.

In hawks, storks, and other large birds, incubation starts with the first egg, so that the young hatch at one- or two-day intervals. This is an adaptation, for if food is sparse, the older nestlings are so much stronger than the younger that they get all of it, while if the food is plentiful, the larger nestlings are sated and the younger are fed; hence the brood size comes quickly to correspond with the feeding conditions at the time, and food is not wasted on young that would starve later. Another adaptation is the growth rate of the nestlings, for the same quantity of food per day can be used to raise a larger brood more slowly or a smaller one more quickly. This is probably why hole-nesting songbirds have larger clutches than those with open nests; the latter suffer such heavy predation that there must be strong selection for rapid growth, but fewer young can then be raised together. A slow growth rate may also be advantageous for species that find difficulty in bringing enough food for even one nestling, such as various large raptors and seabirds.

Another general tendency is for clutches to be larger at higher than at lower latitudes. At the higher latitudes, summer days are longer, so the parents can collect more food per day. Many species breed with the flush of insects after the winter dearth in which many adults have starved, so that food becomes plentiful in relation to adult number, and large broods can be fed. Similar conditions hold in tropical savannas, where birds breed with the rains after a long dry season. In tropical evergreen forests, however, food may be available in nearly the same quantities throughout the year; hence, the number of adult birds may stay close to the limit set by food, there being only enough extra food for small broods.

Although ducks, unlike most birds, do not feed their young, there is a broad inverse correlation between the number and size of the eggs in different species. This suggests that the female's food reserves may be used for more and smaller, or fewer but larger, eggs. Presumably, natural selection has favoured the evolution of a larger egg (and therefore a smaller clutch) in those species in which it is advantageous for the young to be larger, or to carry greater food reserves, at hatching. In a few other birds, including the common swift (*Apus apus*) and the red grouse (*Lagopus scoticus*), the clutch is slightly larger when more food is available for the laying female, but this is a very minor factor.

Natality is also affected by the number of broods raised. Most species raise one a year; many songbirds raise two, some even three, and the Senegal fire finch (*Lagonostricta senegalla*) raises four. At the other extreme, probably because their food is sparse, a few large raptors and seabirds take more than one year to raise a nestling; they breed successfully only once every two years.

Deferred maturity

The young of some finches and doves first breed when two to four months old; most birds when just under a year old; various water birds, raptors, and others not until several years old; and large albatrosses not until about the age of ten. Such "deferred maturity" (like a small clutch) has been seen as an adaptation to reduce natality in long-lived species. But it can as readily be explained in terms of natural selection, provided that those individuals that defer maturity ultimately leave more descendants than those that start breeding when younger. This will hold if (1) younger individuals are unlikely to raise young, and (2) the attempt to breed involves a greater chance of death for the adults. It has been found that in pelicans and herons, which have deferred maturity, immature individuals catch food less efficiently than adults and thus might be unable to feed a brood. Again, in the royal penguin (*Eudyptes schlegeli*), subadults weigh less than adults, presumably because they find it harder to obtain food, and only the heaviest birds breed; presumably this is because big food reserves are needed by the female to form eggs and by the male to take the first long incubation stint. Many species with deferred maturity lay only one egg, which suggests that they find it hard to obtain food for their young. In various seabirds, however, deferred maturity may simply result from an insufficient number of safe nesting sites. Finally, deferred maturity is also found in the males but not the females of various polygynous and promiscuous birds, in which there is such intense competition for mates that younger males may well fail to secure them and in which the elaborate plumage displays probably involve extra mortality from predation. One may conclude that, in birds, the age of first breeding may well have been evolved in relation to the maximum number of young that the adults can raise during their lifetime. Still, the alternative view—that breeding age is adapted to mortality—has not been disproved.

Natality in mammals

Mammals. Mammals produce from one to about 12 young at a birth, the latter being the figure for the African multimammate rat (*Rattus coucha*). In some species, individuals breeding for the first time have rather smaller litters than older parents; in others, such as hares and rabbits, there are seasonal variations in litter size; and in some species litter size varies with latitude. These parallels with birds suggest that similar factors operate in both birds and mammals. It has been shown that, in laboratories, infant mortality in the guinea pig (*Cavia porcellus*) rises with increasing litter size, but the extent to which it may do so in the wild is not known. Similarly, in man, the proportion of stillbirths is lowest for single babies, higher for twins, and much higher for triplets; it is likely that, in primitive conditions with poor food supplies, infant mortality also rises with the number of young at a birth.

Many rodents have several litters a year; many other mammals breed once annually and some only once in two or more years. The female meadow vole (*Microtus arvalis*) is fertile when 25 days old, many mammals when one year old, and other mammals not until several years old. As in birds, larger mammals tend to mature later than smaller ones, but there are many exceptions: at least two species of large whales first breed when two years old, whereas elephants and men mature in their teens. Maturity is also influenced by phenotypic factors. Thus a reduced diet delays maturity in various domestic and wild species; this is because it retards the growth rate, and the species concerned breed at a particular size rather than a particular age. Humans are capable of producing young when quite undernourished, but in the near-starvation conditions of some concentration camps in World War II, many women ceased to menstruate and could not have conceived.

Fishes. In fishes, as in ducks, there is a broad inverse correlation between the numbers and sizes of the eggs; this implies that egg production is limited by the food reserves of the female, and that larger eggs may in some circumstances be sufficiently advantageous to offset the disadvantage of smaller numbers. In general, marine fishes with planktonic larvae have many small eggs, and the larvae hatch with abundant food around them so do not need large food reserves; on the other hand, various deep-sea fishes and those that breed in polar coastal waters have fewer and larger eggs, because food is less abundant for the young and it is advantageous for them to be larger at hatching. Some species that have only a few large eggs protect them by making a case for them or even by staying beside them, and a very few fishes are viviparous (producing their young alive from eggs retained in the body). This has given rise to the idea that, because the eggs are protected, fewer are "needed"; but as suggested earlier, natural selection must favour those individuals leaving the most offspring. Presumably, the species in question leave the most offspring when they utilize their food reserves to produce a few well-nourished and well-protected eggs rather than many small and unprotected eggs.

Most temperate-zone fishes, once they mature, breed in successive years until they die. A few species living in

lakes that dry up each summer breed once and die, their eggs withstanding the drought. More remarkably, various salmon and eels grow for several years and then undertake a long migration from the sea to freshwater (or conversely in the case of eels), where they breed once and die. The long distance between the growing and breeding grounds of salmon and eels doubtless makes it disadvantageous for the female to breed in successive years. If a female can put virtually all her food reserves into eggs, she can produce more at one time than if she has to survive afterward; even so, most species of fishes can probably lay more eggs in a lifetime by breeding in successive years.

The relation between breeding and food supplies

Most fishes, like various mammals, first breed at a certain size rather than at a certain age, and they grow faster and mature earlier when food is more plentiful. Each individual also lays more eggs when it is larger. A striking illustration is the history of the North Sea herring (*Clupea harengus*). In the years around 1925, most of these herring first bred at the age of five; between 1950 and 1952 they bred at the age of four; and after 1952 they bred at the age of three. This was linked with an increase in the supply of their main food, the crustacean *Calanus finmarchicus*. The young of many other marine fishes have also grown faster and matured earlier after commercial fishing made their food more plentiful by removing many of the larger fishes.

Freshwater crustaceans. The inverse correlation between egg number and egg size is also found in crustaceans. Thus the "clutch" (retained in a brood pouch) of the freshwater copepod *Eudiaptomus graciloides* consists of nine to 18 small eggs in spring and of four larger eggs in summer, the total volume being in both cases the same. Food is plentiful for the larvae hatching in spring but not for those hatching in summer, for which food reserves in the egg are therefore advantageous. Similar variations have been found in other species. In the water fleas (*Daphnia*), as in fish, breeding starts at a particular size rather than a particular age, and the number of eggs laid tends to increase as the body size increases. Water fleas also have asexual generations, and the descendants of one female (a single clone) have the same genetic constitution. Individuals of different clones living in the same environment at the same time may differ consistently from each other in egg number, which suggests that there are hereditary differences in the size of the clutch.

Insects. In insects there is also a general tendency for species in which the larvae hatch with abundant food to lay many small eggs and for other species to lay fewer but larger eggs. This reaches its extreme development in the few viviparous species (in which the young develop inside the parent), of which the tsetse flies (*Glossina*) produce only one young at a birth. In some insects, such as the bordered white moth (*Bupalus piniarius*), the number of eggs laid is proportional to the size of the female's body and hence to the amount of nourishment she received as a larva.

In insects that lay their eggs on a limited source of food for the larvae, such as a flow of sap from a tree, a ripe fruit, a cowpat, or a corpse, there is some adjustment of the number of eggs laid to the duration of the food supply and to the number of eggs or larvae already present. An insect is likely to leave more survivors if it seeks another source of food than if it lays its eggs in a crowded or deteriorating source. Aphids, for instance, lay more eggs on fresh young leaves rich in nutrients than on old leaves poorer in nutrients, and a predominance of old leaves may inhibit breeding. Comparable adaptations are found in parasitoid insects; *i.e.*, those that lay their eggs in the larvae or pupae of another species, and in which the larvae obtain their food by consuming the host's body. Those that parasitize species of similar size to themselves lay only one egg in each host and can also detect whether another individual of their species has already laid an egg there. In contrast, species that are much smaller than their host lay many eggs in it. Finally, in the specialized social insects, such as ants and bees, many sterile workers provide food for, and protect, the larvae hatching from eggs laid by the queens. This greatly increases the number of eggs a queen can lay, since egg laying is thus her main or sole duty; the modification reaches an extreme among those termites in which a queen lays 6,000 to 7,000 eggs every 24 hours for a period that may extend over years.

Flatworms. Small animals are often thought of as having more young than large animals. But a freshwater flatworm in the genus *Polycelis*, which is less than 1 centimetre (0.4 inch) long, produces only 2.7 young per cocoon; and the average natality is only 1.0 per adult because many adults do not breed. This low reproduction rate has been shown to be the result of a limited food supply: in one experiment, natality rose by seven times when much extra food was provided in a pond.

Flowering plants. In certain fishes and insects, as already mentioned, the number of eggs laid by different individuals of the same species varies somewhat with their body size. This variation is far greater in flowering plants. In the poppy *Papaver rhoeas*, for example, the number of seeds produced by different individuals of the same genetic constitution, but grown under different conditions, varies between one seed capsule with four seeds and 400 seed capsules with 2,000 seeds each. In some trees, the number of seeds produced by the same plant varies enormously in different years, depending partly on climatic conditions and partly on a tendency for a good crop to be followed by a small one.

Seed variations in plants

When species of plants are compared, it is found that the size of the seeds tends to be smaller when there are more of them. Small seeds are advantageous, not only because more of them can be produced but also because they are dispersed more readily in the air. They are characteristic of those species that colonize broken ground. Because their seeds disperse so readily, species characteristic of broken ground, such as many of the daisy family

From D. Lack, *Natural Regulation of Animal Numbers*, published by Clarendon Press, Oxford

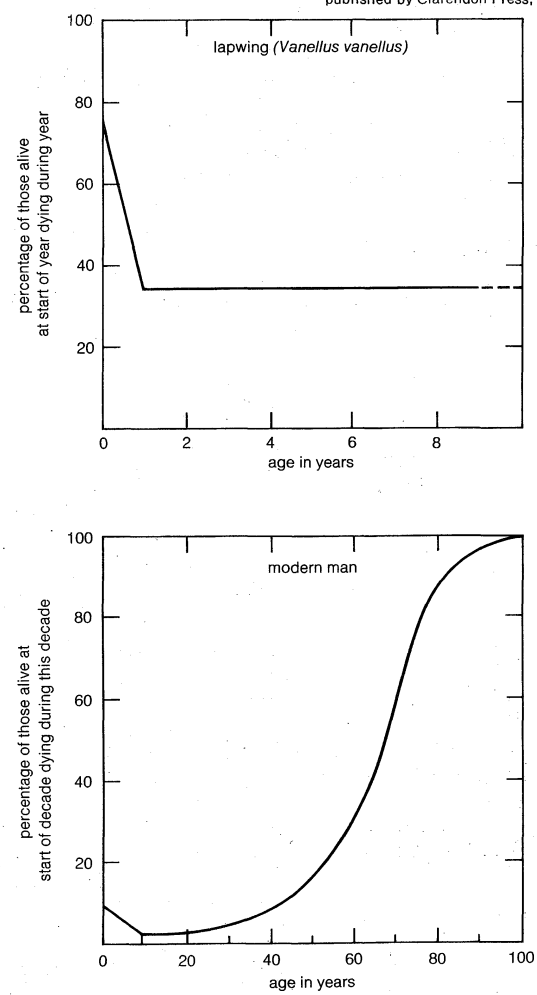

Figure 2: Mortality rate for (top) lapwing (*Vanellus vanellus*) in Britain and (bottom) white men in U.S. between 1929–31.

Compositae, are among the first to reach oceanic islands where, in the absence of competitors, some of them have evolved into trees that have larger and much less dispersible seeds. The seeds of forest trees usually have to germinate in deep shade, so it is advantageous for them to have large food reserves to give them a good start. Some plants, as already mentioned, have two means of reproduction: a seed requires fewer nutrients from the parent plant than a vegetative shoot but has a much smaller chance of survival than a shoot that remains attached to the parent plant until it is viable.

Mortality. The death rate varies at each stage of the life cycle. In long-lived species, the "potential age" to which survival is possible is much higher than the average age at death. Hence it is useful to calculate the mortality and the expectation of further life separately for each age group.

If an animal population is kept under favourable conditions in the laboratory, with plentiful food and without enemies, the annual adult mortality is much lower, and the expectation of further life much higher, than in a wild population of the same species. In the laboratory, mortality may be fairly high in the small young, but it is low in large young and in young adults; and while it rises with increasing age, it is high only in the elderly. At the opposite extreme, among wild birds in natural conditions, the losses of young and juveniles are extremely high. Adult mortality is also relatively high but does not rise with increasing age, nor does the expectation of further life decrease, until the individual reaches senility, as in the case of the lapwing (Figure 2). Relatively few individuals reach that age, however. A similar contrast is found in mankind: mortality in Western civilization (Figure 2) is similar in pattern to that of a protected laboratory animal, whereas that of Neanderthal man and of men living in Roman times seems to have been similar to the pattern of various wild mammals, though not quite so extreme in its characteristics as that of wild birds. Curves for the expectation of further life under different conditions are compared in Figure 3.

Birds. Two methods are available for determining the mortality of birds. The whole of a particular breeding population may be marked, and the number returning in each later year recorded; or the age can be determined of all those birds, banded by many different observers, that are later found dead and reported by others. The former method gives a lower figure for the annual mortality than the latter, probably because breeding birds comprise the most successful part of a population.

In all the birds so far studied, mortality is much higher in juveniles than adults, and it is particularly high soon after the young become independent of their parents. The highest known adult mortality is 70 percent per annum (which means an expectation of further life, at any given time, of only about 11 months), found in the Senegal fire finch (*Lagonosticta senegalla*). The lowest figure is 3 percent (expectation of further life, 33 years) in a very small population of the royal albatross (*Diomedea epomophora*) in New Zealand. As already mentioned, in a stable population, mortality equals natality; correspondingly, the Senegal fire finch has four broods each year with a mean of 3.4 young per brood, while the royal albatross raises, at most, only one young every two years. The mortality of various birds is summarized in Table 2.

Table 2: Annual Adult Mortality in Various Birds

species	average annual mortality (percent)	expectation of further life (years)
Fire finch *Lagonosticta senegalla*	70	nearly 1
Typical songbirds, ducks, gallinaceous birds, and doves shot for sport (northern Europe, North America)	50 (45–55)	1½
Herons, gulls, terns, waders, plovers, and one species of pigeon, in northern Europe and North America	30–40	2–3
Swifts *Apus melba* and *A. apus.*	18–20	5
Penguin *Megadyptes antipodes* (New Zealand), kittiwake *Rissa tridactyla* (Britain), manakin *Manacus manacus* (Trinidad)	10	9½
Gannet *Sula bassana* (Britain) and Australasian shearwaters *Puffinus tenuirostris* and *P. griseus.*	6	16
Manx shearwater *P. puffinus* (Britain)	4	25
Royal albatross *Diomedea epomophora* (New Zealand)	3	33

Mammals. The age of some mammals can be told from the annual rings on their teeth or horns, and that of a few others has been determined by marking. In wild rats, mice, and shrews, virtually all the adults die within a year, while at the other extreme only about 3 to 5 percent of adult African elephants (*Loxodonta africana*) die each year, varying somewhat with conditions. In all the wild mammals so far studied, adult mortality rises steeply with age after the first few years. In the Himalayan tahr (*Hemitragus jemlahicus*), a goat introduced into New Zealand, about half the young die in their first year; in the second year mortality is only 1.3 percent, after which the figure rises steadily to 38 percent in the 12th and 13th years; omitting the first year, overall average mortality is 15 percent. In the male waterbuck (*Kobus defassa*), annual mortality in the second to fourth years is only 2 percent, but in the eighth year it is 14 percent; thereafter it increases steeply, and the overall figure is similar to that in the tahr. Because mortality rises with increasing age, the average annual mortality is a less meaningful figure in wild mammals than in wild birds. In young adult mammals, mortality ranges between 50 and 67 percent in various larger rodents and smaller carnivores; it is between 15 and 40 percent in various deer; but it is apparently only 5 percent in the mountain sheep (*Ovis dalli*) and slightly less in the hippopotamus (*Hippopotamus amphibius*).

High mortality among young fishes and insects

Fishes. The ages of fishes that live in high latitudes can be determined from the annual rings on the scales, bones, and the otoliths in their ears. Fish fry have a huge mortality. In the few unfished populations so far studied, adult mortality rises with age as it does in mammals. In the whitefish *Coregonus clupeaformis*, for example, the figure rose in one lake from 8 percent in the 12th year to 17 percent in the 20th year and to 45 percent in the 27th year; in another lake it rose from 41 percent in the 7th year to 59 percent in the 13th year. Such figures show that annual mortality may differ greatly in different

From D. Lack, *Natural Regulation of Animal Numbers*, published by Clarendon Press, Oxford

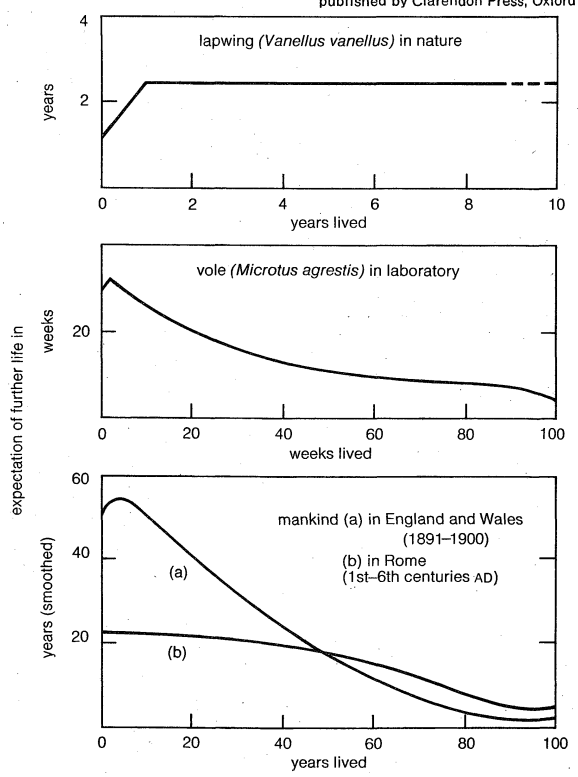

Figure 3: Life expectancy for (top) lapwing (*Vanellus vanellus*), (center) vole (*Microtus agrestis*), and (bottom) man.

populations of the same species. In the Queen Charlotte Islands' herring (*Clupea pallasii*), annual mortality increased from 28 percent in the 6th year to 72 percent in the 11th year. With heavy commercial fishing, however, annual mortality becomes much higher and may be almost independent of age. In one lake, the most common age group of the whitefish had been those aged 6, but after five years of heavy fishing the two-year-olds became most common. The annual mortality of adult plaice (*Pleuronectes platessa*) in the North Sea was 10 percent during World War II, when fishing was suspended, but rose to 50–60 percent afterward.

Insects. In most insects, as already noted, the adults die after breeding; interest therefore centres on the losses in earlier stages. The spruce budworm (*Choristoneura fumiferana*), the larvae of which eat the balsam fir, may be taken as an example. Each female lays about 200 eggs, of which an average of 19 percent are lost (nearly half through insect parasitoids and one-third through predators), leaving 162. Of the newly hatched larvae, 82 percent are lost (mainly through failure to establish on suitable parts of the food plants), leaving an average of 29.2. Of the surviving larvae, 86 percent are lost (nearly half through insect parasitoids and over one-tenth through predators), leaving 2.7 to emerge as adults. Of the adults, about one-fifth are lost before they breed, leaving one male and one female to repeat the cycle.

III. Changes in population characteristics

GROWTH OF POPULATIONS

If a few fruit flies (*Drosophila*) are put in a milk bottle with banana mash suitable for their larvae, or a few flour beetles (*Tribolium*) are put in a tin of flour, or a few water fleas (*Daphnia*) are put in a jar of pond water, they increase through breeding, first slowly, then rapidly, then slowly again. If their numbers are plotted against time, as in Figure 4, they form an S-shaped curve with the ends flattened. The initial slow, and later rapid, increase may actually represent a constant rate of change. A population that doubles its numbers in each generation seems to increase slowly from two to four to eight, and much more rapidly from 256 to 512 to 1,024. This type of population growth is called exponential or geometric.

From W.C. Allee *et al.*, *Principles of Animal Ecology*, 1st ed. (1949); W.B. Saunders Company

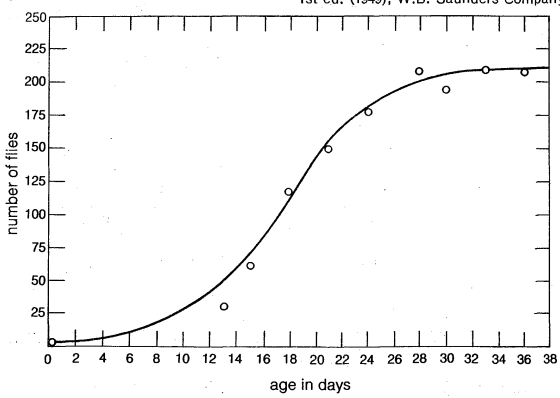

Figure 4: Logistic growth of a laboratory population of the small fruit fly (*Drosophila melanogaster*). Open circles indicate the points resulting from one experiment.

Variable rates of increase

When an animal is introduced by man to a new region suitable for it, it increases at first slowly and then rapidly, probably in an exponential way. After an animal has become abundant where introduced, its numbers in that area may stabilize while at the same time it is spreading into new areas. In this way the house sparrow (*Passer domesticus*) spread from the Atlantic to the Pacific coasts of the United States in less than 40 years. Similar spectacular increases have been recorded among plants: the water fern *Salvinia auriculata* was introduced to Ceylon in 1939, and only 16 years later had put more than 25,000 acres of rice paddy out of production.

Some laboratory populations eventually level off in numbers, but the situation is artificial in that their food supply is constantly renewed. The evidence suggests that, in nature, a successfully introduced population usually declines after a time and does not again reach its first high level, probably because its food supply declines. A few reindeer (*Rangifer tarandus*) introduced to St. George Island in the Pribilovs in 1911 increased to 200 by 1922, fell to 50 in 1926, and fluctuated somewhat below this figure in succeeding years. Another 29 reindeer introduced in 1944 on St. Matthew Island increased to 6,000 by 1963, decreased to less than 50 in the following year, and two years later were practically extinct. They had destroyed their food supply. In the late 19th century the cattle egret (*Ardeola ibis*) crossed from the Old World to the New, where it is increasing and spreading rapidly, but in a habitat (grass pasture with cattle) made by man. Man has also caused the rapid increase of various species in their natural habitats by changing their food situation. The herring gull (*Larus argentatus*) has been increasing rapidly on the coasts of Europe and North America; in the latter continent it has been doubling in numbers every 12 to 15 years since 1900, mainly because it now feeds extensively on fish waste and on rubbish dumps outside towns.

Examples of rapid increase by natural means in natural and undisturbed habitats are far less common because there are usually no ecological niches to be filled. A rapid though temporary natural increase can be observed when numbers have been greatly reduced by a catastrophe, such as a severe winter; the species involved usually attain their former numbers within a few years.

While the rate at which a population can increase is influenced by natality, this is not the main factor determining eventual numbers. Species with a high natality are not likely to be more abundant than those with a low natality. As pointed out by Darwin, the fulmar petrel (*Fulmarus glacialis*) is extremely abundant (and, since he wrote, has greatly increased in western Europe) but has an exceptionally low natality since it lays only one egg a year and requires several years to mature.

FLUCTUATIONS IN STABLE POPULATIONS

A stable population defined

All animal populations eventually stabilize at a level around which they fluctuate between relatively narrow limits compared with what is theoretically possible. The extent of the fluctuations, however, does vary greatly; for example, in studies over a period of 40 years of the gray heron (*Ardea cinerea*) in the Thames basin in England, the largest breeding population seen was about double the smallest. At the other extreme, in studies of the bordered white moth in a German pine forest, the largest population in a period of 60 years was 100,000 times the smallest. But even the largest observed variation is negligible compared with what is theoretically possible. The duckweed (*Lemna minor*) can double in numbers each 2½ days, and at this rate an initial square inch of duckweed would cover one acre in 55 days: yet the waters of the world are not all covered with duckweed. A pair of European robins (*Erithacus rubecula*) producing ten young a year could theoretically increase to over 120,000,000 in 10 years. Since even the largest observed fluctuations are negligible compared with what is theoretically possible, animal populations are said to be "stable"; it should be understood, however, that this term allows for fluctuations of the size mentioned, provided that, in the long term, numbers tend to fall when high and to rise when low. The only unstable populations in nature are those recently introduced to a new area and those decreasing to extinction.

Most biologists consider that populations as stable as those found in nature must be regulated by "density-dependent" factors; *i.e.*, factors that tend to reduce numbers when they are high and to allow them to rise when they are low. The contrary view, still advocated by some workers, is that animal numbers fluctuate irregularly by chance and should not be spoken of as controlled or regulated. The conflict in opinion has been partly the result of a difference in interest. Some biologists have been interested primarily in annual fluctuations (particularly if a pest is numerous only in

occasional years), which may be caused by climatic or other factors acting independently of population density. Others have been mainly concerned with the level about which such fluctuations occur, and it is in determining this level that density-dependent factors are important. Density-dependent factors may affect natality, mortality, or movements of the population; though some populations may be regulated by a single factor, in others two or more factors—for example, food supply and predation—may interact, or the effect of a density-dependent factor may be greatly influenced by that of a density-independent one.

Causes of seasonal fluctuations

Seasonal fluctuations in numbers. Nearly all animal populations show seasonal changes, often quite large. In small organisms, some changes of this type are linked with the time needed to complete one generation, or in marine organisms they may be related to tidal cycles; but by far the biggest fluctuations are connected with seasonal change in the environment—from winter to summer at high latitudes, and from the dry to the rainy season in tropical grassland and savanna. This is because nearly all the animals in such places breed at one time of the year, usually in late spring or summer at high latitudes and in the rainy season (or just after it) at low latitudes. They increase greatly in numbers toward the end of the breeding season and thereafter decline until breeding commences the following year. Hence in studying statistics of animal populations based on annual censuses, it should be remembered that between the annual counts there is each year a big and rapid increase in numbers, followed by a corresponding but more gradual decline, and that these seasonal fluctuations in numbers may be much bigger than those between one year and the next. Figure 5 shows the amplitude of these fluctuations in one species of bird.

In a few natural habitats, notably evergreen forests, tropical lakes and oceans, and the deep sea bottom, seasonal changes are small or almost absent. Even in a rain forest, however, there are small regular differences from month to month in rainfall, vegetation, and the availability of insects; these seem to affect the breeding seasons of many birds. On the other hand, many tropical seabirds that feed on marine organisms on or near the sea surface may breed in any month of the year, which suggests great uniformity in the numbers of their prey and hence also in the food of their prey.

From D. Lack, *Natural Regulation of Animal Numbers*, published by Clarendon Press, Oxford

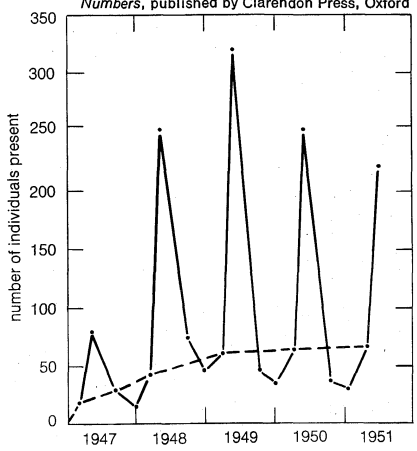

Figure 5: Seasonal changes in population of great tit *(Parus major)* in a wood near Oxford. Solid line represents total population, including juveniles; dashed line, number of breeding adults.

Importance of the climatic factor

Irregular annual fluctuations. All populations fluctuate in numbers to some extent, most fluctuations being irregular. (The few regular cycles are described later.) Large annual fluctuations are usually connected with climatic factors that affect natality or the survival of the young; they are most marked in animals or plants that live for only one year or at least have a high adult mortality, since in such species the young of one year form all, or at least most, of the adult population of

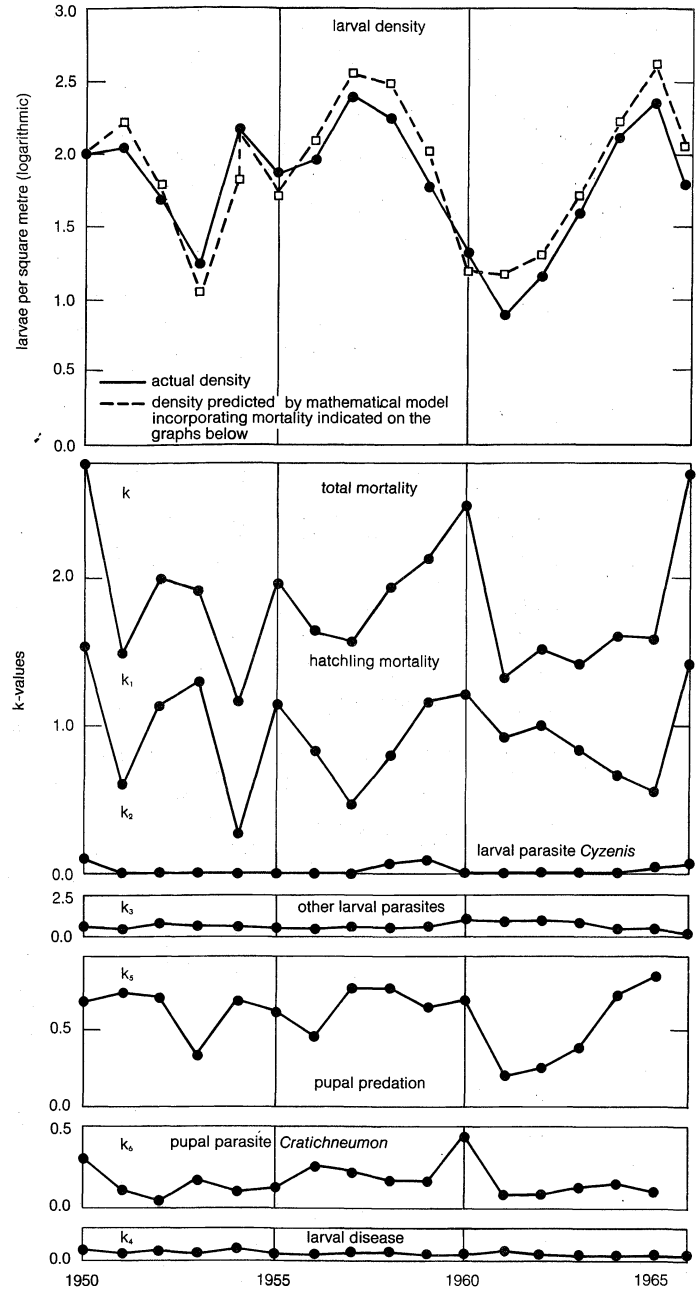

Figure 6: Study of winter moth *(Operophtera brumata)* over 16 years in Wytham Woods, Oxford, showing (top) total population and various sources of mortality (plotted on logarithmic scale). The k-value is the logarithm of the ratio of populations before and after the mortality in question has acted. Note that hatchling mortality k_1 is the only one that parallels annual pattern of total mortality.

From T.R.E. Southwood (ed.), *Insect Abundance;* Blackwell Scientific Publications, Ltd., Oxford

the following year. Large annual fluctuations in the production of young (or of seeds) may, however, cause little change in the numbers of a species in which the adults have reached the limit set by space or food supply, especially if the adults have a low mortality. Also, not all annual fluctuations result from variations in the birth and survival of young; in a species living near the northern limit of its range the adult mortality linked with winter cold may vary greatly from year to year.

Irregular fluctuations in numbers have been of special interest to entomologists, particularly in respect to species that remain comparatively scarce for many years and then have a huge outbreak. Examples are the spruce budworm moth, the larvae of which occasionally devastate the forests of balsam fir in northeastern America, and several other species of moths, the caterpillars of which occasionally strip German pine forests of their

needles. It is thought that in most years the numbers of such species are held down by insect parasitoids or predators, but that if climatic factors lead to an exceptionally high production of larvae, especially in two or more consecutive years, the natural enemies do not have time to increase proportionately; thus, the caterpillars then increase rapidly until they are so numerous that they defoliate the trees and eventually die in large numbers of starvation.

Such occasional huge outbreaks are rare. A more usual picture is presented by the annual fluctuations of the winter moth (*Operophtera brumata*) in a wood near Oxford, shown by the continuous line in Figure 6 (plotted on a logarithmic scale). Figure 6 shows on the top line the mortality of the same species at each stage of its life history; the mortality assignable to each parasite, predator, and disease organism has been plotted separately. Only the hatchling mortality (that is, the loss of larvae between hatching and settling on the young leaves) fluctuates parallel to the overall mortality; it therefore must be reckoned as the key factor in the annual fluctuations in numbers. The numbers of various other species of caterpillars on the same oak leaves fluctuate parallel to those of the winter moth, suggesting that a climatic factor is responsible. This graphic method of key-factor analysis is important in entomological research.

The great tit breeding near Oxford has also fluctuated irregularly in numbers, varying in one wood between 20 and 86 breeding pairs. In this species, the key factor has proved to be the mortality of the juveniles between the time they leave the nest in midsummer and the following November; in that month the juvenile to adult ratio has varied in different years between 0.2 to 1 and 2.6 to 1, parallel to the subsequent size of the breeding population. The cause of these juvenile losses is not known, but it is probably linked with a climatic factor since the number of breeding pairs has fluctuated more or less in parallel for 20 years in broadleaved woods in England and The Netherlands and also in pine woods (a suboptimal habitat) in both countries. The related blue tit in the same woods has fluctuated in a like manner.

Another species with marked annual fluctuations in numbers is the red grouse. The adult grouse eat mainly heather. The average clutch is slightly higher and the proportion of surviving young much higher in summers when the heather has a high nutritive value. The actual mechanism of the link between the state of the heather and juvenile survival is not known. In the years when many young survive, the size of the autumn territories is smaller (see below *Density-dependent natality*), and the breeding population of the following year is larger. These fluctuations in numbers are proportionately greater in areas of low, rather than high, average density of grouse.

The population of the gray heron in England fluctuates as a result of differences in adult mortality; it decreases markedly after each severe winter, presumably because of starvation, recovers quickly in the next one or two years, and thereafter stays more or less stable until the next hard winter. The speed with which numbers return to their earlier level shows the potentiality for increase discussed earlier. That this potentiality is not realized except after a setback in numbers shows that some other factor holds it in check.

Reproduction rates and population density

Density-dependent natality. Density-dependent effects may be of two types: direct, in which increasing population exerts a negative effect on factors causing population growth; or indirect, in which increasing population exerts a positive effect, tending to promote further population increase. The latter would not, however, regulate numbers. The natality of many animals is known to be influenced by food supplies, and since food may be scarcer when the animals are more numerous, it is at least theoretically possible that natality varies inversely with population density. An example is the African elephant (*Loxodonta africana*); as shown in Table 3, both the age of maturity and the average interval between successive calves vary with population density. This is perhaps because, at higher densities, each elephant obtains less food, although the point has not been studied. Another probable example is provided by the southern elephant seal (*Mirounga leonina*). On the island of South Georgia, where adults are killed in large numbers, cows first have pups at the age of three; bulls first arrive on the breeding ground at the age of four and first hold harems at the age of seven. In contrast, on Macquarie Island, where the animals are protected, cows first have pups at a mean age of six; bulls first arrive at the age of six to eight and breed much later (one marked bull at 13 or 14). The age of first breeding depends on body size, and young seals grow much faster on South Georgia than on Macquarie, presumably because the removal of many adults on South Georgia leaves more food for the young. In the North American mule deer (*Odocoileus hemionus*), the average age of first breeding is also known to vary somewhat with population density. The same is doubtless true of other mammals.

Table 3: Reproduction of African Elephant Loxodonta Africana in Relation to Population Density

locality	density per sq mi	mean age at puberty (years)		mean interval between calves (years)
		female	male	
Mkomasi (very dry)	3	11	...	3.1
Tsavo (dry)	3	12½	14½	6.8
Murchison North (less dry)	4	14	15	7.0
Murchison South (less dry)	6	18	19½	8.9
Budongo (forest)	6–7	20	...	...

In the great tit at Oxford (in which the fluctuations in the number of breeding pairs have already been described) clutch size has been observed to vary inversely to some extent with population density, falling by an average of two eggs when the population doubles. This is, as yet, the only such example demonstrated in birds. In fish subjected to heavy fishing, the natality of the remainder rises, because with fewer numbers more food is available and the fish grow faster; both the age of first breeding and the number of eggs vary with body size. In the aphid *Drepanosiphum platanoides*, and doubtless other species, crowding inhibits breeding; this may reflect reduced food supplies, since breeding is also inhibited by food shortage. The number of eggs produced per female is also density dependent in the pine beauty moth, because when the larvae are crowded each forms a smaller pupa, and hence, in the following year a smaller adult, which lays fewer eggs than a larger adult. Again, the number of eggs laid by an insect parasitoid is equal to the number of unparasitized hosts it finds, and the latter number depends in part on the population density of the parasitoid species. Natality is also density dependent in triclad planarians: when two-thirds of the adults of a *Polycelis* species were experimentally removed from a pond, the natality of the remainder was 12 times as high as before, because the remaining adults grew much larger, a higher proportion of them bred, and the average number of eggs per cocoon increased; this effect was presumably the result of an increase in the food supply, because a similar effect was produced in another experiment simply by adding food to a pond, leaving the number of adults untouched.

Density-dependent mortality. A simple example of density-dependent mortality was cited earlier for nestling European swifts in which the mortality from starvation is much higher in broods of four than of three. Broods of young are not, however, independent populations. Three examples from such populations follow.

Density-dependent mortality in sockeye salmon

Salmon fry. In British Columbia, the adults of sockeye salmon come up the rivers to spawn in freshwaters between July and November. The proportion of eggs that fail to hatch rises markedly with an increasing density of adults. Latecomers may expose eggs laid by earlier females; many individuals are forced to lay in suboptimal places susceptible to either drying out or freezing; and

crowded eggs may die from fungal infection or shortage of oxygen. These factors are not sufficient to regulate the size of the population, however, since the total number of young that hatch continues to rise, although at a slower rate.

The small fry suffer heavy predation, chiefly from fishes of other species, on the way from where they hatch to the lake nurseries where they grow. Probably this predation is proportionately less when population density is high. This is evidently because, in years when prey is sparse, the numbers of the predators are held down by the numbers of their prey, and hence in a year with far more fry than usual there are proportionately fewer predators (as their numbers have not yet increased). In such years, small fry have a greater chance of survival than usual, which is probably why, as mentioned earlier, one of the four successive sockeye populations is much larger than the others.

After the fry reach the lake nurseries there is further heavy mortality from predatory fishes, especially in the first 100 days. This is directly related to population density and therefore affects their numbers. While the immediate cause of their mortality is predation, it is closely linked with food shortage, because when the fry are at higher densities their food is sparser; they grow more slowly than at other times, and because they are smaller they are more vulnerable to predation.

The growth rate of the fry is inversely related to their population density, and so is the average weight of the smolts when they set off for the sea. Moreover, the proportion of smolts returning later to breed is strongly correlated with their weight at departure and hence with their density as fry in the lakes. The population density of the fry is therefore inversely correlated with their subsequent survival at several stages of their life history; its overall effect on the production of adult salmon is summarized in Figure 7. The density-dependent mortality of

From *Mitteilungen der Internationalen Vereinigung fur Theoretische und Angewandte Limnologie* (1965)

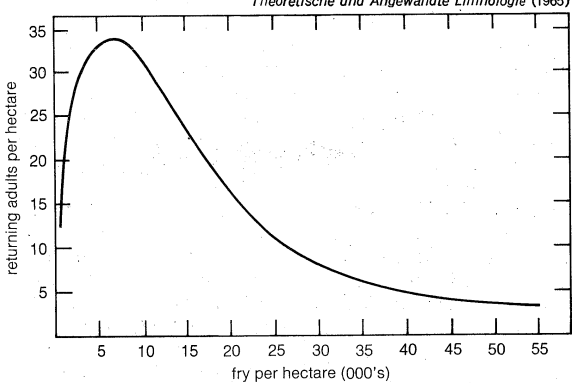

Figure 7: Density-dependent relationships in sockeye salmon *(Oncorhynchus nerka)*: relation between density of fry in lakes and that of returning adults.

the salmon fry regulates their numbers, bringing them down when they are high and allowing them to increase when they are low. The causal factors are predation acting in combination with food shortage.

Density-dependent mortality in flatworms

Adult flatworms. Food shortage also limits the population density of freshwater flatworms (genera *Polycelis* and *Dugesia*), though in a complex way because these relatively simple animals have the power, when food is short, of feeding from their own tissues. A *Polycelis tenuis* eight to nine millimetres (about 0.33 inches) long can survive without food for eight months, during which it shrinks to 1.5 millimetres (0.06 inch). Only the large individuals breed. Three species studied in North Wales feed on oligochaete worms, one of them also on pond snails. When their food supplies start to increase in spring, the surviving large adults breed. But their numbers are sufficiently close to the food limit to mean that the appearance of many small young produces a shortage, as a result of which many large adults become small and many young fail to grow. A little breeding continues until autumn, at which time food is sparse and hardly any large individuals remain; the heavy mortality of small individuals from starvation allows the remaining adults to grow larger. As mentioned previously, the experimental removal of two-thirds of the adults from one pond, and the provision of much extra food in another, caused a large increase in natality. In addition, in both ponds the mortality fell and the proportion of big adults increased. In an experiment in which a population was kept without food, the large individuals shrank to medium size, the medium sized became small, and the small died.

Plant seedlings. Poppies (*Papaver*) have small seeds with small food reserves. When experimental plots are sown with seeds at different densities, the mortality of the seedlings becomes higher at the higher densities, until it is so high that the addition of further seeds does not produce any further increase in the number of surviving plants and may even cause a decrease. The mortality among densely planted seedlings in this and other species has a number of causes, including higher humidity and hence greater fungal infection, more blanching because the plants partly screen each other from the light, and a great attraction of predators such as wireworms.

In similar experiments involving plants with large seeds, such as the corn cockle (*Agrostemma githago*), each seedling has more food reserves and mortality does not rise with increasing density, so that the greater the density of seeds, the greater the density of plants produced. At the higher densities, however, the rate of growth of each plant is greatly reduced, and above a certain density there is no further increase in the total weight of plant matter per unit of area, or in seed production per unit of area. Corn or maize (*Zea*) is another large-seeded plant in which the rate of growth decreases markedly with increasing density of seedlings; above a certain density, the number of seeds on the plants falls, not merely per individual plant but per unit area, although the total weight of green shoots continues to rise. These findings are of importance in determining the most economic density at which to sow crop seeds.

Predator–prey oscillations. In the examples so far considered, mortality was directly dependent on density, in the sense that the higher the density, the greater the proportion of individuals dying. But in some cases the effect of population density on mortality is delayed, notably when a prey species and its predator (or an insect parasite) each limit the numbers of the other. If, for example, both species are scarce, the prey can increase rapidly through reproduction; but the predator can then also increase in numbers, and the process continues until the predator is so numerous that it begins to reduce the numbers of its prey; this in turn brings down the numbers of the predator, and the cycle starts again. In such a cycle, the relationship between prey numbers and prey mortality is not simple and direct. Instead, the prey mortality is low throughout the phase of increase and high throughout the phase of decrease. A particular density of prey is followed by an increase in numbers at one phase of the cycle and by a decrease at the other. This is because the increase of the predator lags behind the increase of the prey.

Early mathematical analyses suggested that, in a predator–prey interaction of this type, the numbers of both species should oscillate regularly and that the oscillations might increase in amplitude with time. Efforts to test this idea in the laboratory ran into difficulties in achieving ecological balance: the predator tended to increase, exterminate its prey, and then die out. Regular oscillations

From *Hilgardia* (1958)

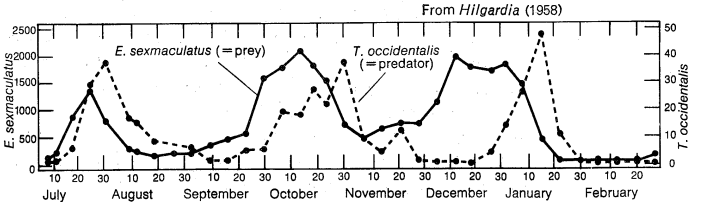

Figure 8: Laboratory study of oscillations in population density of a predator and its prey. The predatory mite *(Typhlodromus occidentalis)* preys upon the orange-feeding, six-spotted mite *(Eotetranychus sexmaculatus)*.

were finally produced in a closed laboratory population (Figure 8), but only when the situation was complicated by the addition of launching posts to assist the prey to reach undiscovered food sources within the culture and of partial barriers to reduce the movements of the predator between these sources.

Permanent reduction in numbers

Few natural populations of predators and prey oscillate regularly in numbers. In some cases in which a predator has been successfully introduced to control a pest, the predator has at first increased greatly; as a result the prey has decreased greatly, and after it the predator, following which both species have remained extremely scarce. This happened when the ladybird beetle was introduced and successfully controlled the cottony-cushion scale insect *Icerya purchasi* in the citrus groves of California. The same result followed when the moth *Cactoblastis cactorum* was introduced and successfully controlled the prickly pear *Opuntia* in Australia. As of 1971 there were over 60 cases in which an insect pest had been greatly reduced through the introduction of a predator or insect parasite and a number of others in which a harmful plant had been similarly controlled by a phytophagous (plant-feeding) insect. These large-scale field experiments show that a single predator is capable of holding the numbers of its prey to a level far below that which prevailed before its arrival. It is generally supposed that the prey continues to survive and to multiply in little pockets, but before it has multiplied far, the pockets are discovered and eliminated by the predator, by which time, however, further pockets have appeared elsewhere. This capacity for movement of both prey and predator can only with difficulty be reproduced in the laboratory.

A phytophagous mite that damaged strawberry plants was maintained at a low enough level by a predator so as to cause minimal harm. The reverse can occur, however, in populations that lose their predators. An example is the mule deer (*Odocoileus hemionus*) on the Kaibab Plateau in Arizona, following the removal of carnivorous mammals and human hunters. A population of about 4,000 deer in 1906 increased to about 100,000 in 1924 but then fell dramatically to about 20,000 in 1931 and to less than 10,000 in 1939, probably because overgrazing prevented adequate regeneration of the food plants (a delayed density-dependent interaction). Similar effects occurred in other parts of the United States following the removal of the natural enemies of the deer. In parts of Alaska where wolves are present, mule deer have a light winter mortality from starvation and the range remains in fair condition; but in parts where wolves are absent, the deer have a heavy winter mortality from starvation and there is marked deterioration in the condition of the range. Thus the interaction between the wolves and the deer greatly modifies the interaction between the deer and their plant food.

A similar situation is found on Isle Royale in Lake Superior, to which a few moose (*Alces americana*) crossed early in the present century. They increased to about 3,000 by 1930, when their food supplies were badly damaged, decreased through starvation to 200 in 1935, rose again to 800 in 1948, and decreased to 500 in 1950. Shortly before 1950, 20 wolves (*Canis lupus*) arrived; after that, up to the last published count in 1961, moose numbers stabilized around 600. The wolves tended to take calves or debilitated animals.

Regular fluctuations in numbers

Regular, large, and continuing cycles occur in the numbers of some wild mammals. If a cycle is regular, one may be reasonably certain that its cause is simple. The best attested example is that of the lynx (*Felis lynx*), which the records of the Hudson's Bay Company, covering over a century, show to have a remarkably uniform periodicity of nine to ten years. The years of peak numbers are similar in its prey, the varying hare (*Lepus americanus*), and clearly its numbers are determined by those of the hare. This is probably not a simple predator–prey interaction, for there is no evidence that the numbers of the hare are brought down primarily through predation by the lynx. The regularity in the successive declines of the hare suggests a simple interaction with some other factor, and the continuation of each decline for several successive years is characteristic of a delayed density-dependent factor; interaction with plant foods is perhaps involved, but this has not been investigated.

The best known regular fluctuations in numbers are the four-year cycles of lemmings. The only population so far studied for a long period is that of the brown lemming (*Lemmus trimucronatus*) at Barrow, Alaska. Lemmings are vegetarian, and at the peak in numbers, about every fourth year, there is heavy overgrazing followed by starvation. Grazing transfers most of the nutrient salts from the vegetation to the lemmings, but the nutrients eventually return to the soil and thus, after delay, become available again to the plants, which regenerate only slowly in the cold soil. Once the plants have regenerated, the lemmings increase again, and the cycle is repeated. Removal of the plant cover by the lemmings also exposes them to predatory birds and mammals, but the latter are not the primary cause of their decline.

Several alternative theories of the lemming cycle have been proposed. One is that lemmings regulate their own numbers by emigration. Emigration is particularly characteristic of the European species *L. lemmus*, which moves out of areas where food has become sparse to others where food is present. But when all suitable ground has been colonized and overgrazed, emigration is of no further benefit; the lemmings then descend in large numbers from the tundra and may even cross rivers or fjords. Another theory is that physiological stress caused by overcrowding (not starvation) induces metabolic deficiencies in the lemmings, especially in the endocrine system, that reduce fecundity or kill them. A third theory advanced to explain the continuation of the declines after numbers have fallen is that genetic changes occur in the population at different stages of the cycle.

The mammals and birds that prey on lemmings, like the predators of the varying hare, fluctuate in numbers with their prey. The goshawk (*Accipiter gentilis*) and the American red fox (*Vulpes fulva*) are of special interest in this connection because in some areas they prey on lemmings and have a four-year cycle, and in other areas they prey on varying hares and have a ten-year cycle. The numbers of grouse and ptarmigan living in the same areas also fluctuate in parallel, for unknown reasons, but presumably because their numbers are linked with those of the rodents through common foods or common predators.

Irregular fluctuations in numbers

The examples discussed so far concern simple, or apparently simple, interactions; but most animals, especially those living in natural habitats outside the Arctic, eat diverse foods and have diverse enemies. Because a diversity of factors is involved, their fluctuations are likely to be irregular. The population of the winter moth at Oxford has already been described in relation to key factors (see Figure 6). This species has a single food, the leaves of the oak, but its diverse enemies include larval and pupal parasites, a disease organism, and several pupal predators. Detailed analysis of the mortality attributable to each of these causes has shown that the main density-dependent factor is predation on pupae in the soil by staphylinid beetles, moles, and shrews, and that the mortality from this cause is sufficient to regulate numbers. A ten-fold increase in the density of pupae, for example, is accompanied by an increase in mortality equivalent to 55 percent.

In 1949 the winter moth was found to have become established as an introduced species in Nova Scotia, where it caused severe damage to trees through defoliation; its numbers were limited periodically by starvation. When the tachinid parasite *Cyzenis* was introduced from Europe, the numbers of the winter moth fell to one-thousandth of what they had been, and defoliation ceased. Although *Cyzenis* is present at Oxford, it is unimportant in controlling numbers there. This illustrates a point made earlier, that the numbers of a species may be regulated in different ways in different parts of its range. To give another example, much of the mortality of young barnacles (*Balanus*) on the rocks in Scotland is the result of intraspecific crowding, but in San Juan Island in the state of Washington, it is the result of predation by

snails (*Thais*); these very different factors govern both the distribution and abundance of the barnacles in the areas concerned.

MOVEMENTS

Movements often have an important effect on the size of a population, especially in mitigating temporary food shortage or overcrowding and are of four main types: migration, emigration, dispersion, and dispersal.

Migration. As commonly understood, migration is a regular, seasonal, long-distance, large-scale movement of populations in set directions between two areas, one of which (rarely both) is used for breeding. The term is also used for short movements, in any compass direction, to a special habitat for breeding, such as are found in many types of land, freshwater, and marine animals.

Migratory species

Many birds breed at high latitudes in summer and move for the winter to low latitudes or to coasts or to the sea. Many others have extensive movements between a breeding and a nonbreeding area within the tropics. A very few, notably the redpoll (*Carduelis flammea*) in northern Europe, the quail (*Coturnix coturnix*) around the Mediterranean, and the quelea (*Quelea quelea*) in tropical Africa, almost certainly breed in two areas in succession, but this is not yet fully proved. In mammals, also, certain bats and the caribou (*Rangifer tarandus*) migrate to breed at high latitudes in summer; various whales feed and form fat stores at high latitudes in summer and breed at low latitudes in winter. Various antelope migrate in the grasslands of tropical Africa. Some fishes and at least one squid migrate regularly like birds. In various eels and salmon, each individual moves once in its life from a breeding to a feeding area, returning after several years to the breeding area and then dying. Various northern butterflies breed in the north in summer; their offspring migrate south and breed; and their offspring in turn fly north the following spring, so that while each individual migrates only once, there is a twice-yearly migration of the population. The monarch butterfly (*Danaus plexippus*), on the other hand, migrates from a northern breeding area to hibernate in the south, the same individuals returning to the northern breeding area the following summer. Other butterflies migrate within the tropics.

The migratory habit enables a species to breed in one area and to survive the winter in another, or to grow large in one area and to breed in another, or even to breed in two areas at different seasons. Nonmigratory animals may have to survive cold or drought in a resting stage as eggs or pupae, or, if adult, in hibernation or aestivation.

Certain northern birds are partial migrants, some of the population leaving and the rest staying for the winter in the breeding area. In such species, the advantages of leaving or staying must be almost equal; this view is supported by the fact that the proportion migrating increases toward the north of the range, where the winters are more severe. Like other adaptations, migratory movements are anticipatory. If food will become scarce, it is advantageous for an animal to move away before this occurs, and similarly it is advantageous to leave a wintering area so as to arrive on time in the breeding area. Many migrant species have evolved special abilities that enable them to sense time, accumulate fat reserves, and navigate over long distances—strong circumstantial evidence that migration is advantageous to the species concerned.

Animals that emigrate

Emigration. Emigration differs from migration in that it occurs at irregular intervals, in a variety of directions, without a set return movement, and in direct response to food shortage or overcrowding. The European red squirrel (*Sciurus vulgaris*) and the Siberian nutcracker emigrate from the taiga in years when they are numerous and coniferous seed crops fail; the waxwings *Bombycilla garrulus* and some other northern birds emigrate when particular berry crops fail; the lemmings (*Lemmus*) move from the tundra when they have overeaten their vegetable foods; the hawks and owls that prey on lemmings also move when the latter decline; water birds breeding beside shallow lakes in the steppes leave in the occasional summers when the lakes dry out; locusts move when overcrowded, producing a special migratory form; and various aphids, after multiplying greatly on a food plant, produce winged forms that drift away (the last response has been shown in *Drepanosiphum platanoides* to be density dependent at the fourth instar—*i.e.*, before the adult stage). Some emigrations are combined with migration, in that they may occur at set seasons and in set directions with later return movements, but the numbers participating are much greater in occasional years than in others.

Emigration is advantageous for any individual that has a greater chance of survival if it moves than if it stays, and hence the habit is explicable in terms of natural selection. It may be specially advantageous in cases of local crowding or local food shortage, when small and inconspicuous movements suffice to take the emigrants to suitable new areas. Even in occasional catastrophic years, when many emigrants die, the chance of survival may be higher for an individual if it moves than if it stays; recoveries of marked birds have shown that some of the emigrants, in fact, survive and return later to their breeding grounds. There is no positive evidence for the alternative idea that the emigrants constitute a doomed surplus that moves out to die in order to save a remnant of the species from starvation; no means are known by which a species can evolve behaviour that benefits unrelated members of the species but is harmful to the participating individuals.

Dispersion. The small and usually inconspicuous movements by which various animals space themselves out, especially for breeding, lead to what is called dispersion. Birds that are solitary breeders tend to be spaced out fairly evenly but with a tendency to be denser where food and other conditions are more favourable; in colonial species, both the spacing and the size of the breeding colonies vary somewhat with the availability of resources. Since adult birds usually breed from year to year in the same place, dispersion is brought about mainly by the younger individuals that are settling for the first time; they seek the preferred habitat of their species, but if it is densely oocupied, they may settle in suboptimal habitats. The latter may give them a better chance of raising young than would otherwise suitable but crowded areas, and therefore suboptimal habitats are occupied chiefly in years of high numbers. Similarly, the young adults of colonial species tend to settle in established breeding colonies but may move elsewhere if these are crowded in relation to resources. In winter, birds join feeding flocks if this helps them to obtain food and leave them if it does not. Similar principles apply to many other kinds of animals.

Dispersal. Dispersal is often used as a general term for animal movements but also in a special sense for the movements of young animals or plant seeds from their birthplace to where they settle down. It has little effect on numbers, although it is an important means by which an increasing species gradually extends its range. In various sedentary or sessile marine animals, however, and in many land plants, specialized larvae or seeds have adaptations for active or passive transport that enable them to settle at long distances from their birthplace.

IV. Interactions of populations

INTERACTIONS BETWEEN MEMBERS OF A POPULATION

Members of the same population may cooperate or compete with each other. Both forms of behaviour are the products of natural selection, in that they benefit the individuals concerned or their offspring.

Examples of cooperation

Cooperative behaviour. Much the most common example of cooperation is parental behaviour, found in simple form in various insects, fishes, and reptiles that protect their young. All mammals, many birds, and solitary wasps feed their young. So do social insects such as ants and termites, but in a specialized way. Cooperative breeding on a small scale occurs in a few birds. In one Australian songbird, a young male of the previous year's brood helps its parents to feed the new brood; in another, several pairs, all offspring of an initial pair, lay eggs in the same nest and feed a combined brood; and in yet another bird, a flightless rail, two males (usually broth-

ers) mate with one female and raise a joint family. In these ways the birds raise more young than they would otherwise, and since the extra helpers are close relatives, the habit can be evolved through natural selection. In certain mammals, family groups of young born in different years also stay together.

Social behaviour between unrelated individuals can be evolved through natural selection only if each participant is likely to benefit. The synchronized swarming for mating of various insects and marine invertebrates probably reduces the chance that any individual will be taken by predators; in polychaete worms it may also increase the chance of the eggs being fertilized. Similarly, the aggregation for mating of certain promiscuous male birds probably helps females to find them and increases the chance that an approaching predator will be noticed. The latter holds true also in the many species of birds, herbivorous mammals, and fish that feed in flocks, herds, or shoals. It has been shown that a solitary wood pigeon spends more time looking for possible predators, and therefore less time looking for food, than does one in a flock. If a predator is seen by one of a group, that member's alarm behaviour alerts the others. Aggregation may also increase feeding efficiency. Birds that search for localized foods, such as seeds, fruits, or shoals of fish, often locate them when they see feeding members of their own species. Certain pelicans and cormorants even help each other to catch prey by driving fish in groups. Lions, wolves, and hunting dogs cooperate in hunting herbivorous mammals.

Competitive behaviour. Competition occurs when resources are sparse in relation to the number of individuals requiring them and when the activities of one individual significantly reduce the resources available for another. In animals or plants of the same species, competition is mainly for food (nutrients); sometimes it is for space—in a sessile animal or a flowering plant for space in which to settle, and in various higher animals for a feeding or breeding territory. There may also be competition for mates.

Methods of competition

Most competition for food between members of the same species happens simply because each individual consumes whatever prey or nutrients it finds. However, in various flock-feeding birds that search for discrete items, such as seeds, one individual may drive another from what it has found. In a first encounter there may be an actual fight, but in later ones the individual defeated on the first occasion usually retreats to avoid a fight. In this way an order of precedence ("pecking order") may be developed throughout a whole flock.

The influence of both flocking and peck order on numbers has been studied in the wood pigeon in rural England. The number of birds that survive the winter each year is closely correlated with the annual variations in the availability of their main food, the leaves of clover in pasture. In the winter flocks, some individuals consistently displace others from food items, and these dominant birds are better nourished and heavier. The rate of disappearance of marked individuals during the winter, presumably from starvation, was found to be greater among subordinate than among dominant individuals, among lighter than among heavier individuals, and among juveniles than among adults. Further, the size of each flock was found to be correlated with the density of clover leaves in the area: when the flock becomes too large for the available clover, the subordinate individuals suffer disproportionately and tend to leave; but if they feed solitarily, they find even less food because of the time spent in looking for predators, and hence they starve. These individuals may also show symptoms of physiological stress such as enlarged adrenal glands, but this is the result of starvation, not crowding. A consequence of the pecking order is that, at any one time, only a few individual wood pigeons—those lowest in the hierarchy—will be starving, while the rest will be well nourished.

Competition often involves the possession and defense of territory. A few bird species that are solitary feeders, especially those that pounce on their prey from perches, defend individual feeding territories. Many more species of birds defend breeding territories, some of them solely for obtaining mates, others solely for nesting, but some for both breeding and collecting food. A few species, like the raven (*Corvus corax*) and the oyster catcher (*Haematopus ostralegus*), maintain an almost constant number of breeding pairs from year to year, presumably as a result of their territorial behaviour. The tawny owl (*Strix aluco*) also appears to maintain stable numbers through territorial behaviour. Its food supply, woodland rodents, is extremely variable; indeed, in some years the birds cannot breed, but they remain on their territories, perhaps because they hunt most efficiently when they know an area well. In contrast, the territories of the nomadic short-eared owl (*Asio flammeus*) are much smaller in years when, and places where, their rodent prey is abundant. Territory size also varies greatly in the same place in different years in the great tit (but here it is unrelated to food supplies) and red grouse; if owners are shot, other individuals take their place—coming, in the great tit, from suboptimal habitats, and in the red grouse, from individuals without territories that will die unless they obtain them. The pressure to obtain territories is evidently great, but the general significance of bird territory in relation to population density and food supply remains unknown.

Many rodents, ungulates, and carnivorous mammals fight each other at times. The significance of such fighting in nature, and its possible role with respect to regulating numbers or food supplies, is not known. Much fighting, of course, is connected with mating, especially in polygynous mammals, but this is not of concern here. Where fighting is related to population density, one may guess that it stems from a shortage of food or from some other factor that constitutes the primary means of population regulation. Territorial and other fighting also occurs in various lizards and fishes, and in sticklebacks it appears to limit the breeding density.

Dragonflies and ant colonies are also territorial. So are a number of marine invertebrates, the food of which is uniformly distributed, notably the grazers and those that eat detritus. The marine amphipod crustacean *Erichthonus braziliensis* defends its feeding territory from wandering individuals of its species, and, as it grows larger and feeds over a larger area, it evicts smaller individuals that have settled within this area. Barnacles also compete, in this case for space in which to settle and later to grow, and they destroy neighbours in the process.

INTERACTIONS BETWEEN POPULATIONS OF DIFFERENT SPECIES

The principle of competitive exclusion

Competition among species. It is generally agreed that two species with the same ecology—that is, which relate in the same way to the same environment—cannot persist in the same area. Where resources are limited, this is an inevitable consequence of natural selection, since it is unlikely that both species will be equally well adapted. If they meet, either one eliminates the other or each replaces the other in parts of the same range or habitat. Where two species coexist, each depends on different foods or other resources. This principle of competitive exclusion is fundamental to the understanding of animal and plant communities.

The main evidence in nature for competitive exclusion is that, in fact, no two species living in the same area have the same ecology; and in many cases of apparent overlap, important differences have been found by careful observation. Instances are known among birds in which one species has replaced another. The habitat of suburban Singapore was at one time colonized by a native munia, *Munia majah*, which was later replaced by the introduced *Munia punctulata*. It was also colonized by a native tailorbird, *Orthotomus sericeus*, but as forests were cleared to the north a related Indian species, *O. sutorius*, spread south and replaced it, though the native species still holds its own in the original coastal habitat. The fields and towns of the Canary Islands were formerly inhabited by the rock sparrow (*Petronia petronia*); but the Spanish sparrow (*Passer hispaniolensis*) later established itself in the towns, and the rock sparrow is now confined to the

countryside. Replacement has also been observed in wholly natural conditions. The brambling (*Fringilla montifringilla*) has replaced the chaffinch (*F. coelebs*) in the extreme north of Europe, and in recent warmer summers the boundary between the two species has shifted north, presumably because of competitive exclusion. Similarly the more southern curlew (*Numenius arquata*) has spread north at the expense of the related whimbrel (*N. phaeopus*).

In birds, no two species are known to coexist and eat the same food supplies, except where food is temporarily superabundant. But animals that are not limited in numbers by food can persist in the same place, even though they eat the same types of food. That is why several species of caterpillars can be found on the leaves of the same tree; they are limited in numbers by insect parasitoids, and each caterpillar species is parasitized by a different species or set of species. It is less easy to see how plants can coexist, since they depend on the same basic resources of light, nutrients, and space; but their roots descend to different depths, they grow at different seasons or to different heights, and they respond differently to the insects that eat them. Laboratory experiments have shown that two species of grasses, or a species of grass and of a clover, can coexist in a stable manner. Other experiments involving microscopic plants, protozoans, flour beetles, and other small animals have demonstrated competitive exclusion among them; while the principle itself scarcely needs such demonstration, the experiments have provided quantitative analyses of the ways in which such competition works under different conditions and of the effects of the differing adaptations of the competing organisms.

Animals that live upon one another

Negative direct interactions. Other species of animals interact with each other because one lives upon another. A predator is usually, though not always, larger than its main prey; a parasite is much smaller; while insect parasitoids, the larvae of which eat the living larvae or pupae of another species, are intermediate in various respects between predators and true parasites. Predators and parasitoids destroy their prey. The young of brood parasites, such as cuckoos (*Cuculus*) and cuckoo bees (*Psithyrus*), are raised by other birds and by social insects, respectively; in some cases they destroy the host young. Many internal parasites do little harm. Some disease organisms kill their prey and others seriously weaken them, but many have evolved less harmful effects, since it is usually not advantageous to them to destroy their home. Most blood-sucking and other ectoparasites do little harm, except as carriers of disease organisms. There are also bird "pirates," such as skuas or jaegers (*Stercorarius*), which merely rob other birds of their prey.

Most predator species take a variety of prey species. Many take different main prey in different areas or at different seasons in the same area, and if their normal main prey becomes scarce, they often turn to other species. Insect parasitoids, in contrast, often have specific hosts; their time of emergence coincides with that of the larvae or pupae that they parasitize, so their effect on prey numbers is somewhat different from that of predators. Both predators and parasitoids, however, may hold plant-eating prey species below the level at which they seriously damage the vegetation.

The role of disease in regulating numbers is uncertain. In various mammals, such as the mule deer (*Odocoileus hemionus*), in which undernourished animals often die of disease, food shortage is the critical factor. Diseases caught from introduced birds have eliminated various native birds from Hawaii and probably New Zealand, but these are examples of elimination rather than regulation of numbers. Since disease organisms spread more readily in crowded than in sparse populations, their influence is potentially density dependent; but this may be offset by their tendency to evolve less deleterious effects with time. Nearly all the attempts to control insect pests by disease organisms have failed. In Australia, however, huge numbers of the rabbit *Oryctolagus cuniculus* were killed by a viral disease (myxomatosis) in the years immediately after it was introduced, and two decades later, their numbers were well below what they had been. In laboratory populations of the flour beetle *Tribolium castaneum*, the level at which numbers are maintained with a constant food supply is 2½ times as high in the absence of the sporozoan parasite *Adelina* than when the parasite is present. In experiments on competitive exclusion, *Tribolium castaneum* usually eliminated the related species *T. confusum* in the absence of the parasite, but when it was present in both species, *T. confusum* was the more successful.

Cooperation among species

Positive direct interactions. Brief mention may be made of the ways in which different species may help each other, although these do not have a direct influence on populations except in allowing a species to fill an ecological niche it otherwise would not fill, or to obtain food more easily, or to obtain greater defense from predators. In some such associations, each species is entirely dependent on the other, as for instance in the fungus and green alga that comprise a lichen, or in the mycorrhizal fungi on the roots of various trees and orchids, or in the intestinal micro-organisms that break up cellulose for herbivorous mammals or termites. In other cases, although both species benefit, each can exist without the other—for example, in the associations of crabs and sea anemones, in which the crab gains protection through the anemone's tentacles, and the anemone gains food fragments from the crab. Again, the greater honey guide (*Indicator indicator*) finds wild bees' nests, to which it guides the ratel or honey badger (*Mellivora capensis*); the latter breaks them open, after which both feed on the contents. In many other associations, only one of the two species benefits. Various birds follow, or ride upon, large mammals, catching the insects they disturb. Small birds nest alongside the homes of stinging hymenopterans or large raptors, thus gaining protection from predators. There are even looser associations, such as the mixed-species herds of mammals in which all the individuals probably benefit from the greater awareness of the approach of a predator.

Populations, Human

Human populations can be studied on the basis of nation, language, religion, degree of economic or political complexity, or number of inhabitants per square mile, but the most basic approach involves analysis of population differences in biological composition. Usually designated as race, the biological variation among human populations is one aspect of man's relation to the rest of the animal kingdom. Wherever its members may live now, each race was once a geographical unit, a collection of genetically related local populations, differing from other geographical units of the habitable parts of the earth in heritable biological characteristics, including visible ones, such as skin colour, hair form, facial features, and body proportions, and invisible ones, such as the numerous blood groups now known. Unlike the visible characteristics, which can be expressed by a series of measurements, the latter cannot be expressed statistically in terms of overall biometric statistics, by ranges, means, standard deviations, standard errors, and the like; and thus they are not morphological (having to do with form or structure). They are rather expressed in terms of calculated gene frequencies, something that cannot yet be done with polygenic criteria (which are based on the interplay of two or more genes), such as the crown diameters of the teeth. To this uncertainty may be added individual differences influenced by growth, aging, and use, such as the breadth of the human face. Current limitations on the ability to calculate gene frequencies, however, force anthropologists to use morphological techniques in order to study human variation.

Race as a geographical unit

Regardless of the methods used to study them, however, races have long existed in time and space. Without a knowledge of human variations in time, the concept of race becomes two-dimensional, lacking depth and impossible to understand clearly. Because virtually all of the known remains of ancient humans lack soft parts, it is not possible to do blood-typing or other tests to determine the genetic composition of prehistoric populations. The specimens that must be used to reconstruct the evolution of living races are fossils consisting of bones and teeth, from which only morphological information can be gained. Modern population genetics is a welcome addition to the store of knowledge and methodology used in the study of human populations, but it cannot completely replace morphology because of the impossibility of carrying out genetic studies of human populations of times past.

Evolution and genetic variability

Evolution involves the interaction of the forces of mutation, variation, and selection. At any given moment its end product is a change in the frequencies of genes in a given population, and this change constitutes adaptation to either or both of the twin aspects of environment, the physical and the behavioural. For human beings, behavioural selection is more or less synonymous with cultural selection.

In man, the evolutionary result of behavioural patterns (behavioural selection) primarily concerns success in reproduction, which may vary greatly between individuals, particularly in societies in which men may marry several wives. This was probably a common custom in the period when modern human races were being formed, about 10,000 years ago, when all men were still hunters and gatherers, living in bands of between 20 and 100 persons, probably averaging close to 40. Population densities in such eras were less than one person per square mile. This projection is made by studying the ways of life of hunting peoples who survived into the 19th and 20th centuries in scattered parts of the world. Among such hunters each band seeks its food within its own territory.

Although the mating procedures of human groups 10,000 years ago probably varied, it is probable that most or all forbade sexual relations between parents and children and between brothers and sisters. By extension of this kinship relation, first cousins were sometimes also sexually out-of-bounds, either on both sides of the family, if descent were traced through both father and mother, or on one side only, if descent were traced through a single parent. The application of these incest rules plus the small sizes of the bands usually made exogamous marriages (marriages outside the group) necessary. The usual breeding unit was thus a number of neighbouring bands that habitually exchanged marriage partners and occupied one more or less unified geographical area containing several food-gathering territories.

The members of such a cluster of contiguous bands spoke their own language, observed their local customs, and guarded their sources of food from trespass by others. Strong cultural ties developed and bound them together and set them apart from outsiders. Within such a unit everyone was, from a modern point of view, quite closely related to everyone else. Under these circumstances local genetic combinations could vary considerably over short geographical distances.

Culture, kinship, and human variability

Behavioural selection also took place on an individual basis. A poor hunter, unable to bring in much game, might not be able to obtain a wife, and the genes that made him an economic liability would thus be reduced in the local gene pool. An outstanding hunter and leader in counsel and war might acquire several wives and beget more than his share of children. His favourable genetic characteristics and those of the women who shared his favours would be disproportionately high in the next generation and might thus contribute to an overall genetic change, including the incidental proliferation of other genes unrelated to procreative success (fitness).

THE PREHISTORIC BASIS OF HUMAN RACES

The primary breeding grounds of early man. During the late Pleistocene (the last geological epoch before the present one, lasting from about 2,000,000 years ago to about 11,000 years ago) many bands and groups of related bands of hunters occupied the habitable parts of the world's primary geographical regions, known to zoologists as the Ethiopian, Palearctic, Oriental, Australian, Nearctic, and Neotropical regions. When modern human races were first evolving, toward the end of the Pleistocene, only the first three regions were inhabited by human beings. Those of the New World (Nearctic and Neotropical) and the Australian were separated from the continental landmasses of the Old World and its islands by Wallace's Line (the observed dividing line between Asian and Australian faunal distribution) in the East Indies, by the cold landmass of Eurasia north of the winter frost line, and by the Bering Strait (Figure 1).

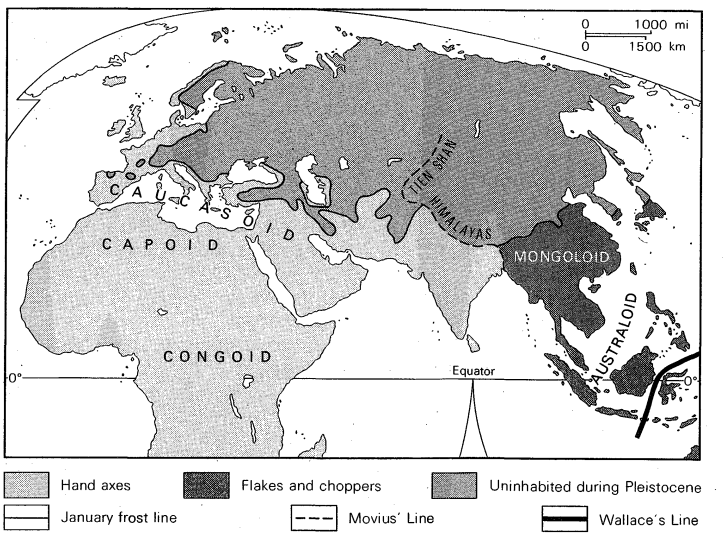

Figure 1: Distribution of human groups through habitable regions of the world in the late Pleistocene.

The geographical range of early man

For ancient peoples still lacking adequate environmental protection, the area of Europe habitable in winter was a stretch of land along the Atlantic, Mediterranean, and Black Sea coasts, tempered by the Gulf Stream and by large inland bodies of water. Nearly all of central and eastern Europe and of central and northern Asia were

too cold to support human life and so acted as a barrier to migration. Pleistocene people lived in parts of Anatolia, all of Syria, Palestine, and Arabia, and parts of Iran and Afghanistan. Nearly all of Pakistan and India were habitable, as were Southeast Asia, most of Indonesia, and much of eastern China. The entire continent of Africa was warm enough to be habitable, but water created certain barriers. Before the Nile had broken through to the Mediterranean, a band of shallow lakes stretched across the southern border of the Sahara (then a fertile plain). The Congo River Basin was also flooded until after the end of the Pleistocene.

The Palearctic, African, and Oriental faunal regions are thus narrowed down into six major breeding grounds of early man, each more or less isolated. One was in Europe and western Asia, a second in Africa north of the sub-Saharan water barrier, a third south of it and excluding the Congo River Basin, a fourth on the Indian subcontinent, a fifth in Southeast Asia and Indonesia, and a sixth in eastern China. Paleontologists have discovered early fossil remains in all of them except India, where geological conditions are generally unfavourable for the preservation of bone. Fossil remains in the other five indicate that each area contained a morphologically distinct human population of its own. Some may have contained more than one such population, and what kind or kinds of men lived in India is not yet known. Science may have one clue in stone tools. In all of the inhabited regions, west of Movius' Line (see Figure 1), where hand axes were made, stone-tool cultures were similar. In the eastern regions a different series of stone-tool cultures is found, based on flakes and choppers rather than hand axes. In India the two overlap.

The braincases, facial bones, and teeth of each of the five known major geographical populations differed in varying degree from the others, and these differences are reflected to a certain extent in the corresponding bones and teeth of peoples still living in the regions or in more recently settled regions inhabited by migrants from the originally inhabited areas. Available evidence thus indicates that some of the basic morphological differences among living human races (which are greater than those between geographical races of most other mammalian species) are very old and that the living races of man may not, as some anthropologists believe, have arisen from a single parental population some 30,000 years ago and then have become rapidly differentiated into the living races.

The major divisions of mankind during the Pleistocene. The Pleistocene human populations of the six major breeding grounds of the Old World are represented by a number of individual skeletons or parts thereof, not all of which have been adequately described in published articles. Most are cranial fragments and mandibles, with or without teeth. The number of fossil remains are approximately as follows: Europe, 200 individuals; western Asia, 40; North Africa and the Sahara, 15; sub-Saharan Africa, four; India, none; Southeast Asia and Indonesia (mostly from Java), 30; Australia, three; North America, three.

Grade and line variation

These specimens vary in two ways, known to paleontologists as grade and line variations. The former concerns the stage of evolutionary development of the individual as seen in progressive increases in brain size and progressive decreases in bony struts on the braincase generally related to jaw musculature. Browridges and nuchal crests (bony ridges at the back of the skull that anchors neck musculature) and, to a lesser extent, teeth grow smaller, and a chin emerges in specimens of more advanced grade. Since all races have gone through such changes, they are not really racial criteria, except in the limited sense that some groups show these "advanced" characteristics in more extreme form than others.

Most authorities postulate two sequential grades, called *Homo erectus* and *Homo sapiens* (*qq.v.*). Others favour the insertion between them of an intermediate stage, that of *Homo neanderthalensis*, though the label is a misnomer in that it tends to confuse the European and western Asian Neanderthals, a local population or race, with populations in other parts of the world, who were probably unrelated to the real Neanderthals, whose morphological features were derived in part from the fact that they had rickets.

Differences in line are racial. While living races differ in many cranial and dental details, the easiest to trace in the available fragmentary fossil material are the degree of facial flatness found in the region of the eyes and nose and the relative size of the front teeth compared to that of the cheek teeth (incisors and canines versus premolars and molars).

The faces of the European and western Asian skulls are the least flattened and have the most prominent nasal skeletons. The Chinese and, apparently, the North African skulls have the flattest faces. In the Chinese specimens the front teeth are large compared to the cheek teeth, and in the Javanese specimens the reverse is true. Chinese incisor teeth are particularly noted for their concave lingual (back) surfaces (shovel-shaped incisors). These differences are seen also in living populations from the same region, which thus seem to be descended, at least in part, from these fossil types of an earlier evolutionary grade.

Fossil evidence of racial distinctions

Because of these apparent continuities, fossil specimens from Europe and western Asia have been called Caucasoid; those from Java, Borneo, and Australia itself have been considered Australoid; those from eastern Asia and North America are termed Mongoloid; those from North Africa and the Sahara may be called Capoid (a term applied to the living Bushmen and Hottentots, who resemble the Pleistocene North African fossils in skull morphology); and those from southern Africa from Tanzania southward may be classed as Congoid. In southern Africa the Congoid peoples apparently preceded the Bushmen. The term Negroid (which usually includes Capoid and Congoid) is avoided for Negroes proper because it fails to include the Pygmies, who also belong in it, and Negroid also had been commonly used to imply such features as spiral hair and black skins, shared by Africans with Melanesians, Negritos, and other Asiatic and Oceanic peoples genetically unrelated to African Negroes.

As far as anthropologists can tell, the Pleistocene distribution of these five major geographical races of man were as indicated in Figure 1.

Prehistoric racial movements. During the latter part of the Würm, or Wisconsian (last), glaciation (from about 30,000 years ago to about 10,000) continental ice caps immobilized enough of the earth's water to lower the oceans more than 300 feet below their present levels. At that time only a narrow strait at Wallace's Line separated the Sunda and the Sahul shelves, facilitating human migration from Southeast Asia and Indonesia into Australia, New Guinea, and Tasmania. The Bering Strait was a flat plain several hundred miles wide, over which the ancestors of the earliest American Indians were able to enter North and South America, hitherto empty of human habitation. Meanwhile, the Nile had broken a channel through what are now its cataracts to empty into the Mediterranean Sea, thus draining most of the sub-Saharan lakes and swamps that had formed a water barrier between the central and western Sahara and tropical Africa. Considerably later, the Congo River eroded its way through Livingstone Falls to the Atlantic, draining its basin, into which the Pygmies later migrated, presumably from the swamps to the north.

Expansion of human populations with the introduction of agriculture

At the end of the Pleistocene, while the ice caps were shrinking and the seas rising, the previously glaciated regions of Europe, Asia, and North America were first occupied, by Caucasoids, Asiatic Mongoloids, and American Indians, respectively. By that time or soon afterward, some peoples in both hemispheres had begun to grow crops and to domesticate animals, allowing an increase in population density and causing expansion and migration. Mongoloid peoples moved down from China into Southeast Asia and Indonesia, displacing some of the indigenous Australoids, who took refuge in the mountains and islands. Capoids travelled through the eastern African highlands from the Sahara to South Africa, while European and western Asian hunters invaded North Africa,

to become the ancestors of the Berbers. Dravidian-speaking Caucasoids carried Western agriculture to India, while Munda-speaking peoples, part Australoid and part Mongoloid, introduced Southeast Asian plants to eastern parts of India. Agricultural people had settled numerous islands of the Pacific and Indian Oceans, notably Polynesia, Micronesia, Melanesia, and Madagascar.

By the time that Columbus and Magellan had completed their intercontinental voyages, the racial composition of the world's human population was already much more complex than it had been during the Pleistocene but less so than it has become since. The colonizations that followed the Age of Discovery gave birth to the intricate racial mosaics that now exist, and this distribution would have been difficult to understand without some idea of racial prehistory and early history.

THE LIVING RACES

Now that most of the world's populations have been described by human biologists, the five original geographical races, plus the American Indians, can be divided into several living components. Within its own extended region, each geographical race shows variations in body size, body proportions, head and face form, pigmentation, hair form, and body-hair distribution. These variations within a single geographical race are comparable in magnitude to those found within entire species of other animals across their geographical ranges. Among such geographical variations are differences in gross body size in response to temperature gradients also seen in other animals. According to Bergmann's Rule, in warm regions body size, in terms of weight, tends toward a minimum; it increases as temperature falls to a certain critical threshold and decreases again in regions of greater cold. According to Allen's Rule, body proportions also vary climatically. Lean trunks and long, slender extremities may be observed in arid regions, where greater skin-surface area in proportion to body weight may facilitate heat loss; stockier builds with relatively short extremities characterize the inhabitants of damp and cold places.

Extremes of variation in body size and hair form

Also, the Australoids and Congoids are divided between full-sized and pygmy populations. Among other animals, dwarf races, such as the pygmy hippopotamus and the pygmy chimpanzee, are often considered by zoologists to be separate species. The Australoids are further divided into populations having wavy hair and those having spiral hair. The extreme variation in hair form in man, with the coarse, straight hair of the Mongoloid at one extreme and the finely coiled, peppercorn hair of the Bushmen at the other, also exceeds the range found in nonhuman mammals, including the rest of the primates.

Races also differ physiologically and anatomically from one another. These differences involve the blood (and blood vessels), the endocrine hormones, the nervous system, and, to a certain extent, behaviour. Blood supplies the body with nutrients and oxygen, prevents certain infectious diseases, and helps maintain the heat balance of the body. It also humidifies and warms air entering the lungs through the nose. In deserts, mountainous regions, and the Arctic, a long, narrow nose serves as a better humidifier than a short, broad one, which is adequate in damp tropics. Since all of these functions are closely concerned with environmental protection, and each geographical race occupies a range of environments, certain parallels may be seen between those populations of most of the human races that occupy similar environments.

Physiological and cultural adaptations

Physiological adaptation to damp heat comes mainly from dense skin pigment, which absorbs solar heat and activates the sweat glands, cooling the air immediately around the skin. Adaptation to moderate cold comes either from a high basal metabolism with a heavy consumption of fat or from reduced circulation in the extremities in order to preserve heat needed for the more sensitive organs of the abdomen and for the brain. Adaptation to extreme cold is mostly cultural, through the use of warm clothing and housing, plus a heavy fat consumption. Adaptation to high altitude requires a large volume of blood and large lungs, supplying extra oxygen to compensate for the thinness of the atmosphere.

A yellowish or light-brown skin reflects light most efficiently in regions of intense sunlight, such as deserts and snowfields. Persons with fair skin may suffer from an overdose of vitamin D_2, particularly in deserts, while those with black skins may become overheated. In less brightly lit regions the latter may absorb too little vitamin D_2 to prevent rickets without dietary compensation.

Cultural behaviour is again responsible for differences within segments of populations living in urban civilizations. There a surplus of food, combined with the need for the skilled services of full-time specialists, has allowed for the rise of metalworkers, scribes, clergy, and the like. Craftsmen, scholars, and administrators tend to marry within their own groups, and through the generations their offspring are selected for their special capacities. On the other hand, a relaxation of selection also occurs, which may transmit such traits as myopia and colour-blindness, which would be selected out as disadvantageous among hunters. Individuals who migrate from farms to cities also have been shown to be different in some biological respects from those who remained behind, and comparable differences have been observed between migrants to new continents and those who chose to stay at home. The flood of scientists and scholars from despotic regimes in Europe to the New World exemplifies this principle, as does the more recent "brain drain."

Blood and race. In addition to morphological data, there are now broad geographical data on blood groups and factors, except from Arabia, China, and Siberia, where little information has yet been obtained. These blood groups and factors include the so-called transfusion (ABO) group, the Rhesus (Rh) group, the MNSs group, and numerous other factors, including variant hemoglobins and haptoglobins (for discussion of the various human blood groups, see BLOOD GROUPS). These conform more or less to the geographical distribution of morphological races, although no genetic association has yet been demonstrated between any blood factor and any somatic criterion. The transfusion group blood types have been shown to have a relationship to certain diseases. For example, blood type A resists smallpox, and B resists various cancers and possibly plague, and both A and B alternately resist different strains of *Escherichia coli*, which may cause infant diarrhea. Both Rh and transfusion-group incompatibilities can cause spontaneous abortion as a result of a reaction to the fetal blood as foreign. Sickle-cell anemia and thalassemia, genetic diseases involving abnormal hemoglobins, help affected individuals resist malaria.

Distribution of blood-type frequencies

Caucasoids and Congoids have two A factors in the transfusion blood group, A_1 and A_2, and both have the Rh-negative blood type. Both of these are almost or completely lacking in other races. Blood type O is highest in the populations of lands first occupied during the late Pleistocene (*i.e.*, Australia and the Americas, except for the Eskimo), possibly because of negative selection due to the absence of those diseases against which blood types A and B offer protection. Blood type M in the MNSs system is at its peak in the Americas, type N in Australia. The Pygmies have a special haptoglobin factor and the Bushmen a special hemoglobin factor, both of which other Africans lack. On the whole, European, western Asian, and African populations present an overall constellation of serological factors, with many local variations; eastern Asia, Australia, Oceania, and the Americas present another. Like morphology, serology divides the native populations of the world into two broad geographical realms, western and eastern.

Fingerprints and race. Like blood groups, fingerprints vary racially in frequency of types and are inherited. They are probably not influenced by environment, since their development is complete by the 18th week of fetal life. There are three basic fingerprint patterns: arches, loops, and whorls (see Figure 2). In general, Caucasoid populations have between 1% and 10% of arches, Negroes between 3% and 12%, and Pygmies and Bushmen between 10% and 16%. All other populations studied, except the Ainu of Hokkaido, Japan, have 5% or less. As for loops, Europeans, Africans, and Ainu range from

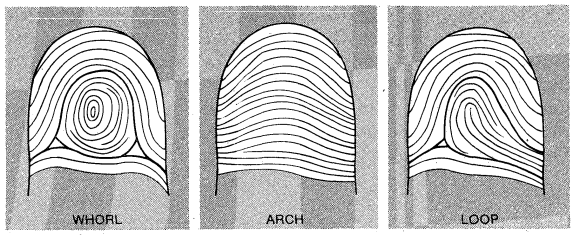

Figure 2: Basic types of fingerprints.
From H. Cummins and C. Midlo, *Fingerprints, Palms, and Soles: An Introduction to Dermatoglyphics* (1961); Dover Publications

52% and 76%, and all others range from 28% to 64%. In whorls, the Europeans, Africans, and Ainu range from 16% to 42%. Western populations exceed the eastern in arches and loops, and within the western group the Pygmies and Bushmen distinguish themselves from Negroes; eastern peoples, again excepting the Ainu, exceed westerners in percentage of whorls. The division of the world on this basis parallels that of the distribution of blood-group factors.

CAUCASOIDS

The Europeans. Modern Europeans are descended in part from the Pleistocene inhabitants of Europe and in part from migrants who have entered it from western and central Asia in more recent times. Most of them speak Indo-European languages, except the Finns, Lapps, Esths, Magyars, and others, who speak Finno-Ugric languages; and the Turks, Tatars, and (until recently) the Mongolian-speaking Kalmyks, who speak Altaic languages. Most Europeans are (or were) Christians, but there are Muslims in Turkey, Yugoslavia, and Albania; the Kalmyks were Buddhists; and there are people of Jewish faith in most European countries.

In 1899 the American economist W.Z. Ripley divided European populations into three main "races," the Nordic, Alpine, and Mediterranean. Later writers postulated more numerous divisions. As no rigid taxonomy of European populations on a subracial basis can be biologically justified, one can speak only in a broad sense of northwestern Europeans (Ripley's Nordics), southern Europeans (his Mediterraneans), central Europeans (his Alpines), and eastern Europeans (whom he included under Alpines).

Physical characteristics of Europeans

On the whole, the Europeans have the fairest skin in the world and the greatest frequencies of blond hair and light eyes. Depigmented skin incapable of tanning is concentrated around the North Sea and in Ireland. Blue eyes have the same general distribution, being most prevalent in Ireland. Blond hair has its centre farther to the east, around the Baltic, where it is commonly accompanied by gray eyes and fair skin capable of tanning. The darkest pigmentation of skin, hair, and eyes in Europe is found in Portugal, the countries bordering the Mediterranean, and in some of the Balkan countries, particularly Romania. Hair varies from curly to wavy to straight and is usually fine to medium-coarse. The curliest hair is found in the Mediterranean region. Beards and body hair (in males) are most abundant in central Europe.

The tallest European populations live near the winter frost line (32°F [0°C]), particularly in Scandinavia, Scotland, Yugoslavia, and Albania. The shortest are the Lapps, other Arctic Europeans, and some of the inhabitants of the Mediterranean regions, including Portugal. On the whole, Europeans have relatively long trunks in comparison to limb length, and the stockiest builds are found in central and eastern Europe. The Europeans also vary considerably in head form. Dolichocephaly (in which the head is long from back to front) is commonest in Scandinavia, the British Isles, Portugal, Spain, and southern Italy and its fringing islands. Brachycephaly (in which the head is comparatively short from back to front) is prevalent in central and eastern Europe. In some Balkan countries, notably Crna Gora (Montenegro) and Albania, an exaggerated degree of brachycephaly is produced by cradling infants in wooden cradles and thus flattening the back of the head (occiput).

European blood-type distribution

In the transfusion blood group, blood type O is particularly prevalent in western Ireland, northern Wales, the Scottish highlands, and Iceland. In this respect the Icelanders resemble the Irish more than they do the Norwegians. Blood type A exceeds type B in western Europe, and type B rises to exceed A in moving eastward from the Gulf of Bothnia to the Urals. In Europe, type A is divided between types A_1 and A_2, and A_2 reaches a world peak of 35 percent among the Lapps, three times higher than anywhere else. At a polar extreme in another respect are the Basques, who share with some Moroccan Berbers the world's highest frequency of the Rh-negative gene (Rh blood-group system), reaching over 50 percent. On these bases some serologists have postulated that the Lapps and Basques represent two fundamental racial components of the Europeans. Sardinia, too, has a unique population of Mediterranean morphological type, coupled with high frequencies of blood types O (transfusion system) and M (MNSs system) (75 percent each) and the lowest Rh-negative in Europe except for the Lapps. In parts of southern Europe and among European Jews, the so-called African Rhesus gene rises to 5 percent, higher than among other Europeans.

The western Asians. The peoples of western Asia may be regarded as an eastern extension of the European population, or the Europeans as a western extension of the western Asian Caucasoids, for there have been population movements in both directions. As in the Alpine zone of Europe, there are populations of stocky build, with abundant beard and body hair, including convergent eyebrows, in the mountains and plateaus of the north and lean, Mediterranean-like peoples in the deserts to the south and on the Yemen plateau. There is no northern tier of light-pigmented populations as in Europe, although blondism occurs sporadically among the Turks of the western shore of the Aegean, the Kurds, some of the Caucasian mountaineers (notably the Cherkess, or Circassians), northern Armenians, and the Kaffirs (Nuristanis) of northeastern Afghanistan and northwestern Pakistan. The Anatolian Turks show little physical evidence of their partly Mongoloid origin. The mountaineers who speak the Caucasian languages are closely similar in fingerprint patterns to the Basques, also linguistic relics.

Physical characteristics of western Asian peoples

The Arabs of the deserts and of the Yemen plateau are mostly lean in build and long headed, with narrow, often aquiline noses. They are less hairy than the mountain peoples to the north and characteristically brunet in colouring, although about 25 percent have mixed iris colours (brown with rays or zones of blue, gray, or green). There is a strong Negro element on the Yemen coast. The Persians of the Iranian plateau are mainly brunet and European in appearance, while the nomadic Baluchis of the south and the Pathans of Afghanistan are tall, lean, and often aquiline. The Tadzhik of northern Afghanistan are Persians physically as well as linguistically, while the Ḥazāra of the northern mountains are Mongols, remnants of an invasion, like the Kalmyks of southeastern Russia.

Serologically, most of the western Asian peoples have been incompletely studied or not studied at all. In the mountain areas, blood type B exceeds A in the transfusion system, as in eastern Europe, and the Rh-negative blood type is as common as in most of Europe. Both the Arabs and Persians are high in blood type O. On the whole, the blood-type distribution appears to consist of variations on a European theme.

North African Caucasoids. Four different kinds of peoples are native to Africa: Caucasoids, Pygmies, Capoids (mostly Bushmen and Hottentots), and Negroes, as well as many mixed populations. The Caucasoids apparently entered Africa from both Europe and western Asia, toward the end of the Pleistocene and later. In northwest Africa and the Sahara live the Caucasoid Berbers, now geographically separated into discrete groups by Arabs whose ancestors came from Arabia in two principal waves, during the 7th and 11th centuries AD. The first wave consisted largely of urban and agricultural peoples, many from Yemen. They built cities and absorbed some

of the Berbers, Romanized settlers, and Jews, including Judaized Berbers. The members of the second wave were Bedouins from the Syrian Desert (Bādiyat Shām), who continued their ancestral way of life, denuding the North African landscape and mixing little with the earlier inhabitants, who were mostly Berbers.

Berbers

Most of the Berbers, like the southern Europeans, could be classed as Mediterraneans, but some groups in the Moroccan Rif, middle Atlas Mountains, and the Jebel Nefusa of northwestern Libya include many individuals with fair skin, blue eyes, and light hair, particularly in their beards. The blood types of these Berbers are like those of northwestern Europeans, but in some tribes of the Moroccan middle Atlas the Rh-negative gene reaches a frequency elsewhere found only among Basques: 55 percent in one tribe. The same peoples are very high in blood type O.

The nomadic Arabs differ in no essential way from their kinsmen in the Syrian Desert. In Libya, which is mostly desert and oasis, there is a visible Negroid element in the sedentary populations, and the same is true of the Fellahin of Egypt, whether Copt or Muslim. Osteological studies have shown that the Negroid element was stronger in predynastic times than at present, reflecting an early movement northward along the banks of the Nile, which were then heavily forested.

CONGOIDS AND CAPOIDS

Congoids: the Pygmies. The Pygmies, who number about 150,000, now live in various enclaves in the tropical rain forest of Africa, between latitudes 5°N and 5°S, from Gabon to Lac Kivu and the slopes of the Ruwenzori Mountains; most of them, however, live in the Congo River Basin. This could hardly have been their original home, because it was underwater until some 7,000 years ago. There is historical evidence that Pygmies also once inhabited the swamps of the White Nile as well as the forests of West Africa. Living Pygmies, who are hunters, live in enclaves separated by agricultural Negroes, who entered the forest in recent times.

Physical characteristics of Pygmies

Most of the male Pygmies average five feet (150 centimetres) or less in height and about 70 pounds (32 kilograms) in weight; the women are shorter and lighter. Their legs are relatively short, their arms long, and their limb joints mobile. Running on fallen logs and grasping lianas, they can glide through dense forest more easily than larger and heavier people. Their babies are of normal size at birth, but experience no growth spurt, as seen in full-sized races, during adolescence. Their small size is not due to dietary deficiency, because they eat much protein, both meat and insects. No deficiency in growth hormone has yet been established. They are said to have the highest basal metabolic rate in the world.

At birth their skin is light, but it darkens later. Some in the west are yellowish as adults; those in the Ituri Forest are mahogany coloured; while those on the shores of Lac Kivu are nearly black and are taller and heavier than those living on lower ground. All of them have tightly coiled hair, the men are bearded, and some have heavy body hair. Their genitalia are not dwarfed but of normal size. Their eyes tend to bulge; their noses are short, concave, and broad; they have large teeth and alveolar prognathism (protrusion of the upper jaw).

Where Pygmies and Negroes mix, it is almost always in one direction: Negroes take Pygmy wives, but not the opposite. The Pygmies, thus, are essentially unmixed, though there is a Pygmy element in the Negro gene pool. Serologically, the Pygmies are high in both blood types A and B, the African Rh gene, and in the gene for sickle-cell anemia. They share these traits with Negroes. One blood factor has been found in Pygmies alone, Pyg-2.

The Pygmies vary among local populations in blood-type frequencies as in other respects. The Binga Pygmies of the west are closer to the Negroes, who have absorbed Pygmy genes, and the Mbuti of the Ituri Forest are closer to the Bushmen than the Binga and Mbuti are to each other. In fingerprints, too, the Binga resemble Negroes, while the Lake Kivu Pygmies and the Mbuti are high in arches and low in whorls, the Mbuti reaching a world extreme in the latter respect. These and other items of evidence suggest that at least two and possibly three kinds of Pygmies reflect separate episodes of dwarfing and that the western Pygmies have contributed the most to the Forest Negro gene pool, while the eastern Pygmies are in some way related to the Capoids.

Congoids: the Negroes. The Negroes are now the principal inhabitants of Africa, but their origins are little known. The only Pleistocene skeletal fossil material comes from Tanzania southward to the Cape of Good Hope, in which regions the Negroes apparently preceded the Bushmen. Remnants of old hunting-gathering Negro populations survive in southwest Africa (the Bergdama) and in southwestern Angola (the Kwáde). A clue to the origins of Negroes farther north may be found in the remains of a people who lived along the shores of Lake Rudolf (Kenya) as long as 9,000 years ago and harpooned hippopotamuses and large fish. Their characteristic implements have also been found in the Nile Valley as far north as Egypt and along the former rivers and lakes of the southern Sahara and Sudan and as far west as Sierra Leone. As early as 4000 BC, Negroes living in the Sudan began to cultivate local plants, and they later moved down the stretch of savanna that extends southward to Dahomey and Togo. The introduction of Indonesian plants—taro, yams, and plantains—about the beginning of the first millenium AD facilitated forest cultivation in former Pygmy country, and the later introduction of American cultivated plants, including maize (corn) and American beans, allowed further expansion into central Africa and then East Africa, where the ancestors of the living Bantu speakers of East and South Africa acquired cattle, multiplied rapidly, and thence expanded into South Africa, arriving there mostly after the European colonists.

Physical characteristics of Negroes

Though the physical characteristics of Negroes vary from region to region, they generally are spiral haired, have beards but little body hair, and are dark skinned. Stature varies regionally, the tallest being in the White Nile country and the shortest those in the Congo Basin who have mixed with Pygmies recently. Both arms and legs are usually long in proportion to trunk length, and the muscles of their extremities have long tendons and short bodies. The soles of their feet usually have a thick pad of fibrous fat, which causes the erroneous impression that their heel bones are elongated. Facial features are variable, but everted lips are common, as is prognathism, and their teeth are characteristically large. Anatomical as well as archaeological evidence suggests some early mixture with Caucasoids, particularly in East Africa among the ancestors of the Amharas, Tigre, and Tigrinya and those of the Gallas, Somalis, and other Hamitic-speaking peoples from the west, long before the invasions of the Horn of Africa by pre-Islamic south Arabians.

Serologically, Negroes resemble Europeans in having high frequencies of blood types A_2 and Rh-negative (the latter, 20–25 percent), but they differ in having about 60 percent of the African Rh blood type (*cDe*), the world's highest percentage of blood type P_1 in the P blood-group system (over 80 percent), and high frequencies of the abnormal hemoglobin that gives rise to sickle-cell anemia (hemoglobin S) in regions of chronic malaria, particularly where the Negroes have mixed most with Pygmies. While they are a distinct race, the Negroes have also derived genetic elements from the three other races of Africa: Caucasoids, Pygmies, and Capoids.

Capoids: the Bushmen and Hottentots. Aside from two relic groups in northern Tanzania, the Hadza and Sandawe, the living Capoids consist of the Bushmen hunters and Hottentot pastoralists of southern Africa. Bushmen today number some 55,000 in Botswana, southwest Africa, and southwestern Angola; and there are about 35,000 Hottentots, some mixed, in the northern Cape Province of South Africa and in southwest Africa. In 1500 the two peoples shared Africa south of the Zambezi and must have numbered in the millions.

Early Capoid skeletons from the Sahara, Sudan, and East Africa are those of full-sized people; the living Bushman males are about five feet tall and the Hottentots

some four inches taller. The Bushmen have peppercorn hair, growing in tufts on their heads; beards and body hair are absent or minimal. Their skins are yellowish, deeply wrinkled in old age; their ears are characteristically small, with straight upper borders, and lobeless. An epicanthic fold (Mongoloid eyefold) over the upper eyelid is common. Their limb proportions are not Negroid, and their arm and leg muscles have long bellies and short tendons. Their hands and feet are small. Fat-padded buttocks (steatopygia) are particularly developed among the females, who also have elongated vaginal lips, partly genetic in origin and partly developed by manipulation. Morphologically, the Hottentots resemble the Bushmen in most respects, but the peculiarities of the Bushman buttocks and genitalia are even more pronounced in the Hottentots, and many Hottentot men even lack axillary (armpit) and pubic hair.

Bushmen

The Bushmen have low frequencies of both A and B blood-type genes, lack the Rh-negative type, and have more of the African Rh gene (*cDe*; 89 percent) than nearly all Negroes. They also have a 40 percent frequency of the gamma globulin gene HL-A, elsewhere found only among Asiatic Mongoloids and Ainu. The Hottentots also have two cytogenetic peculiarities not yet studied in the Bushmen. Their Y-chromosomes are unusually long, like those of the Japanese and unlike those of the Caucasoids and Negroes. Twenty-four percent of a sample studied have fewer and 23 percent have more than 46 chromosomes, the standard human number.

AUSTRALOID AND OCEANIC PEOPLES

Australoids: The Tasmanians and Australian Aborigines. At the time of European discovery, Australia had about 300,000 native inhabitants, Tasmania about 4,000. In Australia the Aborigines were concentrated near the coast, particularly in the east and southeast and in the Murray River Valley. In Tasmania the inland bands used to visit the coast periodically for shellfish.

The Tasmanians, who became extinct except in mixed forms in 1876, were black skinned, woolly haired, and prognathous (with projecting jaws), and most of them had receding chins, deep nasal notches, and broad noses. The majority were of medium to short stature, though a few chiefs stood six feet tall. There is no direct information about their blood types available. They had probably been isolated from the Australian continent since about 7000 BC by the sinking of the land bridge across Bass Strait.

Australian Aborigines

The Australian Aborigines resemble the Tasmanians physically in many ways, but most of them are taller, the men averaging about five feet seven inches (170 centimetres) and the women about four inches less. As a rule they have straight or wavy hair, but woolly hair is found among some individuals, particularly along the coast. The men have full beard growth, and some have heavy body hair, and their hair turns gray early in adult life. On the densely wooded Atherton Plateau in northern Queensland, a local population has short, almost Pygmy-like stature and woolly hair. In other respects the Aborigines also vary regionally to a certain extent. The northerners, the tallest, are relatively lean; those in the southwest tend to be stockier and hairier. The desert people are lean, and some have convex nasal profiles. Blond hair, along with light-brown skin, is quite common.

Except in the north, where Indonesian contact has existed for several centuries, Australians have no blood type B. Type A averages 17 percent and is highest in the south. With figures reaching over 70 percent, their M blood type (MNSs blood group) is the most numerous in the world (it reaches similar frequencies in New Guinea), and the percentage of whorls in their fingerprints reaches a global maximum.

Archaeologists now believe that Australia has been inhabited since at least 26,000 BC, and the few fossil skulls yet found are all more massive than those of most living Aborigines, many of whom still have heavy browridges. Either this is representative of evolutionary processes in Australia or there have been multiple invasions by different peoples or both. In support of multiple invasions are the late appearance of the dingo (which could only have been introduced by man) no earlier than 5000 to 7000 BC, and the marginal distribution of woolly hair, possibly a characteristic of the first wave of migration. The ancestors of the Tasmanians and Australians could only have arrived there from Indonesia and Southeast Asia, where the Australoid racial line initially evolved.

Australoids: the Papuans. The Papuans proper are the indigenous peoples of New Guinea, living mostly in the interior but reaching the coast in the west and south; the rest of the coastline is occupied by Melanesian-speaking invaders. The Papuans speak many languages of their own, and comparable languages are spoken on Sumbawa, Halmahera, and Timor in Indonesia and in small enclaves on the Admiralty Islands, the Bismarck Archipelago, the Louisades, Solomon Islands, and New Hebrides. There may be 700 to 1,000 such languages, mostly in New Guinea.

The Papuans of New Guinea are Australoid, and some of them resemble Australian Aborigines in appearance, but all have woolly hair, brown skins (some of which are quite light), and in many cases high-bridged, aquiline noses. Like the Tasmanians and Australians, they have thick but mostly uneverted lips. Since the highlands of New Guinea are chilly and proteins are scarce, the natives are short, some falling to a mean male stature of five feet or lower, but they are not Pygmies; children from this region brought up on the coast reach normal stature. In the highland, blond individuals are not uncommon. As for their blood types, A is below 30 percent and B runs from 10 percent to 15 percent. Rh genes *C* and *e* both exceed 90 percent, and the commonest genotype is *CDe*.

Australoids: the Negritos. Small enclaves of Negritos, dark-skinned, spiral-haired peoples of reduced stature, comparable but genetically unrelated to African Pygmies, still survive in the Indonesian and Asiatic homelands of the Australoids. They include one element in the Kadar of the Cardamon Hills in Kerala State, India; the Andaman Islanders; the Semang of the northern mountains of the Malay Peninsula; the Aeta of the Philippines; and various groups in the Papuan-speaking parts of the islands of Sumbawa and Timor.

Andaman Islanders

Andaman Islanders include the Great Andamanese (now nearly extinct); the Jarawa, who live in the dense, hilly forests of South Andaman Island; and the Önge of Little Andaman. They are black skinned, frizzly haired, beardless, and steatopygous (having fat deposits on the buttocks), craniologically similar to African Negroes but with smaller teeth. The Önge, who alone have been studied serologically in adequate numbers, have over 50 percent of blood type A, and more B than O. Like the Papuans, they have 92 percent of Rh type *CDe*. Despite the prevalence of malaria, there is no sickle-cell anemia or related genetic abnormality. On the whole, the Andamanese may be genetically unique, descended from a few canoeloads of castaways landing on previously uninhabited islands.

The Semang of Malaysia

The Semang of the Malay Peninsula are also black skinned and spiral haired, but they are bearded, with a male mean stature of slightly over five feet. Their general morphology is Australoid. They are high in blood type O, with 15 percent of type A and 9 percent of type B and, uniquely for this part of the world, 27 percent of *cDe*, the African Rh type. The Philippine Negritos, remnants of the islands' pre-Indonesian population, live today in seven enclaves on the island of Luzon and one each on Palawan and Mindanao. Their skin colour varies from almost black to yellowish brown, their hair is tightly curled, and their facial features suggest those of some Australian Aborigines but usually lack excessive browridges. A few individuals are considerably taller than the others and more Australian or Tasmanian in appearance.

On the whole, the Negritos described above seem to represent dwarfed variants of the original Australoid population from which came the Tasmanians, the Papuans, and the first postulated wave of ancestral Australian Aborigines; the Andamanese are the most deviant.

Melanesians, Micronesians, and Polynesians. Melanesians inhabit much of coastal New Guinea, particularly

in the north, and on most of the islands stretching from the Bismarcks to New Caledonia and Fiji. According to a conventional classification, their languages belong to the Austronesian family, along with Indonesian, Micronesian, and Polynesian.

The Melanesians of the New Guinea coastal areas are darker skinned than the Papuans; many are actually black. Their facial features are more Negroid, and they usually lack the Papuan aquiline nose. On the Melanesian islands proper there is much local physical variation. The Solomon Islanders are the blackest, the New Caledonians brown-skinned, thick-set, and heavy-boned. Some have heavy browridges and jaws. Some have blond hair, partly from bleaching in seawater but probably also partly genetic. Individuals with pinkish or reddish skins are found on some of the islands, notably on Fergusson Island in the D'Entrecasteaux group, and in the interior of Malaita, where light skins may be combined with wavy or lightly curled hair. The origin of these wide variations in Melanesia is unknown.

The Micronesians contain a strong Melanesian element mixed with Mongoloid. Their hair ranges from frizzly to straight, and they are relatively light skinned but lack the blond element. Linguistically, Micronesian is closest to Melanesian, and the physical differences between the two peoples may perhaps be partly attributed to geographical selection related to the presence of malaria in Melanesia and its relative absence in Micronesia.

The Polynesians differ physically to a certain extent from island to island in stature, skin colour, head length, face form, and body build. On the whole they are taller than the Micronesians, more heavily built, and fatter. Some of the noblemen and royalty are of great size. Despite their wide geographical range, from Hawaii to Easter Island to New Zealand, they are physically more homogeneous than either the Melanesians or Micronesians.

Oceanic blood-type frequencies

In blood factors the Melanesians and Micronesians are very similar, with blood type A found in between 20 percent and 30 percent of the population and type B in between 10 percent and 20 percent. Blood type N exceeds M in the MNSs system, and in Micronesia Nc reaches 65 percent. The Rh *C* gene has an 80 percent to 90 percent frequency, most commonly in the *CDe* blood type. Most of the blood-group data in Polynesia come from Hawaii and New Zealand. Type A is higher than B, which is completely lacking on some islands; in general, A occurs in between 35 percent and 40 percent of the population but falls to 22 percent on Easter Island; type B ranges from zero to 5 percent. Among the New Zealand Maori the Rh blood type *CDe*, commonest elsewhere in Oceania, falls to below 50 percent, and *cDe* is elevated. This situation is paralleled only among the Indians of the American northwest coast and is partly responsible for the theory that the Polynesians may be of American Indian origin.

PEOPLES OF EAST ASIA

Northern Mongoloids. The Mongoloid peoples, not including the American Indians, account for over 71 percent of the world's population of 3,500,000,000. For present purposes they may be divided into two types, northern and southern, comprising about 64 percent and 7 percent, respectively, of the total 71 percent of the world's population. The northern group includes the Chinese, totalling about 2,000,000,000 people (not including Chinese overseas); the Koreans; the Tibetans; the Mongols; the Turkish-speaking peoples of central Asia; the Japanese; the natives of central and eastern Siberia; and the Eskimo.

Northern Mongoloid physical traits

The principal morphological traits of the Mongoloids include coarse, straight, black head hair; little beard and body hair; graying delayed until old age; yellowish skins ranging in hue from the equivalent of brunet white to dark brown; trunks relatively long compared to limb lengths; hands and feet usually small, with curved nails; flattish faces, with prominent cheekbones; noses either low bridged or aquiline; brown eyes, with epicanthic eyefolds present in varying percentages in different populations; large incisor teeth with some degree of shovelling (tongue side of tooth curves inward at the sides); and broad lower jaws. While their blood types are locally variable, A_2 is usually lacking, *CDe* is the most common Rh type, and Rh-negatives are mostly confined to China and Japan. Mongoloid fingerprints are high in whorls.

In China, statures range from quite tall in the north, including Manchuria, to short in the south, and the northern Chinese are relatively long headed, long faced and light skinned. Some skulls of Caucasoid appearance have been found in the royal burial pits of the Shang dynasty at An-yang, dated at about 1400 BC. There may be, thus, a Caucasoid element in the north Chinese, which shows up in their ABO frequencies, and especially in the "European" type, A_2.

Among Tibetans, aquiline noses are common, and skin colour is dark. The Mongols and their Siberian relatives, the Buryats, are mostly of medium stature and stocky build, with large, round, low-vaulted heads and medium-dark skin. The Turkish-speaking Kirgiz-Kazaks of central Asia are similar to the Mongols but taller, and many have aquiline profiles, while the Turkmen who live along the borders between the U.S.S.R., Afghanistan, and Iran are partly Caucasoid, usually tall and of rangy build and with variable facial features. Many are long faced and thin nosed; some are heavily bearded. They are apparently the mixed prototype of the Turkish invaders of Anatolia, whose descendants became essentially Caucasoid through mixture. The Koreans, whose language is related to that of the Tungus and, more remotely, to Turkish, are mostly medium to tall in height and robustly built, with brachycephalic heads (short from back to front) and long to medium faces.

The Japanese are characteristically of short stature (although the younger generation, whose diet includes meat and milk products, are taller), and the men can grow beards. Their facial features vary from broad, with concave nasal profiles, to long and narrow, with convex profiles, as seen among the nobility and geishas. The Siberian natives include the Yakuts, who are forest-dwelling Turks; the Evenki or Tungus (related to the Manchus); the Paleosiberian-speaking Yukaghirs, Koryaks, and Chukchi; and the Asiatic Eskimo, whose kinsmen live along the coast of North America as far as Labrador and Greenland. These people usually have long faces, narrow noses, and epicanthic folds. Their blood is high in type O, and B exceeds A, except in the American Eskimo, among whom A exceeds B, as it does in the Chinese, Koreans, and Japanese. The presence of type B differentiates the Eskimo from the American Indians, who have none.

Southern Mongoloids. The southern Mongoloids, as designated earlier, inhabit Vietnam, Laos, Cambodia, Thailand, Burma, Malaya, Indonesia, Brunei, and the Philippines and were the aboriginal inhabitants of Taiwan. The Malagasy Republic (formerly Madagascar) also is partly Indonesian racially.

The mountains of Southeast Asia run from north to south, and the mountain peoples are splintered into many ethnic and linguistic groups, while the lowland populations are more nearly uniform. The Lomwe, Miao-Yao, and Li live mostly in the north. Their ancestors came down from the mountains of southern China, where many of these tribesmen still live. The Thais, Laotians, and Mon-Khmer speakers (Cambodians) include both lowland and mountain groups, such as the Montagnards.

Physical characteristics of southern Mongoloids

The Southeast Asians are of short stature, and many of them are darker skinned than most Chinese; they also have a lower incidence of epicanthic eyefolds. The mountain peoples are taller than the plainsmen and have a higher incidence of convex nasal profiles. The Khmer of Cambodia are partly Australoid, with darker skin, broader noses, and more wavy or curly hair than most of the others. The Malay have mixed to a certain extent with Arabs from southern Arabia, the Javanese with invaders from India, and the Filipinos with Spaniards. There is also a Negrito strain in the inhabitants of the Outer Sundas and possibly an Ainu-like strain among the Taiwan Atayals. Among most of these peoples, blood type B exceeds A, except in the Sea Dayaks of Borneo and the northern Taiwan aborigines. The *CDe* blood type is the

commonest Rh combination, and Rh-negatives are absent or extremely rare.

Madagascar, the westernmost outlier of Indonesia in an ethnic sense, was first settled about the time of Christ by Indonesians who made use of monsoon winds to propel their boats across the Indian Ocean. The languages of Madagascar seem to be most closely related to languages spoken in Borneo, which was more densely populated before the epidemics of the 16th century. The Indonesians brought Negroes from eastern Africa to the western and least mountainous part of the island, and the result is a general mixture, with the Indonesian racial element most evident in the highlands and the African element most evident in the west and south, possibly because the Negroes are more resistant to malaria and less resistant to high altitude than the Mongoloids. Serologists have estimated that the inhabitants of Madagascar as a whole are about two-thirds African and one-third Indonesian in origin.

The Ainu. One of the great mysteries of physical anthropology is the racial affiliation of the Ainu, an apparently exotic Caucasoid people living by hunting and fishing on the outskirts of Mongoloid territory. Remnants of them still live on Hokkaido (Japan) and southern Sakhalin (U.S.S.R.). Until the 12th century AD some Ainu were still to be found on northern Honshū and, until 1873, on the Kuril Islands. Their long, wavy hair and full beards, body hair as abundant as on Armenians, light-brown (and in a few individuals greenish) eyes, brunet white skin colour, lack of an epicanthic fold except in mixture, broad faces, widely spaced eye sockets, and in most cases snubbed noses, have led to the anthropological cliché that Leo Tolstoy could have passed for an Ainu. The Eta, an outcaste class in Japan, resemble Ainu, at least in hairiness, and an Ainu-like element has been noted in the Ryukyu island population as well as among the Atayal aborigines of northern Taiwan.

Caucasoid features of the Ainu

Serologically, the Ainu communities are locally variable, but, on the whole, the gene for blood type A reaches 23 percent and that for B 28 percent, and there is no A_2. The Ainu resemble the Lapps in having 4 percent Rh-negative blood type and the world's highest incidence of the NS combination (in the MNSs system). The Ainu's fingerprints are Caucasoid, with loops outnumbering whorls by two to one.

Three theories have been postulated as to the origin of the Ainu: they are related to European or western Asian Caucasoids; they are related to the Australian Aborigines; or they are a race of their own as yet otherwise unrepresented in the fossil record. The Australian resemblance may be more a matter of grade than of line, and the third possibility, although remote, is probably the most likely.

THE PEOPLES OF THE INDIAN SUBCONTINENT

Aborigines. The Indian subcontinent includes the independent nations of India, Pakistan, Bangladesh, Nepal, Bhutan, the Indian protectorate of Sikkim, and Sri Lanka (Ceylon), which was a part of the subcontinent during the Pleistocene and is ethnically a part of it. Greater India contains members of all Old World races except the African ones. Although the subcontinent currently holds some 675,000,000 persons, parts of it are still thinly populated, particularly the forested, mountainous regions of southern India; the Thar Desert (shared by India and Pakistan); and the Terai Forest, lying mostly in southern Nepal.

The earliest inhabitants are represented by numerous scattered tribes of hunters and gatherers in the southern peninsula and by the few remaining Veddas of Ceylon. The Birhors of Chotanāgpur, the Chenchu of the Amradabad Plateau of Andhra Pradesh, and the Veddas are short, dark-skinned people, with hair mostly in ringlet form and facial features intermediate between those of Caucasoids and Australoids, the Australoid ingredient seen particularly in a depressed nasal root and, in some cases, wide nostrils. Exceptional are the Kadar of the Cardamon Hills of Kerala. Except for individuals recently mixed with Hindus from the plains, the Kadar contain two racial elements, a frizzly-haired Negrito and straight or wavy-haired Australoid. The Oraons of Bihār State and the Gonds of central India (both now agricultural) are mostly Australoid and mostly straight haired. Many other aboriginal peoples have been absorbed into the outcaste and lower caste populations of the Dravidian and Aryan speakers among whom they live.

Australoid populations of India

Dravidians. The Dravidians are the agricultural and urban peoples of southern India who speak Kannada, Telugu, Tulu, Malayalam, and Tamil. Tamil is also spoken by the inhabitants of the northern part of Ceylon; some of their ancestors came from southern India centuries ago, others more recently after the rise of the tea plantations. The Brahui of Pakistan, who live among the Baluchis, are also Dravidian speakers. It is generally believed that the Dravidians of southern India migrated to their present homes from the Indus Valley region before and during the Aryan invasions.

These Dravidians are divided into the usual Hindu castes. They are dark-skinned Caucasoids in all essential characteristics, but they differ among themselves principally in skin shade and nose form, the higher castes having a tendency to lighter skins and narrower noses. Prevalent among Dravidians, particularly the Tamils of Ceylon, is an excess growth of hair on the ears. This is a genetic trait also noted among southern Europeans. The Brahuis are lighter skinned than the other Dravidians and quite hairy.

Munda and Austro-Asiatic speakers. Scattered along the northeastern edge of the Deccan Plateau live about 5,000,000 casteless agricultural people who speak languages of the Munda group, a branch of Austronesian. Their ancestors probably migrated from Southeast Asia in pre-Aryan times, introducing the cultivated food plants of that region. They are mostly Australoid with a Mongoloid element more visible in some individuals than in others and are racially akin to the Cambodians. North of the Ganges, the Khasi inhabit the Khasi Plateau of Assam and have their capital at Gauhāti. In their territory is Cherrapunji, which has the highest recorded annual rainfall in the world. Their language belongs to the Mon-Khmer branch of the Austronesian family, and their ancestors, like those of the Munda speakers, probably migrated from Southeast Asia. They are mostly Mongoloid, with light skins, as may be expected in their cloudy, dimly-lit environment.

Mongoloid elements in Indian populations

Another isolated, mostly Mongoloid people are the Newars of the Kāthmāndu Valley of Nepal, who lived there before the arrival of the now-dominant Aryan-speaking Nepalese. They are mostly urban. Their language is Tibeto-Burman. They are light-yellowish skinned, and some of them resemble Chinese. The same is true of the Lepchās, the natives of Sikkim, now outnumbered by Nepalese immigrants. Another Mongoloid people are the Nāgas of the Nāga Hills of northeastern Assam; they are darker skinned, and many have convex nasal profiles.

Aryans. The peoples of India, Pakistan, Nepal, and Ceylon who speak Sanskrit-derived languages form the bulk of the subcontinent's population. They are mostly descended from Bronze-Age invaders from the northwest who crossed the Hindu Kush Mountains during the second millenium BC, replacing the probably Dravidian-speaking inhabitants of the Indus Valley and spreading out over the Indo-Gangetic plain wherever they could pass with their ox-drawn wagons. They introduced the major features of the Hindu religion to India and the framework of their present, highly elaborate caste system, with its basic fourfold division into priests (Brahmins), warriors (Kṣatriya), tradesmen and cultivators (Vaiśya), and inferior craftsmen (Śudra). By practicing endogamy (marriage within the group) and observing strict dietary restrictions, they have preserved genetic continuity with their Aryan ancestors to a considerable extent, particularly in the upper castes, while the lower castes physically suggest, in varying extents, the absorption of earlier Dravidians, particularly in skin colour, the fairest skins being found in northwestern India and West Pakistan.

Upper-caste Aryans are mostly dark-haired and brown-eyed Caucasoids, resembling Europeans. Blue eyes are

occasionally seen among some of them, particularly Sikhs and Kashmiris, and some of the previously mentioned Kaffirs of northwest Pakistan are blond, with Nordic features. Undoubtedly, climatic selection over the millenia has been partly responsible for the reduction in blondism among most of the upper-caste Aryans. In Nepal, Aryan invaders overran much of the kingdom, and most of the Nepalese are partly Caucasoid. The Mongoloid element increases past the upper-altitude limit of malaria in the foothills of the Himalayas. The Sherpas of the high Himalayas are Mongoloid Tibetans, as are the Bhutanese.

Sinhalese

The principal Indo-European-speakers of Sri Lanka (Ceylon) are the Sinhalese, whose ancestors invaded the island by sea from Bengal in the 6th century BC. Except for Tamil tea-plantation workers, the Sinhalese are still the principal inhabitants of the southern part of the island and the mountainous interior. The Sinhalese are mostly dark-skinned Causasoids with a minor Mongoloid element, probably brought from Assam. This element is most apparent in the highlanders, from Kandy to Nuwara Eliya, and some of the statues of ancient kings show Mongoloid features.

Blood-type distributions in India. The Hindus of caste, whether Aryan or Dravidian, have a blood-group distribution like that of the eastern Mediterranean region of Europe and west Asia, with type B more frequent than A, some A_2, and about 24 percent of Rh-negative. The Brahmins tend to have more of type A than B, and, on the whole, B surpasses A more often in the east than in the west. Casteless Hindus and aboriginal tribesmen are high in B, as are the food-gathering groups of the south, who lack Rh-negative. Among Hindus of caste, blood type M exceeds N in the MNSs system, and M is usually accompanied by S; but, among the aboriginal Chenchu, M and N are about equal, and S is tied to N, an Australoid linkage. The data covered here indicate what morphology also shows, that the Dravidians and Aryans are both of Caucasoid origin, while the aborigines contain an Australoid ancestral element.

THE WESTERN HEMISPHERE AND THE COLONIAL POPULATIONS

The American Indians. The American Indians, except for the Eskimo and Aleuts, were the sole inhabitants of the New World before its discovery by Europeans, and, as far as is known, all of the Indians' ancestors entered North America over the Bering Strait when it was above sea level during the last Ice Age. Owing to the distribution of Late Pleistocene glaciers, their initial routes southward would have been in the western part of the continent. The northeast, which became ice-free more recently, was first inhabited no earlier than was the tip end of South America.

It is not known how the ancestors of the American Indians got to the Bering Strait, but the most feasible route, considering the climate during the Ice Age, would have been along the eastern Asian coast, from lands occupied by Mongoloids and possibly by ancestors of the Ainu. Nor is it known what the Indians' ancestors looked like, because there is as yet no pertinent skeletal material from northeast Asia. The best is from three skeletons found in the Upper Cave at Chou-k'ou-tien, near Peking; they could have been ancestral Indians or Tibetans or Nāgas.

Physical characteristics of the American Indians

Whether their origin was single or multiple, the American Indians are more nearly homogeneous than the inhabitants of any other large landmass. Like the Asiatic Mongoloids, most of them have shovel-shaped incisor teeth; a fingerprint pattern high in whorls; brown eyes, occasionally with epicanthic folds; coarse, straight, black head hair that grays late in life; and scanty beards and body hair. But some of them, such as the Indians of the northwest coast and northern California and the Alakaluf of southern Chile, can grow full beards. Skin pigmentation ranges from almost Caucasoid brunet white in northwestern Canada through various shades of reddish brown in Central America and the Andes to a pale yellowish in the shady atmosphere of the equatorial forests to almost white among the Alakalufs, who also have blue patches, indicating deeply underlying pigment, on their backs and genital organs.

In response to latitude and climate, their stature range is great. The tallest Indians live in the North American Great Plains, the South American pampas, and Patagonia. The shortest are found among the highland Maya of Guatemala, some Andean populations of Colombia, and in the tropical forests. In some of the highland groups this reduced stature may be attributed to malnutrition, inbreeding, or both.

Among the Indians as a whole, body build varies relatively little. They usually have long trunks, little or no spinal curvature, and small hands and feet. Facial features are variable but mostly within the Asiatic Mongoloid ranges. Aquiline noses are common in cool regions and in mountains, while concave profiles are frequent among the forest Indians of tropical South America. Some of these South American Indians also have moderately everted lips—their Old World counterparts may be found in Borneo.

Despite this essentially Mongoloid anatomy, many Indians have a Caucasoid appearance, especially in facial features and particularly among the New England Indians. Prehistoric Indian skulls from this region have narrow faces and noses that are hard to fit into the Mongoloid pattern, and the same has been found among the skulls of the Ona of Tierra del Fuego. Whether the Caucasoid morphological factor is of genetic origin or due to parallelism is not known.

Blood-type distribution of the American Indians

In terms of blood groups, the American Indians show at least as great regional diversity as they do in morphology, although they are uniform in the absence of blood types A_2, B, and Rh-negative. In Mexico, Central America, and South America, only blood type O is found in the ABO blood group among full-blooded Indians. In North America, A ranges from less than 1 percent in the south to 35 percent in the north, with a pocket of 59 percent among the Bloods and Blackfoot. This world's highest frequency of blood type A may be no accident but the focal point of a cline. It is known that in 1837 smallpox was introduced from a fur-company steamer at Fort Kenzie, Montana, and thence spread to Canada, killing off two-thirds of the Bloods and Blackfoot and many Piegans. If these Indians had originally possessed, say, 35 percent of A, the partial immunity against smallpox attributed to the gene for blood type A could explain the rise of the blood type to its present elevated figure in the next century.

The Rh gene *C* falls between 50% and 60% in most American Indian populations. It rises to over 60% in eastern Brazil and southern California and dips to 30% to 40% on the northwest coast. A comparable regional variation may be seen with *E*, which is over 50% on the northwest coast and down to 20% to 30% in Mexico and below 40% in eastern Brazil. Among most Indian groups the frequency of Rh blood types *CDe* and *cDe* is about 50% each, but among the northwest coast Indians *cDe* exceeds *CDe* by about 20%, as it does among the New Zealand Maoris. The gene for blood type M is elevated among all American Indians but hits a high of 90% to 95% in a belt centred in Mexico and Central America and reaching north into the United States and south into South America.

The rare Diego-positive (Di +) blood type is also characteristic of the American Indians but occurs mostly in South America, where it reaches 34 percent among tribes on the Colombian–Venezuelan border. Diego-positive has also turned up sporadically among Japanese, southern Chinese, and the Sea Dayaks of Borneo and among a handful of European Caucasoids lacking known Mongoloid ancestry.

The present distribution of human populations. In AD 1500 the population of the world was probably about 500,000,000, a small percentage of what it is today. This significant increase has not been equally shared by all races. The Caucasoids and Asiatic Mongoloids have grown the most in numbers, while the Capoids have suffered the greatest decline. Especially among the Cauca-

soids, a large part of the increase is due to their settlement of previously thinly populated regions in the Americas, Australia, and New Zealand, where the distribution of races has consequently changed the most.

The United States and southern Canada have become extensions of Europe, as have southern Brazil, Uruguay, and Argentina. About 11 percent of the population of the United States is Negro. These North American Negroes have about 20 percent of European genes, while the percentage of Negro genes in the white population is negligible. In the West Indies, the percentage of the population that is Negro, with or without mixture, ranges from 100 percent in Haiti to about 25 percent each in Cuba and Puerto Rico. In French Guiana the Negro element is 91 percent; in Brazil, 11 percent, as in the United States.

From Mexico to Uruguay and Argentina the percentages of unmixed Caucasoids ranges from 2 percent in Honduras to 30 percent in Chile, except for Costa Rica, with 80 percent, and Brazil, with 62 percent. Uruguay's population is 90 percent unmixed Caucasoid and Argentina's 97 percent. Indians comprise 29 percent of the population in Mexico, 60 percent in Ecuador, 46 percent in Peru, and 53 percent in Bolivia. Elsewhere in Latin America the population is 11 percent Indian or less. Mestizos, who are European–Indian mixtures, outnumber Caucasoids in these countries, except in Costa Rica, Brazil, Uruguay, and Argentina, where there are relatively few Indians. The Mestizos also outnumber the Indians everywhere but in Ecuador, Peru, and Bolivia, where the thin air of the Andean altiplano has inhibited the reproduction of Caucasoids and Negroes. In South Africa, out of a little over 16,000,000 persons, 3,000,000 are listed as White, 11,000,000 as Bantu, and 1,500,000 as Coloured, as well as 500,000 Asiatics, mostly from India. All of these peoples settled South Africa after AD 1500, except some ancestors of the Coloureds, who were Hottentots.

In other countries, where Caucasoids have colonized lands previously occupied by other Caucasoids, the fate of the settlers has been different. The French quit Algeria after 150 years of colonization, and the Israelis have had much trouble with the Arabs in Palestine. What will happen to the races of man, even in the near future, is hard to predict, except that a general mixture of races (panmixia) will not follow, and that some of the marginal populations of the world may stage a comeback, such as the American Indians, Siberian tribesmen, and even the Australian Aborigines. The Bushmen, at the bottom of the racial population ladder, may hold their own or even increase. Chances are at least fair that the children and grandchildren of today's adults have the privilege of seeing all the major races of man—at least on television.

Porifera

The sponges, which comprise the phylum Porifera, are among the most primitive multicellular animals. They number approximately 5,000 described species and inhabit all seas, where they occur attached to surfaces from the intertidal zone to depths of 8,500 metres or more. One family, chiefly, the Spongillidae, is found in fresh water. Adult sponges lack a definite nervous system and do not show conspicuous movements of body parts.

Early naturalists regarded the sponges as plants because of their frequent branching form and their lack of obvious movement. The animal nature of sponges, first described in 1755, was confirmed in 1765 after observations of their water currents and the movement of their openings. In structure, function, and development, sponges are distinct from other animals. Many zoologists regard sponges as occupying an isolated position in the animal kingdom and classify them in the subkingdom Parazoa; on the other hand, sponges are sometimes considered relatives of another invertebrate animal group, the coelenterates.

The phylum Porifera may be divided into three classes on the basis of the composition of the skeletal elements —the Calcispongiae and Hyalospongiae include about 20 percent of the known species of sponges; the remainder are placed in the class Demospongiae (see Figure 1).

From (*Spongia*) T.J. Parker and W.A. Haswell, *A Textbook of Zoology*, St. Martins Press, Inc., Macmillan & Co., Ltd.; (others) G.C. Pimentel, *Natural History*

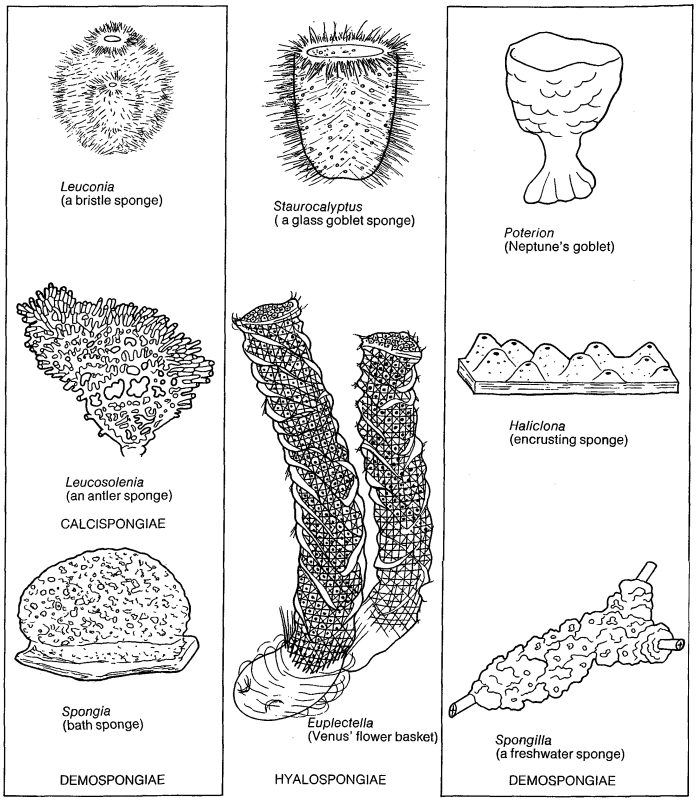

Figure 1: Representative sponges.

GENERAL FEATURES

Importance. Sponges derived from certain species of the Demospongiae—*e.g.*, *Spongia officinalis, Hippospongia communis, Spongia zimocca, Spongia graminea*—have been known since ancient times. Familiar household items in ancient Greece and Rome, sponges were used to apply paint, as mops, and as substitutes for drinking vessels. During the Middle Ages, burned sponge was reputed to have therapeutic value in the treatment of various diseases. Natural sponges now are used mostly in arts and crafts such as pottery and jewelry making, painting and decorating, and in surgical medicine. Synthetic sponges have largely replaced natural ones for household use.

Commercial value

The living sponge is a mass of cells and fibres, its interior permeated by an intricate system of canals that open as holes of various sizes through the tough dark brown or black skin, which may be hairy from fibre ends that pierce it. Only after it has been completely cleaned of its

millions of living cells does a sponge resemble the sponge of commerce; *i.e.*, a soft and elastic spongin skeletal framework. Commercially valuable sponges, which may be found from tidal level to a depth of about 200 feet, usually are harvested by hooking or harpooning in shallow waters, by skin diving or by deepwater fishing. Although the most valuable sponges are found in the eastern Mediterranean area, they also are harvested off the west coast of Florida and the Florida Keys, in the West Indies, off Mexico and British Honduras, and, to a limited extent, off the Philippine Islands. Because they have the ability to regenerate lost parts, sponges can be cultivated from small fragments.

Sponges are valuable from a scientific point of view because of their unusual cellular organization (the cells do not form tissues such as those found in other animals), their ability to regenerate lost parts, and their biochemical features (they have many compounds not known in other animals). Sponges comprise an important part of the organisms that live in the depths of the sea (benthos) and may be associated with other organisms; *e.g.*, many types of animals live in sponges.

Size range and diversity of structure. Most sponges are a few centimetres in size, but some urn-shaped or shapeless ones are less than a centimetre; others, shaped like vases, tubes, or branches, may be one to two metres tall, and broad rounded masses may be one to two metres in diameter. Size within a species may vary with age, environmental conditions, and food supply.

The external appearance of sponges is variable. They may appear bushy or treelike and have fingerlike projections. Some, particularly in the class Demospongiae, are shapeless, or amorphous, masses that form thin encrustations on objects or are cushion shaped. A few Demospongiae have well-defined spherical shapes as in *Tethya aurantium*, the sea orange; others may be cup- or fan-shaped. Calcispongiae of the genus *Scypha* are shaped like tubular sacs, with an opening (osculum) at the tip. Members of the Hyalospongiae are erect or cylindrical, with a stalklike base.

Range of colour. Colour among sponges is variable. Deep-water sponges usually show a neutral colour, drab or brownish; shallow-water sponges, frequently brightly coloured, range from red, yellow, and orange to violet and occasionally black. Most Calcispongiae are white.

Effects of symbionts

Some sponges (*e.g.*, the Spongillidae) are often greenish because green algae live in a symbiotic relationship within them; others are violet or pinkish, because they harbour symbiotic blue-green algae. These symbionts endow the sponges with colour as long as light is available; the sponges become white in the dark when no photosynthesis occurs and the algal pigments utilized in photosynthesis are no longer produced. Another variable character in sponges is consistency, which may range from the soft and viscous state of some encrusting species to the hard stonelike quality of the genus *Petrosia*. In addition, the surface of a sponge may be smooth, velvety, rough with protruding skeletal elements called spicules, or conulose (*i.e.*, provided with conical protrusions called conuli).

Distribution and abundance. The Porifera are present at all water depths, from the tidal zone to the deepest regions (abyss). They occur at all latitudes and are particularly abundant in Antarctic waters. Calcispongiae and Demospongiae are found mainly on the rocky bottoms of the continental shelf; the Hyalospongiae are characteristic of the deepest muddy bottoms of oceans and seas. In some environments, sponges are the dominating organisms; sometimes they cover wide areas, especially on rocky overhangs and in the caves of the littoral, or shore, zone. A restricted number of species are adapted to brackish waters; and members of the family Spongillidae (class Demospongiae) populate the fresh waters of rivers and lakes.

NATURAL HISTORY

Life cycle. Most sponges reproduce sexually, although asexual reproduction may occur. Sponges are generally hermaphroditic (male and female germ cells in one animal); sometimes sex inversion, in which male and female germ cells develop at different times in the same animals, occurs.

Sexual reproduction. The fertilization of an egg by a spermatozoan is peculiar in sponges in that a spermatozoan, after its release from a sponge, is carried by the water current until it is captured by a specialized cell called a choanocyte, or collar cell, in another sponge; the choanocyte transforms into an amoeboid-shaped cell called a carrier cell, which gives up the spermatozoan to an egg, lying near a chamber formed by choanocytes and containing long lashlike appendages called flagella.

Types of larvae

Development of the embryo may occur in one of several ways characteristic of the different groups; as a result, more than one type of larva is found. The characteristic larva of the Calcispongiae and of some Demospongiae (*e.g.*, *Oscarella*), called an amphiblastula, is oval in shape and has a cavity in the middle; the front half of the larva consists of cylindrical, flagellated cells, the other half of round cells without flagella. The larva swims with the flagellated portion forward. The amphiblastula is preceded by a stage (stomoblastula) in which the central cavity of a hollow mass of cells (blastula) opens outward and is surrounded by round granular cells (macromers), which are distinguished from other cells with flagella (micromers). The most common larval form among the Demospongiae is called a parenchymula; it is solid and compact, with an outer layer of flagellated cells and an inner mass of cells.

A larva swims for a period of time that may vary from a few hours to a few days before it descends to find a surface suitable for attachment. After attachment, the larva undergoes developmental changes (metamorphosis) becoming a young individual called an olynthus in the Calcispongiae, a rhagon in the Demospongiae; the young individual gradually develops into an adult sponge. The metamorphosis following larval attachment involves changes in the relative positions and functions of larval cells. In one larval type (parenchymula), the flagellated outer cells become the collar cells (choanocytes) of the interior of the adult sponge; the interior cells of the larva give rise, in the adult, to the cell layer (pinacoderm) and the different cells (*e.g.*, archaeocytes, collencytes) found in the amorphous substance (mesohyl) that fills the sponge. In the amphiblastula, the choanocytes are derived from the forward flagellated region; the other cells and the mesohyl are derived from the posterior half.

The sexual maturation of sponges is connected with the temperature of the water in which they live. In the temperate regions, maturation occurs mainly from spring to autumn; sometimes two distinct periods of reproduction occur, one in spring, the other in autumn. Some sponges mature at any time of the year; *e.g.*, *Scypha*, formerly called *Sycon*. Tropical sponges also apparently mature any time throughout the year. Sponges for the most part bear living young (*i.e.*, are viviparous); the larvae are released through the canals of the excurrent (outgoing) water system and an opening (osculum) also involved in that system. A few sponges (*e.g.*, *Cliona* and *Tethya*) lay eggs (*i.e.*, are oviparous).

The life-span of sponges is not well known; the small encrusting forms probably live about a year, disappearing during a season unfavourable to their survival; small fragments of an individual, however, may persist and reproduce new individuals in the next season. The large species have a much longer life-span; bath sponges (*Spongia, Hippospongia*), for example, attain a commercially desirable size after seven years and may live as long as 20 years.

Asexual reproduction. Asexual reproduction also occurs in sponges in various ways; the best known method is called gemmulation. Gemmulation begins when aggregates of cells, mostly archaeocytes, which, when they become laden with reserve food granules, are called thesocytes, become isolated at the surface of a sponge and are then called gemmules. These are expelled from the adult sponge and, in some marine species, serve as a normal reproductive process or, sometimes, as a means

Gemmules

to carry the sponges over periods of unfavourable conditions when the adults degenerate; *e.g.*, drought, temperature extremes.

The freshwater Spongillidae undergo a slightly different gemmulation. Gemmules consist of aggregates of archaeocytes laden with reserve granules; in addition, however, they are surrounded by protective membranes formed by the archaeocytes. The protective covering is generally reinforced by spicules, which vary in shape according to the species and are useful in classification. Freshwater sponge gemmules allow a species to survive unfavourable conditions in a state in which vital activities are almost completely suspended. In cold regions, gemmulation occurs in winter, and the inactive gemmules are said to hibernate; in warm regions, gemmulation occurs in summer, and the gemmules are said to estivate. In spring or autumn when favourable conditions return, the gemmules germinate, their archaeocytes emerge through an opening (micropyle), the various cellular types differentiate, and a new sponge grows. Other methods of asexual reproduction include formation of stolons (rootlike extensions) and fragmentation of individuals.

Regeneration. The extraordinary capacity of sponges to regenerate is manifested not only by restoration of damaged or lost parts but also by complete regeneration of an adult from fragments or even single cells. Sponge cells may be separated by mechanical methods (*e.g.*, squeezing a piece of sponge through fine silk cloth) or by chemical methods (*e.g.*, elimination of calcium and magnesium from seawater). Dissociated cells settle, migrate, and form active aggregates in which the archaeocytes play an important role. In order for small aggregates of cells to form larger aggregates, the cells must generally become attached to a surface, where they flatten and develop an envelope of special cells (pinacocytes); this is called the diamorph stage. Reconstitution of the choanocyte chambers and of the canal system follow soon afterward, resulting in a young sponge that is functional and able to grow. It is generally believed that the reconstitution process, even if it involves cell division, is not comparable with embryonic development, because the various types of dissociated cells participate in the formation of the new sponge by sorting and rearranging themselves, rather than by differentiating from primitive cell types. Regeneration in sponges is of theoretical interest in connection with certain cell properties; *e.g.*, adhesion, sorting out, and movement.

During unfavourable conditions, sponges are reduced to small fragments that may consist only of masses of archaeocytes covered by layers of pinacocytes. A complete sponge forms from these fragments when favourable conditions return.

Individuality of sponges

The regenerative abilities of sponges, their lack of a central coordinating organ (brain), and the peculiar migratory ability of cells within the organisms combine to make it somewhat difficult to define the individuality of a sponge. Various attempts to establish whether sponges are individuals or colonies have failed to solve the problem, and, thus far, no completely satisfactory criterion for defining a sponge has been found. Zoologists involved in the study of sponges empirically define a sponge individual as a mass that is enveloped by a common ectoderm, *i.e.*, by a common cellular layer.

Ecology. Most Porifera, very sensitive to a wide range of ecological factors, are difficult to raise under laboratory conditions. Few species (*e.g.*, *Hymeniacidon sanguinea*) are able to tolerate long periods of emersion and variations in such physical factors as light, temperature, and salinity.

Habitats. Light is a limiting factor for the survival of most sponges in a given habitat. Littoral-dwelling sponges generally develop in caves, on shadowed walls, or under small shelters such as those provided by crevices. Some species, mainly in the tropics, however, are covered by a metre or less of water and thus are almost completely exposed to irradiation from the sun. Symbiotic relationships between algae and sponges usually occur in strongly illuminated zones; the algae may act as a protective device because they deposit pigments in the superficial cell layers of the sponge. In some sponges (*e.g.*, *Petrosia ficiformis*), colour is related to the number of symbionts; in a cave, for example, sponges gradually change from intensely coloured specimens to light-coloured, sometimes white, ones in the depth of the cave where the number of algae decreases.

Porifera of the family Clionidae (class Demospongiae) live in galleries they excavate in shells of mollusks, in corals, in limestone, and in other calcareous materials. The boring activities of clionids are accomplished by the excavation, possibly involving both chemical and mechanical action, of numerous, small chips of calcium carbonate. Cytoplasmic projections and films put out by sponge cells in contact with a calcareous surface apparently come into intimate contact with the calcium carbonate, resulting in the removal of particles of relatively uniform size. Clionid sponges weaken limestone breakwaters and coral reefs, making them more easily subject to further abrasion by waves. In addition, they weaken oystershells.

Attachment to a surface

Although most sponges settle and grow on hard or rocky surfaces, some anchor to a firm object on soft bottoms, on sand, on mud, or on debris. Unattached sponges are rare. Different species may compete for a surface, and superposition of one species on another sometimes occurs; the presence of a rich population of different species on the same surface may help them to survive by the modifications each contributes to the environmental microclimate surrounding them, thereby providing protection against extreme fluctuations of physical factors such as temperature and light.

Associations with other organisms. The Porifera often grow on or near other organisms, sometimes killing those they cover; the sessile (attached) barnacle *Balanus*, for example, may be killed in this way. In other cases, associations may provide advantages to both organisms, particularly those between sponges and crustaceans. Some crustaceans, mainly crabs, use sponges for camouflage by removing a piece of a living sponge and holding it against their carapace (shell); the best known example of this type of mutualistic association is that of the sponge *Suberites domuncula* and hermit crabs, which live in the shells of gastropod mollusks. The advantage to the sponge is that it is carried by the mollusk; the hermit crab gains protection not only by living in the shell of the mollusk but also through the disagreeable smell and taste of the sponge, which discourages attack by fishes and other enemies.

Various plants and animals may live on the surface of a sponge or inside its canals and cavities. In some cases the associations are specific; *e.g.*, the coral *Parazoanthus axinellae* grows on the sponge *Axinella*. The organisms that live in the cavities of sponges include crustaceans, nematode and polychaete worms, ophiuroid echinoderms (brittle stars), and bivalve mollusks; some inhabit a sponge for occasional shelter or nourishment, others establish more intimate associations as parasites or predators. Young shrimps of the genus *Spongicola* penetrate certain sponges of the class Calcispongiae, live in them in pairs, and presumably are trapped for life in the rigid skeleton of the sponge; the Japanese consider these shrimps a symbol of matrimonial faithfulness. The number of organisms that live within a single sponge may be very high; thousands of organisms of various species, for example, may be found in *Spheciospongia vesparia*, a Caribbean sponge.

Some organisms that live on (called epibionts) and in (called endobionts) sponges act as parasites. Cyclopoid copepods are the most important parasites of marine sponges; in fact, some genera of these crustaceans have become modified as a consequence of their parasitic existence. Freshwater sponges also are attacked by parasites such as rotifers and mites, which lay eggs in them; larvae of the neuropteran insect family Sisyridae (spongillaflies) live in, and feed upon, freshwater sponges. In general, sponges are protected from predators by their disagreeable taste and smell and by their hard skeletal elements (spicules). In some cases, however, sponges are eaten by other organisms; *e.g.*, mollusks—gastropods such as

snails and nudibranch slugs, prosobranchs such as *Patella* and *Littorina*, and chitons—some crustaceans, and some fishes (especially on coral reefs).

Algal associations

The most important symbiotic associations of sponges occur with single-celled and multicellular algae. The algae may live in the surface layers of the sponge, inside the cells, or among them. The sponge protects the algae from enemies, from unfavourable environmental conditions, and from their own metabolic waste products; the sponge uses the algae as a source of oxygen, as a mechanism for eliminating its products of metabolism, as a screen against sunlight, and as a food source (consuming both algal waste products and dying algae). Sponges of the freshwater Spongillidae and various species of marine littoral sponges consume dying green and blue-green algae respectively. The algae, which provide the Spongillidae with their characteristic green colour, may be transmitted through the gemmules. In some boring clionid sponges (*Cliona viridis*) of the class Demospongiae, some single-celled brown algae are constantly present. The marine sponges may also harbour multicellular blue-green algae (*e.g., Oscillatoria*), red (Rhodophyceae) and green (Chlorphyceae) algae. Red and green algae sometimes provide skeletal support for certain sponges.

Diseases of sponges. Sponges may be attacked by diseases of epidemic character, the agents of which are not well known. The commercial sponges of the West Indies once were nearly completely destroyed by a fungus-like micro-organism; other sponges were not damaged.

FORM AND FUNCTION

The Porifera are unusual animals in that they lack definite organs to carry out their various functions. The most important structure is the system of canals and chambers, called a water current system, through which water circulates to bring food to the sponge.

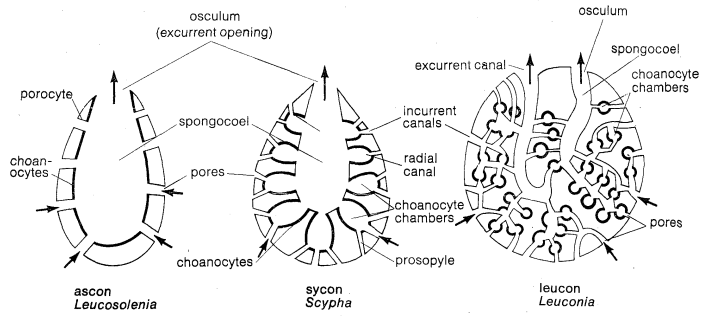

Figure 2: Water current systems in calcareous sponges. Arrows indicate the direction of water flow.

Water current system. The essential elements of the water current system include the pores, or ostia, through which water enters the sponge (incurrent system); the choanocytes, or collar cells, which are flagellated cells that capture food; and the oscula, openings through which water is expelled (excurrent system). Three types of water current systems of increasingly complex structure may be distinguished by the arrangement of choanocytes and the development of canals—ascon, sycon, and leucon (Figure 2). The simplest, or ascon, type, found only in certain primitive genera of Calcispongiae (*e.g., Leucosolenia*), is characterized by an arrangement of choanocytes around a central cavity that directly communicates with the osculum. The walls of these sponges are thin, lack canals, and are perforated by pores, which actually are openings through cells (porocytes). The sycon type of water current system, found also in Calcispongiae is at first characterized by choanocytes that surround fingerlike projections called radial canals of the sponge wall. Water enters the radial canals directly through pores, makes its way into the central cavity, or spongocoel, and leaves by way of an osculum. In most syconoid sponges (*e.g., Scypha*) the radial canals are bordered by incurrent canals through which passes the water entering the pores; other openings (prosopyles) allow water into the choanocytes, from which it passes directly into the internal cavity and out of it through the osculum. In the leucon type, which is found in the more advanced Calcispongiae and in the other classes (Demospongiae and Hyalospongiae), the radial canals are replaced by numerous small flagellated chambers in which the choanocytes are localized; the chambers, scattered throughout the body of the sponge, have pores through which water passes into a complex system of incurrent canals, then into a spongocoel (internal cavity) by way of excurrent canals. Water enters very small pores found among the cells (pinacocytes), which line the outer surface of the sponge. After passing through a system of incurrent canals and cavities, also lined with pinacocytes, the water reaches the flagellated chambers, enters them through openings (prosopyles), and leaves through other openings (apopyles). The water is expelled through the osculum after passing through a system of excurrent canals and cavities lined with pinacocytes. During the development of many sponges, a simpler water current system (rhagon) precedes the leucon type. The rhagon type is characterized by reduced excurrent canals and by a large central cavity. In some Demospongiae the body is organized in two parts, an external ectosome without choanocytes, and an internal choanosome with choanocytes.

Leucon water current system

Cell types. The sponges lack a well-defined organization of tissues. Single layers of cells line the outer surface of the body and the internal cavities; other cells, both motile and fixed, and fibres occur in an amorphous substance (mesohyl), gelatinous in nature. It has not been possible thus far to identify with certainty similarities of origin (homologies) between the various types of sponge cells and those of higher animals. Each type of sponge cell performs particular functions; the cells either may gather in certain areas of the sponge or form layers and membranes. They are easily modified, both in form and function, during larval development and during adult life. Furthermore, they have a remarkable ability to migrate and to transform from one cell type to another, although the mechanisms involved are not known. Three principal types of cells may be distinguished—choanocytes, archaeocytes, and pinacocytes-collencytes (Figure 3).

Choanocytes and archaeocytes. The choanocytes are provided with a flagellum, which is surrounded by a collar composed of cytoplasm. The main function of the flagellum apparently is to produce the water current, that of the collar is to capture food particles.

The archaeocytes, which are scattered in the mesohyl, have remarkable potentialities for transformation into various cell types, especially in the Demospongiae. Some persist and reproduce during the life of the sponge without specializing, thus forming an embryonic reserve from which other cellular types may be derived; others become specialized to carry out particular functions. Archeocytes, often called amoebocytes, are amoeboid cells (*i.e.*, they have the ability to move); their cytoplasm contains large quantities of ribonucleic acid (RNA), and their large nuclei contain small bodies known as nucleoli. Amoebocytes function in regeneration and in transportation of food particles acquired at the choanocytes throughout the body of the sponge. During this distribution process, they carry granules consisting of various substances. Depending on the nature of the substance, amoebocytes may be known by several names; *e.g.*, granulocytes, thesocytes. Amoebocytes laden with various pigments (carotenoids and melanin, sometimes contained in algal symbionts) confer various colours to the sponge.

The archaeocytes may be important in sexual reproduction, if, as is postulated, male and female reproductive cells are derived from them. This role is disputed, however, since in some cases, mainly in the Calcispongiae, reproductive cells, particularly those of the male, are derived from choanocytes.

Pinacocytes, collencytes, and other cell types. Pinacocytes (Figure 3) form the pinacoderm, a single cell layer found on the body surface and lining the canals. Various types of pinacocytes occur—basipinacocytes are in contact with the surface to which the sponge is attached,

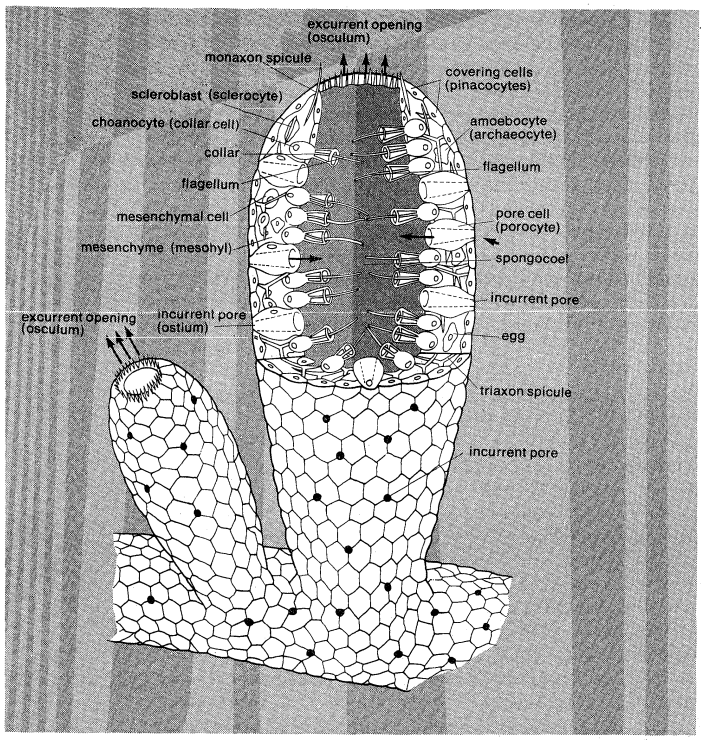

Figure 3: Part of a simple sponge with the upper part cut away to show cell structure.
From R. Buchsbaum, *Animals Without Backbones* (1948); University of Chicago Press

exopinacocytes are found on the surface of the sponge, and endopinacocytes line the canals. Pinacocytes are flattened cells containing many granules; capable of contracting, pinacocytes may cause a reduction in the volume of the sponge if it is disturbed. In the Calcispongiae, the outer surface of the body also contains flattened granular cells called porocytes because they contain the pores needed to allow water into the sponge. The porocytes can contract, thus closing the pores during unfavourable environmental conditions.

Lophocytes, sclerocytes, and myocytes

The collencytes, found in the mesohyl, secrete fibres and often form a net in the cytoplasm. The mesohyl of sponges contains other types of cells (lophocytes, sclerocytes, myocytes) believed to be derived from archaeocytes. Lophocytes, similar to but larger than collencytes, have long cytoplasmic processes at one end, giving them the appearance of a comet; they apparently secrete fibres (spongin) that form skeletal material. The sclerocytes, or scleroblasts, which also produce skeletal material, are classified according to the chemical nature of the spicules; calcoblasts secrete calcareous spicules, silicoblasts siliceous (glasslike) ones. The myocytes are elongated, contractile cells, particularly abundant near the oscula, where they control their expansion and contraction. The presence of nerve cells in sponges is a matter of dispute; the general opinion, however, is that none exist, not even in a primitive form.

Skeleton. The skeleton of sponges is of great taxonomic significance. It may be mineral in nature (calcareous or siliceous) or composed of protein and other components (spongin, see Figure 4). The mineral skeleton is formed for the most part by units called spicules, either scattered throughout the sponge or united to form fibres; spicules are classified as megascleres, which function in support, and microscleres, which function in protection and also aid in support.

Spicule types

Mineral skeletons. Calcareous spicules, characteristic of the Calcispongiae, are composed chiefly of calcium carbonate in crystalline forms; *e.g.*, calcite, aragonite. Most calcareous spicules have one axis (monoaxon), which is usually pointed at both ends; these spicules are called oxeas. Triaxons have three rays and are called triacts; tetraxons have four rays and are called tetracts. Figure 4 shows spicule types.

Siliceous spicules, found in the Demospongiae and in the Hyalospongiae, are made essentially of silicic acid; they also contain some water, a small quantity of other compounds containing sodium, potassium, iron, and chlorine, and a small quantity of organic matter, called spiculin, which forms an axial fibre. The spicules of the Hyalospongiae are variable in form and often have remarkable dimensions. Characteristic spicules of the Hyalospongiae are triaxon forms with three orthogonal axes (that is, six rays); this form is called hexactine, and the class is also known as the Hexactinellida. The spicules are connected in a continuous network, and after the death of the sponge and the loss of its soft parts, the skeleton that remains has a delicate glass texture; *e.g.*, the Venus basket, *Euplectella*. Bundles of large spicules form stalks that allow members of the Hyalospongiae to attach to the muddy bottoms of the deeper parts of the ocean in which they generally live. In the genus *Monoraphis*, the stalk is one enormous spicule that may attain a length of two or three metres and a thickness of approximately one centimetre.

The siliceous spicules, consisting of both megascleres and microscleres, of the Demospongiae have an enormous variety of forms. The megascleres may be monaxons with both ends pointed (oxeas), with one end pointed and the other rounded (styles), or with both ends rounded (strongyles). If one end is swollen styles are called tylostyles and strongyles tylostrongyles; the spicules with both ends swollen are called tylotes. If the surface of the spicules is spiny instead of smooth, the spicules are called, respectively, acanthoxeas, acanthostyles, and acantho-

From (top right, dictyonine framework) R. Buchsbaum, *Animals Without Backbones* (1948), University of Chicago Press; (others) C. Villee *et al.*, *General Zoology*, 3rd ed. (1968), W.B. Saunders Company, Philadelphia

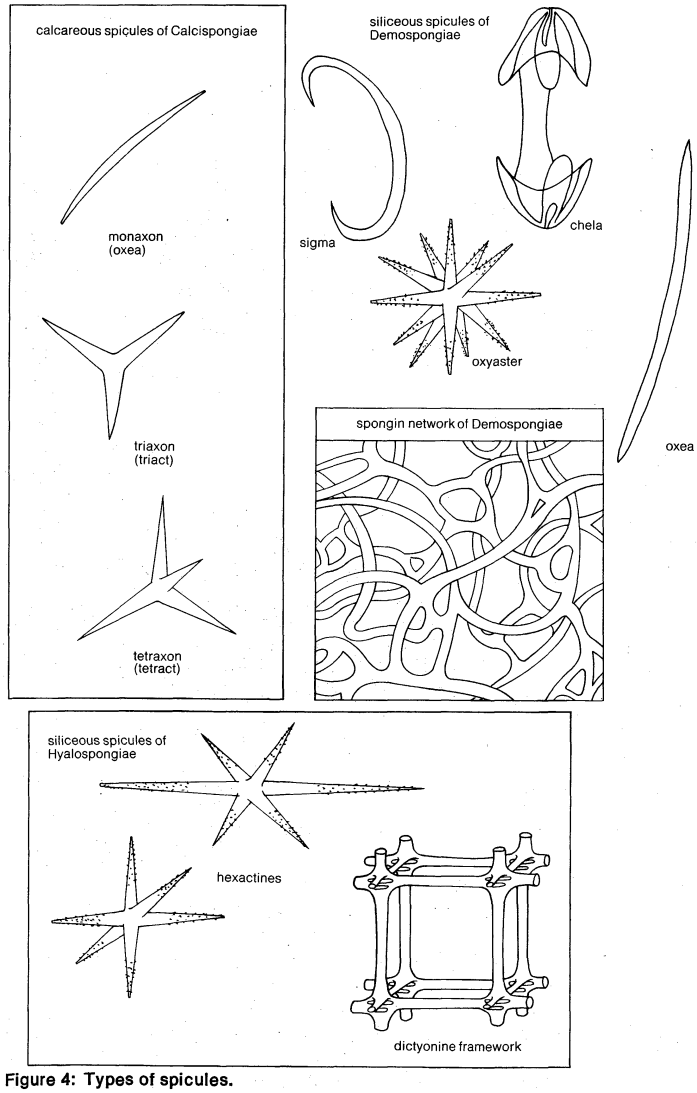

Figure 4: Types of spicules.

strongyles. The megascleres also include triacts with three rays and tetracts, called calthrops, with four rays. Tetracts with one axis (rhabdome) longer than the other three (collectively the cladome) are called protriaenes, plagiotriaenes, anatriaenes, or dichotriaenes, depending on the way the rays of the cladome are directed.

All of the microscleres apparently are derived from a spherical type with many axons (polyaxon); the result is a series of star-shaped spicules, or asters, with various numbers of rays. Spicules with rays missing or reduced (called spheres, sterrasters, and discasters) often form a protective armour around the sponge. More specialized types of microscleres include sigmas, toxas, chelas, and anchoras; the last two have plates or teeth at each end and may be distinguished as isochelas and isanchoras or anisochelas and anisanchoras, depending on whether the ends are equal or unequal.

Other types. A few Demospongiae (*e.g., Oscarella, Halisarca,* and *Chondrosia*) lack skeletons. One group (Ceractinomorpha) has a type of spongin, which, in certain orders (Axinellida, Poecilosclerida, and Haplosclerida), cements the spicules in bundles or meshes, thereby increasing the elastic nature of the skeleton. In another group of Demospongiae (Keratosa), spongin fibres constitute the entire skeleton; the spongin fibres may be branched (order Dendroceratida), netlike (order Dictyoceratida), without inclusions (commercial sponges, which are therefore soft and elastic), or with inclusions (*e.g.*, grains of sand, fragments of spicules). In the genus *Ircinia,* the fibres are accompanied by thin spongin filaments that fill the mesohyl.

Spongin

Specialized types of skeletons in two groups of great paleontological importance are now represented by only a limited number of species, in the Calcispongiae and Demospongiae. Those in the Calcispongiae (Pharetronida) have skeletons formed by an amorphous mass of calcium carbonate, with which few spicules are associated. Those in the Demospongiae (Lithistida) form a heterogeneous group in which irregularly branched spicules (desmas) form a compact skeleton. Some Demospongiae, found mainly on the coral reefs, possess a compact calcareous skeleton, which incorporates both siliceous spicules and organic fibres.

Functional features. *Feeding and digestion.* The Porifera are filter feeders, utilizing food particles suspended in the water and captured by the choanocytes. Food particles consist essentially of bacteria, other micro-organisms, and particles of organic debris; sponges also probably absorb dissolved organic substances. Experiments with starch grains, bacteria, and particles of carmine pigment show that the particles ingested by the choanocytes are transferred by thesocytes (specialized amoebocytes) throughout the sponge. Intracellular digestion occurs in both choanocytes and thesocytes. A large quantity of food is absorbed by a sponge; for example, a sponge ten centimetres tall with a diameter of one centimetre has about 2,250,000 flagellated chambers and utilizes about 22.5 litres (about 23 quarts) of water a day. The water current system, therefore, is efficient, in spite of the lack of a nervous coordinating centre. The water flow into and out of the sponge is maintained by continuous movement of the flagella of the choanocytes; flagellar movement pushes water into the choanocyte chambers, creating in them a pressure that extends to the excurrent canals, as water passing into the pores is drawn along the system of incurrent canals. Water flow, which is also regulated by contraction and expansion of the pores and of the oscula, is slow at the pores, fast at the oscula; as a result, water expelled with force through the oscula cannot contaminate water entering the pores. Toxic or irritating substances cause the pores to close.

Oxygen uptake and excretion. Respiratory organs are lacking in sponges; oxygen is supplied by a direct exchange between the tissues and the surrounding water. Consequently, the consumption of oxygen is related to the velocity of the current. Excretion occurs through both the oscula and the surface of the sponge. Special amoebocytes disintegrate in the mesohyl, and their granules are expelled through the canals. The excretory products of the sponges—ammonia and other nitrogen-containing substances—account for their characteristic unpleasant odour and probably make them undesirable as food for other animals. Many sponges (*e.g.*, the tropical sponge *Tedania ignis*) exude large quantities of mucus, and some species produce toxic substances, which may cause inflammation and skin reactions in man.

Coordination. A sponge usually contracts if it is handled or removed from water. The oscula close for various reasons—if the sponge is exposed to air, if oxygen is not available, if harmful chemical compounds are present, or if temperatures are extremely high or low. The absence of a nervous system would seem to be confirmed by the lack of coordination in the behaviour of oscula, pores, and choanocytes and by the slow reaction of sponges to stimuli. A primitive system of coordination, probably chemical in nature, apparently exists. Contraction of myocytes occurs around the oscula and along the peripheral canals of Demospongiae. Some Calcispongiae of the ascon type reduce their volume through contraction of the superficial layer of pinacocytes.

Biochemical aspects. The sponges produce substances with antibiotic activity (*e.g.*, ectyonin), which possibly function during the selection of bacteria and other micro-organisms on which they feed. The Porifera contain a greater variety of fatty substances (*e.g.*, sterols) than do other animals. Some of these sterols (*e.g.*, clionasterol, poriferasterol) are found only in sponges; others (*e.g.*, cholesterol) are common in other animals. Numerous carotenoid pigments occur in sponges; as many as 15 different ones have been found in one sponge. Although carotenoid pigments are among the most important pigments found in sponges, melanin, chlorophyll, and phycoerythrin, which are derived from algal symbionts and from the diet, also occur. Sponges accumulate silicon, calcium, and considerable quantities of metals; *e.g.*, iron, manganese, nickel, and gold. The spongins are iodine or bromine-containing scleroproteins similar to the keratin found in skin, claws, hair, and feathers of other animals. The two types of spongin, known as A and B, differ in composition and structure.

Sterols and pigments

EVOLUTION AND PALEONTOLOGY

Sponges have evolved in their own way along a developmental line foreign to that of other animals. They probably arose from the Protozoa, most likely from some flagellated stock. The group of flagellates that gave rise to the sponges is uncertain. The choanocytes of sponges resemble a group of protozoans, the choanoflagellates; one genus, *Proterospongia,* was so named because its structure seemed to indicate it as a possible sponge ancestor. Choanoflagellate protozoan colonies, however, do not develop through embryological stages as do the sponges. The primitive structure of the Porifera does indicate affinities with certain types of protozoan colonies; both lack integration of parts, mouths, and digestive systems, and both have a type of skeletal formation in which single elements are produced by a single cell or by a small group of cells.

The Porifera appeared in the Early Cambrian Period of the Paleozoic Era (about 550,000,000 years ago). Of the classes known in the Middle Cambrian Period (Hexactinellida or Hyalospongiae, Heteractinellida, and Demospongiae), the Heteractinellida are extinct; the Calcispongiae appear in the Carboniferous Period (about 345,000,000 to 280,000,000 years ago). Sponges have undergone a very limited evolution; *i.e.,* living forms do not differ substantially from many groups represented in the Paleozoic Era.

The Porifera, in spite of their mineral skeleton, are not well preserved as fossils; usually, only the type of spicules known as megascleres are preserved. The only groups well represented as fossils are those with a compact skeleton; *e.g.*, pharetronids (Calcispongiae), lithistids (Demospongiae), and Dictyonina (Hyalospongiae). Since these are specialized groups, they cannot provide a precise picture of the history of the phylum.

The oldest sponge fossils, from the Lower Cambrian, are well represented in the Burgess Shale of the Middle

Cambrian in western Canada by *Protospongia*, a member of the Hyalospongiae, and by *Eiffelia*, of the extinct Heteractinellida. They resembled a pouch and had very thin walls; their spicules were arranged in a single layer, and their water current system was probably of an ascon type. Various genera of the order Lyssacina (Hyalospongiae) are known from the Paleozoic from spicules. In the Mesozoic Era (about 225,000,000 to 65,000,000 years ago), the Hyalospongiae gave rise to a group (order Dictyonina) with the compact skeleton commonly found in sediments. Beginning with the Late Cretaceous Period (about 100,000,000 years ago), the species of Hyalospongiae have affinities with recent ones.

Fossil Calcispongiae appear in the Carboniferous Period (about 345,000,000 to 280,000,000 years ago). The first Pharetronida (Calcispongiae) from the Permian Period (about 280,000,000 to 225,000,000 years ago), have both a compact calcareous skeleton and spicules; because calcareous spicules are easily dissolved during fossilization, Calcispongiae which lack a compact skeleton have left few traces.

According to some experts, the Demospongiae followed a line of evolution originating in Tetractinellida (with four rayed spicules) and advancing, after reduction of the tetraxon spicules into monoaxons, to Keratosa; in addition, the polyaxon microscleres (asters) evolved into specialized forms (sigmas and chelas), and spongin appeared to cement the spicules, finally developing into a skeleton formed exclusively of horny fibres. According to the recent opinion by some zoologists and paleontologists, however, the Demospongiae are a diphyletic class, which is separable into two large groups (Tetractinomorpha and Ceractinomorpha). The Tetractinomorpha are characterized by four-rayed megascleres, asters, and no spongin; on the other hand, the Ceractinomorpha have monaxon megascleres, no asters, and spongin. That these morphological differences are accompanied by important embryological differences is supported by the facts that the oldest Demospongiae, from the Cambrian, are monaxonid (with only oxeas) and that the four-rayed spicule originates later, in the Carboniferous Period. Well-represented since the Paleozoic, the Lithistida have a siliceous skeleton of netlike desmas and are considered polyphyletic; the lithistid modification of the skeleton appeared independently in different lines of the Demospongiae. Few lithistid genera are extant. Demospongiae lacking a compact skeleton are poorly represented in sediments.

The phylogenetic relationships among the classes are difficult to ascertain, although common spicular characters may be found among Calcispongiae, Hyalospongiae, and tetractinellid Demospongiae. Noteworthy is the existence of sponges with both calcareous and siliceous elements in their skeleton; these sponges show affinities with both the pharetronid Calcispongiae and the Demospongiae. The extinct Archaeocyatha, with a cup-shaped body fixed on a surface and a skeleton of porous walls, were aberrant forms that lived exclusively in the Cambrian and that are generally considered as a separate phylum, even though they do show some affinities with the Calcispongiae.

CLASSIFICATION

Distinguishing taxonomic features. The most important feature used to distinguish sponges is the skeleton. The general architecture of the skeleton is used to differentiate families, the particular combinations of spicular types to define genera, and the form and dimensions of single spicule types to differentiate species. Other morphological characters used to define the systematic categories include shape, colour, consistency, and surface (smooth, rough, or conulose) of the sponge and distribution and character of the oscula. These characters, best studied in living specimens, often have, as in the case of skeletal features, remarkable interspecies variability. Observations of living samples and estimates of the range of variability, however, may allow the identification of a species without microscopic examination of the skeleton. Cytological and embryological features are used as diagnostic characters in both general classification and species identification of the Demospongiae and Calcispongiae. Ecological and distributional characters are important in distinguishing species, particularly in groups (*e.g.*, haliclonids) in which skeletal and embryological characters are so uniform as to be of little taxonomic value. Although biochemical criteria—for instance, amino acid composition—have been used in some cases to evaluate general phylogenetic problems and separate orders, the results do not differ substantially from those obtained with other criteria.

Annotated classification. The classification below, which refers to the three living classes of sponges, is adapted from that of E. Topsent as modified by C. Levi on the basis of embryological data; it is accepted by most experts in the field.

PHYLUM PORIFERA (sponges)

Primitive aquatic invertebrate animals; about 5,000 species in all seas; attach to surfaces from intertidal zone to depths of 8,500 m or more; propel water containing food particles through a system of canals in body (filter feeding); composed of many cell types (archaeocytes of various kinds, pinacocytes, collencytes); structure of water current system variable (ascon, sycon, leucon); skeleton either mineral (calcium carbonate or silicic acid), spongin, sometimes lacking, or of mixed composition; skeletal units (spicules) variable in form; both sexual and asexual reproduction (gemmulation); ability to regenerate lost parts; contain many unique chemical compounds; form symbiotic relationships with many other types of organisms.

Class Calcispongiae

Skeleton of spicules of calcium carbonate; species either vase-shaped compact structures, loose networks of thin tubes, or irregular massive colonies; mostly small in size; inhabit shallow waters of all seas, from intertidal regions to depths of 200 m; a few species to 800 m; about 300 species.

Subclass Calcinea

Larva called parenchymula (solid, compact, with outer layer of flagellated cells, inner mass of cells); flagella of choanocytes (collar cells) arise independently of nucleus; some 3-rayed spicules in most species; water current system ascon, sycon, or leucon type; includes pharetronid sponges with rigid skeleton of fused spicules or of a calcareous network; genera include *Clathrina, Leucetta, Petrobiona* (a pharetronid).

Subclass Calcaronea

Larva called amphiblastula (oval in shape with front half of flagellated cells, rear half without flagellated cells); flagella of choanocytes arise directly from nucleus; spicules 3-rayed, with one ray characteristically longer than other two; water current system ascon, sycon, or leucon type; *Leucosolenia, Scypha* (formerly called *Sycon*), *Grantia, Lelapia* (with a rigid skeleton composed of bundles of modified rayed spicules).

Class Hyalospongiae (Hexactinellida)

Skeleton basically of hexactinal (6-rayed) siliceous spicules and lacking in spongin; exclusively marine, in deeper waters of all seas, depths from 25 to 8,500 m; commonly fixed firmly to a hard surface, some species anchored in soft bottom sediments; *Hexactinella, Aphrocallistes, Farrea, Dactylocalyx, Euplectella, Rhabdocalyptus*; about 500 species.

Class Demospongiae

Skeleton either of 1- or 4-rayed siliceous spicules, spongin fibres, or both; skeleton lacking in a few primitive genera; most abundant and widely distributed group of sponges (about 4,200 species); occur from intertidal regions to depths of about 5,500 m in seas; Spongillidae the chief freshwater sponge family; species vary greatly in form and size; range from thin encrustations several cm in diameter to huge cake-shaped species 2 m in diameter; many species with desmas (develop as a result of secondary deposits of silica around ordinary spicules); evolution independently among several orders of interlocking of adjacent desmas to form a stony skeleton (lithistid sponges).

Critical appraisal. The living orders of sponges are distributed in the Calcispongiae, Hyalospongiae, and Demospongiae. The Calcispongiae may be separated into two subclasses (Calcinea and Calcaronea), which represent two phyletic series separated mainly by cytological and embryological characters; this classification has replaced the traditional classification of the calcareous sponges into Homocoela and Heterocoela, which was based on the types of the water current system. The tradi-

tional classification of the Hyalospongiae into the orders Lyssacina and Dictyonina is still valid. The separation of the Demospongiae into orders is not well defined, because the phylogeny of the group is not well known. Two groups of orders may be distinguished within the Demospongiae. One, in which spongin is an important skeletal element (Ceractinomorpha), includes Poecilosclerida, Haplosclerida, Dendroceratida, and Dictyoceratida, the latter two derived from another subdivision, the Keratosa. The other group (Tetractinomorpha) includes Homosclerophorida, Tetractinellida, Epipolasida, Hadromerida, and Axinellida; four-rayed spicules are important only in the Homosclerophorida and in the Tetractinellida, but the other orders are clearly related to them. Hadromerida, Axinellida, and Epipolasida are placed together in a group called the Clavaxinellida. The Epipolasida, an ill-defined order, are nearest to the Tetractinellida. Many genera of Demospongiae, mainly in the Tetractinomorpha, are transitional, and their actual phylogenetic position is not clear.

Alternate subclassification systems

Other classifications of sponges may concern only differences in detail; *e.g.*, the rank of order or of suborder given to the Dictyoceratida and Dendroceratida, the inclusion of the Homosclerophorida in the Tetractinellida, or the abolition of the order Epipolasida. A classification for the Demospongiae, proposed in 1936, is similar to that stated above in its subdivision into orders but is revolutionary with regard to the placement of families and of genera. It has not been followed in general by the other systematists of the group.

Still another classification of the Porifera places them in a subkingdom of the Parazoa as two phyla (Nuda and Gelatinosa). The Nuda includes a single class and order, the Hexactinellida; the Gelatinosa is divided into two classes (Calcarea and Demospongia). The separation between Nuda and Gelatinosa is based only on the absence or presence of an intercellular matrix of fluids and fibrils around the net of cells. Although the proposal has not yet been evaluated critically, it seems justifiable to keep the Porifera in a single phylum because of the common structural basis regarding their many characters, (*e.g.*, anatomy, function, and embryology). Other proposals include establishment of a new order Pharetronida separated from the Calcinea and Calcaronea in the Calcispongiae, and the creation of a new class (Sclerospongiae) for the silicocalcareous or coralline sponges.

An important controversy in the systematics of the sponges concerns the value given to species described using traditional criteria. The use of species in classifying sponges is justified by the great variability of diagnostic characters, especially the spicules. Attempts to merge large groups of species into single systematic units have resulted in excessive lumping of species, which has been much criticized. In classifying sponges, therefore, one diagnostic feature (*e.g.*, characters of skeleton or spicules) is not sufficient; rather, all diagnostic characters should be considered.

Portugal

One of the oldest countries in Europe, with established frontiers since 1297, Portugal lies on the extreme western rim of the European Continent. It is bordered on the east and the north by Spain and on the west and the south by the Atlantic Ocean. A narrow rectangular country, occupying slightly more than 15 percent of the Iberian Peninsula. Portugal has a total area of 34,170 square miles (88,500 square kilometres). Despite its small area, the country displays a great diversity of geographical features and rises to 6,539 feet (1,993 metres) at its highest point on the Serra da Estrela. To the west and southwest lie the Atlantic islands of the Azores and Madeira, which are part of metropolitan Portugal. In addition, Portuguese overseas territories include the Cape Verde Islands, São Tomé e Príncipe, Portuguese Guinea, Angola, and Mozambique, all in Africa; Macau in Asia; and Timor in Oceania. The Portuguese consider these overseas provinces as integral parts of Portugal, a single national territory that is juridically one despite its geographical separation. The United Nations, however, defines the Portuguese overseas territories as non-self-governing territories.

One of the poorest countries in western Europe and still one of the most politically authoritarian, Portugal was showing signs of greater liberalization in the early 1970s. Some observers have noted that the war against the African liberation movements has placed a heavy strain on an otherwise potentially buoyant economy. As a member of the European Free Trade Association (EFTA) and the North Atlantic Treaty Organization (NATO) and by virtue of its overseas possessions, Portugal plays a much greater role in both European and world affairs than its small size would suggest.

This article covers only metropolitan Portugal; there are separate articles on the overseas territories. (See ANGOLA; CAPE VERDE ISLANDS; MACAU; MOZAMBIQUE; and PORTUGUESE GUINEA. For a related physical feature, see TAGUS RIVER. See also LISBON.)

THE LAND

Most of Portugal consists of lowlands, with only 11.6 percent of its area lying above 2,300 feet—and most of that north of the Tagus River (Rio Tejo), which cuts the country in two. Southern Portugal is a region of plains and low tablelands, of broad river basins, and of gently undulating country, with rare outcrops of hills and only one mountain range rising over 3,280 feet. In the north, however, over 90 percent of the area lies above 1,300 feet. Mountains more than 3,280 feet high rear up only 30 miles from the sea, and huge plateaus are cut by deep valleys.

Physical geography. *Minho.* In the northwest, the mountains of Minho province, surmounted by Mt. Larouco, 5,003 feet (1,525 metres) high, form an amphitheatre facing the Atlantic Ocean. The area is composed of metamorphic rocks (crystalline schists, slates, and quartzites) and intrusive or granitic rocks, marked by fault lines and hot springs. Parallel to the mountainous ridges, rivers such as the Lima and Cávado flow through deep gorges and flat-floored valleys. Along the coast a narrow beach rises gradually to meet the low hills, which lie just a few miles inland.

Trás-os-Montes e Alto Douro. Behind the mountains of Minho is the province of Trás-os-Montes e Alto Douro bordered on two sides by Spain. It is an extension of the Meseta, a high, partly fractured plateau (from 2,000 to 2,600 feet high) composed largely of ancient Precambrian rock, such as granites, schists, and slates, deeply gashed by rivers, which have carved canyons as deep as 1,600

feet. The Rio Douro at Paradela suddenly curves to the southwest, cutting deeply into the old plateau surface. The plateau is surmounted by Nogueira (4,324 feet [1,318 metres] high), one of the remnants of the ancient mountains.

The Beira provinces. The rocks and landscape of Minho extend southward beyond the Rio Douro into the Beira Litoral, to a point north of Coimbra on the Rio Mondego. Most of central Portugal is included in the Beira provinces. The heart of Beira Alta is an elevated peneplain, partly dissected by the Mondego and Vouga river systems. Like Trás-os-Montes e Alto Douro, this high plain is an extension of the Meseta of Old Castile, Spain. The low, protected valleys, which are subject to climatic conditions very different from those of the high plateau directly above them, are called the *terra quente* (hot country). The high plain of the Beira is bounded to the northwest by the Serra do Caramulo (3,524 feet [1,074 metres]), the Montemuro Mountains (4,534 feet [1,382 metres]), and their foothills. To the south and southeast it is bordered by the great escarpment of the Serra da Estrela, which forms the backbone of the Beira as a gigantic granite and schist block that acts as a barrier between the northern and southern parts of Portugal. To the southwest, the mountain chain extends to the Serra de Açor (4,623 feet [1,409 metres]) and the Serra da Lousã (3,943 feet [1,202 metres]). To the south of Beira Alta and to the east of the Serra da Estrela lies the bleak plateau of Guarda, which has an average height of almost 3,000 feet. Farther south the eroded plateau of Beira Baixa drops to an altitude of from 1,600 feet to 700 feet. It slopes toward the Tagus River in the south and merges almost imperceptibly into the highlands of Alto Alentejo.

The role of Serra da Estrela

Beira Litoral and Estremadura. North of Lisbon, the western provinces of Estremadura and Beira Litoral form a region totally without crystalline rocks. A narrow band of Triassic sandstones run north and south from Coimbra to Tomar. To the west and southwest of the sandstones lies a broad band of Jurassic limestones, interspersed by large areas of Cretaceous sandstones and conglomerates. Erosion has produced a landscape of rolling sandy hills, plateaus of basalt, steep escarpments, and arid, desolate slopes.

Alto Alentejo. The south of Portugal is characterized by the rolling countryside of the Alentejo, formed from ancient schistose, granitic, and marble rocks. With an average height of between 700 and 1,600 feet, Alto Alentejo slopes downward toward the west and south.

Ribatejo. Between Beira Baixa, Estremadura, and Alentejo lies the Ribatejo, a part of a large sedimentary basin forming the lower section of both the Tagus and Sado river systems. The northern edge of the Rio Sado faces the calcareous cliffs of the Serra da Arrábida (1,644 feet [501 metres]) and a long spit of sand dunes extends to the south.

Baixo Alentejo and the Algarve. The southern edge of the plain of Baixo Alentejo rises into the schistose mountains of the Serra do Caldeirão (1,893 feet [577 metres]) in the east. To the west lie the more extensive scarps and hills of the Algarve, composed of Mesozoic limestones and sandstones. The highest peak is the Monchique (2,959 feet [902 metres]), a dissected massif of syenite, an igneous rock.

Rivers and coasts. *River systems.* All the main rivers of Portugal flow from Spain over the edge of the Meseta in a series of defiles and gorges. Consequently none of them is navigable between the two countries (with the possible exception of the lower Minho and Guadiana). The longest river crossing Portugal is the Douro (200 miles), whereas the longest river solely in the country is the Mondego (137 miles), rising in the Serra da Estrela. The principal exclusively Portuguese rivers, all of which are partly navigable, include the Vouga (85 miles), the Mondego, the Sado, and the Zézere (a tributary of the Tagus). North of the Tagus, most of the rivers flow from the northeast to the southwest, whereas most of those in the south flow from the southeast to northwest.

Harbours. The coast has only a few natural harbours, the most important at the mouths of rivers: Lisbon, at the Tagus; and Setúbal, at the Sado. Other harbours depend on the protection of headlands. North of the mouth of the Douro the artificial harbour of Leixões has been built. Sandbars at the entrance of many rivers block passage of ships. Lisbon, with its fine harbour, was the only obvious choice for a large port. The changing fortunes of the ports of the Algarve and the Beira Litoral have reflected the variations of silting along their coasts. Long sandbars extend along most of the Portuguese coast, interrupted by rocky capes and by great lagoons.

The climate. The extreme southwesterly position of Portugal in Europe explains its mild, humid winters and its relatively equable, dry summers. The effect of the ocean and the contrasts of relief offer an extremely varied climate marked by transitional features between west temperate (Marine West Coast) and Mediterranean conditions. In winter the northern half of Portugal is dominated by the North Atlantic cyclones, and in summer the Azores high-pressure system advances northward over the country.

Temperature ranges

In January the average temperatures range from 52° F (11° C) in the southwest to about 45° F (7° C) in the northeast. Severe cold is usually associated with the incursion of high pressure conditions from the Spanish Meseta or from Siberian anticyclones. The highest areas of the Serra da Estrela, or the region of Bragança (to the northeast of Trás-os-Montes e Alto Douro) register temperatures of less than 32° F (0° C), and snow lies on the mountain summits for several months. Evening sea breezes cool the summer heat of the coastal zones. August is usually the hottest month, with an average temperature of 68° F (20° C).

Northern Portugal receives considerable rainfall, and everywhere on the coast humidity is relatively high for the latitude. In the northwest annual rainfall is over 40 inches, and a large part of Minho receives between 40 and 80 inches, with mountain slopes recording up to 100 inches. Near the northwestern frontier, the summer drought is not pronounced, but toward the northeast and especially south of the Tagus the intensity of summer drought is more marked. Porto has a mean annual rainfall of 45 inches, falling within 137 rainy days; Lisbon 24 inches in 99 days; Lagos 15 inches in 90 days. Relief also plays its role, and the Serra da Estrela receives more than 110 inches. The leeward position of Trás-os-Montes e Alto Douro and the Douro Valley partly explains their lower rainfall of 30 to 40 inches in 90 to 130 rainy days.

Vegetation. Portugal exhibits a mixture of Atlantic deciduous flora and Mediterranean and African evergreens. About two-thirds are general European species and about one-third Iberian and African.

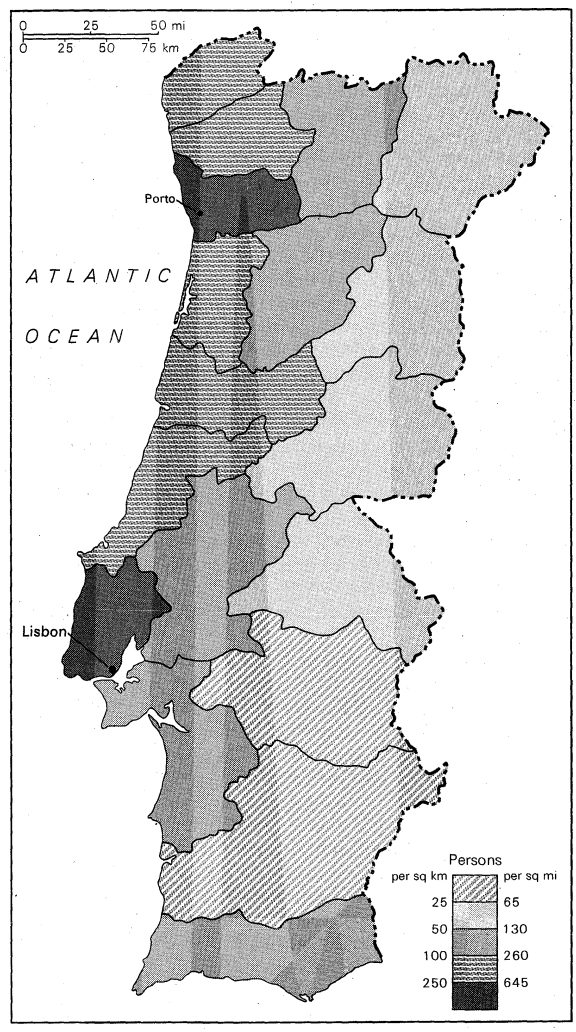
Two species of pine (*Pinus pinaster* and *Pinus pinea*) and three species of oak (*Quercus robur*, or english oak; *Quercus toza*, or Pyrenean oak; and *Quercus lusitanica*, or Portuguese oak) predominate in the northern half of Portugal, with notable concentrations of maritime pine on the predominantly siliceous coastal soils. The chestnut, linden, elm, and poplar, like the olive, are widespread. South of the Tagus River there is a quite different vegetation region. Maritime pine is replaced in the western Alentejo by the Italian stone pine (*Pinus pinea*). The dominant trees, however, are the cork and holm oaks. Both cultivated and wild olives grow well.

The far southern Algarve is renowned for its groves of carobs (locusts, or St. John's bread), almonds, and figs, but there are also figs near Tomar and almonds in the upper valley of the Douro in the north. The olive, once concentrated in the south, is now widespread, especially in the Algarve, central Portugal, and the Douro Valley. The Australian eucalyptus flourishes in the poorly drained valleys of the Tagus and the Sado systems. Notable specialized flora include the aquatic plants of the Aveiro lagoons, the beautiful woodlands of the Serras do Arrábida, Sintra, and Bussaco, and the alpine flora of the Serra da Estrela.

THE PEOPLE

Historical origins. *Racial groups.* The Portuguese display diverse racial origins. The Moorish occupation has

left its mark in the dark eyes and sallow skin of many Portuguese, in contrast with the blue- or gray-eyed people in the north. Along the coasts and especially in the south, Negro characteristics are a reflection of the 18th-century slave trade.



Linguistic features. Although the language appears superficially rooted purely in Latin, with a great similarity to Spanish, it contains a number of words of Germanic and Semitic origins. The language is remarkably uniform throughout Portugal, the only true dialect existing at Miranda do Douro in the northeast.

Religious groups. The vast majority of Portuguese belongs to the Roman Catholic Church, and, although freedom of worship is allowed, there are few adherents to other creeds.

Population density of Portugal.

Demography. *Population, births, and mortality.* At the beginning of the 20th century the population of metropolitan Portugal had reached about 5,000,000. By 1930 it had risen to 6,400,000, and at the 1960 census the total was 8,851,000 representing an average density of 242.4 persons per square mile. Portugal's population had risen to about 9,000,000 by the early 1970s; the birth rate stood at about 20 per 1,000 and the mortality rate at 11.1 per 1,000. Although the infant mortality rate had decreased, at 59.2 per 1,000 it was still one of the highest in Europe. About 38 percent of the population is under 20 years of age, 29 percent between 20 and 40 years of age, 21 percent between 40 and 60, and 12 percent over 60 years of age.

Birth and death rates

Migration. Portugal has one of the highest rates of emigration in Europe. Before 1960 most of its migration was to Brazil and a few other Latin American countries. In 1965 about 100,000 persons of eligible working age left the country, while the natural population increase was 115,112. By 1970 emigration to foreign countries stood at 66,360, 33 percent of whom went to France, 30 percent to the Federal Republic of Germany, 0.5 percent to the United States and 17 percent to other North and South American countries (Brazil, Canada, and Venezuela).

Population distribution. Population and settlement reveal striking contrasts between the denser northern and the more sparse southern parts of the country. A number of rural areas have suffered considerable population losses resulting in economic and social depression, particularly in parts of the north, the central east, and the southern coastal areas. The coastal zones between Braga in Minho, and Setúbal just south of Lisbon, with their low-lying plains and urban development, have encouraged a large proportion of the population to settle there. Only the industrial areas of Lisbon, with about 19 percent of the country's population, and Porto, with about 17 percent, are able to absorb their own working populations. Other areas that are currently going through the process of industrialization are Aveiro, Coimbra, Setúbal, and Faro.

Areas such as the humid Minho, the fluvial central plains, and the coastal areas of the Algarve are seriously overpopulated. In the main, however, rural settlement is dispersed, with the inhabitants living in small villages under a system of open-field farming. The Beira Litoral and Estremadura have settlements varying between dispersed and clustered farmsteads. In the region of Aveiro, clusters of farmsteads and other dwellings are strung along roads in strips, which are often of considerable length and density. Fishing, one of the earliest occupations of Portugal, still plays an important role in coastal settlement.

At the time of the 1960 census approximately 23 percent of the population lived in urban communities; by 1970 the percentage had risen sharply to over 37. The growth of Lisbon and Porto has been particularly significant. This urban growth has been achieved at the cost of an equally significant rural depopulation.

Population growth

THE NATIONAL ECONOMY

Agriculture, forestry, and fishing. The picture of Portuguese agriculture is one of a sector in a state of decline

from its past pre-eminence and dwindling as a source of production. Two distinct factors explain this downward trend: first, the incidental and short-term influence of relatively adverse weather conditions and, secondly, the predominance of antiquated agricultural techniques. Small farms strongly predominate particularly in the north where they are too small and made up of too many dispersed holdings to allow integrated farming and rational crop rotation. In the south (except in Algarve) the system of *latifundia* (large estates) prevents more intensive cultivation. Half of the farms in metropolitan Portugal have an area of less than 2.5 acres, and almost 90 percent of them have less than 12 acres. Only 0.3 percent of Portuguese farms, occupying 39 percent of the cultivated area, have more than 494 acres; only three have more than 37,000 acres. As well as the problem of farm size, there is also that of land fragmentation. Although the average size of a complete farm is about 20 acres, the average size of the individual holding may be only 1.4 acres. About 30 percent of the total number of farms are made up of from six to more than 20 non-adjacent holdings. Fewer than two-thirds of the farms are entirely cultivated by their owners; a little over one-sixth are cultivated partly by the owner and partly under rent or sharecropping. Despite the small size and fragmentation, mechanization of agriculture has been slowly progressing.

The migration of workers from the countryside to the towns and abroad affects the various regions of the country in different ways. There is still, however, an excessively high proportion of labourers in agriculture, productivity is quite low, and the late 1960s indicated stagnation rather than a steady improvement of yields.

Efforts have been concentrated in Portugal on costly irrigation projects and the introduction of more efficient techniques of cultivation and farm management to obtain a substantial increase in agricultural productivity. Whereas internally agriculture is feeling the impact of developments in other sectors of the economy, externally it has to face the prospect of being plunged into competition with more advanced methods of agriculture.

Most of the mountainous areas of Portugal are well suited to forestry, and forest products (cork, resins, and pine and eucalyptus lumber) have increased their market value and find a growing demand in industry. For these reasons considerable reforestation has been conducted since the last quarter of the 19th century in areas where yields are low and erosion is rapidly destroying soil fertility. The area of forest land exceeds 7,900,000 acres.

Importance of the fishing industry

Portugal's extensive coastline and the abundance of fish in the surrounding waters have favoured the development of the fishing industry. Sardines, anchovies, and tuna caught near the coasts, together with other species such as cod from the North Atlantic fishing grounds, make a large contribution to food supplies. The fishing industry has prospered, and its products are exported all over the world. There are about 35,309 registered fishermen and about 20,000 additional persons employed in the fishing industry. Matosinhos, Setúbal, Portimão, and Olhão are the main fishery centres.

Industry and power. In the early 1970s, 28 percent of Portugal's active population was still occupied in agriculture, forestry, and fishing, 42 percent was engaged in industry, and 29 percent in the service sector: in 1950, the respective percentages were 49, 25, and 26. Since World War II there has been a decisive change in the economic life of Portugal. New occupations are encouraged as the population increases, and government initiatives aim to raise the standard of living.

Three main groups of industries

In its level of industrial development, Portugal occupies an intermediate, but fairly favourable position among the southern European countries. Since the 1930s attempts have been made to broaden the country's industrial base. Three main groups of industries—foodstuffs and beverages, textiles, and metals—together produce over half of the country's total industrial product and employ about 55 percent of the industrial labour force. Capital intensity varies widely among the industries included in these broad groups, and industrial centres are unevenly distributed throughout the country. The more prosperous and rapidly growing industries are concentrated around the larger towns, especially Lisbon and Porto. The construction of a steel mill at Seixal, the great new shipyards at Cacilhas-Barreiro, the installation of vast chemical plants at Sacavém, and the opening of two oil refineries at Lisbon and Porto have accentuated this industrial concentration.

Portugal has only a small and quite inadequate mineral production. Iron ores and coal are extracted at Torre de Moncorvo (hematites), Marão (magnetites), Montemor-o-Novo (magnetites and iron pyrites), São Pedro da Cova and Pejão (anthracites), and Bussaco (black coal). Other metallic ores, such as wolfram (tungsten ore), cassiterite (tinstone), and copper pyrites are found in small scattered deposits.

Hydroelectric resources are being developed, and a number of projects have been realized in the valleys of the Cávado, Douro, and Zêzere, among others. About 80 percent of the electrical production comes from hydro plants, the remainder from thermal plants. The total consumption of electric power had reached over 7,000,000,000 kilowatt-hours by the early 1970s, compared to only 2,797,650,000 in 1960.

Foreign trade. Portugal has a large foreign trade relative to its total population, and its composition changed considerably during the 1950s and 1960s.

Portugal's foreign trade has shown an annual increase in imports of nearly 10 percent. Food imports have not risen much, but imports of chemicals and fuel have continued to increase rapidly, as well as some groups of manufactured articles, especially motor vehicles and electrical machinery and appliances. The annual increase in exports has been about 12 percent, sustained by a fairly significant expansion in the sales of basic and semifinished materials. Some of the more important exports include cork, cotton yarn and textiles, canned fish, and wines. Portuguese exports to the main countries of the European Economic Community (EEC) have shown the highest growth rates, despite an indifferent performance in exports to Great Britain. Exports to other Western European countries have also increased rapidly. Shipments to Portugal's overseas territories, which account for about one-quarter of total exports, have accelerated somewhat, whereas deliveries to the United States have remained virtually static.

Export commodities

Portugal nevertheless suffers from a significant trade deficit. As a result of a substantial improvement in the balance of invisible trade, including expenditures by the growing influx of foreign tourists, the surplus in current transactions has, however, increased considerably.

National finance. The Portuguese monetary unit is the escudo (100 centavos) with the conto equivalent to 1,000 escudos. The official exchange rate was stabilized at $1 U.S. to 28.75 escudos in 1949, but after the 1971 international monetary reorganization the currency was being allowed to float.

The only bank issuing currency is the Bank of Portugal, founded in 1846. More than 20 commercial banks operate in Portugal and the islands of Madeira and the Azores. In 1959 the Bank of Development was set up to act as an investment bank for both Portugal and the overseas territories.

Monetary policy. The main aim of monetary policy has been price stability. Taxation of industry and incomes is moderate compared to that of other European countries, and there are provisions for a high rate of depreciation on equipment. The channelling of savings to long-term investment is still a weak feature of the system.

The Third Economic Development Plan

Economic prospects. The government's Third Economic Development Plan, covering the period 1968 to 1973, aimed at an average annual growth of real gross domestic product (GDP) of 7 percent. The investments specified for metropolitan Portugal totalled 123,000,000,000 escudos. To achieve the overall growth targets of the plan it was estimated that real gross fixed-asset formation would have to be increased at an annual rate of 8.5 percent, with the total value of fixed assets reaching 22.5 percent of the gross national product (GNP) in 1973 (at 1963 prices), compared with 19 percent in 1967.

Transportation. Although transport and communications have been seriously neglected in the past, there has been a strong effort in recent decades to improve this sector of the economy. The nature of the landscape dictates that metropolitan Portugal relies on many forms of transport.

Roads. Several of the country's main roads date back to ancient times, but now 11,185 miles (18,000 kilometres) of main roads connect the largest towns and extend to the border and ports. Secondary roads link the towns with almost every part of the interior. The total road network of more than 20,000 miles is being extended. By the early 1970s there were over 700,000 motor vehicles, most of which were automobiles.

Railroads. The Portuguese railroad network consists of almost 3,000 miles of track. The main Lisbon–Porto line was electrified in 1965, and by the early 1970s the rail service was accounting for more than 2,200,000,000 passenger-miles and 440,000,000 ton-miles of freight a year.

Shipping. The merchant fleet is one of considerable size, constituting a total of 926,000 gross tons in the early 1970s, compared to a little over 500,000 gross tons in the early 1950s. Well over 8,000 vessels stop at Portuguese ports annually.

Air transport. The Portela de Sacavém airport at Lisbon is an important junction for intercontinental flights and is also the base of the Portuguese airline, Transportes Aéreos Portugueses (TAP), which provides regular service to the overseas territories, as well as the usual commercial routes. There are other important airports at Porto and Faro. By the early 1970s almost 900,000 passengers a year were travelling by Portuguese airlines and more than 22,000,000 ton-miles of freight accounted for.

(I.M.P. do A.)

ADMINISTRATION AND SOCIAL CONDITIONS

Structure of the government. *Constitutional framework.* Portugal has been a republic since the overthrow of the monarchy in 1910, and is administered as a corporative state. According to the constitution of 1933, which was last revised in 1971, the chief of state is the president of the republic. He is indirectly elected by the nation through an electoral college for a seven-year term. The president appoints the chairman of the Council of Ministers (the prime minister), fixes election dates, represents the nation and directs foreign policy, makes and adjusts international treaties, and promulgates the laws and resolutions of the National Assembly.

Council of State and Council of Ministers

The president of the republic is advised when necessary by a Council of State, which is composed of the prime minister and the presidents of the leading political institutions, with ten public men. The prime minister forms his own cabinet (Council of Ministers) with the president's approval. The cabinet's duties consist of endorsing the acts of the president, drawing up laws, approving international conventions and treaties, and generally supervising public administration.

Parliament. The parliamentary body is the National Assembly of 150 members who are elected every four years by direct suffrage. Its duties include discussing and voting upon basic legislation. Bills passed by the National Assembly are sent to the president for promulgation as law. A Corporative Chamber acts as an advisory and technical body, expressing its opinion on bills and drafts of laws, and on the ratification of treaties, conventions and international agreements. It is composed of more than 200 representatives of the existing corporations (comprising all those engaged in any one trade or industry, the employers in guilds [*grêmios*] and the workers in syndicates [sindicatos]), local autonomous bodies, and other national interests.

Other institutions. There are eight economic corporations, covering agriculture, industry, trade, transport and tourism, credit and insurance, entertainments, fisheries and canned goods, and press and printing. Employers and workers collaborate on the drafting of contracts and collective wage agreements, the solving of labour and wage problems; they are members of employers' associations, trade unions, rural Peoples' Centres, and Fishermen's Centres. There is also a corporative organization of social and cultural bodies in the sectors of literature, science, welfare, physical education, and sports.

Local and regional government. Portugal is divided into 18 administrative districts (*distritos*), each with a civil governor who is appointed by and responsible to the central government through the minister of the interior. He administers with the help of a board. The country is also divided into 11 provinces: Minho, Trás-os-Montes e Alto Douro, Beira Litoral, Beira Alta, Beira Baixa, Douro Litoral, Estremadura, Ribatejo, Alto Alentejo, Baixa Alentejo, and Algarve, but this provincial division is no longer used administratively.

Townships and parishes

The 18 districts are subdivided into municipalities, or *concelhos*, and parishes, or *freguesias*. Each municipality is administered by a town council (câmara municipal), the president or mayor of which is a government appointee and whose members are elected by local bodies. Each parish has its council elected by the direct vote of local citizens.

The political process. The president of the republic is elected every seven years by the Electoral College composed of members of the National Assembly, the Corporative Chamber, and representatives of the municipalities and of the governor of the legislative councils of the overseas provinces. Elections for the 150 deputies to the National Assembly take place every four years by direct suffrage. They are preceded by a period for electoral campaigning during which lists of candidates are put up by each constituency. Voting takes place on each list as a whole. Opposition groups (which have no legal political status) are allowed to put up candidates and run an electoral campaign during this period. Lists of government candidates are put up by the Acção Nacional Popular, a nationwide political group that supports government policy, and of which the prime minister is head. The various groups of the opposition (except the outlawed Communists) also put up their lists of candidates in the constituencies they choose. This practice, with the exception of Lisbon and Porto, is confined to areas in which there is a basic liberal or left-wing tendency. The elector casts his vote for the whole list.

Portugal is thus a one-party state with one group giving support to the government. Supporters of the former monarchy are allowed official status as a nonparty group, but democratic opposition has no legal status outside the electoral periods for the National Assembly, which occur every four years. The Portuguese Communist Party is outlawed and only operates clandestinely.

The electorate is restricted to citizens who have reached 21 years of age or have been emancipated by law, who can read and write or who pay a minimum annual tax and have appeared on an official census. Both men and women who fulfill these conditions can vote. Those who have been deprived of their civil rights for any criminal offense may not vote.

The courts. Portuguese justice is carried out independently of the legislature and government through a hierarchy of courts. These range from "courts of the first instance" and courts of appeal to the Supreme Court of Justice. They deal with criminal, civil, and commercial misdemeanours. Special courts handle juvenile-delinquency and domestic-affairs cases, and members of the armed forces are tried by military tribunals. Special courts also review the legality of decisions taken by administrative authorities. Judges are appointed for life by the Higher Council of the Judicature after competitive examination before a panel of judges and professors of law. The attorney general is appointed by the minister of justice, on whose ministry he is dependent, and is represented in all courts and tribunals.

Penal institutions. There is no death sentence in Portugal, and long terms of imprisonment may be commuted after half the term has been served. Imprisonment may be in a political jail, such as the Fort of Peniche; in one of the civil prisons in an urban centre; or in a penal colony. In cases such as juvenile delinquency, prisoners may be remanded to their homes. Political prisoners may be subject to "security measures," as, for example, further terms

Detention of political prisoners

of detention after completing their sentence. A citizen may be detained without trial on serious suspicion of a political crime.

The armed forces. The Ministry of Defense coordinates the country's armed forces, which consist of an army, navy, and air force. Subsidiary organizations exist such as the National Republican Guard (Guarda Nacional Republicana), the Customs (Guarda Fiscal), and the voluntary, paramilitary Portuguese Legion, which is in charge of civil defense. Besides the minister of defense there are ministers of the army and the navy and a secretary and under secretary of state for air.

All male citizens over the age of 18 are subject to compulsory military service. Suspensions may be granted for family, health, or educational and professional reasons. The service consists of between three and four years, two of which consist of active service against the African liberation movements in Angola, Portuguese Guinea, and Mozambique. The reserve list includes men up to the age of 45.

Portugal is divided into seven military regions and eight independent military commands. Angola and Mozambique constitute separate military regions. As a member of NATO, Portugal provides the headquarters for the Iberian Atlantic (Iberlant) Command and various munitions depots and communications centres. An air base at Lajes in the Azores is used by the United States, which under an agreement signed in December 1971 is allowed to remain there until February 1974 in return for more than $500,000,000 in aid to Portugal.

The social sector. *Education.* Primary education in Portugal is compulsory between the ages of six and 14. Illiteracy was officially computed to be 75.9 percent in 1880. By 1950 it was 40.4 percent, by 1960, 32 percent, and by 1970, 21 percent. Private schools supplement the state schools, which provide free education for the majority of people. Secondary training in a high school, or *liceu,* prepares pupils for the universities and for specialized educational establishments such as technical and commercial colleges and teacher-training centres.

The universities

There are five universities: Lisbon Classical University, Lisbon Technical University, Coimbra University (which is one of the oldest in Europe), Porto University, and the Catholic University, founded in 1968, in Lisbon. Besides the universities there are other establishments for higher education such as the Military School, Naval School, and School of Fine Arts. In 1971 the government founded an educational scheme (Acção Social Escolar) to help underprivileged students with such matters as fees, transport, and meals. A youth movement, the Mocidade Portuguesa, was also founded in 1936 by the government chiefly to direct extra-curricular school activities and provide moral and political training for both primary and secondary schoolchildren. Until 1971 membership was compulsory, but in October of that year it was made optional.

Welfare services. The Portuguese welfare system is divided into four types of institutions that insure workers against sickness, disablement, and old age and provide for payment of pensions and family allowances. The first type consists of the Trade Union Provident Funds, which include the People's Centres (Casas do Povo) and Fishermen's Centres (Casas dos Pescadores). The second type is made up of the welfare funds (Fundos de Previdência) for other employee categories. These two are compulsory, unlike the third type—the Mutual Assistance Associations, which have voluntary membership. Finally, there are the provident institutions for the military and civil servants. Both employers and employees contribute to these funds on a basis of about 17 percent and 6.5 percent of wages, respectively. Many big companies conduct their own welfare and sick-benefit schemes and pensions for their employees.

Housing. In general the building of houses in Portugal is financed by private enterprise. Official schemes, however, include low-cost houses for white-collar employees, trade-union members, and public and civil servants. They are built with the cooperation of the government, the municipalities, and the corporative organizations. There are also houses on fixed low rentals that can be purchased by the tenant on a long-term basis and limited-rental houses built in groups by private enterprise with the consent of the municipalities. Institutions such as the Salazar Foundation obtain funds from public benefactors to provide homes for the very poor. A special type of low-rent housing is available for fishermen and is controlled by a central board.

Low-rent housing

Police services. The Portuguese police are under the control of the Ministry of the Interior and are divided into three main categories: the Public Security Police (Polícia de Segurança Publica), the General Security Directorate (Direcção Geral de Seguranca), which replaced the International State Defense Police (Polícia Internacional e de Defesa do Estado) in 1970, and the road police, which in 1971 became a special branch of the National Republican Guard (Guarda Nacional Republicana), which is also responsible for rural armed guards who patrol the countryside and have outposts in the main townships and larger villages. The duties of the Public Security Police are the general maintenance of public order, directing the city traffic, and the prevention of crime. The Security Directorate acts to discover and prevent subversion, to patrol the frontiers, and to seek out illegal political organizations.

Wages and the cost of living. Compared with most other western European countries, the level of wages and salaries is very low in Portugal. This has created an outflow of more than 50,000 emigrants a year (not including several thousand illegal emigrants) to higher income countries—such as France and the Federal Republic of Germany. Wages in Portugal are governed by collective labour contracts in the various industries and have generally risen steadily, although women are still paid less than men. Wage increase has been moderately faster than increase in the price of consumer goods.

Medical services. The hospital network in Portugal includes both state and private institutions. Portugal has ten principal hospitals, nine of which are designated Civil Hospitals; Lisbon has seven and Porto two. The remaining one is designated a University Hospital—in Coimbra. Regional hospitals are located in the main provincial centres and subregional ones in smaller centres. Charity hospitals (the Santas Casas de Misericórdia) give free treatment to the poor. The Civil Hospitals, which are mainly run by the local municipalities with state support and funds from welfare and social organizations, charge according to the means of the patient. There are dispensaries and clinics for mothers and infants all over the country. Special institutions include a cancer hospital and research unit in Lisbon, a school of tropical medicine, a sanatorium in the northern mountains, and a modern rehabilitation service for the disabled near Lisbon. Ancient scourges such as leprosy have been almost stamped out; but a lepers' colony still exists, and a mobile squad of health officers attends cases that do not need isolation. A recent government scheme has attracted considerable sums for building new hospitals and improving old ones.

General social and economic features. The movement from an agrarian to an industrial society in Portugal has meant the erosion of the former feudal class and the consolidation of a middle class comprising not only industrialists and businessmen, professional men and women, and white-collar workers but also technicians and skilled labourers. The new impetus given to industry has not only caused the migration of workers from the land to the urban centres but the bringing of industry to the countryside. Industry, which has been concentrated largely around Lisbon and the country's second city, Porto, has come under a new plan for decentralization. As a result factories are springing up in rural areas, thus increasing the local population and raising the standard of living. A new property-owning class is being created by the pay-as-you-rent house-purchase system in all areas. The emigrant and his family are forming a new social class and consumer group, since remittances sent home by workers abroad contribute substantially to raising the standard of living of a large sector of the once impoverished rural population.

CULTURAL LIFE AND INSTITUTIONS

The cultural background. Portuguese culture is based on a past that dates from prehistoric times into the eras of Roman and Moorish invasions. All have left their traces in a rich patrimony of archeological remains, including prehistoric cave paintings at Escural, the Roman township of Conimbriga, the temple of Diana in Évora, and the typical Moorish architecture of such southern towns as Olhão and Tavira. Throughout the centuries Portugal's arts have been enriched by foreign influences, including Flemish, French, and Italian. The voyages of the Portuguese discoverers opened the country to oriental influences, and the revelation of Brazil's wealth of gold and diamonds fed the Baroque flame in decoration. Buildings are repaired and conserved as part of the national heritage, and museums show the finest examples of the country's arts and crafts. Classic art is fostered in educational establishments, and young artists receive state and other aid as they experiment with modern forms.

Artistic influences of the past

Architecture. Romanic and Gothic influences have given the country some of its greatest cathedrals, and in the late 16th century a national style (Arte Manuelina) was synthesized by adapting several forms into a luxuriant ornamental whole of complicated decoration. The Baroque later dominated decorative themes until French Neoclassicism swept into fashion with its reversion to Gothic imitations. These in turn have yielded to the stark realism of the modern concrete age. Outstanding examples of Portuguese architecture include Jerónimos Monastery in Lisbon, an elaborate example of ornate Manuelin style; Lisbon's Sé (cathedral), which still shows the remains of Romanic construction in part of the façade; the new Palace of Justice in Lisbon, a fine soaring example of austere modern architecture; the Convent of Christ in Tomar, formerly the seat of the Knights Templars; the late-Portuguese-Gothic monastery of Santa Maria at Batalha; Porto's granite Rococo Clérigos tower; and Braga's Romanic cathedral.

Sculpture. After pre-Roman and Roman times, sculpture found rich expression in the magnificent tombs of the 12th and 13th centuries. The Renaissance and Baroque periods also left traces leading to the lyrical period of the 19th and 20th centuries. Outstanding are the examples of late-18th-century Baroque sculptures in wood, of which the Christmas cribs of Machado de Castro are the finest.

Painting. A school of primitive painters headed by Nuno Gonçalves was prominent in the 15th century, and subsequently a wave of Flemish artists influenced the native style, decorating palaces and convents and leaving a rich heritage of religious art. The 19th century saw another rebirth of national art with a late romantic period. A movement of naturalist realism that followed gave way to the experimental 20th century: Vieira da Silva is the country's finest modern abstract painter, and Carlos Boteho is noted for his portraits of Lisbon and street scenes.

Music. Portuguese music reached a peak of national achievement during the Renaissance. Its modern revival was primarily the work of Luis de Freitas Branco, whose Neoclassic tradition has been perpetuated by Joly Braga Santos. A new group of young composers is acquiring prestige both at home and in international competitions. There is a very active National Broadcasting Symphony Orchestra, and Porto has had its own symphony orchestra since 1962, the year in which the Chamber Orchestra was set up by the Gulbenkian Foundation, of the late Portuguese oil magnate Calouste Gulbenkian. In 1971 the Lisbon Municipal Orchestra was created, replacing the defunct Lisbon Philharmonic Orchestra. The official workers' recreation group, the Federação Nacional de Alegria no Trabalho (FNAT), created the Portuguese Operatic Company, which encourages national singers, producers, and conductors. Folk music and the traditional *fado*, a song form that expresses the sad romantic mood of the nation, remain as the country's fundamental forms of musical expression.

Literature. The Portuguese language became synthesized in the 12th century, and a lyrical quality was outstanding both in poetry and prose. A soldier-poet, Luiz Vaz de Camões, gave expression to the nation's epic genius in the 15th century, as the poet Fernando Pessoa expressed its decadence in the 19th century. Lyrical poetry still flourishes. The tendency of fiction, however, has been to deviate from the romantic form of the 19th and early 20th centuries and take a more realistic form. José Maria Eça de Queiróz was the outstanding realist novelist at the end of the 19th century; his works include *Os Maias* (1888; "The Mayans") and *A Cidade e As Serras* (1901; "The City and the Mountains"). In the 20th century the late Aquelino de Ribeiro was the outstanding regionalist novelist whose works include *Jardin das Tormentas* (1913; "Garden of Torments") and *O Homem que Matou o Diabo* (1930; "The Man Who Killed the Devil"), while Ferreira de Castro is the outstanding modern realist novelist with *A Selva* (1930; *Jungle*, 1934) and *Os Emigrantes* (1928; "The Emigrants").

Theatre and cinema. After a long period of stagnation the theatre is resuming a more active role. The film industry is also recovering after years of depression with aid from the Gulbenkian Foundation. While the state has for years promoted a ballet company whose works are based on Portuguese regional folk dancing and music, the Gulbenkian Foundation has now formed a ballet company with a repertoire in the classical and modern tradition. International opera, theatre, and ballet are prominent in regular seasons in the Lisbon São Carlos Opera House and other theatres.

Folk traditions and popular culture. The folk traditions still survive, particularly in the northern countryside where the old songs and dances grace local religious festivals. The government is also doing much to promote and preserve them both as a national tradition and a tourist attraction. Some of the best examples of regional dances are the *vira*, *chula*, *corridinho*, *tirana*, and fandango. National dress has been generally abandoned for everyday use, but it is still worn in the northern Minho province for marriage and other festivals. Traditional garments such as the green-and-red stocking cap of the Alentejo cattleman with his *samarra* (a short jacket with a fox fur collar) and *cifões* (chaps) survive. In the northern Trásos-Montes e Alto Douro province, the shepherd wears a straw cloak.

Regional fairs abound throughout the year, many of them combining with religious festivals. Christmas and other religious customs include the burning of the yule log in the porch (atrium) of the country church, the fight between Saint George and the Dragon in the streets of Monção at Corpus Christi. A folk museum in Lisbon features the furniture, tools, and customs of the various provinces of Portugal, including the pottery, regional embroideries, and other crafts that are a living part of rural life.

Cultural institutions. *Academies and societies.* Among Lisbon's chief institutions are the Geographical Society with its library, museum of overseas exhibits, and lecture halls; the Lisbon Academy of Sciences, the Portuguese Academy of History, the National Academy of Fine Arts, the Music Academy of Santa Cecília, and the Musical Circle. There were also organizations concentrating on literary activities, including the Society of Writers and Composers, which had been disbanded by government order on a charge of subversion but which has now been reformed. Nonpolitical popular organizations, such as the Voice of the Worker (Voz do Operário), give classes and lectures to workers, the youth movement (Mocidade Portuguesa) organizes cultural classes and entertainment for the young, and official students' associations run extra-curricular activities for university students.

Museums, libraries, and art galleries. Portugal is rich in museums, libraries, and art galleries. In Lisbon, besides the Gulbenkian Foundation which houses Calouste Gulbenkian's collections, the most outstanding are the Museum of Ancient Art, the Coach Museum, which contains Europe's finest collection of ancient vehicles, the Museum of Contemporary Art, and the Ricardo Espirito Santo School of Decorative Arts, which trains craftsmen in

Terraced vineyards along a tributary of the Rio Douro in the province of Trás-os-Montes e Alto Douro, Portugal.
Yan—Rapho Guillumette

ancient handicrafts. The Biblioteca Nacional (National Library) and Palácio Nacional de Ajuda (National Palace of Ajuda) have fine libraries, while outside Lisbon the libraries of the Convento de Mafra and the University of Coimbra have historical importance.

Press and broadcasting. A new law was passed in 1971 that gave greater freedom of action to the press and restricted official censorship to news concerning the war against the African liberation movements and other matters pertaining to national defense when deemed necessary.

Lisbon has five morning and four evening newspapers. Other main newspapers are published in most of the large Portuguese towns and in Madeira and the Azores. Periodicals include a glossy review of international news, women's magazines, technical, ecclesiastical, and juvenile publications.

Broadcasting facilities consist of both a state network and private stations. The state Emissora Nacional is maintained by license fees paid by listeners. It possesses a network of 47 medium and shortwave transmitting stations. The most important privately owned stations are Radio Clube Português, Radio Renascença, and Emissores Associados de Lisboa, Lda.

Radiotelevisão Portuguesa holds the concession for operating television in Portugal. Regular programs were introduced in 1957, and in the early 1970s the station was on the air for some 11 hours a day on two channels. Colour television is to be introduced on the system's second channel.

THE OUTLOOK

Portugal is in a phase of relatively significant political, economic, social and cultural change. When Marcello Caetano succeeded Antonio Salazar as prime minister in 1968, he directed government activities toward freeing the country from its tangled bureaucracy, easing economic restrictions, reforming industry, and passing laws for relaxing censorship and for religious freedom. A complete scheme of educational reform was introduced, and intellectual life in Portugal began to experience liberalization and change. Coordinated efforts by the authorities to preserve the country's historic and artistic heritage and the ancient skills of the craftsman continued, but at the same time a definite stirring was felt in modern artistic endeavour. This awakening partly stemmed from the easing of restraints such as censorship and partly from the increasing contact with European cultural movements. Modern technology continued to change the style of life more and more rapidly in both town and countryside. While emigration and the war against the African liberation movements in the overseas territories drained manpower from labour, women were increasingly absorbed into the professions, business, and industry. This in itself was a radical social change in a country where middle and upper class women were still traditionally kept at home. Increased purchasing power at home and revenue from emigrants abroad have fostered a higher standard of living, particularly among people living in the rural areas.

Experimentation in all art forms, a modern adaptation of architectural concepts to meet the exigencies of modern living, and the spread of popular education through the press, radio, and television are all playing their part in producing a nation aiming to achieve the social and economic progress that will enable it to participate equally in the European community. Portugal, History of

Portugal became an independent monarchy in the 12th century AD. Its name derives from Portus Cale, a pre-Roman or Roman settlement near the mouth of the Douro River. The southern part of the Roman province of Gallaecia was occupied by a Germanic people, the Suebi, in

AD 411, and Portucale (Porto) was held by them. They were subdued by the Visigoths, whose state was overthrown by the Muslim invasions in the 8th century. A Christian territory of Portugal was constituted in 868; it later became a county and was extended to Coimbra. Afonso Henriques assumed the title of king (1139) and annexed Lisbon. His successors took Alentejo and Algarve from the Muslims (by 1252). Portugal now includes the "adjacent islands" of Madeira and the Azores, first settled in the 15th century.

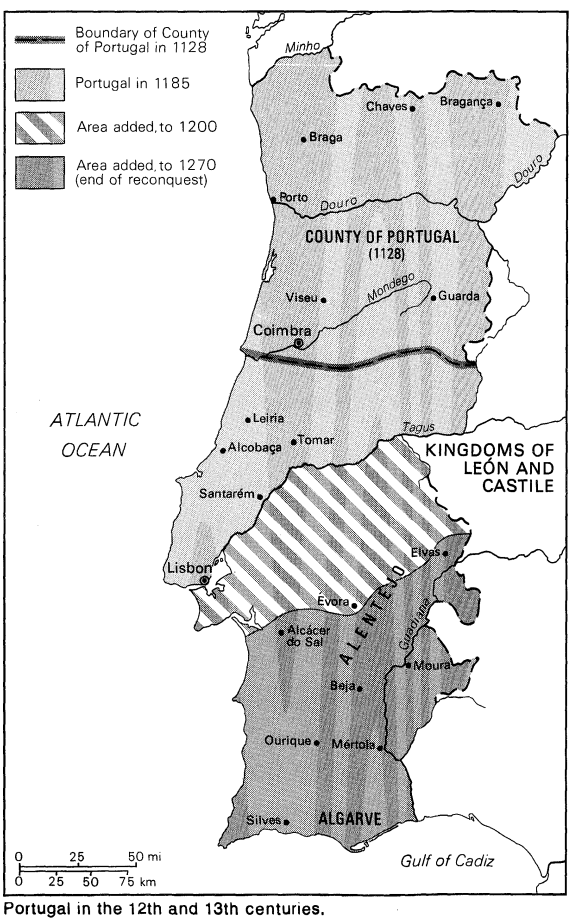
PRE-ROMAN, ROMAN, GERMANIC, AND MUSLIM PERIODS

The earliest human remains found in Portugal are Neanderthal-type bones from Furninhas. Most peninsular Paleolithic industries are represented, but a distinct culture first emerges in the Mesolithic middens of the lower Tagus Valley, dated *c.* 5500 BC. Neolithic cultures entered from Andalusia. There are varied types of beehive huts and passage graves: agriculture, pottery, and the working of soft metals followed by the same route. In the first millennium BC, Celtic peoples entered the peninsula by the Pyrenees, and many groups were projected westward by natural pressure. Hallstatt cultures brought ironworking to the Tagus Valley. Phoenician and later Carthaginian influence reached southern Portugal in the same period. By 500 BC, Iron Age cultures predominated in the north. Celtic hilltop settlements (*castros, citânias*) retained their vitality after the Roman conquest.

Celtic tribes

After the Second Punic War (218–201 BC), Rome dominated the eastern and southern seaboards of the peninsula, and Celtic peoples who had partially absorbed the indigenous population occupied the west. A Celtic federation, the Lusitani, resisted Roman penetration under the brilliant leadership of Viriathus; but after his assassination (*c.* 140 BC), Decius Junius Brutus was able to march northward through central Portugal, cross the Douro River, and subdue the Gallaeci. Julius Caesar governed the territory for a time. In 25 BC Augustus founded Augusta Emerita (Mérida) as capital of Lusitania, which incorporated the present central Portugal. Gallaecia, to the north of the Douro, became a separate province under the Antonines. In Roman times the region of Beja and Évora was a wheat belt. The valley of the Tagus was famous for its horses and farms, and there were important mines in Alentejo. Notable Roman remains include the "Temple of Diana" at Évora and the site of Conimbriga (Condeixa). Christianity reached Lusitania in the 3rd century and in the 4th Gallaecia, where the heretical and ascetic teaching of Priscillian long held sway.

Suebi, Visigoths, and Muslims



With the collapse of the Rhine frontier (AD 406), barbarian peoples forced their way into Gaul and crossed the Pyrenees. A Germanic tribe, the Suebi, was settled in southern Gallaecia, their rulers residing at or near Bracara Augusta (Braga) and Portucale. They annexed Lusitania and for a time overran the rest of the peninsula, but the Visigoths were sent to subdue them and extinguished their monarchy (AD 469). The records are silent until *c.* 550, when the Suebic monarchy had been restored and was reconverted to Catholicism by St. Martin of Braga. The Visigoth Leovigild again overthrew the Suebic monarchy and annexed the territory, but it remained distinct from Gothic Spain. St. Martin's church grouped together the bishoprics of the Suebic territory until *c.* 660, when the ecclesiastical divisions were adjusted to the old Roman provincial system and the region to the south of the Douro was restored to Lusitania. With the Muslim invasion of 711, the only serious Gothic resistance was made at Mérida; on its fall the northwest submitted. Berber troops were placed in central Portugal and Galicia, but with the revolt of the Berbers and famine (740–750) the latter was evacuated. Braga was abandoned, but the rural population remained or was restored. When ʿAbd ar-Raḥmān I set up the Umayyad monarchy at Córdoba (756), there was some resistance in the west, and he perhaps stationed Berber allies at Mérida and Coimbra. Lisbon was independent for a few years (*c.* 805). The restoration of the Christian sees of Galicia, the discovery of the supposed tomb of St. James, and the erection of his shrine at Santiago de Compostela were followed by the organization of the frontier territory of Portucale (868) by Vimara Peres; Coimbra was annexed by the Christians but later lost again.

THE COUNTY AND KINGDOM OF PORTUGAL (TO 1383)

By the 10th century the county of Portugal (north of the Douro) was held by Mumadona Dias and her husband Hermenegildo Gonçalves and their descendants, one of whom was tutor and father-in-law to the Leonese ruler, Alfonso V. But when this dynasty was overthrown by the Navarrese-Castilian house of Sancho III the Great, the western county lost its autonomy. Sancho's son, Ferdinand I of Castile, reconquered Coimbra in 1064 but entrusted it to a Mozarabic governor. When the African Almoravids annexed Muslim Spain, Alfonso VI of León (1065–1109) and Castile (1072–1109) provided for the defense of the west by calling on Henry, brother of Duke Eudes (Odo) of Burgundy, whom he married to his illegitimate daughter Teresa and made count of Portugal. From 1095, therefore, Henry and Teresa (who used the title of queen) ruled Portugal and Coimbra. On the death of Alfonso VI, his realms passed to his legitimate daughter Urraca and her little son Alfonso (VII). Henry of Portugal sought power but had achieved little when he died in 1112, leaving Teresa with an infant son, Afonso Henriques. Teresa's intrigues with her Galician favourite, Fernando Peres of Trava, lost her the support of the Portuguese barons, and in 1128 followers of her son defeated and drove her into exile. Thus Afonso Henriques became count of Portugal. Though at first obliged to submit to his cousin Alfonso VII, he began to use the title of king, traditionally because of a victory over the Muslims at Ourique (July 25, 1139; but perhaps a symbolic legend). In 1143 his cousin accepted his autonomy, but the title of king was formally conceded only in 1179, when Afonso Henriques placed Portugal under the direct protection of the Holy See, promising an annual tribute. He had captured Santarém (March 1147) and Lisbon (October 1147), the latter with the aid of English, French,

Afonso Henriques

Portugal in the 12th and 13th centuries.

German, and Flemish crusaders bound for Palestine. An English priest, Gilbert of Hastings, became first bishop of the restored see of Lisbon. Although the new Moroccan dynasty of the Almohads struck back (1179–84), when Afonso I died (Dec. 6, 1185) the Portuguese frontier was firmly established on the Tagus. The new military orders, the Templars, those of Calatrava (from *c.* 1156), and of Santiago (from *c.* 1170), etc., governed castles and territory on the frontier, and the Cistercians were responsible for the introduction of agriculture and architecture in central Portugal (Alcobaça).

The kingdom and the reconquest. Although Afonso Henriques began to grant charters to new settlements, it was his son Sancho I (1185–1211) who enfranchised many municipalities (*concelhos*), especially in eastern and central Portugal. The privileges of these communities were embodied in charters (*forais*), which attracted settlers from the more feudal north. Even Muslims were enfranchised, though on the other hand many of them were enslaved. Assisted by passing crusaders, Sancho captured Silves in Algarve (1189); but in 1190 an al-Muwāhhidūn army from Africa advanced to the Tagus and, although Lisbon, Santarém, and Tomar stood firm, the Muslims recovered Silves in 1191, together with most of the land south of the Tagus. In his later years Sancho was involved in a quarrel with Pope Innocent III over the payment of tribute due to the Holy See and with the bishop of Porto, who received Innocent's support. But peace was made before his death, and it was left to his son Afonso II, the Fat (1211–23), to endeavour to strengthen the power of the throne at the expense of the church.

Though Afonso II was an unwarlike king, his followers were beside the Castilians at the great Christian victory of Las Navas de Tolosa in 1212 and, again assisted by crusaders, recovered Alcácer do Sal in 1217. Meanwhile Afonso repudiated the bequests of large estates made by his father to his brothers and accepted those to his sisters only after a war with León and in a form, settled by the pope, that recognized Afonso's sovereignty. In the first year of his reign, Afonso called a meeting of the Cortes at Coimbra, to which the nobility and prelates were summoned (representatives of the commoners were not to appear until 1254). Both estates obtained important concessions; in fact, the position of the church and the orders was now so strong that Afonso II and his successors were involved in recurrent conflicts with Rome. Afonso himself instituted (from 1220) *inquirições*, or royal commissions, to investigate the nature of holdings and recover whatever had been illegally taken from the crown. In his last years, Afonso quarrelled with the archbishop of Braga, who was supported by Pope Honorius III, defied the papacy, and was excommunicated.

The Cortes

Little is known of the reign of his son Sancho II (1223–*c.* 1246), but the reconquest of Alentejo was now completed and much of Algarve was reduced. On his accession, Sancho found the church in full ascendancy as a result of the agreement made before his father's death. Conflicting reports exist of Sancho's own government, but in his later years the kingdom seems to have slipped into anarchy. At all events, his younger brother Afonso, who had become count of Boulogne by his marriage (1238) with Matilde, daughter of Count Raynald I of Dammartin, was granted a papal commission (1245) to take over the government, and Sancho was ordered to be deposed by papal bull. When Afonso reached Lisbon (late 1245 or early 1246), he received the support of the church and of the inhabitants of Lisbon and other towns. After a civil war lasting two years, Sancho II retired to Toledo, dying there in January 1248.

On his arrival, the count of Boulogne had already declared himself king as Afonso III, and the death of Sancho without issue gave his usurpation the mantle of legality. He brought together the divided kingdom, completed the reconquest of Algarve, transferred the capital from Coimbra to Lisbon, and, fortified by the support of the towns, summoned the Cortes at Leiria at which for the first time commoners representing the municipalities made their appearance (1254). His conquest of Algarve aroused the jealousy of Castile. Two campaigns were fought (1250 and 1252), Afonso probably being worsted, and peace was made by means of a marriage pact. Although still the husband of Matilde of Boulogne, Afonso married Beatriz, illegitimate daughter of Alfonso X of Castile, holding the disputed territory of Algarve as a fief of Castile until such time as the eldest son of the marriage should reach the age of seven, when Algarve was to return to Portugal. This marriage led to a dispute with the Holy See, in which Afonso was placed under an interdict. Despite his early connection with Rome, Afonso refused to give way; and in 1263 the bigamous marriage was legalized and his eldest son, Dinis, legitimized. Shortly afterward, Afonso launched *inquirições*, as a result of which the church was deprived of much property. The prelates protested these actions of the royal commissions, and most of them subsequently left the country. Although Afonso was excommunicated and threatened with deposition, he continued to defy the church until shortly before his death early in 1279.

First representation of commons

The achievements of Afonso's reign—the completion of the reconquest, the assertion of the royal power before the church, and the incorporation of the commoners in the Cortes—indicate important institutional advances. Under his son Dinis (1279–1325), Portugal was to come into closer touch with western Europe and to acquire a university, the elements of a national literature, and a navy. The chartering of fairs and the increased use of minted money bear witness to the growth of commerce, and the planting of pine forests to hold back the sand dunes near Leiria illustrates Dinis' concern for shipbuilding and agriculture. In 1317 Dinis engaged a Genoese admiral, Emmanuele Pessagno, to build up his navy, having already adopted various measures to stimulate foreign trade. He founded the University of Coimbra (at first in Lisbon) in 1290 and was both a poet and patron of literature. Yet he was especially famed as the "farmer king" (*rei lavradór*) for his interest in the land.

Despite Dinis' attachment to the arts of peace, Portugal was several times involved in strife during his reign. In 1297 the Treaty of Alcañices with Castile confirmed Portugal's possession of Algarve and provided for an alliance between Portugal and Castile. In the later years of Dinis' reign, his son, the future Afonso IV, rebelled more than once, being persuaded to submit by the influence of his mother Isabel, daughter of Peter III of Aragon. This remarkable woman, later canonized as St. Elizabeth of Portugal and popularly known as the Rainha-Santa (the Holy Queen), successfully exercised her influence in favour of peace on several occasions.

St. Elizabeth of Portugal

Disputes with Castile. Afonso IV (1325–57) was also involved in various disputes with Castile. Isabel, who had retired to the Convent of Santa Clara at Coimbra, continued to intervene in favour of peace; but on her death in 1336 war broke out, and terms were not made till 1340, when Afonso himself with a Portuguese army joined Alfonso XI of Castile in the great victory over the Muslims on the Salado River in Andalusia. Afonso's son Pedro was married (1336) to Constança (died 1345), daughter of the Castilian infante Juan Manuel; but soon after the marriage he fell in love with one of her ladies, Inês de Castro, by whom he had several children. Afonso was persuaded to countenance the assassination of Inês in 1355, and one of Pedro I's earliest acts on his accession was to take vengeance on her murderers. During his short reign (1357–67), Pedro devoted himself to the dispensation of justice; his judgments, which he executed himself, were severe and often violent, and his iron rule was tempered only by fits of revelling.

Pedro's son by Constança, Ferdinand (1367–83), inherited a wealthy throne almost free of external entanglements; but the dispute between Pedro the Cruel and Henry of Trastamara (later Henry II) for the Castilian throne was raging, and on the murder (1369) of the former, several Castilian towns offered Ferdinand their allegiance, which he was unwise enough to accept. Henry II duly invaded Portugal in 1369, and by the Peace of Alcoutim (1371) Ferdinand was constrained to renounce his claim and to promise to marry Henry's daughter; however, he instead took a Portuguese, Leonor Teles, although she was already

married and in spite of the protests of the commoners of Lisbon. He also made alliance (1372) with the English in the person of John of Gaunt, duke of Lancaster, who had married the elder daughter of Pedro the Cruel and claimed the Castilian throne. In 1372 Ferdinand provoked Henry II, who invaded Portugal and besieged Lisbon. Unable to resist, Ferdinand was forced to repudiate his alliance with John of Gaunt and to act as an ally of Castile, surrendering various castles and persons as hostages. It was only on the death (1379) of Henry that Ferdinand dared openly to challenge Castile again. In 1380 the English connection was resumed, and in the following year John of Gaunt's brother, Edmund of Langley, earl of Cambridge (afterward duke of York), took a force to Portugal for the invasion of Castile and betrothed his son Edward to Ferdinand's only legitimate child, Beatriz. In mid-campaign, Ferdinand came to terms with the enemy (August 1382), agreeing to marry Beatriz to a Castilian prince. She did, in effect, become the wife of John I of Castile; and when Ferdinand died, prematurely decrepit, Leonor Teles became regent and Castile claimed the Portuguese crown.

Alliance with the English

Leonor had long been the paramour of the Galician João Fernandes Andeiro, count of Ourém, who had intrigued with both England and Castile and whose influence was much resented by Portuguese patriots. Opponents of Castile chose as their leader an illegitimate son of Pedro I, John, master of Aviz, who killed Ourém (December 1383) and, being assured of the support of the populace of Lisbon, assumed the title of defender of the realm. The regent fled to Alenquer and thence to Santarém, and the king of Castile came to her aid, soon however, relegating her to a Spanish convent. Lisbon was besieged for five months (1384), but an outbreak of plague obliged the Castilians to retire.

THE HOUSE OF AVIZ, 1383–1580

The legitimate male line of Henry of Burgundy ended at Ferdinand's death, and when the Cortes met at Coimbra (March–April 1385), John was declared king and became the founder of a new dynasty. This result was not unopposed, for many of the nobility and clergy still considered the queen of Castile the rightful heiress; but popular feeling was strong, and John I had valuable and trusted allies in Nuno Álvares Pereira, "the Holy Constable," his military champion, and in João das Regras, his chancellor and jurist.

Independence assured. A number of towns and castles still held out for Castile when in August 1385 John I of Castile and a considerable army made their appearance in central Portugal. Although much outnumbered, the Portuguese won the great Battle of Aljubarrota (Aug. 14, 1385), in which the Castilian chivalry was dispersed and John of Castile himself barely escaped. The victory, followed by secondary successes won by Nuno Álvares, assured John I of his kingdom and made him a desirable ally. A small force of English archers had been present at Aljubarrota. Now the Treaty of Windsor (May 9, 1386) raised the Anglo-Portuguese connection to the status of a firm, binding, and permanent alliance between the two crowns. John of Gaunt duly went to the Peninsula (July 1386) and attempted an invasion of Castile in conjunction with John I. This was not successful, but the Portuguese king married Gaunt's daughter Philippa of Lancaster (1387), who introduced various English usages into Portugal. The truce arranged with Castile in 1387 was prolonged at intervals until peace was finally concluded in 1411.

The victory of John of Aviz may be regarded as a victory of the national spirit against the feudal attachment to established order. As much of the older nobility had adhered to Castile, John rewarded his followers at their and at the crown's expense. Meanwhile, commerce prospered, and the marriage of John's daughter Isabella to Philip the Good of Burgundy was to be followed by the growth of close trading relations between Portugal and Philip's County of Flanders. With the conclusion of peace with Castile, John found an outlet for the activities of his frontiersmen and of his own sons in the conquest of Ceuta (1415), from which may be dated the great age of Portuguese expansion.

Trade with Flanders

During the short reign of John's eldest son, Edward (Duarte; 1433–38), an unsuccessful attempt was made to conquer Tangier in 1437 by John's third son, Prince Henry the Navigator, and his younger brother Ferdinand, who was captured by the Moors and died, still unransomed, in 1443. On Edward's death, his son Afonso V was still a child, and his brother Pedro, duke of Coimbra, had himself made regent (1440) instead of the widow, Leonor of Aragon. But Pedro's own regency was later challenged by the powerful Bragança family, descended from Afonso, illegitimate son of John of Aviz and Beatriz, daughter of Nuno Álvares Pereira. This family continued to set the young king against his uncle, who was forced to resign the regency, driven to take up arms, and killed at Alfarrobeira (May 1449). Afonso V (1438–81) proved unable to resist the demands of the Braganças, who now became the wealthiest family in Portugal. Having married Joan, daughter of Henry IV of Castile, Afonso laid claim to the Castilian throne and became involved in a lengthy struggle with Ferdinand and Isabella in the region of Zamora and Toro, where he was defeated in 1476. He then sailed to France to entreat the aid of Louis XI, in which he failed, and on his return concluded with Castile the Treaty of Alcáçovas (1479), abandoning the claims of his wife Joan. Afonso never recovered from his reverse, and during his last years his son John administered the kingdom.

Consolidation of the monarchy. John II (1481–95) was as cautious, firm, and jealous of the royal power as his father had been openhanded and negligent. At the first Cortes of his reign, he exacted a detailed oath of homage that displeased his greatest vassals. A suspicion of conspiracy enabled him to arrest Fernando II, duke of Bragança, and many of his followers; the duke was sentenced to death and executed (1484) at Évora, and John himself stabbed James (Diogo), duke of Viseu (1484). As well as attacking the power of the nobility, John lessened the effects of the unfavourable treaty with Castile. Calculating and resolute, he later received the epithet "the Perfect Prince."

John II was predeceased by his legitimate son and therefore succeeded by his cousin, the duke of Beja, as Manuel I (1495–1521), known as "the Fortunate." Manuel, who assumed the title of "lord of the conquest, navigation, and commerce of India, Ethiopia, Arabia, and Persia," inherited, because of the work of John II, a firmly established autocratic monarchy and a rapidly expanding overseas empire. Drawn toward Spain by the common need to defend their overseas interests as defined by the Treaty of Tordesillas (1494), Manuel nourished the hope of joining the whole peninsula under the house of Aviz; he married Isabella, eldest daughter of Ferdinand and Isabella, who, however, died (1498) in giving birth to a son, Miguel da Paz. This child was recognized as heir to Portugal, Castile, and Aragon but died in infancy. Manuel then married Isabella's sister Maria (died 1517) and thirdly Eleanor, sister of the emperor Charles V.

As a condition of the marriage with Isabella, Manuel was required to "purify" Portugal of Jews. John II had admitted many Jewish refugees expelled from Spain (1492) and had taxed them heavily but was also to supply ships for them to leave Portugal. This was not done, and Manuel now ordered all Jews to leave within ten months, by October 1497. On their assembly in Lisbon, every effort was made to secure their conversion by promises or by force. Some who resisted were allowed to go, but the rest were "converted" under promise that no inquiry should be made into their beliefs for 20 years. As "Christians" they could not be forced to emigrate, and they were indeed prohibited from leaving Portugal. In April 1506 a large number of these "new Christians," or *marranos*, were massacred in Lisbon during a riot, but Manuel afterward protected them and allowed many to emigrate to Holland, where their experience of Portuguese trade was put at the service of the Dutch.

Forced conversion of Jews

If Manuel failed to realize his dream of ruling Spain, his son John III (1521–57) lacked the power to resist Castili-

an influence. A pious, retiring man, he was ruled by his wife, Catherine, sister of the emperor Charles V, and encouraged the installation of the Inquisition (1536); the first auto-da-fé was held in 1540. The Society of Jesus, established in 1540, soon controlled education in Portugal. In 1529 the settlement by the Treaty of Saragossa (Zaragoza) of a dispute over the possession of the Moluccas removed an obstacle to Portuguese–Spanish understanding, and the line of Tordesillas was matched by a similar line in the Pacific; all the territories of the New World were in theory divided between Spain and Portugal, while the Reformation (as well as the discoveries) had come between the latter and its English ally.

John III was succeeded by his grandson Sebastian (1557–78), then a child of three. As a boy, Sebastian became obsessed with the idea of a crusade against Morocco. Fanatically religious, he had no doubts of his own powers and listened only to flatterers. He visited Ceuta and Tangier in 1574 and began in 1576 to prepare a large expedition against Larache: this departed in June 1578 and on August 4 was utterly destroyed by the Moors in the Battle of the Three Kings near Alcazarquivir (Ksar el-Kebir). Sebastian himself was killed, 8,000 of his men are said to have died, and 15,000 were captured. Only a handful escaped.

The disaster of Larache

Sebastian was succeeded by his great-uncle, Cardinal Henry (1578–80), a brother of John III. His age and celibacy made it certain that the Portuguese throne would soon pass from the direct line of Aviz. Philip II of Spain, nephew of John III and husband (by his first marriage) of John's daughter Maria, had already made his preparations and, on the death of the cardinal-king (Jan. 31, 1580), summoned the authorities to obey him. An army under the great duke of Alba entered Portugal in 1580; the resistance of António the prior of Crato (illegitimate son of John III's brother Luís), acclaimed António I at Santarém, collapsed; and Philip II of Spain became Philip I of Portugal (1580–98). The claims of the duchess of Bragança (Catherine, daughter of John's brother Edward) were disregarded.

MEDIEVAL SOCIAL AND ECONOMIC DEVELOPMENT

Medieval Portugal comprised regions of considerable diversity. In the north, the old aristocracy of Leonese descent owned large estates worked mainly by serfs. In the southern territory that had been reconquered from Muslim rule, there were many towns, often separated by districts almost barren and depopulated. The initiative in settling these areas was taken by Cistercian monks, who had reached Portugal by 1143; later kings such as Sancho I and Afonso III established *concelhos* (municipalities), granting to them by the issue of *forais* (charters) many privileges designed to attract population. Tax concessions were often given, and freedom was promised to serfs or to Christian captives after a year's residence. But in the south, the *concelhos* were burdened with defense duties, the *cavaleiros-vilãos* (villein knights) being obliged to horse and arm themselves, and the *peões*, or less substantial men, being obliged to serve as foot soldiers in defense of the country and perhaps also on a *fossado* (raid) into Muslim territory.

Court officials

At court, the king was advised by his *curia regis* (court or council), comprising the *majordomus curiae*, the head of the administration, the military chief or *signifer*, the *dapifer curiae* (steward of the household), the chancellor (an official whose origins in Portugal were Burgundian rather than Visigothic), and any members of the greater aristocracy, the *ricos-homens*, who might be at court. This class also comprised the bishops and abbots and masters of the orders of knighthood; many held private civil or military authority. The lesser nobility were without such rights. Below them came various classes of free commoners, such as the *cavaleiros-vilãos* and the *malados*, men who had commended themselves to protectors. There were numerous serfs and slaves.

By the end of the medieval period several shifts in the social structure had occurred. Many of the old aristocracy lost their position at the advent of the house of Aviz, and the new nobility, exemplified in the house of Bragança, was often of bureaucratic or ministerial origin. The privileges granted to *concelhos* forced landlords to compete for labour, and by the time of Afonso III money payments had largely replaced labour services on the estates. Representatives of the commoners, first attending the Cortes in 1254 on behalf of the *concelhos*, took an increasing part in politics. The Cortes were very frequently called in the reigns of John I, Duarte, and Afonso V; but the avenues of power had become wider by the 16th century, and John III's proposal (1525) to call them only every ten years aroused no opposition. Although the trade guilds were slow in developing, they took some part in determining local taxation in the 13th century. Trade increased, Portuguese merchants having connections with the Low Countries from the time of Afonso Henriques and with England from the early 13th century. The political crisis of 1385 was followed by intense inflation and many debasements: there was thereafter no national gold currency until 1435, when West African sources began to be tapped.

THE DISCOVERIES AND THE EMPIRE

The idea of expansion into Africa was a logical result of the completion of the reconquest in the peninsula, and the conquest of Ceuta in North Africa (1415) probably provided the impulse toward further expansion. The simple idea of fighting the Muslims on their own soil was linked with more complicated motives: the desire to explore in a scientific sense, the hope of finding a way to the rich spice trade of the Indies, and the impulse to spread the Christian faith. These purposes were gradually molded together into a national enterprise, though at first they represented the hopes and aspirations of one man, Prince Henry. The third son of John I and Philippa of Lancaster, known rather inaccurately as "the Navigator" (he himself never went farther afield than Tangier), Henry became (1420) master of the Order of Christ, which King Dinis had founded (1319). The resources of the Order were used to draw together skilled geographers and navigators and to equip a series of expeditions that only gradually began to bear fruit.

Henry the Navigator

The date of Prince Henry's earliest expedition is not exactly known but appears to have been about 1418, when the island of Porto Santo was visited; the first call at Madeira probably dates from 1419. An attempt was made to settle in the Canaries, and between 1427 and 1431 the Azores were visited by Portuguese seamen. Both the Azores and Madeira were then uninhabited, and their colonization proceeded fairly rapidly from *c.* 1445. Sugar was exported to Europe and gave the islands great economic importance. Meanwhile, Prince Henry's ships were probing the African coast, passing Cape Bojador in 1434 and Rio de Oro in 1436. The unsuccessful expedition against Tangier (1437) was followed by a break in the discoveries, but in 1439 Prince Henry was authorized to colonize the Azores; and from 1440 further expeditions equipped with a new and lighter ship, the caravel, reached the Bay of Arguin (1443), Cape Verde (1444), and by Henry's death (1460) had explored the coast as far south as Sierra Leone.

Under Afonso V, three military expeditions were sent against Morocco (1458, 1463, and 1471); by the last of them, Tangier and Arzila were captured. The African explorations were not entirely neglected, but it remained for John II, with his sharp sense of the national interest, to found a fortress and trading post in the Gulf of Guinea at Elmina (São Jorge da Mina, 1481–82). Diogo Cam (Cão) discovered the mouth of the Congo in 1482 and then advanced to Cape Cross, 200 leagues southward (1486). A native monarchy, the Manicongo, sought conversion and alliance with the Portuguese: its first Christian king, Afonso I (1505–40), made Mbanza a centre of Portuguese influence, but the "kingdom of Congo" fell into internal strife and Portuguese interests were transferred to the neighbouring kingdom of Angola. Paulo Dias de Novais founded Luanda, the first city in West Africa south of the Equator, in 1576. In 1488, Bartolomeu Dias at length rounded the Cape of Good Hope and reached the East African coast, and the seaway to India lay open.

Bartolomeu Dias rounds Cape of Good Hope

His return was followed in 1493 with the news that Christopher Columbus had, as he thought, discovered the "Indies" by sailing across the Atlantic. Much as this news must have perturbed the Portuguese, Columbus brought no news of the spiceries or the cities of the East; and John II ordered the preparation of an expedition to India by way of the Cape of Good Hope, though this sailed only after his death. John also contested the Spanish claim to all lands discovered west of the Atlantic, and by the Treaty of Tordesillas (June 7, 1494), Spain's rights were limited to what lay more than 370 leagues west of the Cape Verde Islands. Thus the territory that was to become Brazil was reserved for Portugal.

The Treaty of Tordesillas had confirmed Portugal's rights to the exploration of Africa and the seaway to India. In July 1497 Vasco da Gama set sail with four ships on the first expedition to India. They reached Calicut (Kozhikode) the following spring, and the survivors put into Lisbon in the autumn of 1499 with specimens of Oriental merchandise (see also INDIAN SUBCONTINENT, HISTORY OF THE). A second fleet was prepared under Pedro Álvares Cabral, who touched the Brazilian coast (April 22, 1500) and claimed it for Portugal. One of Cabral's ships, under Diogo Dias, discovered Madagascar in 1500; João da Nova discovered Ascension in the following year and St. Helena in 1502. Tristão da Cunha sighted the island named after him in 1506 and went on to explore Madagascar. Meanwhile, trading posts in India had been established by Cabral at Cochin and Calicut (1501) and by João da Nova at Cannanore. In 1502 Vasco da Gama made tributary to Portugal the ruler of Kilwa (Quiloa) in East Africa.

Settlements in the Far East

In 1505 Francisco de Almeida arrived as viceroy of India, strengthening the African station at Kilwa and supporting the ruler of Cochin against the *zamorin* of Calicut. The control of sea trade now instituted became the chief source of Portuguese wealth in the East. It was assured by the defeat of Muslim naval forces off Diu in 1509. Almeida's successor, Afonso de Albuquerque, conquered Goa (1510), which he made the seat of Portuguese power, and Malacca (1511); sent two expeditions to the Moluccas (1512 and 1514); and captured Hormuz in the Persian Gulf (1515). Soon after, Fernão Peres de Andrade reached Canton in China; in 1542 Portuguese merchants were permitted to settle at Liampo (Ning-po), and in 1557 they founded the colony of Macao (Macau).

Albuquerque was responsible for this conception of a system of strong points that secured the trade of the Orient to Portugal for nearly a century. Goa soon became the chief port of western India; Hormuz controlled the Persian Gulf, and Malacca the gateway from the Indian Ocean to the South China Sea, while a string of fortified trading posts secured the coast of East Africa, the gulf and the shores of India and Ceylon (see CEYLON, HISTORY OF: *Ceylon under foreign rulers, 1505–1947*). Farther east, less fortified settlements were set up with the consent of the native rulers from Bengal to China, and the trade of the principal spice islands was in Portuguese hands. The preservation of the whole system was entrusted to a governor, who sometimes held the rank of viceroy, at Goa; and although Portuguese arms had both triumphs and reverses, their control of the Oriental trade remained substantial, if never complete, until the 17th century, when the Dutch, at war with the joint crown of Portugal and Spain and deprived of their traditional trade with Lisbon, began to seek spices from their source and effectively demolished the Portuguese monopoly.

UNION OF SPAIN AND PORTUGAL, 1580–1640

After Philip II of Spain had occupied Portugal in 1580, the island of Terceira in the Azores held out for António of Crato, who himself sought alliances in England and France. In 1582 a French expedition to establish him in the Azores was defeated, and in 1589 an English attempt upon Lisbon, led by Sir Francis Drake and Sir John Norris, failed dismally. But although António died in Paris in 1595, the true symbol of Portuguese independence was not the prior of Crato but King Sebastian himself. The Portuguese people refused to believe that he was dead and nourished a messianic faith in his reappearance, of which four pretenders sought to avail themselves, the last as late as 1600 and as far afield as Venice.

Meanwhile, Philip arrived in Portugal and was accepted as King Philip I (1580–98) by the Cortes held at Tomar (1581). He undertook to preserve Portuguese autonomy, to consider the union as a personal one like that of Aragon and Castile under Ferdinand and Isabella, to appoint only Portuguese to the administration, to summon Cortes frequently, and to be accompanied by a Portuguese council in Madrid. These undertakings were, however, neglected by Philip II (III of Spain, 1598–1621) and completely violated by Philip III (IV of Spain, 1621–40).

Exploitation by the Spanish

Portuguese resentment against Spanish rule was increased by the failure of these kings to visit Portugal, the appointment of Spaniards to Portuguese offices, the loss of trade consequent on Spain's foreign wars, and the levying of taxation to sustain these wars. In 1624 the Dutch seized Bahia in Brazil, only to be expelled by a joint Spanish and Portuguese expedition (1625). But in 1630 they occupied Pernambuco and the adjoining sugar estates, which they held for a generation. The final straw was the conde-duque de Olivares' plan (1640) of using Portuguese troops against the equally discontented Catalans. Two Portuguese insurrections, in 1634 and 1637, had failed to attain dangerous proportions, but in 1640 Spain's powers were extended to the utmost by war with France and revolt in Catalonia. The French minister, Cardinal de Richelieu, already had agents in Lisbon, and a leader was found in John, duke of Bragança, a grandson of the duchess Catherine (niece of John III) whose claims had been overridden in 1580 by Philip II of Spain. Taking advantage of the unpopularity of the governor, Margaret of Savoy, duchess of Mantua, and her secretary of state Miguel de Vasconcelos, the leaders of the party of independence carried through a nationalist revolution on Dec. 1, 1640. Vasconcelos was almost the only victim; the Spanish garrisons were driven out; and on December 15 the duke of Bragança was crowned as John IV (1640–56).

THE HOUSE OF BRAGANCA, 1640–1910

Although the Cortes confirmed the accession of the dynasty of Bragança and John's coronation on Jan. 28, 1641, the success of the new regime was not finally assured till 1668, when Spain at last recognized Portuguese independence. Faced with the threat of a Spanish invasion, John had sent missions to the courts of Europe in quest of alliances. France now refused a formal treaty. The Dutch, having seized northern Brazil, accepted a truce in Europe and proceeded to capture Angola from Portugal. John made a treaty (1642) with Charles I of England, which was made void by Charles's execution (1649). Meanwhile, the Portuguese defeated the Spaniards at Montijo (May 26, 1644) and warded off several invasions. In 1654 they negotiated a treaty with the English Commonwealth, obtaining aid in return for commercial concessions. The Dutch were now finally expelled from Pernambuco in northern Brazil. By a secret article of the Treaty of the Pyrenees (1659), France promised Spain to give no further aid to Portugal, but in 1661 Portugal signed a treaty of alliance with the restored English monarchy. In 1662 Charles II of England married John's daughter Catherine of Bragança and, in return for a large dowry, including the cession of Bombay and Tangier, provided arms and men for the war with Spain. Portuguese defense was organized by the German soldier Friedrich Hermann von Schönberg (later duke of Schomberg); in June 1663 Sancho Manuel, count of Vila Flor, defeated Don John of Austria at Ameixial, and in June 1665 von Schönberg won the important victory of Montes Claros. Peace was finally made by the Treaty of Lisbon early in 1668.

Treaties with England

On the death of John IV, his second son Afonso VI (1656–83) was 13 years of age. Afonso's mother, Luísa de Gusmão, acted as regent until, in June 1662, he began to rule. Afonso himself was feebleminded, but the country was capably governed by Luiz de Vasconcelos e Sousa, conde de Castelo Melhor, until 1667. The French prin-

cess, Maria Francesca of Savoy, who married Afonso in the previous year, now entered into an intrigue with his more personable brother Pedro (afterward Pedro II). They contrived to dismiss Castelo Melhor and to have Maria Francesca's marriage annulled. She at once married Pedro (1668), who was declared regent. Afonso was imprisoned until his death. During the reign of Pedro II (1683–1706), Portugal recovered from the strain of the Spanish wars and began to benefit from the discovery of gold and precious stones in Brazil. The first strike of gold in Minas Gerais took place in 1693, and in the last years of the 17th century, considerable wealth was being extracted; however, it was not until 1728 that diamonds were discovered: the mineral wealth of Brazil then formed a very substantial part of the revenue of the Portuguese crown.

Mineral wealth from Brazil

The 18th century. The War of the Spanish Succession (1701–13) saw Portugal's recent friends, England and France, on opposing sides; and although Pedro sought at first to remain neutral, Portugal joined the Anglo-Austrian Grand Alliance in 1703, by which it afforded a base for the archduke Charles (later the emperor Charles VI) to conduct his war for the Spanish throne. In the same year (December 27) the English envoy, John Methuen, also concluded the treaty that bears his name, by which the exchange of port wine for English woollens became the basis for Anglo-Portuguese trade. Although the treaty of 1654 had secured great privileges for English merchants in Lisbon, neither it nor the treaties of 1642 and 1661, by which the traditional alliance was restored, had created trade. This was now done, and by reason of the wealth that soon poured into Lisbon from Brazil, the English merchants gained a commanding position in the trade of Portugal. The political treaties of 1703 proved less fruitful. The Portuguese general António Luís de Sousa, marquess of Minas, entered Madrid in 1706; but French and Spanish forces were victorious at Almansa (1707), and in 1711 the French admiral René Duguay-Trouin sacked Rio de Janeiro. At the conclusion of the war Portugal negotiated a peace treaty with France (April 1713) but did not conclude peace with Spain until 1715.

Under Pedro's son John V (1706–50), Portugal attained a degree of prosperity unknown since the restoration. The tax of a royal fifth levied on the precious metals and stones of Brazil gave the monarchy an independent source of wealth. The Cortes, which had met irregularly since 1640, was no longer summoned, and government was carried out by ministers appointed by the king. John V desired the absolute authority enjoyed by Louis XIV. He did not fail to convert his wealth into papal and other dignities: the archbishop of Lisbon became a patriarch (1716), and Pope Benedict XIV in 1749 gave John the title "his most faithful majesty"; and royal academies, palaces, and libraries were inaugurated. But in his later years his ministers proved inadequate and the kingdom sank into stagnation. On John's death, his son Joseph (1750–77) appointed as minister Sebastião José de Carvalho e Melo, later conde de Oeiras and marquês de Pombal, who soon gained a complete ascendancy over the king and endeavoured to replace the stagnant absolutism with a more active type of despotism that, with some qualifications, deserves the epithet enlightened. His full powers date from his efficient handling of the crisis caused by the disastrous Lisbon earthquake of November 1755; but even before this he had reformed the sugar and diamond trades, set up a national silk industry (1750), and formed one chartered company to control the sardine and tunny-fishing industry of Algarve and another to trade with northern Brazil. In 1756 he founded the Junta do Comércio, a board of trade with powers to limit the privileges enjoyed by the English merchants under the treaties of 1654 and 1661, and set up the General Company for Wines of Alto Douro (Companhia dos Vinhos do Alto Douro) to control the port wine trade. Industries for the manufacture of hats (1759), cutlery (1764), and other articles were set up with varying success.

Enlightened despotism of Pombal

Pombal's methods were arbitrary and his enemies numerous. His reform of the wine industry provoked a riot in Porto (1757) that was savagely repressed; but his principal victims were the Jesuits, expelled in 1759 from all the Portuguese dominions, and the nobility, in particular José Mascarenhas, duque de Aveiro, and the Távora family, who were accused of an attack on the King (Sept. 3, 1758), condemned, and executed (Jan. 12, 1759). Having eliminated the Jesuits from the educational system, Pombal applied regalist principles in the reform of the University of Coimbra (1772) and the royal board of censorship (1768), which supervised the system of lower education from 1771.

Expulsion of Jesuits

While Pombal succeeded in modifying the ascendancy of the British merchants in Portugal, he invoked the English alliance in 1762 when Spain, prompted by the renewal of the Bourbon Family Compact alliance with France, invaded Portugal. The Portuguese Army was reformed by Wilhelm von Schaumburg-Lippe, and an English force was led by James O'Hara, 2nd Baron Tyrawley, and John Campbell, 4th earl of Loudoun. Peace was signed in February 1763 at Fontainebleau. On the death of Joseph (Feb. 24, 1777), his daughter Maria I (1777–1816), who had married his brother, her uncle (Pedro III), acceded; Pombal was dismissed (1777) and eventually found guilty on several charges. His successors made peace with Spain by the Treaty of San Ildefonso (1777).

The French Revolutionary and Napoleonic Wars. Maria I suffered from melancholia after the loss of her consort (1786) and eldest son John (1788). In 1792 her mental balance was further disturbed, probably by the news of the French Revolution, and she ceased to reign. Her son, who on her death became John VI (1816–26), then ruled in her name and in 1799 became prince regent. In 1793 Portugal joined England and Spain against France, sending a naval division to assist the English Mediterranean fleet and an army to the Catalan front. The Peace of Basel (July 1795), by which Spain abandoned its allies, left Portugal still at war. Although subjected to pressure from the French Directory and from the Spanish minister, Manuel de Godoy, Portugal remained unmolested until 1801, when Godoy sent an ultimatum and invaded Alentejo. By the Peace of Badajoz (June 1801), Portugal lost the town of Olivenza and paid an indemnity.

From the Peace of Amiens (1802) until 1807, Portugal was once more immune from attack, though subjected to continuous pressure to break off the English connection. By the Berlin decree of Nov. 21, 1806, Napoleon sought to close all continental ports to British ships. Portugal endeavoured to maintain neutrality, but the secret Franco-Spanish Treaty of Fontainebleau (October 1807) provided for its eventual dismemberment by Napoleon I and Godoy. Already Gen. Andoche Junot was hastening across Spain with a French army, and on November 27, the prince regent and the royal family and court embarked on a fleet lying in the Tagus River and were escorted by British vessels to Brazil; the court remained 14 years at Rio de Janeiro. Junot declared the Braganças deposed, but his occupation of Portugal was challenged in August 1808 by the arrival of Sir Arthur Wellesley (later duke of Wellington) and 13,500 British troops in Mondego Bay. Winning the victories of Roliça (August 17) and Vimeiro (August 21), Wellesley enabled his superiors to negotiate the Convention of Sintra (August 31), by which Junot was allowed to evacuate Portugal with his army. A second French invasion (1808–09) led to Sir John Moore's death at La Coruña (January 1809) and the reembarkation of the British forces. In February, William Carr (later Viscount) Beresford was placed in command of the Portuguese Army, and in March Marshal N.J. de Dieu Soult advanced from Galicia and occupied Porto. Wellesley returned to Portugal in April, drove Soult from the north, and after his victory of Talavera de la Reina in Spain (July), withdrew to Portugal. The third French invasion followed in August 1810 when Marshal André Masséna with Marshal Michel Ney and Junot entered Beira province. Defeated by Wellington at Bussaco (September 27) near Coimbra, the French found themselves facing the prepared lines of Torres Vedras, north of Lisbon, where they wintered amid great privations. By the spring of 1811 they could only retreat and, on March 5,

Flight of royal family to Brazil

Lines of Torres Vedras

began the evacuation of Portugal, harassed all the way by English and Portuguese attacks and crossing the frontier after a defeat at Sabugal (April 3).

Portugal made peace with France on May 30, 1814. It was represented at the Congress of Vienna but played little part in the settlement. The series of Anglo-Portuguese treaties concluded between the years 1809 and 1817, however, was important insofar as it extended many of the conditions of the Anglo-Portuguese alliance to Brazil and had an influence on the future of Africa. England's efforts to get Portuguese collaboration in suppressing the slave trade resulted in the treaty of Jan. 22, 1815, and in the additional convention of 1817, by reason of which Portugal's claims to a considerable part of Africa were formally recognized.

Constitutionalism. The Napoleonic campaigns had caused great devastation in Portugal, and the absence of the royal family and the presence of a foreign commander (Beresford) combined with revolutionary agitation and the influence of Spanish liberalism to produce an atmosphere of discontent and restlessness. On Dec. 16, 1815, Brazil was raised to the rank of a kingdom united with Portugal, and John VI, who succeeded in March 1816, showed no desire to return to Portugal. In 1817 Beresford suppressed a conspiracy in Lisbon, and the Masonic leader Gen. Gomes Freire de Andrade was executed. Unrest increased, and when Beresford himself went to Brazil (March 1820) to press John to return, a constitutionalist revolution began in Porto (Aug. 24, 1820), spread over the country, and led to the formation of a junta in Lisbon (October 4). On Beresford's return (October 10) he was not allowed to land, and British officers were expelled from the army. A constituent assembly was summoned that drew up a very liberal constitution, thus confronting John VI with an accomplished fact.

John's reluctance to return was at last overcome, and he left his elder son Pedro to govern Brazil, landing at Lisbon on July 3, 1821. He swore to uphold the constitution, but his wife, Carlota Joaquina, and their second son, Dom Miguel, refused to take the oath and were sentenced to banishment, though this was not carried out. The Portuguese constitutionalists, not appreciating the determination of Brazil not to yield up its status as a kingdom, sought to compel Pedro to return; but he, rather than sacrifice the rule of the Braganças in Brazil, declared for Brazilian independence (Sept. 7, 1822) and became emperor of Brazil as Pedro I (see also BRAZIL, HISTORY OF). This enabled his brother Miguel to appeal to absolutist forces in Portugal to overthrow the constitutionalists, and an insurrection led by Miguel almost succeeded (April 30, 1824); but through the action of the foreign ministers, John VI was restored and Miguel went into exile in Vienna (June 1824).

Independence of Brazil

War of the Two Brothers. John VI acknowledged the independence of Brazil in 1825, assuming *pro forma* the imperial title and then yielding it to Pedro; but when John died (March 10, 1826), no provision had been made for the succession except that his daughter Maria Isabel was now named regent. Pedro, as Pedro IV of Portugal, issued from Brazil a charter providing for a parliamentary regime by the authorization of the monarchy and not based on the sovereignty of the people. He then made a conditional abdication (May 1826) of the Portuguese throne in favour of his daughter Maria da Glória, age seven, provided that she should marry her uncle Miguel and that he should swear to accept the charter. This compromise could not be effective. The absolutists had hoped that Pedro would resign all rights to the Portuguese crown, and the council of regency hesitated to publish the charter until Gen. João Carlos de Saldanha (later duque de Saldanha) forced their hand. In 1827 Miguel took the oath and was appointed regent, landing in Lisbon in February 1828. His supporters at once began to persecute the liberals. A form of Cortes met in Lisbon, and in July 1828 repudiated Pedro's claims and declared Miguel rightful king.

Only the island of Terceira in the Azores sustained the liberal cause. In June 1829, however, a regency on behalf of Maria da Glória was set up in Terceira; and in 1831 Pedro, having abdicated the Brazilian throne, went to Europe and began to raise money and men for the conquest of Portugal. In February 1832 the expedition sailed to Terceira, and in July the liberals, led by Pedro, disembarked at Mindelo near Porto, which city they soon occupied. The rest of the country, however, stood by Miguel, who besieged the liberals in Porto for a year (July 1832–July 1833). By now, Miguelite enthusiasm had waned; and António José de Sousa Manuel, duque de Terceira, and Capt. (later Sir) Charles Napier, who had taken command of the liberal navy, made a successful landing in Algarve (June 1833). Terceira advanced on Lisbon, which fell in July 1833, and Miguel capitulated at Evora-Monte in May 1834.

Further political strife. The War of the Two Brothers ended with the exile of Miguel (June) and the death of Pedro (Sept. 24, 1834). Maria da Glória became queen as Maria II (1834–53) at the age of 15. While Maria necessarily came under the influence of the successful generals of the civil war, her principal aim was to defend her father's charter (which had been granted by the crown) from those who demanded a "democratic" constitution like that of 1822, asserting the ultimate sovereignty of the nation.

In September 1836 the latter, thenceforth called Septembrists, seized power. The chartist leaders rebelled and were exiled, but by 1842 the Septembrist front was no longer united, and António Bernardo da Costa Cabral restored the charter. In 1846 the movement of Maria da Fonte, a popular rising against higher taxation to improve roads and reforms in public health in which almost all parties joined, put an end to Costa Cabral's government but left Portugal divided between the Septembrists, who held Porto, and Saldanha, now in Queen Maria's confidence, in Lisbon. Saldanha negotiated for the intervention of other members of the Quadruple Alliance (formed in April 1834 by England, France, Spain, and Portugal), and a combined British and Spanish force received the surrender of the Porto junta in June 1847 and ended the war with the Convention of Gramido (June 29, 1847). Saldanha governed until 1849, when Costa Cabral resumed office only to be overthrown in April 1851. Saldanha then held office for five years (1851–56), and the period of peace at length permitted the country to settle down. The "Regeneration" ended civil strife and established party government.

Septembrists and chartists

Maria II was succeeded by her eldest son by her second husband, Ferdinand of Saxe-Coburg, Pedro V (1853–61), who married Stephanie of Hohenzollern-Sigmaringen in 1858. He gave promise of being a capable and conscientious monarch but died of typhoid fever on Nov. 11, 1861. His brother Luís I (1861–89) seemed to have inherited a country that had recovered from the Napoleonic invasions and from civil wars, political strife, and *pronunciamentos*. But although the main parties were now defined as Historicals (*i.e.*, radicals) and Regenerators (or moderates), the alternation of governments gradually ceased to reflect any semblance of popular feeling, and in the last years of Luís' reign republicanism was already beginning to gain ground.

Colonial policies. With the accession of Carlos I (1889–1908), a serious dispute with Great Britain occurred. Portugal's possessions in Africa had been recognized by Great Britain in the treaty of 1815, but more recently Germany and Belgium had entered the colonial field; and at the Conference of Berlin (1885), the definition of "effective occupation" was adopted as the basis for possession of colonial territories. A colonial movement had gained momentum in Lisbon, and a Portuguese scheme, known as the "Rose-Coloured Map," which laid claim to a colony stretching across Africa from Angola to Mozambique, was recognized by France and Germany (1886). Although the Marquess of Salisbury registered a protest (1888), the Portuguese foreign minister Henrique de Barros Gomes sent Maj. Alexandre Alberto da Rocha de Serpa Pinto to the Shire Highlands (modern Malawi), with a view to their annexation. He became involved in a fight with the Makololos, who were under British protection, and a series of communications between London and

The "Rose-Coloured Map"

Lisbon ended in the dispatch of the British ultimatum of Jan. 11, 1890, demanding the withdrawal of all Portuguese from the Shire. Amid great popular excitement, Barros Gomes had no alternative but to comply, and the government resigned. The incident caused the deepest resentment in Portugal, not only against the ancient ally but also against the monarchy, which was menaced by an attempted republican revolution in Porto (Jan. 31, 1891).

During the following years, the Portuguese African colonies were defined as a result of the Anglo-Portuguese treaty of July 1891, but the financial position of the country was so bad that it seemed unlikely that the efforts to consolidate the African colonies would succeed. In 1897 it became clear that Portugal would require a considerable loan, and Germany demanded to partake in any assistance that was offered. On Aug. 30, 1898, A.J. (later the earl of) Balfour, temporarily in charge of the British Foreign Office, concluded a secret Anglo-German convention assigning spheres of influence in the Portuguese colonies to Great Britain and Germany in the event of such a loan. This was, however, denounced by the prime minister, Lord Salisbury, and in 1899 when the Germans endeavoured to persuade the Portuguese to accept a loan, Salisbury's action and the imminent danger of a conflict in the Transvaal caused an Anglo-Portuguese approximation. On Oct. 14, 1899, the ancient treaties of alliance were reaffirmed in a secret declaration, later made public (the so-called Windsor Treaty).

Meanwhile, the financial situation showed little improvement, and the republicans continued to progress. In 1906 João Franco, formerly a Regenerator, came to power as champion of the failing monarchist cause. Unable to obtain the support of the other monarchists, he began to govern by decree. Although Franco bravely undertook to reform the finances and administration, he was accused of illegally advancing money to the King. These scandals were followed by rumours of plots, and on Feb. 1, 1908, Carlos and his heir, Luís Filipe, were assassinated as they rode in an open carriage in Lisbon. Whether or not the regicides were isolated fanatics or agents of a hidden organization such as the Carbonária, a republican secret society, the deed was applauded by the republicans, who immediately began their preparations for a final attack on the monarchy.

Assassination of Carlos I

King Manuel II (1908–10) found no unity among the monarchist politicians. The general election of August 1910 showed republican majorities in Lisbon and Porto, and on October 3 the murder by a madman of one of the republican leaders, the distinguished physician Miguel Bombarda, offered the pretext for a rising that was already organized. Armed civilians, soldiers, and the men aboard some ships in the Tagus began the republican revolution on October 4 and, after faltering, their movement, in which António Machado Santos played the predominant part, succeeded on October 5. Manuel escaped to Ericeira and thence by sea to Gibraltar and to England. On his death in 1932 his body was returned to Portugal.

Social and economic conditions. From the time of the Portuguese overseas conquests, the flow of wealth from the new territories and trading posts, if it sustained the court and capital, did little to improve the domestic economy, still largely rural. The favourable financial position of the late 15th century, derived from trade in slaves, gold, and spices, did not long survive into the 16th century, when the expenses of maintaining far-flung and unproductive foreign stations and the depredations of pirates quickly absorbed any surpluses. There were few native industries. Not only were manufactured goods such as cloth, tapestry, and metalware imported but also basic foodstuffs, salt meat, cured fish, and dairy produce. Agriculture was little regarded, and insufficient land was available for small holdings. During the years of Spanish domination, the ports were closed to English merchants; and by the time they were reopened after 1640 the flow of trade had found new channels, and the Dutch and English had outstripped Portugal as colonial powers. The discovery of gold in Brazil at the end of the 17th century brought about a revival in the country's economy, but gold production was in decline by 1750, while the diamond market was saturated. The later 18th century saw a series of protectionist measures, many introduced by Pombal. The Methuen Treaty with England (1703) had strengthened the port wine trade at the expense of Portuguese cloth; later further attempts were made to improve the export value of port wine. Support was also given for the production of woollen goods, linen, paper, porcelain, and cutlery and to the tunny and sardine fisheries. Pombal attempted to create an educated bourgeoisie, but the Portuguese textile industry could not withstand mechanized competition. After 1850 public works, railways, and ports were given priority, but Portugal had to wait until the 20th century for any sustained attack upon its economic difficulties.

Economic difficulties

THE REPUBLIC, FROM 1910

The new regime formed a provisional government under the presidency of Teófilo Braga, a well-known writer. This in turn issued a new electoral law giving the vote to adult Portuguese males and presided over the election of a constituent assembly, which opened on June 19, 1911. The constitution was passed by the assembly on August 20, and the provisional government surrendered its authority a few days later (August 24) to the new president, Manuel José de Arriaga.

Evolutionists, Unionists, and Democrats. Although a monarchist invasion was unsuccessfully attempted by Henrique de Paiva Couceiro in October 1911, the main danger to the new regime came from its internal divisions. For the moment, it was fairly united in denouncing monarchism and persecuting the church. The religious orders were expelled (Oct. 8, 1910) and their property confiscated. The teaching of religion in primary schools was abolished and the Roman Catholic Church disestablished. The conditions under which Catholics and monarchists were imprisoned attracted attention abroad, and it was only gradually that this legislation was modified. New universities were founded at Lisbon and Porto; but the task of destruction proved easier than that of construction, and before long the republicans were divided into Evolutionists (moderates), led by António José de Almeida; Unionists (centre party), led by Manuel de Brito Camacho; and Democrats (the left wing), led by Afonso Augusto da Costa. A number of prominent republicans had no specific party. The whirligig of republican political life offered little improvement on the monarchist regime, and in 1915 the army showed signs of restlessness. Gen. Pimenta de Castro formed a military government and permitted the monarchists to reorganize, but a Democratic revolution (May 14) led to his arrest and consignment to the Azores. President Arriaga resigned and was succeeded by Braga and then by Bernardino Machado (Aug. 5, 1915–Dec. 8, 1917). The Democratic regime, in which Costa was paramount, was ended by the revolution (December 1917) of Maj. Sidónio Pais, who established a "New Republic" of a right-wing tendency, supported at first by the Unionists. On their withdrawal (March 1918), a new National Republican Party gained control. Sidónio Pais' "presidentialist" regime was abruptly ended with his assassination on Dec. 14, 1918, when, after the provisional presidency of Adm. João do Canto e Castro, power passed gradually back to the Democrats.

Roman Catholic Church disestablished

Meanwhile, on the outbreak of World War I, Portugal had proclaimed its adhesion to the English alliance (Aug. 7, 1914) and on November 23 committed itself to military operations against Germany. On September 11 a first expedition left to reinforce the African colonies, and there was fighting in northern Mozambique, on the Tanganyika frontier, and in southern Angola, on the frontier of German South West Africa. In February 1916 Portugal seized German ships lying in Portuguese ports, and Germany declared war (March 9). A Portuguese expeditionary force went to the western front in 1917, under Gen. Fernando Tamagnini de Abreu; on April 9, 1918, they were under heavy German attack in the Battle of Lys. By the Treaty of Versailles (1919) Portugal received 0.75 percent of the indemnity payable by Germany and the

Fighting during World War I

Quionga (Kionga) area of Mozambique captured by Portuguese forces in East Africa.

Almeida completed his term of office as president (Oct. 5, 1919–Oct. 5, 1923), but ministries succeeded one another in rapid succession. In 1921 the founder of the republic, António Machado Santos, was among those murdered by enemies of Sidónio Pais; and although António Maria da Silva contrived to govern in the Democratic interest for a year and nine months, his fall in November 1923 was followed by a number of short-lived ministries. Revolutionary movements grew more frequent as the Democratic Party lost its cohesion, and there were signs in the army of impatience with the political turmoil. Although the Democrats obtained a clear majority in 1925 and Manuel Teixeira Gomes (1923–25) yielded the presidency to Bernardino Machado without incident, a military revolt occurred in Lisbon on Feb. 2, 1926. It was quelled, but on May 28 Commander José Mendes Cabeçadas Júnior and Gen. Manuel de Oliveira Gomes da Costa led a successful rebellion at Braga. Machado was deposed from the presidency, and a provisional government was formed.

Military revolt

The "New State." At first, Cabeçadas was head of the provisional government and Gomes da Costa minister of war; but the former was regarded as too close to the politicians, and Gomes da Costa unseated him. Within a few weeks he too was deposed and his place taken by his foreign minister, Gen. (later Marshal) António Óscar de Fragoso Carmona (July 9, 1926). Elected president of the republic in March 1928, he remained in office until his death in April 1951. After an attempt at revolution in February 1927, which resulted in considerable bloodshed, Carmona's government was not seriously interrupted. The program of the military regime was merely to restore order. To remedy the financial plight of the country, it had been proposed to borrow money from the League of Nations, but the conditions offered included supervision of the finances, which was regarded as offensive to national sovereignty. The loan was, therefore, rejected, and Carmona in 1928 called on António de Oliveira Salazar to take the Ministry of Finance.

Salazar, professor of economics at Coimbra University, fully controlled all expenditure and revenue and embarked on a complete overhaul of the administration. As minister of finance from 1928 to 1940, he produced an unbroken series of budgetary surpluses that restored Portugal's financial credit. As prime minister from 1932, he ushered in the new Constitution of 1933; as a minister of colonies in 1930, he prepared the Colonial Act governing the administration of Portugal's overseas provinces; and as minister for foreign affairs (1936–47), he guided Portugal through the difficulties caused by the Spanish Civil War and during World War II practiced a form of neutrality compatible with the Anglo-Portuguese Alliance. In May 1940 a concordat was signed with the Vatican, which clarified the position of the Catholic Church in Portugal. The church was reconfirmed in its possession of most of the property it had held before 1910, religious instruction was restored in state schools, private church schools were allowed, and church marriages were to be recognized. On the death of Carmona in 1951, Salazar temporarily assumed under the constitution the attributes of the presidency until Gen. Francisco Craveiro Lopes was sworn in as president in August 1951.

Constitution of 1933

By 1953 Salazar had been a member of the government for 25 years. His "New State," as defined by the Constitution of 1933, provided for a president elected for a period of seven years who appointed a prime minister and a variable number of ministers; a national assembly of deputies elected quadrennially as a block, meeting for at least three months annually; and a corporative chamber consisting of representatives of trades and professions acting as a consultative assembly. At general elections from 1934 onward, all seats in the National Assembly went to government (National Union Party) supporters, although in 1949, 1953, 1957, and 1969 there were a few opposition candidates. General Craveiro Lopes was succeeded (1958) as president by Rear Adm. Américo de Deus Rodrigues Tomás, elected by a large majority over Brig. Humberto Delgado, who shortly afterward went into exile. Meanwhile, the determination of the Indian government to annex Portuguese India led to India's severing diplomatic relations with Portugal (August 1955) and to mass invasions of the Portuguese possessions by Indian "passive resisters," who were repelled. In 1955 Portugal entered the United Nations, and in December 1955 referred the question of free access to the enclaves of Dādra and Nagar Haveli (Havili) to the International Court of Justice, which in April 1960 recognized Portugal's right of passage to the enclaves and India's control of the surrounding territory. On Dec. 18, 1961, India invaded Goa, Diu, and Damão (Daman); the subsequent debate in the UN was stifled by the U.S.S.R.'s veto.

Salazar had made it plain that "decolonization" was not a possible policy for him. Shortly afterward, northern Angola was invaded from the Congo, and a number of settlers and others were murdered. Attempts were later made to invade Guinea and Mozambique, involving a substantial Portuguese military commitment. In Portugal a small rising at Beja failed in January 1962.

The New State pressed on with electrification schemes (the most important being that of the Douro), industrialization (steelworks, assembly of motor vehicles, shipbuilding, etc.), and public works (the Salazar Bridge at Lisbon, the largest in Europe). Many new schools were built. Internal migration swelled the population of the cities, especially Lisbon, and the tide of emigration turned from the New World to Europe, particularly France.

In September 1968 Salazar (died July 1970) suffered a serious stroke, and the president, after consulting the Council of State, asked Marcelo José das Neves Alves Caetano, former minister and rector of Lisbon University, to form a government. Caetano, despite opposition from hard-line Salazarists in cabinet and National Assembly, cautiously introduced some liberalizing measures, including a relaxation of press censorship.

NOWELL, *A History of Portugal* (1952). The standard histories in Portuguese are FORTUNATO DE ALMEIDA, *História de Portugal*, 6 vol. (1922–29); and DAMIAO PERES (ed.), *História de Portugal*, 7 vol. (1928–35). There is a convenient *Dicionário de História de Portugal*, ed. by J. SERRAO (1963). For prehistory, see H.N. SAVORY, *Spain and Portugal* (1968); and on Portuguese origins, H.V. LIVERMORE, *Origins of Spain and Portugal* (1971). OLIVEIRA MARQUES has published a guide to medieval Portugal entitled *A Sociedade medieval portuguesa* (1964); the classic account is still ALEXANDRE HERCULANO DE CARVALHO E. ARAUJO, *História de Portugal*, 4 vol. (1846–53; 7th ed., 8 vol., 1914–16). The best general account of the Portuguese expansion is E. PRESTAGE, *The Portuguese Pioneers* (1933), but much work has since been done on economic aspects: see especially V. DE MAGALHAES GODINHO, *L'Économie de l'empire portugais* (1969). DAMIAO PERES, *História dos Descobrimentos Portugueses* (1959; Eng. trans., *A History of the Portuguese Discoveries*, 1960), is a more recent treatment of Prestage's theme; and C.R. BOXER, *The Portuguese Seaborne Empire, 1415–1825* (1969), carries it forward until the separation of Brazil. F. MAURO, *Le Portugal et l'atlantique au XVII^e siècle, 1570–1670* (1960), deals with the overseas economy in the 17th century. On the Inquisition, see HERCULANO, *Da origem e estábelecimento da Inquisição em Portugal*, 3 vol. (1854–59; Eng. trans., *History of the Origin and Establishment of the Inquisition in Portugal*, 1 vol., 1926); and A.J. SARAIVA, *Inquisição e Cristãos-Novos*, 2nd ed. (1969). A.D. FRANCIS, *The Methuens and Portugal, 1691–1708* (1966), discusses the famous treaties. T.D. KENDRICK has examined the repercussions of *The Lisbon Earthquake* (1956). A. SILBERT, *Le Portugal méditerranéen à la fin de l'ancien régime, XVIII^e–début du XIX^e siècle*, 2 vol. (1966), is a substantial study of underlying agrarian conditions. An outline of the 19th century is given in R.J. HAMMOND, *Portugal and Africa* (1966). The Anglo-Portuguese crisis of 1890 is dealt with by P.B. WARHURST in *Anglo-Portuguese Relations in South-Central Africa, 1890–1900* (1962); and by E. AXELSON in *Portugal and the Scramble for Africa, 1875–1891* (1967). The story of the republic is told by the Spanish historian JESUS PABON, who does not like it, in *La Revolución portuguesa*, 2 vol. (1941–45). Works on Salazar include F. CLEMENT C. EGERTON, *Salazar, Rebuilder of Portugal* (1943); and MICHAEL DERRICK, *The Portugal of Salazar*

(1938), which deal with his earlier years; see also R. VON GERSDORFF, *Portugals Finanzen* (1961); and A. PASQUIER, *L'Économie du Portugal* (1961).

(H.V.L.)

Portuguese Guinea

The West African territory of Portuguese Guinea is roughly triangular in shape and is officially known as the Province of Portuguese Guinea. The United Nations, however, considers it to be a non-self-governing territory, and it is referred to as Guinea-Bissau by African nationalists. It is bounded by Senegal to the north, by the Republic of Guinea to the east and south, and by the Atlantic Ocean to the west. The Bijagós (Bissagos) Archipelago and other islands off the coast also form part of the territory, which is administered as a political unit from the capital, Bissau. The total area is 13,948 square miles (36,125 square kilometres), which includes low-lying ground submerged at high tide.

PORTUGUESE GUINEA

While at the time of the 1960 census the population numbered about 520,000, the present population total remains uncertain because of the guerrilla war, which has been waged against Portuguese rule by African nationalists since January 1963. According to the 1970 census the population numbers 487,000. The conflict in the territory has taken the form of a war of attrition and has played havoc with an already fragile economy. In the early 1970s, Portuguese Guinea was an embattled country with extremely little prospect of an early return to normal conditions. (For coverage of historical aspects, see WEST AFRICA, HISTORY OF.)

The landscape. *Relief.* Almost all of the country is low-lying, except in the northeast where some of the outlying ridges of the Fouta Djallon plateau rise to heights of between 300 and 600 feet. Along the coast there is an extremely dense network of rias (drowned valleys), which deeply indent a partially flooded coastal plain, bordered by swamps to seaward. In the interior the ground slowly rises to form an interior plain to the northwest, between the Rio Geba and the Senegal frontier, and low plateaus to the northeast and east. Crisscrossed by meandering rivers, these plains, which form part of the Sénégal River Basin, are flatlands with some minor relief features and outcrops of lateritic (reddish iron-bearing) rock. Farther to the east, a transitional plateau between the plains and the Fouta Djallon highlands of neighbouring Guinea is formed by the Planalto (plateau) de Bafatá in the middle of the country and the Planalto de Gabu in the northeast. Off the coast a string of low, muddy islands is hardly distinguishable from swampland at high tide. Among these are Caió, Pecixe, Bissau, Areias, Bolama, Como, and Melo. In previous centuries these islands were used by the Portuguese as stepping-stones to the interior; from 1890 to 1941 the capital was at Bolama on the island of the same name. Farther out to sea, the Bijagós Islands were for many years a lair of piratical Africans who could easily hide in the heavily forested archipelago in order to prey both upon the mainland and upon unwary navigators. The main islands of the Bijagós group are Bubaque, Rubane, Orangozinho, Roxa, Galinhas, Meio, Poilão, Uno, Orango, Uracane, Eguba, Carache, Caravela, Formosa, and Ponta. The principal rivers are navigable by flat-bottomed craft far into the interior but split the country into sections between which communication is difficult. From north to south the main rivers are the Cacheu, followed by the Mansôa, the Geba and the Corubal, the Rio Grande de Buba, and the Cacine.

The coastal islands

Climate, vegetation, and animal life. The climate is hot and wet; rainfall occurs between May and October, after which the dry season lasts from November to April. The coast has a monsoonal climate (characterized by seasonal moisture-bearing winds from the sea) with an abundant rainfall, which amounts to 40 to 80 inches a year in the north. The interior is influenced by the savanna (grassland) type of climate, which has greater variation in rainfall and temperature. Everywhere the temperature is high, May and April being the hottest months with temperatures of about 84° F (29° C), and January and December the coldest with temperatures of about 73° F (23° C). There are three vegetation zones. The first is formed by the coastal swamps and plains that are covered with mangrove and palm trees and in some places with rice fields. The second is formed by the interior plain, which is heavily forested. The third zone is a continuation of the savanna that occurs in neighbouring Senegal and Guinea. Portuguese Guinea has a great variety of aquatic birds, including the pelican and the flamingo. Crocodiles, snakes, buffalo, gazelles, apes, eagles, parrots, hyenas, and leopards abound, but lions are now rarely seen. Sharks are found in the estuaries.

Human settlement. There is a striking difference between the swampy, coastal part of the country to the west and the drier hinterland to the east. Patterns of settlement differ accordingly. While the islands and the coast are inhabited by palm oil and rice growers, the interior is used by pastoralists for grazing and is cultivated by peanut (groundnut) producers. The Balante, or Balanta, people, who occupy the area between the Rio Geba and the Casamance River in Senegal, are renowned as rice growers. Villages are almost nonexistent, each extended family being lodged in a hut complex where strongly built storerooms, cattle pens, and intricate palisaded corridors protect the clan from cattle thieves or marauders from other Balante families. Another coastal people, the Bram (Brame), are famous for their skill in farming without irrigation. The Bijagós people inhabiting the Bijagós Archipelago are more at home at sea than on land. Inland are the cattle-raising Fulani and the agricultural Malinke (Mandingo) peoples; both peoples are Islāmized and most of their villages have a mosque.

The Portuguese versus the nationalists

Upon these traditional patterns the war has superimposed a new form of settlement—the strategic hamlet, established by the Portuguese to regroup and protect Africans who have not been won over by the nationalists. Especially among the coastal Mandyako and Balante, the authorities and the nationalists are engaged in a contest for the allegiance of each tribe. In the nationalist-held territories, new regroupings have also taken place in the forests to escape air attacks from the Portuguese. Few sectors of the country remain unaffected either by insurgency or by governmental countermeasures. Many shifts of population also have taken place. As a result of the war, Bissau, the capital, has expanded to accommodate refugees from the interior and has also become an important garrison town. Its population in 1970 numbered 62,000; it is an administrative, commercial, and communications centre with many gardens and fine public buildings. The other city of note, Bolama, the former capital, is slowly decaying. Inland, Bafatá, a market town and military and administrative centre, is important. Other significant posts on the coastal plain are Catió and Teixeira Pinto. Farther east, Bissorã, Mansôa, and Nova Lamego (Gabú) are peanut-collecting points or garrison headquarters. Historically significant Farim and Cacheu on the Rio Cacheu have declined as a result of the war in progress.

People and population. In the past the main population movement was that of the Islāmized pastoralists of the east toward the animist peoples of the coast—a move-

ment partially checked by the Portuguese conquest. The main ethnic divisions among the Africans were last reported at the 1950 census, when they were as follows: Balante 160,000; Fulani (Foulah) 108,000; Mandyako (Mandjak) 72,000; Malinke (Mandingo) 64,000; Pepel (Papel) 36,000; Bram 16,000; Biafada 12,000; Bijagós 10,000; Felup 8,000; Bayot 4,000; Nalu 3,000; Soninke (Sarakole) 2,000; Susu 2,000. While no ethnic statistics were available after the 1960 census, one may consider that the Balante now constitute about 30 percent of the total, the Fulani 20 percent, the Mandyako 14 percent, the Malinke 12.5 percent, the Pepel 7 percent, and others 16.5 percent. In theory, each group originally had its tribal territory (known as *chão* in local parlance); but a Balante expansion, coupled with further movements by the inland people and war, have tended to make the tribal pattern complex if not confused.

The most expansion-prone people are the Balante who, belonging to a stateless society centred around the family, have shown themselves receptive to nationalist slogans of emancipation from the Portuguese and from whatever chiefs the administration has tried to give them. An individualist people, largely animist in belief, they constitute the main body of guerrilla forces. The Fulani, who are divided into subgroups according to the degree of their miscegenation with the people they previously conquered, are essentially Muslim pastoralists. Their society is hierarchical, the relationship between chiefs and their vassals being semifeudal in character. Polygamous if they can afford it, and accustomed to fighting against the animists they try to convert, the Fulanis are impervious to Portuguese culture; paradoxically, however, they have become tactical allies of the Portuguese army against the guerrillas, whom they see as a threat to their religion, feudal society, and traditions. Some smaller groups that are Fulani in culture have, however, joined the nationalists in order to emancipate themselves from the authority of elders and tribal lords. The Malinke, who are agriculturalists, are more sedentary than the Fulani, but their true vocation, now that they are no longer warriors, is trade. Skilled craftsmen, they also seek to convert their neighbours to Islām. The Mandyako are experienced in growing palm trees; the Portuguese and the insurgents are now contesting their territory. The Bram, Biafada, Felup, Bayot, Nalu, Susu, and Bijogo all live in close proximity to the sea; they are farmers and are little influenced by either Portuguese or Islāmic culture.

Assimilados and *mestiços*

Portuguese Guinea also possesses a group of detribalized Africans formerly categorized as *assimilados*; numbering only a few thousand, they are acquainted with Portuguese and European culture and are chiefly civil servants or whitecollar workers. They are not to be confused with the significant colony of Cape Verdean *mestiços* (mulattos) living in the country, who in general tend to side with the Portuguese, though the nationalist leadership, seeking to control the Cape Verde Islands as well as Portuguese Guinea itself, is also largely drawn from this group. Other nationalist leaders are Portuguese Guinean *mestiços*. The non-Africans, mainly Portuguese civil servants, number only a few thousand; the Portuguese have never used the territory for settlement. There are also, however, about 35,000 Portuguese troops permanently garrisoned in the country and who, it might be said, are hastening the promotion of Portuguese culture. Together with the Cape Verdeans, the Portuguese hold almost all posts of authority in the territory, except in insurgent areas.

Each tribe speaks its own vernacular, which in turn is divided into dialects. The Balante vernacular, for example, is divided into Berassé, Benaga, Betxa, and other dialects. The great variety of languages spoken fall into two categories. The first of these is the Mande group, which may be subdivided into a Mande-tan grouping—which in Portuguese Guinea includes Soninke (spoken by the Sarakole and the diminutive tribe of Jacanca) and the Malinke, Bambara, and Dyula languages—and the Mande-fu grouping, which includes the Susu (Soso) language. The second category, the Atlantic (West Atlantic) language group, includes all other African languages spoken in Guinea, among which Nalu, the Balante dialects, Mandyako, Pepel, Bram, Biafada, Bijagós, Felup, Bayot, and the Fulani dialects are prominent. Apart from this mixture of about 20 languages and dialects, the lingua franca is *crioulo*, a sort of Portuguese patois with an Africanized syntax and vocabulary. Resembling the *crioulo* spoken in the Cape Verde Islands, it exerts a unifying influence in the rural areas and is used by the nationalists as a teaching medium.

Portuguese is the official language and is spoken not only by the Portuguese themselves but also by other educated persons. Some Arabic is known by Muslim scholars.

Christianity has made few inroads in Portuguese Guinea. In 1964 there were about 26,500 Catholics, and there were virtually no Protestants. Islām is the dominant religion, having more than 200,000 adherents. Islām in West Africa consists of a series of religious orders; in Portuguese Guinea most adherents belong to the Qādirīyah or Tijānīyah orders. Portugal supports the expansion of Islām to help counteract Marxist influence. Even in Bissau, which is predominantly Catholic, the government builds mosques and also subsidizes pilgrimages to Mecca for Fulani and Malinke leaders. Traditional animist beliefs are nevertheless still strong, even among those inhabitants who have formally adopted Christianity or Islām.

The average population density for the country is estimated to be about 40.5 persons per square mile.

Portuguese Guinea, Area and Population

	area		population	
	sq mi	sq km	1960 census	1970 census
Circumscriptions (*circunscrições*)				
Bijagós	570	1,478	9,000	13,000
Fulacunda	1,573	4,075	35,000	13,000
São Domingos	642	1,663	24,000	21,000
Municipalities (*concelhos*)				
Bafatá	2,326	6,025	71,000	88,000
Bissau	304	788	56,000	119,000
Bissorã	367	950	45,000	21,000
Bolama	58	150	5,000	7,000
Cacheu*	1,076	2,788	70,000	71,000

The economy. The economy is based on traditional farming and on cattle raising. It is now in a chaotic state as a result of the war; even before it started, however, the economy was far from strong. African farmers sell their products to European companies, who are represented by local white or mestiço middlemen. Rice is the staple food. The production of swamp rice from the coastal plain amounts to about 170,000 tons; formerly, in record years, some was exported. The Portuguese as well as the insurgents endeavour to increase its production. Oil palm products are also associated with rice cultivation in the islands and on the coast. Coconuts are exported. Peanuts (groundnuts) form the main cash crop, being cultivated —traditionally by Muslims—in the vicinity of Bafatá, Farim, and Nova Lamego and accounting for about 60 percent of exports. Oil seeds of one kind or another—including not only peanuts but also palm products and copra—altogether account for about 90 percent of total exports, which are mostly sent to Portugal through the monopolistic Companhia União Fabril (CUF). The company has, however, been hurt economically by the various nationalist activities, which have included a boycott.

Farming and ranching

Cattle raising is particularly important among the Fulani and the Balante. In 1970, 260,000 head of cattle, 174,000 goats, and 113,000 pigs were registered; some hides and skins are exported. Fishing is insignificant. Industry is negligible, except for some oil-processing plants in Bissau.

While oil prospecting has been conducted and bauxite deposits are known to exist, the rate of investment has declined, apparently because of war operations. The balance of trade has shown a regular deficit since 1957. In 1968, for example, Portuguese Guinea imported 530,100,000 escudos (28.75 escudos = $1 U.S.; 69 escudos = £1 sterling on December 1, 1970) and exported 111,000. The value of imports, which amounted to about 297,000,000 escudos in 1961, has since grown, while exports, which amounted to 211,200,000 escudos in the same year, have subsequently declined. Insecurity has brought the economic life of the territory, formerly in the hands of CUF and its subsidiaries, into a decline. Public financing now depends upon significant subsidies from Portugal. In 1968 governmental revenue amounted to 333,000,000 escudos, which included a loan of 59,200,000 escudos from Lisbon in addition to substantial sums for health and education. The Third Six-Year Development Plan for the territory, which covers the period from 1968 to 1973, provided for investments of 210,000,000 escudos for 1969, most of which were allocated for mineral prospecting and transportation.

Balance of trade

Transport. There are no railways. Rivers provide the cheapest means of transporting peanuts and palm products, although nationalist guerrillas sometimes ambush rivercraft. In 1966 there were about 1,900 miles of roads, although the distinction between roads and improved tracks in some instances is not clear. For military purposes, a major effort is being made to build more paved roads. The main road artery runs from Bissau to Bafatá, with subsidiary roads leading to Nova Lamego in the northeast, to the riverine ports, and to neighbouring countries. Road traffic to Senegal and to the Republic of Guinea has, however, almost come to a standstill. Bissau is the only modern port. Centrally located, it handles a modest annual traffic of about 200,000 net tons of cargo; about 100 ships call each year. The only other port of note is Binda on the Rio Cacheu. Although all sea and air links with independent African states have been severed, the port of Bissau remains linked not only with Portugal but also with the Portuguese territories of Angola, Cape Verde, and Mozambique by a concessionaire steamship service. Bissau airport handles international air traffic, but this is now restricted to aircraft flying to and from Lisbon and the Cape Verde Islands. Military airfields have been built at Bafatá, Nova Lamego, and other major towns. Insecurity on the roads caused by guerrilla attacks has led to increased reliance on passenger air traffic.

Administration and social conditions. The administration of Portuguese Guinea is by a governor who is a Portuguese general. He is assisted by a secretary general. A legislative council of 14 members (of which three members are elected by direct but nonuniversal suffrage) has limited legislative powers and consultative authority. A government council composed of higher civil servants (including the commander in chief of land, sea, and air forces) and three members elected by the legislative council help the governor in his legislative and administrative functions. Illiterates being barred from the polls, the vote is largely restricted to Portuguese and to educated Africans. As an overseas province of Portugal, Portuguese Guinea is represented in the Portuguese National Assembly, in the Portuguese Corporative Chamber (an advisory body in the Portuguese central government), and in the Portuguese Overseas Council. The territory is divided into ten municipalities (*concelhos*) and three circumscriptions (*circunscrições*) headed by Portuguese administrators. Among the Muslim tribes, powers of the chiefs upholding Portuguese authority have been augmented by the Portuguese administration.

War has disrupted traditional life. Except in the outlying Bijagós and among the most central Fulanis, where the writ of the Muslim chiefs is still obeyed, most of the country is passing through a period of unprecedented change. This is particularly noticeable in education. In 1956, the African population was 99.7 percent illiterate. Eleven years later, in the period 1967 to 1968, there were 76 Catholic primary and rural schools, 48 army-run schools, and 47 official administration schools. There were also two secondary schools and a training college for primary school teachers. In the late 1960s the African nationalists claimed to have more than 150 schools in rural areas controlled by them. There are no institutions of higher learning in the country. Some scholarships are granted by the Portuguese for studies in Portugal. The nationalists have sent some scholars to study in the U.S.S.R. and Eastern Europe.

Cultural life. Bissau has a museum and a library. National radio programs are broadcast by the Portuguese from Bissau. The local press is represented by the Government Gazette, by a cultural bulletin, by a monthly trade publication, and by a daily newspaper whose publication has frequently been interrupted in recent years.

Prospects for the future. Portuguese Guinea is at war, and while it is difficult to reconcile conflicting claims by the contenders, defense is clearly the main activity of the population on either side. The Portuguese have 35,000 European and African soldiers under arms against 5,000 to 10,000 nationalist guerrillas whose strongholds are along the borders of the Republic of Guinea except in the northwest corner, in the region where the Balante live, and in some areas adjacent to Senegal. Sizable areas are said to be controlled by the Partido Africano da Independência da Guiné e Cabo Verde (PAIGC) led by Amílcar Cabral, a *mestiço* agronomist from the Cape Verde Islands who was assassinated in Conakry, Guinea, in early 1973. His partisans claim to have forced the Portuguese and their African allies out of some of their southeastern outposts and are reported to be reorganizing the African population along socialist (communal) lines by establishing hospitals, schools, and cooperatives of their own. Portuguese sources, on the other hand, report that the population resists "liberation" and point out the fact that African contingents are included in the Portuguese forces.

Strengths of the opposed military forces

It appears, however, that in the areas they dominate, the nationalist guerrillas are able to mine and ambush army convoys and to shell Portuguese fortified camps. To counteract their influence, the Portuguese evacuate outlying villages, concentrate their populations around garrisons, and protect the villagers as they till their fields. In 1969 and 1970 the Portuguese, under the slogan "For a Better Guinea," introduced a new policy stressing rural development, including the construction of schools and health clinics, in the hope of severing ties between the insurgents and communities whose allegiance was wavering. The new policy resulted in progress for some areas previously neglected. Most of the country is in the throes of a modernizing process disruptive of old traditions, the outcome of which is as yet hard to gauge.

Positivism and Logical Empiricism

As a philosophical ideology and movement, Positivism first assumed its distinctive features in the work of the French philosopher Auguste Comte, who also named and systematized the science of sociology. It then developed through several stages known by various names, such as Empiriocriticism, Logical Positivism, and Logical Empiricism, and finally, in the mid-20th century, flowed into the movement known as Analytic and Linguistic philosophy (*q.v.*).

Affirmations and negations

The basic affirmations of Positivism are (1) that all knowledge regarding matters of fact is based upon the "positive" data of experience, and (2) that beyond the realm of fact is that of pure logic and pure mathematics, which were already recognized by the Scottish Empiricist and Skeptic David Hume as concerned with the "relations of ideas" and, in a later phase of Positivism, were classified as purely formal sciences. On the negative and critical side, the Positivists became noted for their repudiation of metaphysics; *i.e.*, of speculation regarding the nature of reality that radically goes beyond any possible evidence that could either support or refute such "transcendent" knowledge claims. In its basic ideological posture, Positivism is thus worldly, secular, antitheological, and antimetaphysical. Strict adherence to the testimony of observation and experience is the all-important imperative of the Positivists. This imperative is reflected also in their contributions to ethics and moral philosophy, and most Positivists have been Utilitarians to the extent that something like "the greatest happiness for the greatest number of people" was their ethical maxim. It is notable, in this connection, that Auguste Comte was the founder of a short-lived religion, in which the object of worship was not the deity of the monotheistic faiths but humanity.

There are distinct anticipations of Positivism in ancient philosophy. Though the relationship of Protagoras, a 5th-century-BC Sophist, for example, to later Positivistic thought was only a distant one, there was a much more pronounced similarity in the classical Skeptic Sextus Empiricus, who lived at the turn of the 3rd century AD, and in Pierre Bayle, his 17th-century reviver. Moreover, the medieval Nominalist William of Ockham had clear affinities with modern Positivism. An 18th-century forerunner who had much in common with the Positivistic antimetaphysics of the following century was the German thinker Georg Lichtenberg.

Positivism clearly has its proximate roots, however, in the French Enlightenment, which stressed the clear light of reason, and in the 18th-century British Empiricism, particularly that of Hume and of Bishop George Berkeley, which stressed the role of sense experience. Comte was influenced specifically by the Enlightenment Encyclopaedists (such as Denis Diderot, Jean d'Alembert, and others) and, especially in his social thinking, was decisively influenced by the founder of French Socialism, Claude-Henri, comte de Saint-Simon, whose disciple he had been in his early years and from whom the very designation Positivism stems.

THE SOCIAL POSITIVISM OF COMTE AND MILL

Comte's law of three phases

Comte's Positivism was posited on the assertion of a so-called law of the three phases (or stages) of intellectual development. There is a parallel, as Comte saw it, between the evolution of thought patterns in the entire history of man, on the one hand, and in the history of an individual's development from infancy to adulthood, on the other. In the first, or so-called theological, stage, natural phenomena are explained as the results of supernatural or divine powers. It matters not whether the religion is polytheistic or monotheistic; in either case, miraculous powers or wills are believed to produce the observed events. This stage was criticized by Comte as anthropomorphic; *i.e.*, as resting on all-too-human analogies. Generally, animistic explanations—made in terms of the volitions of soullike beings operating behind the appearances—are rejected as primitive projections of unverifiable entities.

The second phase, called metaphysical, is in some cases merely a depersonalized theology: the observable processes of nature are assumed to arise from impersonal powers, occult qualities, vital forces, or entelechies (internal perfecting principles). In other instances, the realm of observable facts is considered as an imperfect copy or imitation of eternal ideas, as in Plato's metaphysics of pure Forms. Again, Comte charged that no genuine explanations result; questions concerning ultimate reality, first causes, or absolute beginnings are thus declared to be absolutely unanswerable. The metaphysical quest can lead only to the conclusion expressed by the German biologist and physiologist, Emil du Bois-Reymond: *"Ignoramus et ignorabimus"* ("We are and shall be ignorant"); it is a deception through verbal devices and the fruitless rendering of concepts as real things.

The sort of fruitfulness that it lacks can be achieved only in the third phase, the scientific, or "positive," phase —hence the title of Comte's magnum opus: *Cours de philosophie positive* (1830–42; Eng. trans., *The Positive Philosophy of Auguste Comte*, 1853)—because it claims to be concerned only with positive facts. The task of the sciences, and of knowledge in general, is to study the facts and regularities of nature and society and to formulate the regularities as (descriptive) laws; explanations of phenomena can consist in no more than the subsuming of special cases under general laws. Mankind reached full maturity of thought only after abandoning the pseudoexplanations of the theological and metaphysical phases and substituting an unrestricted adherence to scientific method.

Classification of the sciences; sociology

In his three stages Comte combined what he considered to be an account of the historical order of development with a logical analysis of the levelled structure of the sciences. By arranging the six basic and pure sciences one upon the other in a pyramid, Comte prepared the way for Logical Positivism to "reduce" each level to the one below it. He placed at the fundamental level the science that does not presuppose any other sciences—viz., mathematics—and then ordered the levels above it in such a way that each science depends upon, and makes use of, the sciences below it on the scale: thus arithmetic and the theory of numbers are declared to be presuppositions for geometry and mechanics, astronomy, physics, chemistry, biology (including physiology), and sociology. Each higher level science, in turn, adds to the knowledge content of the science or sciences on the levels below, thus enriching this content by successive specialization. Psychology is conspicuously missing in Comte's system of the sciences. Anticipating some ideas of 20th-century Behaviourism and physicalism, Comte assumed that psychology should become a branch of biology (especially of brain neurophysiology), on the one hand, and of sociology, on the other. As the "father" of sociology, Comte maintained that the social sciences should proceed from observations to general laws, very much as (in his view) physics and chemistry do. He was skeptical of introspection in psychology, being convinced that, in attending to one's own mental states, these states would be irretrievably altered and distorted. In thus insisting on the necessity of objective observation, he was close to the basic principle of the methodology of 20th-century Behaviourism.

Among Comte's disciples or sympathizers were Cesare Lombroso, an Italian psychiatrist and criminologist, and M.-P.-E. Littré, J.-E. Renan, and Louis Weber, all French philosophers.

Despite some basic disagreements with Comte, the 19th-century English philosopher John Stuart Mill, also a logician and economist, must be regarded as one of the outstanding Positivists of his century. In his *System of Logic* (1843), he developed a thoroughly Empiricist theory of knowledge and of scientific reasoning, going even so far as to regard logic and mathematics as empirical (though very general) sciences. The broadly synthetic philosopher Herbert Spencer, author of a doctrine of the "unknowable" and of a general evolutionary philosophy, was, next to Mill, an outstanding exponent of a Positivistic orientation.

THE CRITICAL POSITIVISM OF MACH AND AVENARIUS

The influences of Hume and of Comte were also manifest in important developments in German Positivism, just prior to World War I. The outstanding representatives of this school were a philosophical critic of the physics of Newton, an Austrian, Ernst Mach, who was also an original thinker as a physicist and excelled as a historian of mechanics, thermodynamics, and optics, and Richard Avenarius, founder of a philosophy known as Empiriocriticism.

Mach's phenomenalism

Mach, in the introductory chapter of his book *Beiträge zur Analyse der Empfindungen* (1886; Eng. trans., *Contributions to the Analysis of the Sensations*, 1897), reviving the Humean antimetaphysics, contended that all factual knowledge consists of a conceptual organization and elaboration of what is given in the elements; *i.e.*, in the data of immediate experience. Very much in keeping with the spirit of Comte, he repudiated the transcendental Idealism of Kant. For Mach, the most objectionable feature in Kant's philosophy was the doctrine of the *Dinge an sich* —*i.e.*, of the "things-in-themselves"—the ultimate entities underlying phenomena, which Kant had declared to be absolutely unknowable though they must nevertheless be conceived as partial causes of man's perceptions. Hermann von Helmholtz, a wide-ranging scientist and philosopher and one of the great minds of the 19th century, by contrast, held that the theoretical entities of physics are, precisely, the things-in-themselves—a view which, though generally Empiricist, was thus clearly opposed to the Positivist doctrine. Theories and theoretical concepts, according to the Positivist understanding, were merely instruments of prediction. From one set of observable data, theories formed a bridge over which the investigator could pass to another set of observable data. Positivists generally maintained that theories might come and go, whereas the facts of observation and their empirical regularities constituted a firm ground from which scientific reasoning could start and to which it must always return in order to test its validity. In consequence, most Positivists were reluctant to call theories true or false but preferred to consider them merely as more or less useful.

The task of the sciences, as it earlier had been expressed by the German physicist Gustav Kirchhoff, was the pursuit of a compendious and parsimonious description of observable phenomena. Concern with first causes or final reasons was to be excluded from the scientific endeavour as fruitless, or hopeless (if not meaningless). Even the notion of explanation became suspect and was at best taken (as already in Comte) to be no more than an ordering and connecting of observable facts and events by empirically ascertainable laws.

Anti-atomism of Mach and Ostwald

Mach and, along with him, Wilhelm Ostwald, the originator of physical chemistry, were the most prominent opponents of the atomic theory in physics and chemistry. Ostwald even attempted to derive the basic chemical laws of constant and multiple proportions without the help of the atomic hypothesis. To the Positivist the atom, since it could not be seen, was to be considered at best a "convenient fiction" and at worst an illegitimate ad hoc hypothesis. Hans Vaihinger, a subjectivist who called himself an "idealistic Positivist," pursued the idea of useful fictions to the limit, and was convinced that the concept of the atom, along with the mathematical concepts of the infinite and the infinitesimal, and those of causation, free will, the economic man, and the like, were altogether fictitious, some of them even containing internal contradictions.

The anti-atomistic strand in the thought of the Positivists was an extreme manifestation of their phobia regarding anything unobservable. With the undeniably great success of the advancing microtheories in physics and chemistry, however, the Positivist ideology was severely criticized, not only by some contemporary philosophers but also by outstanding scientists. The Austrian Ludwig Boltzmann and the German Max Planck, for example, both top-ranking theoretical physicists, were in the forefront of the attack against Mach and Ostwald. Boltzmann and Planck, outspoken Realists, were deeply convinced of the reality of unobservable microparticles, or microevents, and were clearly impressed with the ever-growing and converging evidence for the existence of atoms, molecules, quanta, and subatomic particles. Nevertheless, the basic Positivist attitude was tenaciously held by many scientists, and striking parallels to it appeared in American Pragmatism and instrumentalism; in parts of the work of the Pragmatists Charles Sanders Peirce, William James, and John Dewey, there is a philosophy of pure experience essentially similar to that of Mach.

The Positivism of Avenarius

Though Richard Avenarius has not become widely known, he too anticipated a good deal of what the American Pragmatists propounded. His Positivism, like that of Mach, comprised a biologically oriented theory of knowledge. From the needs of organisms in their adaptation to the exigencies of their environment develop the conceptual tools needed for prediction of future conditions. In Avenarius' view, the raw material of the construction of the concepts of common sense and of the sciences, however, was "the given"; *i.e.*, the data of immediate sensory experience. Just as Mill in the 19th century considered ordinary physical objects as "permanent possibilities of sensation," so Mach and Avenarius construed the concepts pertaining to what men commonsensically regard as the objects of the real world as "complexes of sensations." Thus, it was maintained that a stone, for example, is no more than a collection of such sensory qualities as hardness, colour, and mass. The traditional assumption that there must be an underlying substance that has these properties was repudiated. To the question "What would be left over if all of the perceptible qualities were stripped (in thought) away from an observable object?" these Positivists answered: "Precisely nothing." Thus the concept of substance was declared not only superfluous but meaningless as well.

In similar fashion, the concept of causation was explicated not as a real operating principle but as regularity of succession or as functional dependency among observable or measurable variables. Because these dependencies are not logically necessary, they are contingent and ascertained by observation, and especially by experimentation and inductive generalization.

The Newtonian doctrine according to which space and time are absolute or substantive realities had been incisively criticized by the 17th-century Rationalist Gottfried Leibniz, and was subjected by Mach to even more searching scrutiny. While Leibniz had already paved the way for the conception of space and time as exclusively a matter of relations between events, Mach went still further in attacking the arguments of Newton, then still highly persuasive, in favour of a dynamic and absolute space and time. In particular, the inertial and centrifugal forces that arise in connection with accelerated or curvilinear motions had been interpreted by Newton as effects of such motions with respect to a privileged reference medium imagined as an absolute Cartesian mesh system graphed upon a real space. In a typically Positivistic manner, however, Mach found the idea quite incredible. How, he asked, could an absolutely empty space have such powerful effects? Mach conjectured that any privileged reference system must be generated not by an imperceptible grid but by material reality—specifically, by the total mass of the universe (galaxies and fixed stars), an idea that later served as an important starting point for Einstein's general theory of relativity and gravitation.

Influence of Mach and Avenarius

The Positivist theory of knowledge, as proposed by Mach and Avenarius, impressed many scholars, most notable among whom was probably the leading British logician and philosopher Bertrand Russell in one of the earlier phases of his thought. In a work entitled *Our Knowledge of the External World* (1914), Russell analyzed the concept of physical objects as comprising classes of (perceptual) aspects or perspectives, an idea that later stimulated the work of Rudolf Carnap, an outstanding philosophical semanticist and Analyst, entitled *Der logische Aufbau der Welt* (1928; Eng. trans., *The Logical Structure of the World*, 1967). Mach remained the most influential thinker among Positivists for a long time, though some of his disciples, like Josef Petzoldt, are now largely forgotten. But *The Grammar of Science* (1892),

written by Karl Pearson, a scientist, statistician, and philosopher of science, still receives some attention; and in France it was Abel Rey, also a philosopher of science, who, along the lines of Mach, severely criticized the traditional mechanistic view of nature. In the United States, John Bernard Stallo, a German-born American philosopher of science (also an educator, jurist, and statesman), developed a Positivistic outlook, especially in the philosophy of physics, in his book *The Concepts and Theories of Modern Physics* (1882), in which he anticipated to a degree some of the general ideas later formulated in the theory of relativity and quantum mechanics.

LOGICAL POSITIVISM AND LOGICAL EMPIRICISM

A first generation of 20th-century Viennese Positivists began its activities, strongly influenced by Mach, around 1907. Notable among them were a physicist, Philipp Frank, mathematicians Hans Hahn and Richard von Mises, and an economist and sociologist, Otto Neurath. This small group was also active during the 1920s in the Vienna Circle of Logical Positivists, a seminal discussion group of gifted scientists and philosophers that met regularly in Vienna, and in the related Berlin Society for Empirical Philosophy.

The Vienna Circle and the Berlin Society

These two schools of thought, destined to develop into an almost worldwide and controversial movement, were built on the Empiricism of Hume, on the Positivism of Comte, and on the philosophy of science of Mach. Equally important influences came from several eminent figures who were at the same time scientists, mathematicians, and philosophers—G.F. Bernhard Riemann, the author of a non-Euclidean geometry; Hermann von Helmholtz, a pioneer in a broad range of scientific studies; Heinrich Hertz, the first to produce electromagnetic waves in his laboratory; Ludwig Boltzmann, a researcher in statistical mechanics; Henri Poincaré, equally eminent in mathematics and philosophy of science; and David Hilbert, distinguished for his formalizing of mathematics. Most significant, however, was the impact of Albert Einstein, as well as that of the three great mathematical logicians of the past 100 years—the ground-breaking German Gottlob Frege and the authors of the monumental *Principia Mathematica* (1910–13), Bertrand Russell and Alfred North Whitehead.

The earlier Positivism of Viennese heritage. The confluence of ideas from these sources and the impressions that they made upon the Vienna and Berlin groups in the 1920s gave rise to the philosophical outlook of Logical Positivism—a label supplied in 1931 by A.E. Blumberg and the Minnesota philosopher of science Herbert Feigl. The leader of the Vienna Circle between 1924 and 1936 was Moritz Schlick, who in 1922 succeeded to the chair (previously held by Mach and Boltzmann) for the philosophy of the inductive sciences at the University of Vienna. By 1924 an evening discussion group had been formed with Schlick, Hans Hahn, Otto Neurath, Victor Kraft, Kurt Reidemeister, and Felix Kaufmann as the prominent active participants. The most important addition to the circle was Rudolf Carnap who joined it in 1926. One of the early activities was the study and critical discussion of the *Tractatus Logico-Philosophicus* (1922) of Ludwig Wittgenstein, a seminal thinker in Analytical and Linguistic philosophy. It seemed at the time that the views of Carnap and Wittgenstein, though formulated and elaborated quite differently, shared a large measure of basic agreement. Parallel, but not completely independent, developments occurred in the Berlin group, in which Hans Reichenbach, Richard von Mises, Kurt Grelling, and Walter Dubislav were the leading spirits.

Scientific, antimetaphysical orientation

Both the Vienna and Berlin groups consisted mainly of philosophically interested scientists or scientifically trained and oriented philosophers. Schlick had already anticipated some of the basic epistemological tenets of the groups in his *Allgemeine Erkenntnislehre* (1918; "General Theory of Knowledge"). But the philosophical outlook was sharpened and deepened when, in the late 1920s, the Viennese Positivists published a pamphlet *Wissenschaftliche Weltauffassung: Der Wiener Kreis* (1929; "Scientific Conception of the World: The Vienna Circle"), which was to be their declaration of independence from traditional philosophy—and, in the minds of its authors (Carnap, Hahn, and Neurath, aided by Waismann and Feigl), a "philosophy to end all philosophies."

Language and the clarification of meaning. The basic ideas of Logical Positivism were roughly as follows: the genuine task of philosophy is to clarify the meanings of basic concepts and assertions (especially those of science) —and not to attempt to answer unanswerable questions such as those regarding the nature of ultimate reality or of the Absolute. Inasmuch as an extremely ambitious Hegelian type of metaphysics, Idealistic and absolutist in orientation, was still prevalent in the German-speaking countries, there were many who believed that the antidote was urgently needed. Moreover, the Logical Positivists also had only contempt and ridicule for the ideas of the German Existentialist, Martin Heidegger, whose interminable torment regarding such questions as "Why is there anything at all?" and "Why is what there is, the way it is?" and especially his pronouncements about Nothingness seemed to them to be not only sterile but so confused as to be nonsensical. The Logical Positivists viewed metaphysics as a hopelessly futile way of trying to do what great art, and especially poetry and music, already do so effectively and successfully. These activities, they held, are expressions of visions, feelings, and emotions and, as such, are perfectly legitimate as long as they make no claims to genuine cognition or representation of reality. What Logical Positivism recommended positively, on the other hand, was a logic and methodology of the basic assumptions and of the validation procedures of knowledge and of evaluation.

An adequate understanding of the functions of language and of the various types of meaning is another of the fundamentally important contributions of the Logical Positivists. Communication and language serve many diverse purposes: one is the representation of facts, or of the regularities in nature and society; another is the conveying of imagery, the expression and arousal of emotions; a third is the triggering, guidance, or modification of actions. Thus, they distinguished cognitive–factual meaning from expressive and evocative (or emotive) significance in words and sentences. It was granted that, in most utterances of everyday life (and even of science), these two types of meaning are combined or fused. What the Logical Positivists insisted upon, however, was that the emotive type of expression and appeal should not be mistaken for one having genuinely cognitive meanings. In such expressions as moral imperatives, admonitions, and exhortations there is, of course, a factually significant core; viz., regarding the (likely) consequences of various actions. But the normative element—expressed by such words as "ought," "should," "right," and their negations (as in "Thou shalt not . . . .")—is by itself not cognitively meaningful but has primarily emotional and motivative significance.

Cognitive versus emotive meaning

Early statements about moral value judgments, such as those by Carnap or by A.J. Ayer, a more radical British Positivist, seemed shocking to many philosophers, to whom it seemed that, in their careless formulation, moral norms were to be treated like expressions of taste. Equally shocking was their condemnation as nonsense (really non-sense; *i.e.*, complete absence of factual meaning) of all moral, aesthetic, and metaphysical assertions. More adequate and delicate analyses, such as that of the American Positivist Charles Stevenson, were soon to correct and modify those extremes. By proper allocation of the cognitive and the normative (motivative) components of value statements, many thinkers rendered the originally harsh and implausible Positivist view of value judgments more acceptable. Nevertheless, there is—in every Positivistic view—an ineluctable element of basic, noncognitive commitment in the acceptance of moral, or even of aesthetic, norms.

The verifiability criterion of meaning and its offshoots. The most noteworthy, and also most controversial, contribution of the Logical Positivists was the so-called verifiability criterion of factual meaningfulness. In its original form, this criterion had much in common with

the earlier Pragmatist analysis of meaning (as in Charles Sanders Peirce and William James). Schlick's rather careless formulation: "The meaning of a [declarative sentence] is the method of its verification," which was really intended only to exclude from the realm of the cognitively meaningful those sentences for which it is logically inconceivable that either supporting or refuting evidence can be found, was close to the Pragmatist and, later, to the operationalist slogan that may be paraphrased by: "A difference must make a difference in order to be a difference"—or (more fully explicated): only if there is a difference in principle, open to test by observation, between the affirmation and the denial of a given assertion does this assertion have factual meaning. To take the classical example from Hume's analysis of the concept of causation, there is no difference between saying "*A* is always followed by *B*" and saying "*A* is necessarily always followed by *B*." That all *effects* have causes is true by virtue of the (customary) definitions of "cause" and "effect"; it is a purely formal or logical truth. But to say (instead of speaking of effects) that all *events* have causes is to say something factual—and conceivably false. (It should be noted that these rather crude uses of "causality" and "necessity" were later replaced by much more subtle analyses.)

Untestability of causation, ether, simultaneity

One of the most important examples that stimulated the formulation of the meaning criterion was Einstein's abandonment, in 1905, of the ether hypothesis and of the notion of absolute simultaneity. The hypothesis that there exists a universal ether, as a medium for the propagation of light (and of electromagnetic waves generally), had been quite plausible and was widely accepted by physicists during the second half of the 19th century. To be sure, there were a number of serious difficulties with the idea: the properties that had to be ascribed to the ether were difficult to conceive in a logically compatible manner; and the ether hypothesis in the last stage of its development (by the Dutch physicist Hendrik Lorentz and the Irish physicist George Fitzgerald) had become objectionable in that it sought to provide excuses for the absolute unobservability of that mysterious, allegedly all-pervasive, universal substance. Similarly, it had become impossible, except at the price of intolerably ad hoc hypotheses, to maintain the notions of absolute time and of absolute simultaneity. Thus Einstein, by eliminating these empirically untestable assumptions, was led to his special theory of relativity.

Modifications of the meaning criterion

Several important changes in the formulation of the meaning criterion took place in the ensuing decades from 1930 to 1960. The original version formulated in terms of verifiability was replaced by a more tolerant version expressed in terms of testability or confirmability. Obviously, universal propositions, such as "All cats have claws," being only partially supportable by positive instances (one cannot examine every cat that exists), are not conclusively verifiable. Nevertheless, scientists do accept lawlike statements on the basis of only incomplete, as well as indirect, verification—which is what "confirmation" amounts to. It was in coming to this juncture in his critique of Positivism that Karl Popper, an Austro-English philosopher of science, in his *Logik der Forschung* (1935; Eng. trans., *The Logic of Scientific Discovery*, 1959), insisted that the meaning criterion should be abandoned and replaced by a criterion of demarcation between empirical (scientific) and transempirical (nonscientific, metaphysical) questions and answers—a criterion that, according to Popper, is to be testability, or, in his own version, falsifiability; *i.e.*, refutability. Popper was impressed by how easy it is to supposedly verify all sorts of assertions—those of psychoanalytic theories seemed to him to be abhorrent examples. But the decisive feature, as Popper saw it, should be whether it is in principle conceivable that evidence could be cited that would refute (or disconfirm) a given law, hypothesis, or theory. Theories are (often) bold conjectures. It is true that scientists should be encouraged in their construction of theories—no matter how far they deviate from the tradition; it is also true, however, that all such conjectures should be subjected to the most severe and searching criticism and experimental scrutiny of their truth claims. The growth of knowledge thus proceeds through the elimination of error; *i.e.*, through the refutation of hypotheses that are either logically inconsistent or entail empirically refuted consequences.

Despite valuable suggestions in Popper's philosophy of science, the Logical Positivists and Empiricists continued to reformulate their criteria of factual meaningfulness. The Positivist Hans Reichenbach, who emigrated from Germany to California, proposed, in his *Experience and Prediction* (1938), a probabilistic conception. If hypotheses, generalizations, and theories can be made more or less probable by whatever evidence is available, he argued, then they are factually meaningful. In another version of meaningfulness, first adumbrated by Schlick (under the influence of Wittgenstein's thought), the philosopher's attention is focussed on concepts rather than on propositions. If the concepts in terms of which theories are formulated can be related, through chains of definitions, to concepts that are definable ostensibly—*i.e.*, by pointing to or exhibiting items or aspects of direct experience—then those theories are factually meaningful. This is the version also advocated by Richard von Mises, an Austro-American mathematician and methodologist, in his *Positivism* (1951) and, later, more technically elaborated by Carnap, in *Minnesota Studies in the Philosophy of Science*, vol. 1 (1956).

Other issues. These views of meaningfulness are essentially refinements of the doctrine of so-called protocol sentences, developed in the late 1920s and early 1930s and elaborated especially by Carnap, by Otto Neurath, a polymath sociologist and philosopher, and also (with some differences) by Schlick. Protocol sentences, originally conceived along the lines of an interpretation, developed in the Vienna Circle, of Wittgenstein's elementary propositions, were identified as those sentences that make statements about the data of direct experience. But Neurath—and independently also Popper—warned of the danger that this doctrine might lead to subjective Idealism and recommended that it be given a rational reconstruction on an intersubjective basis. Thus, Neurath and Carnap preferred that a physicalistic thing-language be employed as the starting point and testing ground of all knowledge claims. Propositions in this language would describe objectively existing, directly observable states of affairs or events. Because all objective and intersubjective knowledge was seen, in such a physicalism, to rest on statements representing things and their properties, relations and ongoing processes as they are found in unbiassed, and presumedly theory-free, observation, the physicalists were thus proclaiming a first thesis of the so-called Unity of Science principle. Though Mach had proceeded from the basis of (neutral) immediate experience, his insistence on the unity of all knowledge and all science was retained—at least in general spirit—by the later Positivists. In this view, all classifications of the sciences, or divisions of their subject matter, were seen as artificial, valuable at best only administratively, but without philosophical justification.

Physicalism and the Unity of Science

Sharply to be distinguished from this first thesis of the Unity of Science is a second that formulates a reductionism of a very different type: whereas the first thesis concerns the unity of the observational basis of all the sciences, the second proposes (tentatively) a unity of the explanatory principles of science. Reductions within physics itself, such as that of thermodynamics to the kinetic theory of heat (statistical mechanics) and of optics to electromagnetics; and, beyond that, the explanation of chemical phenomena, with the help of the quantum theory, in terms of atomic and molecular processes; and, furthermore, the progress that has been made in the physical explanation of biological phenomena (especially in the recent development of molecular biology)—all of these encourage the idea of a unitary set of physical premises from which the regularities of all of reality could be derived. But it must be admitted that, in contrast to the first thesis (which, by comparison is almost trivial), the second, being a bold conjecture about future reductions in the sciences, might well prove to be limited in the scope

of its validity. The most controversial part of this reductionist ideology, however, concerns the realms of organic life and especially that of mind; it concerns, in other words, the reducibility of biology to physics and chemistry and of psychology to neurophysiology—and (though this is clearly utopian at present) of both ultimately to basic physics.

The most serious alternative to this reducibility thesis of the Unity of Science movement is the theory of emergent evolution, according to which life or mind (or both) are genuinely novel forms of reality that could not possibly have been derived from, or predicted by, any laws or theories of the lower or earlier levels of existence.

Historically, it may be plausible that the notorious perplexities of the traditional problem of how mind relates to body motivated both the phenomenalistic Positivists as well as the Behaviourists and physicalists. In either view, the mind–body problem conveniently disappears; it is branded as a metaphysical pseudoproblem. The phenomenalism of Mach and the early Russell was expressed in a position called neutral monism, according to which both psychological and physical concepts are viewed as logical constructions on the basis of a neutral set of data of immediate experience. There are thus not two realities—the mental and the physical; there are merely different ways of organizing the experiential data. In the Behaviourist–physicalist alternative, on the other hand, the philosopher, considering the concepts that are ordinarily taken to characterize private mental acts and processes, defines them on the basis of publicly (intersubjectively) observable features of the behaviour, including the linguistic behaviour, of man.

Neutral monism and mental states

The absolute privacy of mental events was first criticized, however, by Carnap and later by an Oxford Analytical philosopher, Gilbert Ryle; and Wittgenstein, in an argument against the very possibility of a private language, maintained that, unless men have objective criteria for the occurrence of mental states, they cannot even begin to communicate meaningfully with each other about their direct experiences. Wittgenstein thus repudiated the traditional view according to which a man's knowledge of other persons' minds must be based on analogical inference from his own case. In a similar vein, an American psychologist, B.F. Skinner, tried to account for man's acquisition of subjective terms in his language by a theory of verbal behaviour. A man learns to describe his mental states, explained Skinner, from the utterances of others who ascribe these states to him by virtue of their observation of his behaviour (*e.g.*, in the social context; or when a certain stimulus situation prevails in his environment).

Dispositions as conditionals

Both Carnap and Ryle have emphasized that many mental features or properties have a dispositional character. Dispositional terms, whether used in psychology or more broadly, have to be understood as shorthand expressions for test conditions—or test-result conditionals. Thus, even in ordinary life, a man appraises, for example, the intelligence of a person in the light of what he does, how he does it, how fast he does it, when confronted with various tasks or problems. Just as such physical properties as malleability, brittleness, or thermal or electrical conductivity must be defined in terms of what happens when certain conditions are imposed, so also mental dispositions are to be construed as similarly hypothetical; *i.e.*, as (in the simplest case) stimulus–response relationships.

The later Positivism of Logical Empiricism. Logical Positivism, essentially the doctrine of the Vienna Circle (*c.* 1924–38), underwent a number of important changes and innovations in the middle third of the century, which suggested the need for a new name. The designation Positivism had been strongly connected with the Comte–Mach tradition of instrumentalism and phenomenalism. The emphasis that this tradition had placed, however, on the positive facts of observation and their negative attitude toward the atomic theory and the existence of theoretical entities in general were no longer in keeping with the spirit of 20th-century science. Nevertheless, the requirement that hypotheses and theories be empirically testable, though it became more flexible and tolerant, could not be relinquished. It was natural, then, that the word "empiricism" should occur in any new name. Accordingly, retaining the term "logical" in roughly its same earlier meaning, the new name "Logical Empiricism" was coined.

The status of the formal and a priori. The intention of the word "logical" was to insist on the distinctive nature of logical and mathematical truth. In opposition to Mill's view, according to which even logic and pure mathematics are empirical (*i.e.*, are justifiable or refutable by observation), the Logical Positivists—essentially following Frege and Russell—had already declared mathematics to be true only by virtue of postulates and definitions. Expressed in the traditional terms used by Kant, logic and mathematics were recognized as a priori disciplines (valid independently of experience) precisely because their denial would amount to a self-contradiction, and statements within these disciplines were expressed in what Kant called analytic propositions; *i.e.*, propositions that are true or false only by virtue of the meanings of the terms they contain. In his own way, the broad-ranging scholar Gottfried Leibniz had seen this in the 17th century long before Kant. The truth of such a simple arithmetical proposition as, for example, "$2 + 3 = 5$" is necessary, universal, a priori, and analytic because of the very meaning of "2," "+," "3," "5," and "=." Experience could not possibly refute such truths because their validity is established (as Hume said) merely by the "relation of ideas." Even if—"miraculously"—putting two and three objects together should on some occasion yield six objects, this would be a fascinating feature of those objects (rabbits, perhaps); but it would not in the least tend to refute the purely definitional truths of arithmetic.

The analytic and synthetic in mathematics

The case of geometry is altogether different. Geometry can be either an empirical science of natural space or an abstract system with uninterpreted basic concepts and uninterpreted postulates. The latter is the conception introduced in rigorous fashion by a late-19th-century mathematician, David Hilbert, and, still later, by a United States geometer, Oswald Veblen. In the axiomatizations that they developed, the basic concepts, called primitives, are implicitly defined by the postulates: thus, such concepts as point, straight line, intersection, betweenness, and plane are related to each other in a merely formal manner. The proof of theorems from postulates, and with explicit definitions of derived concepts (such as of triangle, polygon, circle, or conic section), is achieved by strict deductive inference. Very different, however, is geometry as understood in practical life, and in the natural sciences and technologies, in which it constitutes the science of space. Ever since the development of the non-Euclidean geometries in the first half of the 19th century, it has no longer been taken for granted that Euclidean geometry is the only geometry uniquely applicable to the spatial order of physical objects or events. In Einstein's general theory of relativity and gravitation, in fact, a four-dimensional Riemannian geometry with variable curvature was successfully employed, an event that amounted to a final refutation of the Kantian contention that the truths of geometry are "synthetic a priori." With respect to the relation of postulates to theorems, geometry is thus analytic, like any other rigorously deductive discipline; but the postulates themselves, when interpreted—*i.e.*, when construed as statements about the structure of physical space—are indeed synthetic, but also a posteriori; *i.e.*, their adequacy depends upon the results of observation and measurement.

Developments in Linguistic Analysis and their offshoots. Important contributions, beginning in the early 1930s, were made by Carnap, by Kurt Gödel, a Moravian-American mathematical logician, and others to the logical analysis of language. Charles Morris, a Pragmatist concerned with Linguistic Analysis, had outlined the three dimensions of semiotics (the general study of signs and symbolisms): syntax, semantics, and pragmatics (the relation of signs to their users and to the conditions of their use). Syntactical studies, concerned with the formation and transformation rules of language

(*i.e.*, its purely structural features), soon required supplementation by semantical studies, concerned with rules of designation and of truth. Semantics, in the strictly formalized sense, owed its origin to Alfred Tarski, a leading member of the Polish school of logicians, and was then developed by Carnap and applied to problems of meaning and necessity. As Wittgenstein had already shown, the necessary truth of tautologies simply amounts to their being true under all conceivable circumstances. Thus the so-called eternal verity of the principles of identity (p is equivalent with itself), of noncontradiction (one cannot both assert and deny the same proposition), and the principle of excluded middle (any given proposition is either true or false; there is no further possibility) is an obvious consequence of the rules according to which the philosopher uses (or decides to use) the words "proposition," "negation," "equivalence," "conjunction," "disjunction," and others. Quite generally, questions regarding the meanings of words or symbols are answered most illuminatingly by stating the syntactical and the semantical rules according to which they are used.

Ordinary versus artificial language

Two different schools of thought originated from this basic insight: (1) the philosophy of "ordinary language" Analysis—initiated by Wittgenstein, especially in his later work, and (following him) developed in differing directions in the works of Gilbert Ryle and John Langshaw Austin, both Oxford philosophers, of the Cambridge Analyst John Wisdom, and others; and (2) the ideology, essentially that of Carnap, usually designated as logical reconstruction, which builds up an artificial language. In the procedures of "ordinary language" Analysis, an attempt is made to trace the ways in which a person commonly expresses himself. In this manner, many of the traditional vexatious philosophical puzzles and perplexities are shown to arise out of deviant uses of language. (Lewis Carroll had already anticipated some of these oddities in his whimsical manner in *Alice in Wonderland.*) The much more rigorous procedures of the second school—of Tarski, Carnap, and many other logicians—rest upon the obvious distinction between the language (and all of its various symbols) that is the object of analysis, called the object language, and that in which the analysis is formulated, called the metalanguage. If needed and fruitful, this process can be repeated, in that the erstwhile metalanguage can become the object of a metametalanguage, and so on—without the danger of a vicious infinite regress.

With the help of semantical concepts, an old perplexity in the theory of knowledge can then be resolved. Positivists have often tended to conflate the truth conditions of a statement with its confirming evidence, a procedure which has led to certain absurdities committed by phenomenalists and operationalists, such as the pronouncement that the meanings of statements about past events consist in their (forthcoming future) evidence. Clearly, the objects—the targets or referents—of such statements are the past events. Thus the meaning of a historical statement is its truth conditions; *i.e.*, the situation that would have to obtain if the historical statement is to be true. The confirmatory evidence, however, may be discovered either in the present or in the future. Similarly, the evidence for an existential hypothesis in the sciences may consist, for example, in cloud-chamber tracks, spectral lines, or the like, whereas the truth conditions may relate to subatomic processes or to astrophysical facts. Or, to take an example from depth psychology, the occurrences of unconscious wishes or conflicts are the truth conditions for which the observable symptoms (Freudian lapses, manifest dream contents, and the like) serve merely as indicators or clues; *i.e.*, as items of confirming evidence.

The third dimension of language (in Morris' view of semiotic)—*i.e.*, the pragmatic aspect—has not been as fully and formally analyzed as the other two dimensions. There is even some disagreement as to whether some of the cognitive activities (such as verifying, refuting, or interpreting), in addition to the noncognitive functions (such as the motivative and persuasive appeals), are to be included in studies of pragmatics.

Undecidability; probability

One of the most surprising and revolutionary offshoots of the metalinguistic (formal) analyses was Kurt Gödel's discovery, in 1931, of an exact proof of the undecidability of certain types of mathematical problems, a discovery that dealt a severe blow to the expectations of the Formalistic school of mathematics championed by Hilbert and his collaborator, Paul Bernays. Before Gödel's discovery, it had seemed plausible that a mathematical system could be complete in the sense that any well-formed formula of the system could be either proved or disproved on the basis of the given set of postulates. But Gödel showed rigorously (what had been only a conjecture on the part of the Dutch Intuitionist L.E.J. Brouwer and his followers) that, for a large class of important mathematical systems, such completeness cannot be achieved.

Both Carnap and Reichenbach, in their very different ways, made extensive contributions to the theory of probability and induction. Impressed with the need for an interpretation of the concept of probability that was thoroughly empirical, Reichenbach elaborated a view that conceived probability as a limit of relative frequency and buttressed it with a pragmatic justification of inductive inference. Carnap granted the importance of this concept (especially in modern physical theories) but attempted, in increasingly refined and often revised forms, to define a concept of degree-of-confirmation that was purely logical. Statements ascribing an inductive probability to a hypothesis are, in Carnap's view, analytic, because they merely formulate the strength of the support bestowed upon a hypothesis by a given body of evidence.

CURRENT CRITICISMS AND CONTROVERSIES

Logical Positivism and Logical Empiricism have from their very beginnings been subjected to searching criticisms. At first it was the verifiability criterion of meaningfulness that produced a storm of oppositions. One group of critics asked whether the criterion was meaningful in the light of its own standard. Carnap replied that the criterion itself was not intended as a factual assertion but rather as a proposal for a better and clearer use of language. Nevertheless, the Logical Empiricists felt that the (tolerant–liberal) formulation of the meaning criterion —far from being an arbitrary injunction—came rather close to what enlightened common sense, and especially the scientific attitude, intended by the difference between sense and non-sense.

Scientific explanation

Other recent and current criticisms concern the Logical Empiricist views regarding the nature of scientific explanation, in regard to which matters are not as simple as they were originally conceived to be. Closer attention to the history of scientific theories has revealed important discontinuities, or revolutions, in the conceptual schemes of the sciences. The significant role of statistical (or probabilistic) explanations in most modern sciences, for example, is receiving increasingly sophisticated analyses.

Nevertheless, the prevalence of scientific revolutions and anarchism or subjectivism in scientific method has been exaggerated in differing ways by several scholars. As has been conceded by all competent philosophers of science and even by the greatest scientist-philosophers of the century—Albert Einstein, Niels Bohr, Erwin Schrödinger, and others—there is no straight logical path, no standard recipe, by which to move from the data of observation and arrive at scientific theories. It may also be admitted that, though scientific creativity has psychologically much in common with artistic creation, the criteria of appraisal are certainly quite different. And, although, from the present critical point of view, all and any scientific assertions are in principle subject to revision, it is nonetheless felt to be grotesque to deny the relative stability of the empirical laws that serve as the testing ground of alternative theories.

Literature on Classical Positivism: J. WATSON, *Comte, Mill and Spencer* (1895); W.M. SIMON, *European Positivism in the Nineteenth Century* (1963); JOHN STUART MILL, *Auguste Comte and Positivism* (1865); AUGUSTE COMTE, *Cours de philosophie positive*, 6 vol. (1830–42; Eng. trans. and cond. by H. MARTINEAU, *The Positive Philosophy of Auguste Comte*,

2 vol., 1853). For further references to the ethical views of the classical Positivists, see the bibliography of Utilitarianism in the *Encyclopedia of Philosophy*.

Literature of Logical Positivism and Logical Empiricism: Many of the original classics, both books and articles, are listed in the ample bibliography of A.J. AYER (ed.), *Logical Positivism* (1959), an anthology that contains, among other important essays, RUDOLF CARNAP's "Psychology in Physical Language." The early history of Viennese Positivism is well told in VICTOR KRAFT, *Der Wiener Kreis: Der Ursprung des Neopositivismus* (1950, 2nd ed. 1968; Eng. trans., *The Vienna Circle*, 1953, reprinted 1969). Another important source is J. JOERGENSEN, *The Development of Logical Empiricism*, vol. 2, no. 9 of the *International Encyclopedia of Unified Science* (1951). For a brief account of the European movement of Logical Positivism and its migration and impact in the United States, see H. FEIGL, "The Wiener Kreis in America," in D. FLEMING and B. BAYLIN (eds.), *The Intellectual Migration: Europe and America 1930–1960* (1969). Books, mainly in the foundations of the sciences, but also in philosophy of language and epistemology, many by the leading Logical Empiricists, are listed in the ample *Bibliography and Index*, in HERBERT FEIGL and CHARLES MORRIS (eds.), *International Encyclopedia of Unified Science*, vol. 2, no. 10 (1969). Of direct relevance are the major works of R. Carnap, O. Neurath, M. Schlick, P. Frank, H. Reichenbach, E. Nagel, C.G. Hempel, R. von Mises, and Charles Morris. For criticisms, those of KARL R. POPPER may be used; and the intellectual autobiography of Carnap, the 26 descriptive and critical essays, and his replies, in P.A. SCHILPP (ed.), *The Philosophy of Rudolf Carnap* (1963). For recent reactions, see P. ACHINSTEIN and S.F. BARKER (eds.), *The Legacy of Logical Positivism: Studies in the Philosophy of Science* (1969); and *Minnesota Studies in the Philosophy of Science*, vol. 1–5 (1956–70).

(H.Fe.)

Postal Systems

In the modern world, the term postal system may be defined as the institution—almost invariably under the control of a government agency—that makes it possible for any person to send a letter, packet, or parcel to any addressee, in his own country or abroad, in the expectation that it will be conveyed according to certain established standards of regularity, speed, and security. The service is paid for in advance by the sender according to a relatively simple scale of fees based on weight. Prepayment is ordinarily made by means of postage stamps or a franking machine impression, and the addressee is not usually called upon to make any payment for delivery.

It may seem tedious to catalog at such length characteristics that are familiar to everyone. Their very familiarity, however, and the consequent unthinking acceptance of them make it important to emphasize that until recently postal systems lacked many of these features. Though the basic need for a system to exchange written communications has been felt by all human societies and has been met in many ways, the evolution of varied postal systems adopted by different societies through the centuries into the basically similar pattern of today's state monopoly service has been a long and difficult process.

Today the governments of many countries use their postal systems to provide a range of services that often have no direct connection with the traditional function of exchanging letters. To provide for the collection, transport, and delivery of letters throughout a country, it has been necessary to establish a network of post offices extending into the remotest areas. Such a network of offices, staffed by agents of the state, provides an efficient banking and money-transfer service in areas in which it would be uneconomic for a commercial or state bank to establish a branch office. Many governments also pay various social security benefits—such as pensions and family allowances—through vouchers that can be cashed at post offices; they also collect certain taxes, normally through the sale of licenses, and revenue or tax stamps. In fact, a wide range of ancillary services is provided through the postal system. In some African and Asian countries, for instance, the postal system helps distribute antimalarial drugs. While the variety of such services significantly indicates the ever-increasing use made of postal systems throughout the modern world, they lie outside the scope of this article, which concentrates on the traditional postal or mail services. The functioning of these services is described, followed by the chief characteristics of the postal service in certain countries, the international system (including the functioning of the Universal Postal Union), and, finally, the impact of modern technology on postal work.

POSTAL OPERATIONS AND MANAGEMENT

The raw material of the postal services, always a single object that demands individual treatment, is something sent by one person or entity to another person or entity who may be anywhere else in the world. Letters and parcels alike go in all shapes and sizes, subject only to the limits of weight and dimensions prescribed by postal legislation. Yet if postal services are to be efficient and economical, the processing of these items, as far as is possible, must be on a mass production basis. Thus, the basic function of postal organization is to convert the individual item as rapidly as possible into something that can be handled on a bulk basis, ensuring, however, that it finally regains its individual status.

The sorting process

The collection and sorting of individual items by the most economic method, concentrating together all items that are going to the same place or in the same direction, involves the use of local transport, usually operated by the postal services themselves, and sorting offices. The size of the sorting office depends on local requirements, but some are, in fact, large industrial concerns that handle several million items a day and employ thousands of personnel. Certain ancillary operations are involved, such as, for instance, the cancelling (by machine in all except the smallest offices) of stamps that have served to prepay the postal charge.

The next stage is to transport the grouped items to different destinations that may be intermediate sorting offices, perhaps a railway sorting carriage. Items are combined by further sorting with mail from other sources to permit grouping the mails for final destinations.

The third stage is the arrival of the mail at the sorting office of the final destination, where it is sorted systematically. The items finally recover their identity and are grouped together for delivery to the individual address. In most countries, delivery is on a house-to-house basis, although boxes at a local post office are sometimes used.

All stages have to be planned and dovetailed together to meet an overall standard of performance. The transport of mail between sorting offices is normally by services not necessarily directly operated by the post office—*i.e.*, by truck, bus, train, marine shipping, or air services. In some countries, however, the administration operates its own air service, usually by night, to supplement the public services. Post office counter services (*i.e.*, the public offices that existed originally as depots where the public could buy stamps, make inquiries, and post and collect correspondence) have in many countries gone beyond the role of accessory to the postal service proper and pose problems of organization that in many ways are completely separate from those of the mail-handling services.

Postal services, because of the nature of the items or business handled, require extensive manpower. Many countries are striving to mechanize or even automate sorting, transport, and counter processes. Postal organization depends largely on geography; large agglomerations of population present the greatest problems. Furthermore, geography usually determines the routing of mails and the intermediate steps between the posting and destination offices. Traffic problems have forced postal managers, over the years, to develop their own approach to the operational aspects of postal organization. They developed their own work study methods and operational research techniques long before these terms were invented.

Problems of postal management

Apart from postal operations as such, postal management is concerned with the efficient administration and deployment of large bodies of manpower, the organization of large transport fleets, many aspects of property management, and financial and economic problems, particularly in an increasing number of countries where the postal services are expected to depend on their

postal revenue to meet all of their costs (including those related to capital expenditure). In this connection, the labour-intensive nature of postal work presents particular difficulties and is obliging some postal administrations to review traditional standards of performance (and charges) against a contemporary background of rapid and easy communications other than by means of letters.

HISTORY

Message-relay systems of the ancient world. Since good communications were clearly essential for governing the extensive empires of the ancient world, it is not surprising that the earliest historical references to postal systems should concern Egypt about 2000 BC and China under the Chou dynasty 1,000 years later. It was probably in China that a posthouse relay system was first developed and was brought to a high state of development under the Mongol emperors. The great Persian Empire of Cyrus in the 6th century BC also employed relays of mounted messengers, served by posthouses. The system was favourably described by the Greek historians Herodotus and Xenophon. The admiration of the Greeks was natural since their political divisions inhibited the growth of a coherent postal system, although each city-state possessed its corps of messengers.

The development of Rome from a small city-state into a vast empire embracing most of the known world brought with it the necessity for reliable and speedy communications with the governors of distant provinces. This need was met by the *cursus publicus*, the most highly developed postal system of the ancient world. The relay stages of the *cursus publicus*, established at convenient intervals along the great roads of the empire, formed an integral part of its complex military and administrative system. The speed with which messengers were able to travel during the peak of the administration was not to be rivalled in Europe until the 19th century: it has been claimed that over 170 miles could be covered in a day and a night. The maintenance of the *cursus publicus* required a high degree of organization; an inspectorial system existed to control its operation and prevent abuse for private ends.

The *cursus publicus*

The fall of the Roman Empire in the west during the 5th century did not completely destroy the *cursus publicus*. Its advantages were evident to the new barbarian rulers; some, such as Theodoric, king of the Ostrogoths, who ruled Italy from AD 493 to 526, are known to have maintained the essentials of the Roman postal system within their own domains. Even in the early 9th century, under the Carolingian Empire, the vestiges of the *cursus publicus* appear to have persisted, and posthouses were maintained. While the service did not follow a regularly organized pattern, it was at least reasonably frequent. The continued decay of the Roman roads, the increasing unwillingness of communities bordering the roads to support the expenses of the system, and the progressive political fragmentation of Europe, however, caused all traces of the Roman postal system to disappear.

The *cursus publicus* fared better in the Eastern Empire because its provinces were eventually absorbed into the Islāmic Empire. The substitution of one centralized imperial regime for another meant that the *cursus publicus* could be incorporated into a similar Arabian postal system based in Baghdad.

The pre-Columbian civilizations of America, responding to the same needs as the imperial states of Asia and Europe, also evolved relay systems, limited to foot messengers. In the Inca Empire, posthouses were maintained at frequent intervals along the remarkable road network, and a like system probably served the Mayan civilization for over 1,000 years.

Growth of business correspondence in the Middle Ages. The end of the Carolingian Empire (987) marked the beginning of two centuries of confusion in Europe, in which it is difficult to trace any postal system worthy of the title. Since the kings of the period were constantly struggling to assert their authority over their unruly feudal vassals, the strong central authority that sustained most postal systems was lacking.

The uncertain political situation did not favour the creation of a regulated postal service, though it necessitated frequent contact between the kings and vassals and among the great princes. They, along with other powerful institutions—the municipalities, the religious orders, and the universities (notably in Paris)—started to maintain corps of messengers to serve their particular needs.

One of the more significant trends of the later Middle Ages was the development of international commerce and, with it, the growth of business correspondence. Many corporations or guilds established messenger systems to allow their members to maintain contacts with customers. Notable among these was the so-called Butcher Post (Metzger Post), which was able to combine the carriage of letters with the constant travelling that the trade required.

The mercantile corporations of Italy, however, provided the most extensive and regular postal system of this period. Of particular importance were the links maintained from the mid-13th century between the great Italian commercial centres like Florence, Genoa, and Siena and six important annual fairs held in the Champagne area of northern France. Two fixed despatches were made to each of these fairs: the first to carry orders and commissions and the second to effect settlements. The service was carefully regulated. Conditions of acceptance, scales of payment, and timetables were laid down; the route was fixed, and hostels were maintained along the route. Since the Champagne Fairs were attended by merchants from all over Europe, the postal system provided a valuable international link.

Early postal links between Italy and France

Italian business interests were also responsible for the only regular extra-European postal link of this period, between Venice and Constantinople. The extent and importance of Venetian business correspondence may be gauged from the fact that in 1320 the King of Persia accorded its couriers the right of free passage throughout his domains.

Russia shared in the general European trend toward the development of postal services in the 13th century. Horses and drivers for the transport of couriers were kept at regular staging posts to provide the so-called carriage express, which gradually developed into an organized system for the exchange of letters.

Growth of the post as a government monopoly. Institutional postal systems that developed during the later Middle Ages also conveyed letters between private persons, with or without official sanction and for a substantial fee in either case. Initially, such letters were relatively few. Outside the institutions with their own postal services, the number of literate people having interests that ranged beyond their own neighbourhoods was small.

In the late 15th century, however, the trend toward improved postal services was reinforced by Gutenberg's printing press (*c.* 1450) and the expansion of education. The growth of demand made letter carrying a profitable business, leading to the rise of private undertakings—the majority, like the Swiss "Stumpelbotten," purely local in scope. Some, however, like the Paar family in Austria, developed postal organizations on a national scale. By far the most famous and extensive of such systems was that built up by the Taxis family, who originally came from Bergamo near Milan, Italy. Under the patronage of the Habsburg emperors, they became the organizers of an extensive network of postal routes linking the imperial possessions. Their system developed throughout the 16th century until it covered most of Europe, using 20,000 couriers to operate a relay system that was speedy, efficient, and highly profitable.

Although the remnants of the Taxis postal system survived in Germany up to 1867, it was essentially out of keeping—like the empire and the petty German states it served—with the main trend of development in Europe, the rise of nation-states with strong central governments. The first reflection of this trend in the postal sphere was the establishment of efficient national systems of relay posts under the control of the state. In France, Louis XI set up a Royal Postal Service in 1477 employing 230 mounted couriers. In England, a "Master of the Posts"

was appointed by Henry VIII in 1516 to maintain a regular postal service along the main roads radiating from London. Neither of these systems was comprehensive, nor were they intended to serve the public. The security and regularity of the service along certain routes, however, inevitably resulted in an increasing amount of unofficial correspondence being carried. After initial attempts to prevent this practice in France, its fiscal advantages were realized, and the carrying of private mails was legalized about 1600. The basis of a real public service was not created until 1627, when fees and timetables were fixed and post offices established in the larger cities. In Britain, a separate public service was set up in 1635 by a royal proclamation . . ."for the settling of the letter-office of England and Scotland." Thomas Witherings, a London merchant, was given the task of organizing regular services to run by day and night along the great post roads.

Legalizing private mails

In both countries, these state systems naturally began to develop into monopolies since such an evolution was seen by rulers as advantageous both to the security and to the revenues of the state. In England, the establishment of state posts along the principal roads was accompanied by the suppression, under the royal monopoly, of private and municipal posts, although "common carriers" were still permitted to convey letters on routes not covered by the royal system.

In France, postal services were declared a state monopoly in 1672, but private undertakings that had established legal rights in this field were allowed to continue. Most private messenger systems, however, were eventually forced out of business by state competition or were bought out. In 1719 the University of Paris, the most important private competitor, gave up its last postal privileges in return for substantial compensation.

There was, nevertheless, still opportunity for private enterprise to succeed by introducing services that were not at that time provided by the state systems. It was in this way that an important step in postal history, the establishment of local collection and delivery services in the great cities of London and Paris, was taken. London was the first city to benefit from an urban service when one William Dockwra set up his "Penny Post" in 1680. Striking features of the scheme were that letters were prepaid and stamped to indicate place of posting and the time they had been sent out for delivery. Deliveries were made almost hourly. Dockwra's scheme was so successful that he was prosecuted for infringing the state monopoly, and his service was closed down in November 1682, only to be reopened by the government. Not until 1760 was a similar local service introduced in Paris. It too was quickly absorbed by the state postal system; but its originator, Claude-Humbert Piarron de Chamousset, was paid compensation. Thus, the state monopolies expanded their scope, happily combining an improved service to the public with greater profitability.

The pace of postal progress in England during the later 18th century was accelerated by remarkable economic growth and a consequent demand for better mail services to the growing commercial and manufacturing centres. The most striking improvements came as the result of an extensive program of road building that began about 1765, paving the way for the era of the stagecoach. These were first used by the post office in 1784 and rapidly superseded the mounted postboys on the main routes. They began by averaging six or seven miles an hour, but continuing improvements in the roads and in the design of the vehicles pushed this up to ten miles an hour in the 1830s. With the stagecoaches making possible a general reorganization of the entire system of mail circulation, letters could be delivered the morning after posting in towns more than 120 miles (193 kilometres) from London. A carefully regulated postal service—unprecedented for its standards of speed, frequency, and security—was evolved during this period.

Use of the stagecoach

Despite the disruptive effects of the Revolutionary and Napoleonic wars, great progress was made throughout Europe in the late 18th and early 19th centuries in improving the speed and regularity of postal service and in providing internal delivery services for most of the larger cities. In the United States too, postal services expanded at a remarkable rate: in 1789 only 75 post offices existed, but 40 years later there were over 8,000.

Rowland Hill's reforms. The publication in 1837 of "*Post Office Reform: Its Importance and Practicability*," by Rowland Hill, a British educator and tax reformer, is justly regarded as one of the most important milestones in postal progress. Based on an exhaustive study of the cost structure of postal operations, it demonstrated conclusively that transit charges were an insignificant factor in the total cost of handling a letter. The then current intricate charging scales based on distance were shown to be irrelevant: they inflated operating costs by requiring a host of clerks to apply them and to prepare complicated interoffice accounts. He also realized that another major item in the current cost structure—the collection of money payments on delivery—was easily avoidable. Hill's solution was a uniform rate of postage, regardless of distance, and prepayment of postage by means of adhesive stamps that the sender could buy at a post office. Hill proposed a basic rate of one penny for each half ounce, calculating the "natural cost of distribution" to be slightly less than this. The cheapest current rate of postage was fourpence, and the average charge 6¼ pence (11.56 cents).

Not surprisingly, Hill's proposals rapidly gained strong support: popular agitation for the "penny post" overcame initial political disinterest, and the uniform rate and a system of prepayment by stamps were introduced in 1840. The originality of Hill's proposal for an adhesive postage stamp has been questioned but is irrelevant in considering the overall merits of his work. The significance of his reforms lies not only in the fact that they brought the post within the means of the mass of the people but also in the less obvious way in which they gave the postal system the technical capacity to deal with the vastly increased demand for postal service that ensued. The radical simplification of postal organization and methods characterizing Hill's reforms are the key to the speed and economy with which modern postal systems in many countries handle tens of millions of letters daily.

The chief features of Hill's system were gradually adopted in varying degrees by other countries throughout the world, first among which were Switzerland and Brazil in 1843.

The introduction of uniform cheap rates of postage for letters was accompanied by the establishment of even lower tariffs for newspapers (carried free in some countries) and for printed matter (*e.g.*, the British "Book Post" of 1848). These reduced rates were perhaps originally intended to favour the spread of education but quickly expanded, under the vigorous pressure of vested interests, to cover all sorts of commercial documents, advertising matter, magazines etc. An inexpensive form of correspondence, the postcard, first introduced by Austria in 1869, was soon adopted by most other countries.

The general postal reforms of the mid-19th century ensured maximum benefit from the technological progress in transport in the great age of the railway and the steamship. These new modes of conveyance permitted a far speedier, more regular, and more reliable mail service, both internally and internationally. Railways in particular had a marked effect on the organization of postal work: instead of merely using trains to carry mailbags more speedily, postal administrations soon introduced the practice of sorting the letters in transit, using specially adapted carriages. This greatly multiplied the advantages of railway conveyance. The first travelling, or railway, post offices ran in 1838 between Birmingham and Liverpool and London and Preston. By the end of the century, Britain, many European countries, the United States, and India had built up a complex network of such services, allowing the delivery of letters the day after posting at distances three or four times as great as had been possible with the stagecoach, exceeding 400 miles (643.74 kilometres) in some cases.

Effect of railways

International postal reform: the Universal Postal Union. The advent of the steamship and the railway had provided the opportunity for speedier international postal

services, and the expansion of commerce ensured a growing demand for such facilities. Unfortunately, serious obstacles to the free exchange of international mails existed. Postal relations between states were the subject of bilateral postal treaties that had multiplied alarmingly during the 19th century. Most large European states were party to at least a dozen of them by the 1860s. Such treaties necessitated the maintenance of detailed accounts between the countries concerned. Owing to the bewildering variety of currencies and units of weight and measurement then in use, the accounts attained a complexity described by a contemporary postmaster general of the United States as "almost beyond belief." Understandably, the users of the post suffered from this chaotic situation and from the high international postage rates that were its natural result.

The first practical step toward reform did not come, however, until May 1863, when the delegates of 15 European and American postal administrations met at the Paris Postal Conference, convening at the suggestion of the U.S. Postmaster General. The Conference established important general principles for the simplification of procedures, which were adopted as a model for subsequent bilateral treaties by the countries concerned.

The final step required the embodiment of these principles in a formal international treaty and the creation of an organization to administer them. An example was set by another conference at Paris two years later, which established the International Telegraph Union. Similar developments in the postal field were unfortunately delayed by the advent of the American Civil War and the Franco-Prussian War.

In 1868, however, a plan for a general postal union was put forward by the director of posts of the North German Confederation. Eventually, an international postal congress met, on September 15, 1874, in Bern. It was attended by the representatives of 22 states, all European except for Egypt and the U.S. On October 9 a "Treaty concerning the Establishment of a General Postal Union" was signed. It was implemented on July 1, 1875, when the General Postal Union came into being. This title was changed in 1878 to the Universal Postal Union (UPU), and the basic treaty was renamed the Universal Postal Convention. The treaty provides a uniform framework of rules and procedures for the exchange of international mails. The Union grew rapidly, increasing its membership to 55 within ten years. By 1914, when China was admitted, it included almost all independent countries.

Activities of the UPU

The scope of the Union's activities also expanded. In addition to its primary role, it gradually extended its functions to cover other international services provided by postal administrations, such as money orders (1878), parcel post (1885), postal checks (Giro; 1920), cash on delivery (1947), and savings bank (1957).

Development of airmail. The most important postal development of the 20th century has been the growth of airmail services. Certain experiments were undertaken before World War I, such as airmail service between Hendon and Windsor in 1911 to mark the coronation of George V and flights between Paris and Bordeaux in 1913. It was not until 1919, however, when the reliability of airplanes had considerably improved, that the first regular international service was introduced—between London and Paris—soon to be followed by other European links. It was over long-distance continental and intercontinental routes, however, that airmail was able to demonstrate its clear superiority over all surface transport. Technical factors delayed progress in opening up longer routes. Although the first American transcontinental airmail flight took place in 1920, a regular service did not begin until 1924. In 1926 a service between Egypt and Karāchi was started and was linked to London in 1929. It was extended to Singapore by 1933 and to Australia in 1934. It was not until 1939, however, that a regular service across the North Atlantic was established.

An important development of the late 1920s was the practice—started by a number of European countries—of forwarding mail by air without a surcharge. This practice had been extended to a number of intercontinental routes just before World War II (*e.g.*, between Britain and almost all parts of the British Empire). Since that war, however, the consistently high costs of airmail conveyance, which increase in direct proportion with the distance flown, have made such arrangements in the international service outside Europe very exceptional.

The aerogram

During World War II, a lightweight air-letter service for correspondence with military personnel abroad was introduced in Britain. Retained as an inexpensive form of airmail, it was widely adopted by other countries. In 1952 it was recognized by the UPU as the aerogram.

Since 1946, airmail services have developed rapidly to provide a network connecting Europe and America with all parts of the world. There are still areas, however, in which airmail services are relatively poor. African countries, for example, while generally enjoying a good airmail service to Europe, often lack direct links with each other.

Despite the immense improvements in postal service that it has made possible and its considerable potential for further development, airmail has not affected the basic organization of national postal systems as profoundly as did the railways. This is unlikely to be true of the other great trend of 20th-century postal development —mechanization and automation of the manual processes involved in handling mail. As this movement can hardly yet be considered part of the history of the post, it will be given separate treatment later in this article.

NATIONAL POSTAL SYSTEMS

The United States. Although the first official reference to overseas mail arrangements (concerning the receipt of overseas mail at Fairbanks' Tavern in Boston) dates back to 1639, little real progress was made in building up a postal system in colonial America until the appointment of Benjamin Franklin, formerly postmaster at Philadelphia, as deputy postmaster general for the American Colonies in 1753. Through diligent personal survey and inspection, he provided a more extensive, frequent, and speedier mail service, both within the Colonies and to England, thereby laying a sound foundation for the postal service in the U.S., of which he fittingly became first postmaster general in 1775.

Postal service expanded rapidly after independence: annual revenue increased from $37,935 in 1790 to $1,707,000 by 1829, when the postmaster general first became a member of the Cabinet. The heavy cost of establishing a postal structure to keep pace with the remarkable economic progress of the country and the accelerating extension of its settled area caused expenditure to rise even faster than revenue. The 1820s saw the beginning of the trend toward annual postal deficits, which commonly exceeded an annual figure of $5,000,000 by the later 19th century.

By 1901, however, this expenditure had produced remarkable results. The accessibility, quality, and range of services provided had improved immeasurably. The number of post offices stood at a peak of 76,945. Postage rates had been considerably reduced with the gradual adoption of Rowland Hill's principles: a single uniform rate regardless of distance was adopted in 1863, after an interim period with two rates since 1845. Postage stamps were introduced in 1847. Free collection services came with the provision of street letter boxes in 1858. A free delivery service was established in 1863, covering 49 cities and employing 440 letter carriers. By 1900 the service was provided at 796 offices by 15,322 carriers. The rural free delivery (RFD) service was introduced in 1896 and village delivery in 1912.

Growth of services

These delivery services have greatly expanded their scope: in 1969 the city and village delivery services were provided from 6,219 offices and employed 158,228 letter carriers. The rural delivery service was maintained by 30,945 carriers. About 80 percent of mail is now delivered by carriers, 18 percent through post office boxes, and only 2 percent at windows or counters. The total cost of carrier delivery services in 1969 was over $2,300,000,000.

The range of services available to the public has also grown steadily since the first supplementary postal service

—registered mail—was introduced in 1855. The major milestones in this progress were postal money order service (1864); international money orders (1867); special delivery (1885); parcel post, with its accessory collect on delivery (C.O.D.) and insurance services (1913); certified mail (1955, to provide proof of posting for items without intrinsic value). In 1911 a postal savings system was inaugurated, reaching a peak of more than 4,000,000 accounts in 1947. A decline to less than 1,000,000 depositors caused the service to be discontinued in 1966. Mail was formally divided into three classes in 1863, and a fourth was added in 1879. First-class, or letter, mail is the basis of the post office monopoly. The other classes were established to regulate the complex and often preferential rate structure applicable to publications, circulars, and samples. Second- and third-class mail is normally regarded as "subsidized," since it pays less than its fully allocated costs.

The post office has played a vital role as a pioneer and major user of all systems of transport as each was developed: the stagecoach, steamboat, canals, and railroads; the short-lived pony express; and, finally, the airlines. It also subsidized their development. A travelling post office system, introduced experimentally in 1862, made the railway mail service the dominant form of mail conveyance for the next century. The gradual reduction of passenger train services during the 1930s led to the birth of a highway post office service in 1941. Both of these services have declined rapidly, however, over the last five years. Railway post office mileage was reduced from 96,400,000 in 1965 to 10,100,000 in 1969, and the number of highway post offices in operation fell from 163 to 64. Conversely, ton-miles of airmail flown have increased from 188,103 to 323,662 over the same period, indicating a significant trend toward air transportation of regular mail without surcharge.

The U.S. Post Office now maintains what is by far the largest postal system in the world, handling almost half the world's volume of postal traffic: 84,800,000,000 pieces in 1970, over 400 items per head of population. Traffic is expected to top 120,000,000,000 by 1981.

To deal with the problem of increasing deficits and to improve the overall management and efficiency of the post office, Congress gave final approval to the Postal Reorganization Act of 1970 (HR 17070) on August 6, 1970. The act transformed the Post Office Department into a government-owned corporation, called the United States Postal Service. Congress no longer retains power to fix postal tariffs (although changes may be vetoed) or to control employees' salaries, and political patronage is virtually eliminated. Government subsidies continue but on a declining basis. The new corporation also has authority to raise capital to modernize its equipment and buildings.

The availability of adequate funds for its mechanization and automation program allowed the post office to benefit fully from its sustained effort in research and development. Already by 1969 over 60 percent of all letter mail was handled by preparation and sorting machines, a trend greatly assisted by the ZIP (Zone Improvement Plan) Code program, which by 1970 had achieved a usage of 84.8 percent.

Great Britain. The development of the British Post Office up to the reforms introduced by Rowland Hill has already been described. After 1840 the volume of postal traffic increased enormously, by 1870 reaching ten times its prereform level. The growth was fostered by the introduction of new facilities, such as registration and postcards, and of preferential rates for books, printed papers, and samples. Financial services were also expanded: a savings bank was established in 1861, and postal orders were introduced in 1881 to supplement the money order service taken over from private interests in 1838. In 1883 a parcel post service was established.

British Post Office social services

The sweeping social reforms of the 20th century have given the post office an additional role as the chief payment agency for social security benefits, beginning with old-age pensions in 1908 and expanding continuously to provide a variety of payments and also to collect large sums for state insurance schemes. The huge volume of these agency services is evident from statistics for 1968–69: over 800,000,000 social security payments were made, totalling over £2,600,000,000, and insurance stamps to the value of £1,244,000,000 were sold. The scale and range of financial transactions has been further boosted by the establishment of a postal check, or Giro, service in 1968, providing improved money transfer arrangements for the settlement of bills, and a current account banking system, which now includes loan facilities.

Another important 20th-century trend has been the gradual recognition of the post office's role as a commercial enterprise rather than as a government revenue department. The slow process of achieving full commercial status ended in October 1969, when the post office became a public corporation. The two great businesses of posts and telecommunications are now directed by a board with full executive authority. Overall political responsibility is vested in a new Ministry of Posts and Telecommunications. The National Savings Bank was transferred to the Treasury.

In the field of mail conveyance, Britain has not been forced to resort to extensive employment of air transport to maintain high-quality service. Although limited use of airmail is made in services between the South of England and Ireland and Scotland, the efficient and extensive network of railway travelling post offices remains the backbone of the circulation system, ensuring a high standard of next-day delivery service. To maintain the quality of this service economically by removing the need to handle nonpriority mail at peak periods, a controversial change to a "two-tier" system of letter classification was started in September 1968. The system abolished the complex preferential rate structure for printed papers and similar material—based on the contents of correspondence—and substituted the more relevant criterion of priority. The sender indicates the urgency of his item as being high (first tier) or lower (second tier) and pays on this basis, which simplifies the work of accepting the mail. Despite initial criticism, the new system has increased the percentage of priority mail given next-day delivery from 92 percent before the change to 94 percent in 1969. Another important measure to improve mail handling and facilitate mechanization has been the gradual introduction of an alphanumeric postal code, which has the unusual advantage of providing for inward sorting at the office of delivery.

France. The chief stages in the pre-Revolutionary development of postal services in France have already been described. With the Revolution, the system of farming or selling the right to operate a postal service was abolished, and the postal service was made a national agency in 1793. By an edict of June 16, 1801, the basic articles of the present postal monopoly were established.

First rural delivery service

In 1829 France became the first country to start a rural delivery service. A uniform internal postal tariff was established in August 1848, and postage stamps were introduced in the same year. Throughout the 19th and early 20th centuries, the scope and range of the services provided by the postal administration continually expanded: money orders (1817), registered letters (1829), postcards (1872), parcel post (1881), savings bank (1881), postal checks (1918). The parcels service is largely operated by railway authorities. France in 1970 had 17,500 post offices, in which a staff totalling 165,000 was employed to provide this extensive range of services.

The development of mail transport has been equally important over this period. A network of railway travelling post offices was built up during the latter 19th century, beginning with the Paris–Rouen service in 1844. Air conveyance was first employed experimentally in 1913 between Paris and Bordeaux, but a regular internal airmail service did not begin until 1933. Since World War II, the French postal administration has been among the pioneers in the field of internal airmail services, creating an autonomous postal fleet of 29 specialized mail transport aircraft to serve a comprehensive network of routes. In the early 1970s, the fleet was modernized. Since the services necessarily operate at night, turbojet aircraft

have been chosen in order to minimize noise. The total weight of mail flown has increased from 2,100,000 kilograms (4,629,700 pounds) in 1948 to 27,400,000 kilograms (60,407,000 pounds) during 1968, now representing over a quarter of the internal letter traffic.

The maintenance of this high standard of service in the face of constant growth in mail volume has posed serious problems. Daily traffic grew from 16,500,000 items in 1950 to 34,000,000 in 1969 (when the annual total exceeded 10,000,000,000). A study of probable future trends indicates that the daily figure will reach 41,500,000 by 1975 and 55,000,000 in 1985. To simplify the problems of handling such vast volumes of mail economically and speedily, the administration introduced a "two-tier" system in January 1969, allowing the customer to choose the priority to be accorded to his letter by paying an appropriate tariff.

West Germany. Postal organization in Germany remained on a relatively small scale until the later 19th century because of numerous sovereign states. The need for a more widely based postal system, to a certain degree, had been met since the 16th century, when the famous Taxis postal service was begun. The fragmented political state of Germany, in fact, allowed the Taxis organization to survive until 1867, when its last privileges were acquired by the postal service of the North German Confederation.

The unification of Germany under Prussia during the second half of the 19th century, culminating in the establishment of the German Empire in January 1871, was followed by the creation of a German postal service in the same year, under a law establishing a state monopoly for conveying letters and newspapers. In 1924 the postal administration was accorded a considerable degree of financial autonomy, allowing it to conduct business on semicommercial lines, taking due account of national economic and social factors in determining rate structure and pattern of service. The post office provides a complete range of normal postal and financial services, operates an extensive postal passenger transport network, and carries out various social security, revenue, and other agency work. In 1968 it maintained 26,333 post offices with a staff of over 275,000.

Establishment of the German postal service

Mail is transported chiefly by the railway, but there also exists an extensive complementary postal road network and an important night airmail service. The air service, started in 1961, carries letters and postcards on an unsurcharged basis.

Owing to labour shortages and the buoyancy of postal traffic, the West German Post Office has followed an energetic policy of mechanization.

Italy. Italy has a long history of organized postal systems, beginning with the *cursus publicus* of the Romans; but the present national postal system was not established until 1862, when the process of unifying the former small sovereign states into the new Kingdom of Italy had been successfully completed.

The new state postal service was given a monopoly for the collection, conveyance, and delivery of letters, printed papers, and newspapers, and a uniform tariff was established. The monopoly was surrendered for printed papers and newspapers in 1873 but was extended to cover parcels up to 20 kilograms (44 pounds) in 1923. A registration service also began in 1862, and postal orders were introduced, extending on a national scale a service that had been made available to the public in the former Kingdom of Sardinia as early as 1845. A Post Office Savings Bank was started in 1875 and now has over 10,000,000 accounts. The postal check service, which began in 1917, is also of considerable importance, carrying out almost 49,000,000 transactions in 1968. In addition to this range of financial services, the post office also acts as an agency for the payment of social security benefits such as state pensions and various other grants.

Railway conveyance for mails, authorized in 1865, has become the chief means of mail transport. Since 1965, however, the annual mileage on postal rail routes has declined, while the use of road transport and of air conveyance has been increasing. The rapid growth of airmail has resulted from the need to provide next-day delivery service between important cities like Milan and Palermo. Even the fastest surface transport takes over 36 hours for transits between north and south.

A program of mechanization and automation is being pursued, facilitated by the general cooperation of the public in using the postal routing code on letters and parcels.

Soviet Union. Since the establishment of the Soviet Union after the October Revolution of 1917, there has been a rapid development of postal services throughout Russia. In 1913 the country was served by only 7,618 official postal and telegraph establishments, four-fifths of which were concentrated in European Russia. In 1970 there were over 79,500 post offices, more than ten times the 1913 figure. The emphasis that has been placed on establishing an efficient postal structure in the Central Asian Republics is evident because postal establishments in these areas have increased over 30 or 40 times. It is also noteworthy that over 70 percent of the post offices are now to be found in rural areas, which were very badly served before 1917.

Central Asian postal service

Greatly improved postal facilities, in combination with the development of education and a high rate of economic growth, have fostered a remarkable increase in the volume of postal traffic. In 1913 the annual total of correspondence was 615,000,000 items; newspapers and magazines, 358,000,000; and parcels, 10,000,000. By 1970 letter post had risen to over 7,600,000,000, newspapers to 31,500,000,000, and parcels to 168,000,000.

To improve mail conveyance in such an extensive country—where the distance covered by postal routes is now almost 2,000,000 miles (3,218,690 kilometres)—greatly increased use of airmail is being made for the transport of both letter mail and newspapers. The amount airlifted has grown from 300,000 short tons (272,160 metric tons) in 1966 to over 350,000 short tons (317,510 metric tons) in 1969. There is also a road network covering over 500,000 miles (804,672 kilometres) and the fleet of postal vehicles exceeds 15,000.

An intensive mechanization program is being implemented, with particular emphasis on a high degree of automation and regulated mail flow at larger postal establishments. At smaller offices, appropriate mechanical aids for laborious and repetitive work are extensively employed. The money-order system has also been extensively automated, featuring a system of accounting machines and electronic computers to process and verify money order operations. Envelope and newspaper vending machines and automatic equipment for registered mail have been installed at offices serving the public.

China. The first use of a posthouse system was in China under the Chou dynasty (*c.* 1122–221 BC). A reference by Confucius in the late 6th century demonstrates that it was already renowned for its efficiency: "The influence of the righteous travels faster than a royal edict by post-station service."

Under the Han dynasty (206 BC–AD 220), posts were extended into conquered lands in Central Asia. Contacts were made with the Roman Empire, and Han historians observed that it maintained a postal system similar to that of China. It was not until the late 13th century, however, that Marco Polo revealed to Europe the scale and speed of the Chinese postal organization under the Mongol emperors. Nothing comparable to it existed in Europe at the time.

The system reached its peak under the Ch'ing dynasty (1644–1911). It was administered by the Post Station Department in Peking, and 16 regional directors supervised two complementary systems: a speedy mounted courier service along the five main routes of the empire, and an extensive network of foot runners. The mounted couriers regularly travelled up to 200 miles a day, occasionally attaining 270 miles on favourable terrain in North China. There were 1,600 posting stations, staffed by 70,000 men, using 40,000 horses. The annual cost in 1902 was estimated to be $3,000,000.

Postal system of the late Ch'ing dynasty

By this time, however, the Post Station Department was in decline; and in 1912 its functions were transferred to

an alternative state system, the Imperial Post, created in 1896. This service was organized on European lines. Unlike the Post Station system, the Imperial Post was not limited to official correspondence. It came into competition, therefore, with private letter-carrying companies, which had proliferated during the 19th century to serve the needs of the growing trading and business community for internal and overseas postal services. More than 300 such companies were registered in the treaty ports alone, with about 60 foreign post offices, maintained by Britain, the U.S., France, Germany, Japan, and Russia. The new state system gradually absorbed the business of the private companies, although the last was not closed until 1934. All foreign post offices had withdrawn by the end of 1922, following the establishment of efficient internal and international services by the Chinese Post Office, which joined the UPU in 1914.

Postal services were not greatly affected by the revolution that overthrew Imperial rule in 1911. Despite the incessant political disturbances that subsequently afflicted republican China, postal traffic and facilities expanded at a remarkable rate, as the Table demonstrates.

Postal Traffic and Facilities in Republican China

year	letter traffic (1,000,000)	post offices
1901	10.5	293
1911	117.0	957
1926	586.0	2,562
1946	1,039.0	3,162

Since the Communist occupation of mainland China in 1949, the postal service in Taiwan has grown rapidly. In 1969 it handled almost 500,000,000 items (compared with less than 30,000,000 in 1946); accordingly, extensive postal mechanization has been installed, including a complete mail-flow system in Taipei.

India. The earliest reference to an official postal system in India was made in the 14th century by the Arab traveller and historian Ibn Baṭṭūṭah, remarking upon the organized official service of mounted couriers and runners. The system was brought to its height during the 16th century under the great Mughal emperor Akbar, with a network of 2,000 miles of post roads.

Two centuries of political turmoil, without a strong central authority, destroyed this courier system. It was not until 1766 that an official post was re-established to serve a new ruling power, being made available for public use in 1774.

Establishment of the Indian Post Office

In 1837 the Imperial Post was established and granted a monopoly to provide efficient postal communications between the seat of government at Calcutta and the principal provincial towns. Within the provincial districts, a complementary local service was maintained. In 1854 the basis of the present Indian Post Office was established when these parallel systems were merged under a director general, and a uniform postage rate was introduced, a step of particular significance in so vast a country.

International postal relations developed rapidly after the establishment of a weekly steamer service between Bombay and England in 1867, with India becoming a member of the Universal Postal Union as early as 1876.

At the same time, the post office began to expand the range of services that it provided to the public: C.O.D. in 1877, an insured service in 1878, money orders in 1880, and savings bank in 1885.

Internal communications were improved to keep pace with the progress made in these other fields. The "bullock train"—the Indian equivalent of the mail coach—gave way to the growing network of railways. A regular travelling post office service was introduced in 1870, and the railway mail service still continues to carry the bulk of the mails, despite the development of airmail.

Although experiments with airmail conveyance started in 1911, a regular inland service did not begin until 1932. Rapid expansion followed in 1949. A complex night airmail network now connects 58 cities, carrying over 22 percent of the mail. Railways are likely to retain much of the traffic as a result of speedier train services.

More traditional forms of transport—the foot runner, horse, mule, camel, bullock cart, and bicycle—still help distribute mail to many of India's 567,338 villages. Over 50 percent of these now have a daily delivery of letters and over 90 percent enjoy at least a weekly delivery.

The number of post offices has been increased from 22,116 at independence (1947) to 105,433 in 1970.

Pakistan. Although Pakistan's existence as an independent sovereign state dates only from 1947, its postal history extends to the official postal systems established by Muslim emperors. Particularly noteworthy was the network of post relays at caravansaries (inns) established by the emperor Shēr Shāh Sūr in the early 16th century. Under British rule in 1852, the province of Sind had the distinction of being the first region in the subcontinent to adopt a uniform letter postage rate.

On becoming independent, Pakistan faced a particularly difficult problem of postal communications because its eastern and western regions were separated by 1,000 miles of Indian territory. The growth of civil aviation services and maritime links overcame the initial difficulty. In 1952 an airmail service was introduced between East and West Pakistan in which letters and postcards were carried without payment of any surcharge. This concessionary airmail system was extended to cover the internal mail service of both regions in 1959. The post office made use of the entire network of the national airline to connect 29 key points throughout the country. The service for printed paper and parcel mail was improved in 1962 by the introduction of direct sea-mail links between Karāchi and Chittagong.

Pakistan airmail service

Postal facilities were greatly expanded throughout the country, the number of post offices being increased from 7,550 in 1952 to a total of 14,200 in 1971. Door-to-door delivery of letters, parcels, and registered items by postmen has long been the standard practice in all towns and is almost universal in rural areas.

The post office is run on a commercial accounting basis but with strong emphasis on the public utility aspect. Postal traffic has grown rapidly. To improve its capacity to deal efficiently with the continuing growth, the postal administration has pursued a carefully considered and moderate policy of mechanization. At some of the busiest offices, machines designed to facilitate the acceptance of registered mail have been introduced. To speed up the handling of mail in sorting offices, electromechanical sorting machines were installed at Karāchi in West Pakistan and at Dacca (then in East Pakistan, now Bangladesh), in 1964 on an experimental basis. Another was installed at Lahore in 1966.

Japan. Although official and private systems of communications had existed in Japan from ancient times, it was not until 1870 that the creation of a comprehensive government-operated postal service was proposed. The idea was put forward by Hisoka Maejima, often called "the Father of the Post" in Japan. It was rapidly accepted by the government, which set up its own service between Tokyo and Osaka on April 20, 1871, extending it throughout the country in July 1872. In 1873 the postal service was proclaimed a monopoly and private courier systems were prohibited, a uniform postal tariff scale was adopted, and postage stamps and postcards were introduced. The first official overseas mail service was established in 1875 to the U.S. International postal relations expanded rapidly, and in 1877 Japan became a member of the Universal Postal Union.

Other landmarks were the introduction of a parcel post service in 1892, express delivery in 1911, airmail in 1929, and the achievement of a special accounting status on semicommercial lines in 1934.

A distinctive feature of the postal scene in Japan is the special New Year's Mail Service, introduced in 1900, which treats the vast number of New Year cards (now over 1,000,000,000) posted between December 15 and 31, separately from normal mail. They are retained at post offices so that all can be delivered together on January 1.

Postal traffic in Japan has been growing at a rate of over

5 percent per annum for several years; to keep pace, the department has greatly expanded the number of post offices; there is now a post office for every 5,000 inhabitants. Manpower expenses account for over 70 percent of the total costs of the postal service. Advanced statistical and work-measurement techniques are therefore employed in all sections of postal work to determine optimum staffing levels.

The shortage of manual labour and the growth in postal business resulting from the country's rapid economic development have also led to the adoption of an extensive mechanization policy. To facilitate this process, a postal code address system was introduced in July 1968. Automatic segregating or culling machines, facing and cancelling machines, and automatic postal code reader-sorters have been specially developed by Japanese firms for the postal department and have now been installed at major post offices throughout the country.

Japan's postal code address system

POSTAL SERVICES IN THE DEVELOPING COUNTRIES

The establishment of efficient and comprehensive postal systems in all developing countries is important on an international plane as well from the purely domestic viewpoint. International postal service depends for its successful maintenance and progressive improvement upon the effective cooperation of all member countries of the UPU.

The internal need for a good postal service is sufficient in itself, however, to justify a high priority. A country-wide network of post offices provides government with many points of contact with its people for implementing administrative programs in such fields as social security, taxation, and public information. When its facilities are properly used, the post office may also become one of the principal employers of labour in a country and help to promote economic growth through its need for buildings, vehicles, and equipment and as a major user of all transport services. The employment potential is evident from the fact that the percentage of the working population engaged in providing postal services is generally about five times as high in developed as in developing countries.

An efficient postal service, as well as promoting national cohesion, provides an essential infrastructure for the expansion of industry and commerce. Postal money transfer and savings services are particularly valuable in developing economies, where banking facilities are limited. In Ghana, for example, the postal savings bank balances are the equivalent of over 7 percent of the gross domestic product.

Postal administrations in developed countries have long appreciated the importance of collaborating in the improvement of postal services throughout the world. In fact, participation in postal technical assistance is an aim embodied in the constitution of the Universal Postal Union. In addition to fostering bilateral assistance between members, the UPU itself has, since 1964, taken part as a specialized agency in the United Nations Development Programme (UNDP). The Vienna Postal Congress of 1964 in particular gave a special impetus to UPU activities in this field.

In view of the rapid expansion of postal business in most developing countries, the training of staff is a most urgent need. The UPU's initial activity has, therefore, been largely devoted to this field: the needs of individual countries are evaluated by itinerant specialists employed by the International Bureau; expert aid is provided for the establishment of national training schools for postal workers and regional centres for middle-grade management staff, such as those set up in Abidjan, Bangkok, and Damascus. Special instructor-training courses are conducted in Britain and France, and seminars are held for higher grade officials, particularly in the developing regions. Specialist aid is also provided, however, to evaluate operational and organizational needs and subsequently to enlist UNDP assistance in meeting them. The missions of experts are thus directed either to the postal services in general or to a certain sector of postal activity. Some larger projects may include overall postal organization as well as postal training. An example is a large-scale project to establish a postal savings bank in Ethiopia and to strengthen the existing postal training school. Fellowships are awarded for overseas study of specialized subjects, such as international mails, philately, and, in particular, instructor training. Most fellowships are paid from UNDP resources, but many fellowships have also been financed by the UPU's own voluntary special fund. Since 1963 over $3,000,000 from multilateral sources has been spent on aid to some 80 recipient countries. Moreover, a considerable amount of aid is given directly by developed countries within the framework of their own bilateral technical assistance arrangements.

UPU's provision of specialist aid

In addition, attention may be called to the important role played by the Restricted Unions in regard to UPU technical assistance.

The necessity for technical cooperation on such an extensive and constantly growing scale is evident when worldwide disparities in standards of postal service are considered. On the average, there is one post office for every 7,000 of the world's population; but this figure cloaks a wide variation between European countries like Norway, Cyprus, and Portugal, with fewer than 1,000 people per post office, and Rwanda with over 300,000. There is a similar divergence in per capita postal traffic, in postal savings, and in other fields.

Many developing countries are not yet able to provide even the minimum scale of postal facilities warranted in their present circumstances. To underline the pressing need for improvement and to provide a yardstick for future progress, the UPU has adopted, for the second Development Decade, certain indicative planning objectives, among which are the following: (1) one post office, on average, to every 40 square kilometres (15 square miles) or 6,000 people; (2) widespread introduction of postal financial services; (3) next-day delivery of priority items within a 500-kilometre (310.68-mile) radius; (4) a progressive increase in the percentage of parcels conveyed by air in the international service. To draw particular attention to the dynamic function of postal services within the national infrastructure, the UPU has also published a valuable "Memorandum on the Role of the Post as a Factor in Economic and Social Development."

UPU planning objectives

THE INTERNATIONAL SYSTEM

International mail has a key role in furthering economic, social, and cultural links between nations. The international postal system is in itself an outstanding example of worldwide organization and mutual trust. A postal administration relies completely upon the postal authorities of other countries to play their parts in ensuring that its foreign mails reach their destination.

International cooperation in this field has been assured by the Universal Postal Union since 1875. It is now the most comprehensive of international organizations, with a membership of 143 comprising 136 sovereign states and seven groups of dependent territories (as of April 1, 1971). The few postal administrations that are not represented, notably that of mainland China, generally follow the rules of the UPU.

These fundamental rules of the international postal service are to be found in the Universal Postal Convention and have been little changed since they were set out in the treaty of Bern. The first basic principle is that all member countries form "a single postal territory for the reciprocal exchange of correspondence." From it is derived the principle of liberty of transit: every member country guaranteeing to respect the inviolability of transit mails, and to forward them by the most rapid transport used for its own mails.

Another important principle is the nonsharing of charges for letter-post items. Since 1875 each country has retained the postage it collects on international mail. Although intermediate countries are paid for transit service, the country in which the mail is delivered receives no payment. This principle was adopted in order to minimize the need for complex international accounts and was justified on the supposition that a letter normally generated a reply. Certain developing countries, however, have found themselves at a considerable disadvantage

under this rule, owing to an excessive imbalance between incoming and outgoing mail. To remedy this, the 1969 Congress of Tokyo has authorized payment to be made in such cases.

Provisions of the Universal Postal Convention

As a further measure of simplification, the convention fixes standard international postal rates, within a limited tolerance, and prescribes weight steps, limits of size, and conditions of acceptance for letter-post items. Disputes between postal administrations, which usually concern allocation of liability for the loss of registered or insured items, are to be settled by arbitration. The convention is completed by two other basic documents: (1) the Final Protocol, which allows member countries to register certain general and specific reservations to the provisions of the convention; and (2) the Detailed Regulations for Implementing the Universal Postal Convention. Apart from these obligatory documents, there are a number of optional agreements concerning supplementary services already mentioned earlier, such as parcel post and cash on delivery. The provision of a registration service is compulsory under the convention.

Mention must finally be made of the constitutive acts of the Union that prescribe its general aims, its organization, its financial structure, and the rules of membership, namely, the constitution and its general regulations.

This comprehensive framework of international regulations is regularly revised to take account of changing circumstances and technical advances. This is the chief function of the Union's quinquennial congress. Between congresses, the continuity of the Union's work is ensured by its elected Executive Council and its permanent office in Bern, the International Bureau. The latter acts as a clearing house for the settlement of international accounts and for the exchange of information between members, especially notifications of important operational and organizational changes. Problems arising in the technical, operational, and economic fields are studied by another permanent organ, the Consultative Committee for Postal Studies.

The UPU Constitution authorizes member countries to establish restricted unions, a provision that enables regional groups such as the Arab and the African Postal Union to conclude agreements aimed at improving postal services between their members by such means as reduced rates of postage or the elimination of transit fees. As such reforms are more easily achieved on a limited regional basis than on a worldwide scale, the restricted unions have a valuable role in the perennial task of the UPU, which is, basically, to improve international postal service by simplifying its organization and reducing its cost.

EMERGING POSTAL TECHNOLOGY

The post office and technological progress in transport. Postal administrations have been among the first to utilize new forms of transport. They have often applied considerable technical skill in maximizing the benefits to be derived from progress in this field, particularly in originating the travelling post office concept and apparatus enabling express trains to pick up and discharge mails without slackening speed. They have also developed their own transport systems to combat traffic congestion in certain busy cities, such as the pneumatic tube used in Paris, New York, and other cities and the automatic underground railway, opened in 1927, which links London's chief mail centres to railway termini.

Looking to the future, various postal administrations and private interests have conducted experiments in the use of rocket-propelled missiles as a means of mail transport. The rocket, however, cannot yet be considered a reliable and practical means of mail conveyance. In the same way, facsimile transmission, which eliminates physical conveyance altogether, is unlikely to prove a practicable general alternative to letters within the foreseeable future. Of more immediate significance for the future is a recent feasibility study into the bulk movement of all classes of mail by air.

Experiments with missilery

Automation of mail handling. During the last 15 years there has been a marked intensification of research and development effort toward applying technology to the handling of mails, especially in countries faced by manpower problems and higher labour costs. The wide variety of projects undertaken in many countries and the progress made have been summarized in several coordinated studies of different aspects of mechanization and automation by the UPU's Consultative Committee for Postal Studies (CCPS).

Actual implementation has generally been rather slower than expected. There have been good reasons for this. Primarily, most postal administrations, as government agencies, are subject to strict control of their capital investment programs. Secondly, mail traffic patterns—with marked peaks of work—make economic utilization of machines difficult: the introduction of measures to counteract this problem takes considerable time. Similarly, the introduction of postal-address codes and the standardization of sizes of envelopes and cards, which are prerequisites for mechanical handling, are relatively slow because of difficulties inherent in the change of procedures.

It is therefore still appropriate, so far as application is concerned, to consider postal technology as "emerging." The trend toward adopting public corporation status for the postal service should, however, alleviate the primary problem of a chronic shortage of capital for investment in comprehensive programs of postal automation.

Materials-handling equipment. Postal systems at present rely heavily on human labour for bulk materials handling and distribution, both at loading bays and between work processes within sorting centres. New mail centres, however, are normally built on factory lines to include all appropriate materials-handling equipment.

Equipment used for loading and unloading sacks of mail, rigid containers, and loose parcels includes mobile belt conveyors, roller conveyors, forklift trucks, mobile and fixed cranes, and table lifts. Handling equipment within buildings includes chain conveyors; horizontal and rising belt conveyors of all types, for the transport of loose letters, packets, and trays of letters (notably used for continuous clearance of public posting boxes); tow conveyors, which allow wheeled containers to be hooked on to a fixed-path underfloor traction system; bucket or pan elevators; and chutes and various other gravity-feed installations.

The use of a wide range of equipment is necessitated by the varied handling characteristics of different types of mail at particular stages. Buffer-storage facilities, in the form of ramps, hoppers, and moving belts, have to be incorporated to compensate for normal postal-traffic fluctuations. The smooth distribution of traffic through the system is often monitored by closed circuit television, which allows effective centralized control. Automatic regulation and recording, using a variety of sensing and counting devices linked to a computer, is the ideal. Modern systems-engineering techniques are thus able to ensure a carefully planned continuous mechanized mail flow with maximum productivity benefits.

Buffer-storage facilities

Segregating, or culling, machines. Mail collected from branch post offices and street letter boxes, although for the most part made up of ordinary letters and cards, also contains packets, newspapers, magazines, and large envelopes. These items, because of their size or shape, cannot be handled on machinery designed for the normal letter and have to be segregated from the majority of standard "machinable" letters. Owing to its varied characteristics, most packet mail has to be manually stamped and sorted, although its movement between work processes may be fully mechanized. So-called packet sorting machines are, in fact, essentially conveyor systems for distributing manually sorted mail.

A commonly adopted type of segregator consists of a laterally inclined rotating drum, into the upper end of which a regulated flow of "mixed" mail is fed from a storage conveyor. Letters within a thickness standard, but of excessive length or breadth, are picked out by various simple mechanical devices installed on the conveyor belt that eventually delivers machinable letters to the storage stacks of the facer–canceller equipment.

Facing and cancelling equipment. Facing is the process of aligning letters so that all will have the address side

facing the canceller, with stamps in a uniform position. The process is normally combined with a separation of the mail into at least two streams, letter and printed-paper rate or first and second class, to allow priority handling for one of the streams.

Facer–canceller machines perform these processes by passing letters through sensing or stamp-detecting units, which identify the presence or absence of a stamp on the side of the envelope facing them, and, when present, its position. Sensing units are also designed to separate mail in the priority class from nonpriority mail by identifying the stamp or commonly used combination of stamps representing the basic postage rate and manipulating selector gates accordingly. This identification is usually achieved by printing distinctive indexes on the stamps in normally invisible, phosphorescent or luminescent inks that are sensitive to ultraviolet radiation emitted by the sensing unit.

Coding and sorting machines. For manual sorting of letters, each operator normally uses a device with between 40 and 50 pigeonholes. This has been found by most administrations to be the optimum arrangement in view of the limited arm span and "memory" of the sorter. The development of various types of postal codes aimed at making the sorting of a coded letter a mechanical process for the operator by dispensing with the need to memorize a sorting plan. Unfortunately, public response to such coding schemes has not been enthusiastic.

For the past decade, therefore, many administrations have concentrated research on using an operator only to impress the postal code on each letter, employing phosphorescent or magnetic ink patterns that can be read by a sensing unit attached to a sorting machine. After the code has been impressed, the letter can be sorted at any subsequent stage by high-speed automatic machines, which are no longer utilized at the pace of a single operator and indeed can take the output of several operators. Furthermore, any second sortation required—even at an intermediate office or where the code includes the necessary information to postmen's routes at the delivery office—does not require further manual operations. Another potential advantage of this method is that letters may be directly encoded by the mail-processing machines used by large-volume mailers.

Optical character recognition. The ultimate aim in automated sorting is a machine that will be able to read certain elements of the address on letters. Research in this field is being carried on in the U.S., Great Britain, the U.S.S.R., Japan, Germany, France, Switzerland, Belgium, The Netherlands, and Australia. The immediate aims of these national research programs vary insofar as the type of character to be recognized is concerned: printed, typewritten, or addressographed characters; stylized handwritten scripts; and even ordinary handwriting. Also, some administrations require the machine to read a purely numeric code, others an alphanumeric code, and others the names of towns or regions. Several different techniques are used for the basic task of pattern matching in identifying the characters. For example, the observed character as a whole may be compared with matrices registered in the memory of the machine. Or the different traits of the character observed—vertical or horizontal strokes, curves, etc.—may be analyzed and their combination successively compared with a series of models registered by the computer.

A successful optical character reader (OCR) could be used either for the direct sorting of mail or for marking the mail with a machine-readable code so that sorting at subsequent stages could be carried out by high-speed automatic machines. The U.S. Post Office has had an alphanumeric optical character reader in operation on live mail since 1965. On the basis of field experience with this model and of technological advances in the computer industry since 1965, an improved Model II optical character reader is under development.

Numerical speech translator. One of the latest lines of research being pursued in the U.S. is the development of equipment that translates three-digit ZIP codes and sorting-code numbers spoken by an operator into instructions for a sorting machine. Since this system would obviate the need for a keyboard, it will leave the operator's hands free, making it particularly valuable in the operation of parcel and sack-sorting machines, where it will also eliminate the need for keyboard training of operators. The testing of the equipment includes determination of the effects of regional speech variations, background noise, and operator speech fatigue.

BIBLIOGRAPHY. Postal services are treated in official publications, such as legislative texts, manuals, working instructions, postal guides, annual reports, and commission reports; much of this material is available to the public. Many postal administrations publish periodical reviews or bulletins informing employees and users of recent events and trends. ROWLAND HILL, *Post Office Reform: Its Importance and Practicability*, 4th ed. (1838), is a work by an expert whose reforms affected subsequent worldwide postal development; G.B. HILL, *The Life of Sir Rowland Hill and the History of Penny Postage*, 2 vol. (1880), provides a fuller account of Sir Rowland's innovations. Detailed studies of specific postal service aspects are A.D. SMITH, *The Development of Rates of Postage* (1917); and A.D. LITTLE, *The Market for Postal Services* (1968). International mail services are treated in G.A. CODDING, *The Universal Postal Union* (1964); and L. ZILLIACUS, *Mail for the World* (1953), a popular treatment; both F. STAFF, *Transatlantic Mail* (1957), and H. ROBINSON, *Carrying British Mails Overseas* (1964), provide detailed treatment of the expansion of international mail conveyance.

General and historical literature includes: H. RACKOW *et al.*, *Handwörterbuch des Postwesens* (1953), a small but comprehensive encyclopaedia; *An Historical Summary of the Post Office* (HMSO 1911); I.G.J. HAMILTON, *An Outline of Postal History* (1910), including information on the history of postal service in India; and H. ROBINSON, *The British Post Office* (1948). Recent studies concerning the United States include: "Towards Postal Excellence," Kappel Commission Report (1968); C.H. SCHEELE, *A Short History of the Mail Service* (1970); and G. CULLINAN, *The Post Office Department* (1968); somewhat dated but still useful are: E.G. DANIEL, *United States Postal Service and Postal Policy* (1941); W. SMITH, *The History of the Post Office in British North America, 1639–1870* (1920); R.A. MCREYNOLDS, *History of the United States Postal Development, 1607–1931* (1937); A.E. SUMMERFIELD, *U.S. Mail: The Story of the U.S. Postal Service* (1960); and W.E. FULLER, *R.F.D.: The Changing Face of Rural America* (1964). The postal history of France is extensively described in E. VAILLE, *Histoire générale des postes françaises*, 6 vol. (1947–55), and *Histoire des postes françaises*, 2 vol. (1946–47). A current and anecdotal publication devoted to the postal system in the Federal Republic of Germany is S. ORTH, *Die Post* (1967). Postal services in developing countries are treated in UPU, *Memorandum on the Role of the Post as a Factor in Economic and Social Development* (1969).

The origins, development, and procedures of the Universal Postal Union are treated in G.A. CODDING, *The Universal Postal Union* (1964); see also the monthly review *Union Postale* (1875–), which is devoted to a wide range of questions concerning the UPU and various general aspects of postal activities.

H. SCHWAIGHOFER, *Postbetriebmechanik*, 2 vol. (1927), treats postal mechanization principles and practices; the *Collection of Postal Studies* (1950–), comprising some hundred UPU reports on postal service modernization, mechanization, economics, transport, and working methods, is available in French with much of the material also in English.

Pottery

Pottery in its widest sense includes all objects made from clay and hardened by fire: earthenware, stoneware, and porcelain. This article deals with pottery as art and craft, covering the kinds of pottery, the processes and techniques of forming and decorating it, and, finally, the history of pottery. Since the subject is so vast, the article will deal only with museum, or art, pottery. Artifacts used for purely utilitarian purposes will be discussed in articles such as AFRICAN PEOPLES, ARTS OF.

This article is divided into the following sections:

I. Kinds, processes, and techniques
  Kinds of pottery
  Forming processes and techniques
  Decorating processes and techniques
  Marking
II. Western pottery
  Ancient Near East and Egypt

Ancient Aegean and Greece
Etruscan and Roman
Islāmic
European: to the end of the 18th century
19th century
20th century
III. East Asian and Southeast Asian pottery
China
Korea
Japan
Thailand and Annam
IV. American Indian pottery
North America
Central America
South America

I. Kinds, processes, and techniques

KINDS OF POTTERY

Clay, the basic material of pottery, has two distinctive characteristics: it is plastic (*i.e.*, it can be molded and will retain the shape imposed upon it); and it hardens on firing to form a brittle but otherwise virtually indestructible material that is not attacked by any of the agents that corrode metals or organic materials. Firing also protects the clay body against the effects of water. If a sun-dried clay vessel is filled with water it will eventually collapse, but if it is heated, chemical changes that begin to take place at about 500° C (900° F) preclude a return to the plastic state no matter how much water is later in contact with it. Clay is refractory substance; it will vitrify only at temperatures of about 1,600° C (2,900° F). If it is mixed with a substance that will vitrify at a lower temperature (about 1,200° C, or 2,200° F) and the mixture is subjected to heat of this order, the clay will hold the object in shape while the other substance vitrifies. This forms a nonporous, opaque body known as stoneware. When feldspar or sooprock (steatite) is added to the clay and exposed to a temperature of from 1,200° C to 1,450° C (2,000° F to 2,650° F), the product becomes translucent and is known as porcelain. In this article, earthenware is used to denote all pottery substances that are not vitrified and are therefore slightly porous and coarser than vitrified materials.

The line of demarcation between the two classes of vitrified materials—stoneware and porcelain—is extremely vague. In the Western world, porcelain is usually defined as a translucent substance—when held to the light most porcelain does have this property—and stoneware is regarded as partially vitrified material that is not translucent. The Chinese, on the other hand, define porcelain as any ceramic material that will give a ringing tone when tapped. None of these definitions is completely satisfactory: for instance, some thinly potted stonewares are slightly translucent if they have been fired at a high temperature, whereas some heavily potted porcelains are opaque. Therefore the application of the terms is often a matter of personal preference and should be regarded as descriptive not definitive.

Earthenware. Earthenware was the first kind of pottery made, dating back about 9,000 years. In the 20th century, it is still widely used.

The earthenware body varies in colour from buff to dark red and from gray to black (see below *Firing*). The body can be covered or decorated with slip (a mixture of clay and water in a creamlike consistency, used for adhesive and casting as well as for decoration), with a clear glaze, or with an opaque tin glaze. Tin-glazed earthenware is usually called maiolica, faience, or delft (see below *Decorative glazing*). If the clear-glazed earthenware body is a cream colour, it is called creamware. Much of the commercial earthenware produced in the second half of the 20th century is heat- and cold-proof and can thus be used for cooking and freezing as well as for serving.

Stoneware. Stoneware is very hard and, although sometimes translucent, usually opaque. The colour of the body varies considerably; it can be red, brown, gray, white, or black.

Fine white stoneware was made in China as early as 1400 BC (Shang dynasty). In Korea, stoneware was first made during the Silla dynasty (57 BC–AD 935); in Japan, during the 13th century (Kamakura period). The first production of stoneware in Europe was in 16th-century Germany. When tea was first imported to Europe from China in the 17th century, each chest was accompanied by a red stoneware pot made at the I-hsing kilns in Kiangsu province. This ware was copied in Germany, the Netherlands, and England. At the end of the 17th century, English potters made a salt-glazed white stoneware that was regarded by them as a substitute for porcelain (see below *Decorative glazing*). In the 18th century, the Englishman Josiah Wedgwood made a black stoneware called basaltes and a white stoneware (coloured with metallic oxides) called jasper. A fine white stoneware, called Ironstone china, was introduced in England early in the 19th century. In the 20th century, stoneware is used mostly by artist-potters, such as Bernard Leach and his followers.

First porcelain

Porcelain. Porcelain was first made in a primitive form in China during the T'ang dynasty (AD 618–907). The kind most familiar in the West was not manufactured until the Yüan dynasty (AD 1279–1368). It was made from kaolin (white china clay) and petuntse (a feldspathic rock), the latter being ground to powder and mixed with the clay. During the firing, which took place at a temperature of about 1,450° C (2,650° F), the petuntse vitrified, while the refractory clay ensured that the vessel retained its shape.

In medieval times isolated specimens of Chinese porcelain found their way to Europe, where they were much prized, principally because of their translucency. European potters made numerous attempts to imitate them, and, since at that time there was no exact body of chemical and physical knowledge whereby the porcelain could be analyzed and then synthesized, experiments proceeded strictly by analogy. The only manufactured translucent substance then known was glass, and it was perhaps inevitable that glass made opaque with tin oxide (the German *Milchglas*, or milk glass, for example) should have been used as a substitute for porcelain. The nature of glass, however, made it impossible to shape it by any of the means used by the potter, and a mixture of clay and ground glass was eventually tried. Porcelain made in this way resembles that of the Chinese only superficially and is always termed soft, or artificial, porcelain. The date and place of the first attempt to make soft porcelain are debatable, but some Middle Eastern pottery of the 12th century was made from glaze material mixed with clay and is occasionally translucent (see below *Islāmic pottery: Egypt*). Much the same formula was employed with a measure of success in Florence about 1575 at workshops under the patronage of Duke Francesco de'Medici. No further attempts of any kind appear to have been made until the mid-17th century, when Claude and François Révérend, Paris importers of Dutch pottery, were granted a monopoly of porcelain manufacture in France. It is not known whether they succeeded in making it or not, but, certainly by the end of the 17th century, porcelain was being made in quantity, this time by a factory at Saint-Cloud, near Paris.

The secret of true, or hard, porcelain similar to that of China was not discovered until about 1707 in Saxony, when Ehrenfried Walter von Tschirnhaus, assisted by an alchemist called Johann Friedrich Böttger, substituted ground feldspathic rock for the ground glass in the soft porcelain formula. Soft porcelain, always regarded as a substitute for hard porcelain, was progressively discontinued because it was uneconomic; kiln wastage was excessive, occasionally rising to nine-tenths of the total.

Hard and soft porcelain

The terms soft and hard porcelain refer to the soft firing (about 1,200° C, or 2,200° F) necessary for the first, and the hard firing (about 1,450° C, or 2,650° F) necessary for the second. By coincidence they apply also to the physical properties of the two substances: for example, soft porcelain can be cut with a file, whereas hard porcelain cannot. This is sometimes used as a test for the nature of the body.

In the course of experiments in England during the 18th century, a type of soft porcelain was made in which bone ash (a calcium phosphate made by roasting the bones of cattle and grinding them to a fine powder) was added to the ground glass. Josiah Spode the Second later added this

bone ash to the true, hard porcelain formula, and the resulting body, known as bone china, has since become the standard English porcelain. Hard porcelain is strong, but its vitreous nature causes it to chip fairly easily and, unless especially treated, it is usually tinged slightly with blue or gray. Bone china is slightly easier to manufacture. It is strong, does not chip easily, and the bone ash confers an ivory-white appearance widely regarded as desirable. Generally, bone china is most popular for table services in England and the United States, while hard porcelain is preferred on the European continent.

FORMING PROCESSES AND TECHNIQUES

Preparation of material. Raw clay consists primarily of true clay particles and undecomposed feldspar mixed with other components of the igneous rocks from which it was derived, usually appreciable quantities of quartz and small quantities of mica, iron oxides, and other substances. The composition and thus the behaviour and plasticity of clays from different sources are therefore slightly different. Except for coarse earthenwares, which can be made from clay as it is found in the earth, pottery is made from special clays plus other materials mixed to achieve the desired results. The mixture is called the clay body, or batch.

To prepare the batch, the ingredients are combined with water and reduced to the desired degree of fineness. The surplus water is then removed.

Shaping the clay. The earliest vessels were modelled by hand, using the finger and thumb, a method employed still by the Japanese to make *raku* teabowls. Flat slabs of clay luted together (using clay slip as an adhesive) were employed to make square or oblong vessels, and the slabs could be formed into a cylinder and provided with a flat base by the same means. Coiled pottery was an early development. Long rolls of clay were coiled in a circle, layer upon layer, until the approximate shape had been attained; the walls of the vessel were then finished by scraping and smoothing. Some remarkably fine early pots were made in this way.

Introduction of the potter's wheel

It is impossible to say when the potter's wheel, which is a difficult tool and needs long apprenticeship, was introduced. A pot cannot be made by hand modelling or coiling without the potter either turning it or moving around it, and, as turning involves the least expenditure of human effort, it would obviously be preferred. The development of the slow, or hand-turned, wheel as an adjunct to pottery manufacture led eventually to the introduction of the kick wheel, rotated by foot, which became the potter's principal tool. The potter throws the clay onto a rapidly rotating disc and shapes his pot by manipulating it with both hands. This is a considerable feat of manual dexterity that leads to much greater exactness and symmetry of form. Perhaps the most skillful of all potters have been the Chinese. Excellent examples of their virtuosity are the double-gourd vases, made from the 16th century onward, which were turned in separate sections and afterward joined together. By the 18th century the wheel was no longer turned by the potter's foot but by small boys, and since the 19th century the motive power has been mechanical.

Jollying, or jiggering, is the mechanical adaptation of wheel throwing and is used where mass production or duplication of the same shape—particularly cups and plates—is required. The jolly, or jigger, was introduced during the 18th century. It is similar to the wheel in appearance except that the head consists of a plaster mold shaped like the inside of an object, such as a plate. As it revolves, the interior of the plate is shaped by pressing the clay against the head, while the exterior, including the footring, is shaped by a profile (a flat piece of metal cut to the contour of the underside of the plate) brought into contact with the clay. Machines that make both cups and plates automatically on this principle were introduced in the 20th century. Small parts, such as cup handles, are made separately by pressing clay into molds and are subsequently attached to the vessel by luting.

Molding

One of the earliest methods of shaping clay was molding. Pots were made by smearing clay around the inside of a basket or coarsely woven sack. The matrix was consumed during firing, leaving the finished pot with the impression of the weave on the exterior. A more advanced method, used by the Greeks and others, is to press the pottery body into molds of fired clay. Though the early molds were comparatively simple, they later became more complex, a tendency best seen in those molds used for the manufacture of pottery figures. The unglazed earthenware figures of Tanagra (Boeotia, central Greece) were first modelled by hand, then molds of whole figures were used, and finally the components—arms, legs, heads, and torsos—were all molded separately. The parts were often regarded as interchangeable, so that a variety of models could be constructed from a limited number of components. No improvement on this method of manufacture had been devised by the 20th century: the European porcelain factories make their figures in precisely the same way.

Plaster of paris molds were introduced into Staffordshire about 1745. They enabled vessels to be cast in slip, for when the slip was poured into the mold the plaster absorbed the water from it, thus leaving a layer of clay on the surface of the mold. When this layer had reached a sufficient strength and thickness, the surplus slip was poured off, the cast removed and fired, and the mold used again. This method is still in common use.

Drying, turning, and firing. Newly shaped articles were formerly allowed to dry slowly in the atmosphere. In 20th century pottery factories, this stage is speeded up by the introduction of automatic dryers, often in the form of hot, dry tunnels through which the ware passes on a conveyor belt.

Turning is the process of finishing the greenware (unfired ware) after it has dried to leather hardness. The technique is used to smooth and finish footrings on wheel-thrown wares or undercut places on molded or jiggered pieces. It is usually done on the potter's wheel or jigger as the ware revolves. Lathe turning, like most hand operations, was tending to disappear in the mid-20th century except on the more ornamental and expensive objects.

The firing process

The earliest vessels, which were sun-dried but not fired, could be used only for storing cereals and similar dry materials. If a sun-dried clay vessel is filled with water it absorbs the liquid, becomes very soft, and eventually collapses; but if it is heated, chemical changes that begin to take place at about 500° C (900° F) preclude a return to the plastic state.

After thorough drying, the pottery is fired in a kiln. In primitive pottery making, the objects were simply stacked in a shallow depression or hole in the ground, and a pyre of wood was built over them. Later, coal- or wood-fired ovens became almost universal. In the 20th century both gas and electricity are used as fuels. Many improvements have been made in the design of intermittent kilns, in which the ware is stacked when cold and then raised to the desired temperature. These kilns are extravagant of fuel, however, and are awkward to fill or empty if they have not had time to cool completely. For these reasons they are being replaced by continuous kilns, the most economical and successful of which is the tunnel kiln. The wares are conveyed slowly from a comparatively cool region at the entrance to the full heat in the centre. As they near the exit after firing, they cool gradually.

The atmosphere in the kiln at the time of firing, as well as the composition of the clay body, determines the colour of the fired earthenware pot. Iron is ubiquitous in earthenware clay, and under the usual firing conditions it oxidizes, giving a colour ranging from buff to dark red according to the amount present. In a reducing atmosphere (*i.e.*, one where a limited supply of air causes the presence of carbon monoxide) the iron gives a colour varying from gray to black, although a dark colour may also occur as a result of the action of smoke. Both of the colours that result from iron in the clay can be seen in the black-topped vases of predynastic Egypt.

DECORATING PROCESSES AND TECHNIQUES

Impressing and stamping. Even the earliest pottery was usually embellished in one way or another. One of

the earliest methods of decoration was impressing the raw clay. Finger marks were sometimes used, as well as impressions from rope (Japanese Jōmon ware of the 1st millennium BC) or from a beater bound with straw (used to shape the pot in conjunction with a pad held inside it). Basketwork patterns are found on pots molded over baskets and are sometimes imitated on pots made by other methods.

Relief decoration

The addition of separately modelled decoration, known as applied ornament (or appliqué), such as knops (ornamental knobs) or the reliefs on Wedgwood jasperware, came somewhat later. The earliest known examples are found on Mediterranean pottery made at the beginning of the 1st millennium. Raised designs are also produced by pressing out the wall of the vessel from inside, as in the Roman pottery known as terra sigillata, a technique that resembles the repoussé method adopted by metalworkers. Relief ornament was also executed—by the Etruscans, for example—by rolling a cylinder with the design recessed in intaglio over the soft clay, the principle being the same as that used to make Babylonian cylinder seals.

Incising, sgraffito, carving, and piercing. The most primitive kind of decoration is that which is incised into the raw clay with a pointed stick or with the thumbnail, chevrons (inverted v's) being a particularly common motif. Incised designs on a dark body are sometimes filled with lime, which effectively accents the decoration. Examples can be seen in some early work from Cyprus and in some comparatively modern work from primitive tribes. Decoration that has been engraved after firing is much less usual, but the skillful and accomplished engraving on one fine Egyptian pot of the predynastic period (*i.e.*, before *c.* 3100 BC) suggests that the practice may have been more frequent than was previously suspected.

Originally, defects of body colour suggested the use of slip, either white or coloured, as a wash over the vessel before firing. A common mode of decoration is to incise a pattern through the slip, revealing the differently coloured body beneath, a technique called sgraffito ("scratched"). Sgraffito ware was produced by Islāmic potters and became common throughout the Middle East. The 18th-century scratched-blue class of English white stoneware is decorated with sgraffito patterns usually touched with blue.

Sgraffito technique

Related to the sgraffito technique is slip carving: the clay body is covered with a thick coating of slip, which is carved out with a knife, leaving a raised design in slip (champlevé technique). Slip carving was done by Islāmic and Chinese potters (Sung dynasty).

Much pierced work—executed by piercing the thrown pot before firing—was done in China during the Ming dynasty (reign of Wan-li). It was sometimes called "demon's work" (*kuei kung*) because of the almost supernatural skill it was supposed to require. English white molded stoneware of the 18th century also has elaborate piercing.

Slip decorating. In addition to sgraffito and carving (see above *Impressing and stamping*), slip can be used for painting, trailing, combining, and inlay. The earliest forms of decoration in ancient Egypt, for example, were animal and scenic motifs painted in white slip on a red body; and in the North American Indian cultures coloured slips provided the material for much of the painted freehand decoration.

Slip, too, is sometimes dotted and trailed in much the same way as a confectioner decorates a cake with icing sugar; the English slipwares of the 17th and 18th centuries are typical of this kind of work. Earthenware washed over with a white slip and covered with a colourless glaze is sometimes difficult to distinguish from ware covered with a tin glaze (see below *Decorative glazing*). In consequence it has sometimes been wrongly called faience. The term for French earthenware covered with a transparent glaze (in imitation of Wedgwood's creamware) is *faience fine*, and in Germany it is called *Steingut*. *Mezza-Maiolica* (Italy) and *Halb fayence* (Germany) refer to slip-covered earthenware with incised decoration.

Slip is also used for combed wares. The marbled effect on Chinese pottery of the T'ang dynasty, for example, was sometimes achieved by mingling, with a comb, slips of contrasting colours after they had been put on the pot.

Combed wares and inlay

The Koreans used slip for their inlay technique called *mishima*. The designs were first incised into the clay, and the incisions were then filled with black and white slip.

Burnishing and polishing. When the clay used in early pottery was exceptionally fine, it was sometimes polished or burnished after firing. Such pottery—dating back to 6500 and 2000 BC—has been excavated in Turkey and the Pan-shan cemetery in Manchuria. Most Inca pottery is red polished ware.

Decorative glazing. Early fired earthenware vessels held water, but, because they were still slightly porous, the liquid percolated slowly to the outside where it evaporated, cooling the contents of the vessel. Thus, the porosity of earthenware was, and still is, sometimes an advantage in hot countries, and the principle is utilized in the 20th century in the construction of domestic milk and butter coolers and some food-storage cupboards.

Porosity, however, had many disadvantages—*e.g.*, the vessels could not be used for storing wine or milk. To overcome the porosity, primitive peoples often applied varnishes of one kind or another. Varnished pots were made, for example, in Fiji. The more advanced technique is glazing. The fired object was covered with a finely ground glass powder often suspended in water and was then fired again. During the firing the fine particles covering the surface fused into an amorphous, glasslike layer, sealing the pores of the clay body.

The art of glazing earthenware for decorative as well as practical purposes followed speedily upon its introduction. On stoneware, hard porcelain, and some soft porcelain, which are fired to the point of vitrification and are therefore nonporous, glazing is used solely for decoration.

Except for tin-glazed wares (see below *Painting*), earthenware glaze was added to the biscuit clay body, which was then fired a second time at a lower temperature. Soft porcelain glaze was always applied in this way. Hard porcelain glaze was usually (and stoneware salt glaze, always) fired at the same time as the raw clay body at the same high temperature.

Kinds of glazes

Basically, there are four principal kinds of glazes: feldspathic, lead, tin, and salt. (Modern technology has produced new glazes that fall into none of these categories while remaining a type of glass.) Feldspathic, lead, and salt glazes are transparent; tin glaze is an opaque white. Hard porcelain takes a feldspathic glaze, soft porcelain usually a kind of lead glaze and can be classified according to the kind of glaze used.

There are two main types of glazed earthenware: the one is covered with a transparent lead glaze, and the other with an opaque white tin glaze.

Tin glaze was no doubt employed in the first place to hide faults of colour in the body, for most clays contain a variable amount of iron that colours the body from buff to dark red. Tin-glazed wares look somewhat as though they have been covered with thick white paint. These wares are often referred to as "tin-enamelled." As noted above, other terms in common use are maiolica, faience, and delft. Unfortunately, these are variously defined by various authorities. The art of tin-glazing was discovered by the Assyrians, who used it to cover courses of decorated brickwork. It was revived in Mesopotamia about the 9th century AD and spread to Moorish Spain, whence it was conveyed to Italy by way of the island of Majorca, or Maiolica. In Italy, tin-glazed earthenware was called maiolica after the place where it was mistakenly thought to have originated. The wares of Italy, particularly those of Faenza, were much prized abroad, and early in the 16th century the technique was imitated in southern France. The term faience, which is applied to French tin-glazed ware, is undoubtedly derived from Faenza. Wares made in Germany, Spain, and Scandinavia are known by the same name. Early in the 17th century a flourishing industry for the manufacture of tin-glazed ware was established at the town of Delft, Holland, and Dutch potters brought the art of tin-glazing to England

together with the name of delft, which now applies to ware manufactured in The Netherlands and England. Some misleading uses of these terms include that of applying maiolica to wares made outside Italy but in the Italian style, and faience to Egyptian blue-glazed ware and certain kinds of Near Eastern earthenware.

Although glazed stoneware does not fall into such definite categories as glazed earthenware, to some extent it can be classified according to the kind of glaze used. The fine Chinese stonewares of the Sung dynasty (AD 960–1279) were covered with a glaze made from feldspar, the same vitrifiable material later used in both the body and glaze of porcelain. Stoneware covered with a lead glaze is sometimes seen, but perhaps the majority of extant glazed wares are salt-glazed. In this process a shovelful of common salt (sodium chloride) is thrown into the kiln when the temperature reaches its maximum. The salt splits into its components, the sodium combining with the silica in the clay to form a smear glaze of sodium silicate, the chlorine escaping through the kiln chimney. Salt glazes have a pitted appearance similar to that of orange peel. A little red lead is sometimes added to the salt, which gives the surface an appearance of being glazed by the more usual means.

Crazed and coloured glaze

Some fusion usually occurs between glaze and body, and it is therefore essential that both should shrink by the same proportion and at the same rate on cooling. If there is a discrepancy, the glaze will either develop a network of fine cracks or will peel off altogether. This crazing of the glaze was sometimes deliberately induced as a decorative device by the Chinese.

One method of applying colour to pottery is to add colouring oxides to the glaze itself. Coloured glazes have been widely used on earthenware, stoneware, and porcelain and have led to the development of special techniques in which patterns were incised, or outlined with clay threads (cloisonné technique), so that differently coloured glazes could be used in the same design without intermingling; for example, in the *lakabi* wares of the Middle East.

Unglazed wares

Earthenware, stoneware, and porcelain are all found in unglazed as well as glazed forms. Wares fired without a glaze are called biscuit. Early earthenware pottery, as discussed above, was unglazed and therefore slightly porous. Of the unglazed stonewares, the most familiar are the Chinese Ming dynasty teapots and similar wares from I-hsing in Kiangsu Province, the red stoneware body made at Meissen in Saxony during the first three decades of the 18th century and revived in modern times, and the ornamental basaltes and jaspers made by Josiah Wedgwood and Sons since the 18th century. Biscuit porcelain was introduced in Europe in the 18th century. It was largely confined to figures, most of which were made at the French factories of Vincennes and Sèvres. Unglazed porcelain must be perfect, for the flaws cannot be concealed with glaze or enamel. The fashion for porcelain biscuit was revived in the 19th century and called Parian ware.

Painting. Painted designs are an early development, some remarkably fine work made before 3000 BC coming from excavations at Ur and elsewhere in Mesopotamia, as well as urns from Pan-shan in Manchuria (Northeast Provinces) that date back to 2000 BC.

The earliest pottery colours appear to have been achieved by using slips stained with various metallic oxides (see above *Slip decoration*). At first these were undoubtedly oxides that occurred naturally in the clay; later they were added from other sources. Until the 19th century, when pottery colours began to be manufactured on an industrial scale, the oxides commonly used were those of tin, cobalt, copper, iron, manganese, and antimony. Tin oxide supplied a useful white, which was also used in making tin glaze (see above *Decorative glazing*) and occasionally for painting. Cobalt blue, ranging in colour from grayish blue to pure sapphire, was widely used in the Far East and Europe for blue-and-white porcelain wares. Cupric oxide gives a distinctive series of blues, cuprous oxide a series of greens, and, in the presence of an excess of carbon monoxide (which the Chinese achieved by throwing wet wood into the kiln), cupric oxide yields a bluish red. This particular colour is known as reduced copper, and the kiln is said to have a reducing atmosphere. (For the effect of this atmosphere on the colour of the biscuit body, see above *Firing*). The colours obtained from ferric iron range from pale yellow to black, the most important being a slightly orange red, referred to as iron red. Ferrous iron yields a green that can be seen at its best on Chinese celadon wares. Manganese gives colours varying from the bright red purple similar to permanganate of potash to a dark purplish brown that can be almost black. The aubergine purple of the Chinese was derived from this oxide. Antimony provides an excellent yellow.

Overglaze and underglaze colours

Pottery colours are used in two ways—under the glaze or over it. Overglaze painting is executed on a fired clay body covered with a fired glaze, underglaze painting, on a fired, unglazed body (which includes a body that has been coated with raw or unfired, glaze material).

Earthenware and stoneware are usually decorated with underglaze colours. After the body is manipulated into the desired shape it is fired. It is then painted, coated with glaze, and fired again. The second firing is at a lower temperature than the first, being just sufficient to fuse the glaze. In the case of most tin-glazed wares the fired object was first coated with the tin glaze, then painted, then fired again. The painting needed exceptional skill, since it was executed on the raw glaze and erasures were impossible. The addition of a transparent lead glaze over the painted decoration needed a third firing. In 18th-century Germany especially tin-glazed wares were decorated with colours applied over the fired glaze, as on porcelain. The wares were sometimes called *Fayence-Porcellaine*.

The body and glaze of most hard porcelain are fired in one operation, since the fusion temperature of body and glaze is roughly the same. Underglaze colours are limited because they must be fired at the same temperature as the body and glaze, which is so high that many colours would "fire away" and disappear. Although the Chinese made some use of copper red, underglaze painting on porcelain is more or less limited to cobalt blue, an extremely stable and reliable colour that yields satisfactory results under both high- and low-temperature firings. On soft porcelain, manganese was sometimes used under the glaze, but examples are rare. All other porcelain colours were painted over the fired glaze and fixed by a second firing that is much lower than the first.

Underglaze pigments are known as high-temperature colours, or colours of the grand feu. Similarly, overglaze colours are known as low-temperature colours, or colours of the petit feu. Other terms for overglaze colours are enamel colours and muffle colours, the latter name being derived from the type of kiln, known as a muffle kiln, in which they are fired. Overglaze colours consist of pigments mixed with glaze material suspended in a medium, such as gum arabic, with an alkaline flux added to lower the melting point below that of the glaze. They were first used in Persia on earthenware (*minai* painting) in the 12th century and perhaps at the same date on Chinese stoneware made at Tz'u-chou.

Lustre painting, gilding, and silvering

Lustre decoration is carried out by applying a colloid suspension of finely powdered gold, silver, platinum, or copper to the glazed and fired object. On a further, gentle firing, gold yields a purplish colour, silver a pale straw colour, platinum retains its natural hue, and copper varies from lemonish yellow to gold and rich brown. Lustre painting was invented by early Islāmic potters.

Pottery may be gilded or silvered. The earliest gilding was done with gold mixed with an oil base. The use of gold ground in honey may be seen on the finest porcelain from Sèvres during the 18th century, as well as on that from Chelsea. Toward the end of the same century gold was applied as an amalgam, the mercury subsequently being volatilized by heating. Silver was used occasionally for the same purposes as gold but with time has nearly always turned black through oxidation.

Transfer printing. The transfer print made from a copper plate was first used in England in the 18th century.

In the 20th century transfers from copper plates are in common use for commercial wares, as are lithographic and other processes, such as silk screen printing, which consists of rubbing the colour through a patterned screen of textile material. Combinations of hand-painted and transfer decorations are often used. The outline or other part of the decoration is put on with a transfer print, then parts of the design, such as leaves, flowers, clothing, or water, are painted in.

MARKING

Most porcelain and much earthenware bears marks or devices for the purpose of identification. Stonewares, apart from those of Wedgwood, are not so often marked. Chinese porcelain marks usually record the dynasty and the name of an emperor, but great caution is necessary before accepting them at their face value. The Chinese frequently used the mark of an earlier reign as a sign of veneration for the products of antiquity and, in recent times, for financial gain.

The majority of European factories adopted a device —for example, the well-known crossed swords of Meissen taken from the electoral arms of Saxony, or the royal monogram on Sèvres porcelain—but these, also, cannot be regarded as a guarantee of authenticity. Not only are false marks added to contemporary forgeries but the smaller 18th-century factories often copied the marks of their more august competitors. If 18th-century European porcelain is signed with the artist's name, it generally means that the painting was done outside the factory. Permission to sign factory work was rarely given.

On earthenware, a factory mark is much less usual than on porcelain. Workmen's marks of one kind or another are frequently seen, but signatures are rare. There are a few on Greek vases.

It is often desirable to identify the provenance and the date of manufacture of specimens of pottery as closely as possible. Not only does such information add to the interest of the specimen in question and increase understanding of the pottery art as a whole but it also often throws fresh light on historical questions or the social habits and technical skills of the time it was made. Since ceramics are not affected by any of the agents that attack metal, wood, or textiles, they are often found virtually unchanged after being buried for thousands of years, while other artifacts from the same period are partially or completely destroyed. For this reason archaeologists use pottery extensively; for example, to trace contacts between peoples, since vessels were often widely distributed in course of trade, either by the people who made them or by such maritime nations as the Phoenicians.

Archaeologists' use of pottery

Pottery making is not universal. It is rarely found among nomadic tribes, since potters must live within reach of their raw materials. Moreover, if there are gourds, skins, and similar natural materials that can be made into vessels without trouble, there is no incentive to make pottery. Yet pottery making is one of the most widespread and oldest of the crafts.

II. Western pottery

ANCIENT NEAR EAST AND EGYPT

Ancient Near East. In the early 1960s, excavations at a Neolithic settlement at Çatalhüyük, on the Anatolian Plateau of Turkey, revealed a variety of crude, soft earthenware estimated to be approximately 9,000 years old. A more advanced variety of handmade pottery, hard-fired and burnished, has proved to be as early as 6500 BC. The use of a red slip covering and molded ornament came a little later.

Handmade pottery has been found at Ur, in Mesopotamia, below the clay termed the Flood deposit. Immediately above the Flood deposit, and therefore dating from a time soon after the Flood (about 3000 BC), was wheel-made decorated pottery of a type usually called Al 'Ubaid. Perhaps the most richly decorated pottery of the Near East, remarkable for its fine painting, comes from Susa (Shushan) in southwest Iran. The motifs are partly geometric, partly stylized but easily recognizable representations of waterfowl and running dogs, usually in friezes. They are generally executed in dark colours on a light ground. Vases, bowls, bowls on feet, and goblets have been found, all dating from about 3200 BC. By 3000 BC pottery was no longer decorated. Earthenware statuettes belong to this period, and a vessel (in the Louvre, Paris) with a long spout based on a copper prototype is the ancestor of many much later variations from this region in both pottery and metal.

Remarkable glazed brick panels have been recovered from the ruins of Khorsabad (Dur Sharrukin), Nimrud (Calakh), Susa, and Babylon. They provide the first instance of the use of tin glaze; although the date of its introduction cannot be certainly determined. A well-known fragment from Nimrud in the British Museum belongs to about 890 BC, and by the 5th century BC extremely large friezes, one of them about 11 yards (10 metres) long, were being erected at Susa. The presence of lead in the blue glazes derived from copper suggests that the lead may have been added deliberately as a flux, and that this glazing technique, like that of tin-glazing, subsequently was forgotten—to be recovered only at a much later date.

First use of tin glaze

Ancient Egypt. In Egypt, pottery was made in great variety in the predynastic period (up to *c.* 3100 BC), and a hard-fired ware of good quality was attained. The earliest forms of decoration were geometrical or stylized animal or scenic motifs painted in white slip on a red body. There is comparatively little variation until the 26th dynasty (*c.* 664–525 BC), when clay was probably imported from Greece. Most artifacts are vessels of one kind or another, although pottery figures of variable quality were made, some of the later examples (after 500 BC) showing signs of Greek influence.

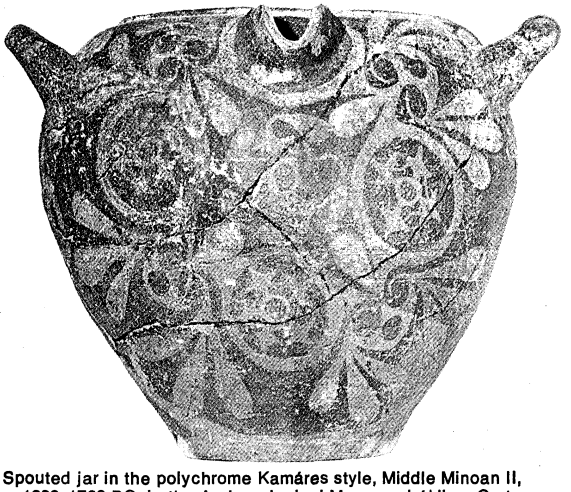
The so-called faience of Egypt is an unfired ware and thus, strictly speaking, falls outside the definition of pottery used in this article. As early as the 1st dynasty, figures, vases, and tiles of this material were covered with a fired glaze that was coloured turquoise and green with copper oxide. Later, the colouring materials common to the Egyptian glassmaker, including cobalt and manganese, were added.

ANCIENT AEGEAN AND GREECE

Neolithic period (c. 6000–3000 BC). The potter's art first reached the Aegean in the Neolithic, or New Stone Age. All Neolithic vases are handmade, and the best are highly polished; in other respects, the various local schools have little in common, since communications were severely limited in this remote period. The main centres of pottery production lay in Thessaly and Crete. Thessalian potters favoured a red monochrome ware but occasionally attempted simple painted decoration consisting of rectilinear patterns, with a vertical or diagonal emphasis. The Neolithic pottery of Crete is remarkable for its finely burnished surface, any decoration usually incised.

Early Bronze Age (c. 3000–2000 BC). On the mainland, the pottery initiative passed from Thessaly to the Peloponnese and Boeotia. Early Bronze Age pottery from these two areas has been classified into Early, Middle, and Late Helladic, each subdivided into stages I, II, and III. Early Helladic wares show how quickly pottery fell under the influence of the new craft of metalworking: the two leading shapes, the sauceboat and the high-spouted jug, both have metal prototypes. Painted ornament is rare before the final stage (Early Helladic III, or EH III); in the central phase (EH II), the surface is coated with a dark pigment formed from a solution of the clay. This type of paint, later much improved by the Athenians (see below *Attic black-figure and red-figure*), remained the normal medium of decoration on all Aegean pottery until the adoption of a true silicate glaze in Byzantine times.

The contemporary wares of the Cyclades are similar, but more use is made of incised ornament; spirals are common motifs, while some vases bear primitive representations of ships. The pottery of Early Minoan Crete bears simple geometrical patterns, at first in dark paint on a light clay ground (EM I–II), and subsequently in white



over a coat of dark paint (EM III). The surface of the ware of Vasilikí in eastern Crete (EM II) has a mottled red and black appearance. The commonest Early Minoan shapes are high-spouted jugs and long-spouted drinking jars resembling teapots.

Middle Bronze Age (c. 2000–1580 BC). After the conquest of the mainland by the first Greeks in the Middle Bronze Age, the local schools of pottery developed on widely different lines. The Minyan ware introduced by the newcomers in an unpainted monochrome body thrown on a fast wheel and fired in a reducing kiln to a uniform gray colour that penetrates the biscuit; the surface is then highly polished and feels soapy to the touch. The shapes are all strongly ridged (carinated) and probably derive from metalwork.

Equally characteristic of this period are the mat-painted wares, which are mainly handmade: here rectilinear patterns are applied in dull black or lilac to a porous white surface. This style, although native to the Cyclades, was also widely imitated on the mainland; in the latest stage the ornament falls increasingly under the influence of the polychrome and curvilinear style of Middle Minoan Crete.

Pottery of Crete

By far the most sophisticated pottery of this epoch was made in Crete, contemporaneously with the first palaces at Knossos and Phaistos. The finest ware (Middle Minoan II) is confined to these two royal capitals and to the Kamáres cave sanctuary whence the style derives its name. Over a dark lustrous ground the ornament is added in red and white, the carefully composed designs striking a subtle balance between curvilinear abstract patterns and stylized motifs derived from plant and marine life. The decoration sometimes takes the form of appliqué molded ornament or barbotine (made of slip) knobs. By the time of MM II the use of the fast wheel had become general, imparting a new crispness to the profiles. Among the commonest shapes are carinated cups (often of eggshell thinness), small, round jars with bridge-spouts, and large storage jars (pithoi). In the course of MM III the fashion for polychrome schemes gradually died out, but at the very end of the period (MM III B) a new naturalistic style was born, inspired by the floral and marine frescoes on the walls of the second palaces. The wide distribution of MM pottery illustrates the vigour of Cretan commercial enterprise; several Minoan emporia were founded in the Aegean Islands, while exports also reached Cyprus, Egypt, and the Levant.

Late Bronze Age (c. 1580–1100 BC). Aegean civilization now reached new heights of prosperity, displayed in the luxurious life of the Minoan palaces and the splendid treasures of the shaft graves at Mycenae. Potters were much influenced by work in richer and more spectacular media: many of their shapes can be traced to originals in gold and bronze found in Cretan palaces and Mycenaean tombs. Their decoration owes much to contemporary wall painting, although the motifs are always carefully adapted to the shape of the vase.

With the spread of Minoan culture around the shores of the Aegean, Cretan potters exercised a profound influence on the other local schools, and for the first two centuries of this period the vases of the mainland (known as Late Helladic or Mycenaean) are closely related to Minoan models. In the 16th century BC (LM I A), Cretan potters reversed their colour scheme, returning to dark-on-light decoration. Their repertoire includes some abstract motifs (*e.g.*, running spirals and vertical ripples) but is mainly derived from nature, a continuation of the figurative style of MM III B: flowers, grasses, and olive sprays are drawn with charm and spontaneity. After 1500 BC (LM I B) marine creatures are much in evidence, rendered with considerable realism: in a setting of coral and seaweed may be found argonauts, starfish, dolphins, and, above all, the octopus, wrapping his tentacles round the vase. On the palace style amphorae of the late 15th century BC (LM II), however, there is a reaction against this extreme naturalism: plants and marine life continue, but in a more stylized and symmetrical form.

After the destruction of Knossos in *c.* 1400 BC, the artistic initiative passed to Mycenae and remained there until the end of the Bronze Age. In the 14th and 13th centuries BC (LH III A and B), Mycenaen vases were widely exported, not only to Egypt and the Levant but also as far west as Italy and Sicily. In the interests of commerce, pottery was mass-produced, and the Mycenaean colonies on Rhodes and Cyprus were as prolific as the mainland. Some shapes, like the stirrup-vase, were imported for their contents of oil and unguents; others, such as the tall stemmed goblets, were prized for the excellence of their form. Yet, in spite of their high technical standards, the decoration shows a lack of invention. In the absence of any new ideas, the old floral and marine motifs were subjected to an ever-increasing degree of stylization: the flowers degenerate into chevrons and dashes, the octopus into wavy lines. At the same time there is a new tendency to concentrate the decoration into a single focal zone, in anticipation of later Greek pottery. A few large jars bear crude representations of human figures in chariot scenes, probably derived from palace frescoes. (No less schematic are the painted female figurines found in tombs and shrines of this period.) In the pottery of the 12th century BC, which saw the collapse of Mycenaean civilization (LH III C), there is an abrupt decline in quality as well as in artistic imagination.

Proto-geometric and geometric styles

Early Iron Age (c. 1100–c. 725 BC). Pottery was the first art to recover its standards after the Dorian invasion and the overthrow of Mycenae. Athens escaped these disasters and in the ensuing dark age became the chief source of ceramic ideas. For a short time Mycenaean motifs survived in debased form but on new shapes. This Submycenaean ware soon gave place to the style known as Protogeometric (*c.* 1100–900 BC) by a natural process of evolution that converted the decaying Mycenaean ornament into regular geometrical patterns; thus, the slovenly spirals were transformed into neat sets of concentric circles, always drawn with a compass fitted with a multiple brush. These circles are the hallmark of Protogeometric decoration, which, like the latest Mycenaean, is confined to the handle zone; in the final stage the rest of the surface is covered with a thick black paint remarkable for its high lustre. Many shapes were inherited from Submycenaean, but all were tautened and vastly improved: the drinking vessels rest on high conical feet, while the closed vases have graceful ovoid bodies. After its invention in Attica, the Protogeometric style spread to other parts of the Aegean world.

In the early 9th century BC Athenian potters introduced the full Geometric style by abandoning circular for rectilinear ornament, the key meander assuming the leading role. At first decoration was restricted to a small reserved area surrounded by the lustrous dark paint; later, as the style approached maturity, more decorated zones were added, until the potter achieved a harmonious balance

between light and dark. In the 8th century, after nearly 400 years of abstract decoration, living creatures appear once again, although their style is hardly less angular than the geometric ornament that supports them. Geometric pottery reached its fullest development in the gigantic amphorae and kraters that served as grave monuments in the Athenian Dipylon cemetery; here a funerary scene, showing the corpse on the bier surrounded by mourners, occupies the main panel, while other friezes contain chariot processions, battles on land and sea, rows of animals, and linear geometric designs. The creators of these monumental vases established a continuous tradition of figured painting that persisted on Greek pottery until the end of the Classical period; the immediate consequence of their innovation was a loss of interest in purely abstract design, which became increasingly perfunctory on the latest Geometric vases.

Period of Oriental influence (c. 725–c. 600 BC). After several centuries of isolation, the renewal of contact with the Near East provided a welcome stimulus to the Greek potter. In art, as well as in commerce, it was Corinth that now led the way. Unlike the Athenians, Corinthian potters specialized in small vases and especially in the tiny aryballos, or scent bottle, which found a ready market all around the Mediterranean. Hence arose the miniature style called Proto-Corinthian, which borrowed much of its repertoire from the fauna and flora of Syrophoenician art. Processions of animals, both real and legendary, are placed in the main friezes, while lotus flowers and palmettes serve as subsidiary ornament. When human beings appear, mythical scenes can often be recognized, reflecting the early diffusion of Homeric epic poetry. It was on Proto-Corinthian vases that the technique known as black-figure was first applied: the figures were first drawn in black silhouette and were then marked with incised detail; further touches were added in purple and white.

First use of black-figure technique

Other notable Orientalizing styles arose in Attica, the Cyclades, Laconia, and Rhodes, regional differences in pottery becoming more clearly marked as the Hellenic city-states grew into self-conscious political units. The Athenians still did their best work on large funerary vases. At first they cultivated a wild and grandiose manner in which the figures of men and animals were elaborated in outline; later, incised ornament introduced from Corinth imposed a salutary discipline. Cycladic potters also attempted the grand manner; Laconian work, on the other hand, is confined to a small scale and owes comparatively little to Oriental influence. The Rhodians rarely progressed beyond animal friezes drawn in outline; their style is known as "wild goat", after their favourite quadruped.

Attic black-figure and red-figure. *Archaic period (c. 750–c. 480 BC).* By *c.* 550 BC Athens had once again become the principal centre of pottery manufacture in Greece, having ousted its Corinthian rivals from the overseas markets. Its success is at least partially due to a sudden improvement in technique, for its potters had learned how to obtain the familiar orange-red surface of their vases by mixing a proportion of ruddle, or red ochre, with their clay. As the main medium of decoration, the Athenians perfected a shiny black pigment that was more lustrous than anything that had been hitherto achieved.

Difference between black- and red-figure techniques

In these centuries most of the more important vases were painted either in the black-figure or in the slightly later red-figure technique, so that some explanation of the essential difference is necessary. The red-figure style can be compared with a photographic print, the black-figure with a negative. The latter figures were painted in silhouette in glossy black pigment on the orange-red polished surface. Details were indicated by incised lines and by the occasional use of white and purple, the female figure, especially, being painted in white. Decoration on the red-figure vases was first outlined in black; the surface outside of the outline was then completely covered by the black pigment, leaving the figures reserved in red. Details were added in black, and in dilutions of the black pigment that appear as brown; purple is occasionally found at first but dies out in mature red-figure work. The use of white was revived on the gaudier vases of the 4th century, where yellow brown, gold, and even blue are sometimes used. The forms of Attic black- and red-figure, in the course of centuries, were limited to certain well-defined types, such as the amphora, kylix, krater, and hydria.

The practice of signing vases, already begun in the 7th century, became more common in the 6th. The signatures record either the potter or the painter or in some cases both. The inscription on the celebrated François vase in the Museo Archeologico in Florence—"Ergotimos made me; Kleitias painted me"—supplies the first positive evidence that, with only occasional exceptions, the two functions had become separate. When the name of a recognizable painter is not known from an inscription, it has become the fashion to name him after the potter with whom he usually worked: thus, the "Amasis painter" is the habitual colleague of Amasis the potter.

The Attic black-figure style was well developed by the beginning of the 6th century. Among the most favoured subjects were the labours of Hercules, Theseus, and the revels of Dionysus with his attendant train of satyrs and maenads. The finest Attic black-figure vases were made between 550 and 520 BC, the figures being rendered in a mature Archaic style much influenced by contemporary developments in sculpture. This is the generation of Exekias, the greatest master of the technique. He excelled in painting and in finely engraved detail; he also succeeded, where others had failed, in endowing his figures with mood and emotion, as well as the capacity for action. With Exekias the possibilities of black-figure were virtually exhausted, and after the introduction of red-figure (*c.* 530 BC) it is not surprising that the best artists soon turned to this new technique, which allowed a greater freedom of expression and more naturalistic treatment of the human body. After *c.* 500 BC the only important vases in black-figure are the amphoras presented to victors at the Panathenaic Festival; these have a figure of Athena standing between two pillars and are usually inscribed "I am one of the prizes from Athens."

Early red-figure artists

The early red-figure artists were not slow to exploit the advantages of the new system. Benefitting from the experience of relief sculptors, they had mastered the problems of foreshortening by the end of the 6th century; but since they still avoided any suggestion of depth in their grouping, they were able to convey the illusion of a third dimension without doing violence to the two-dimensional surface of the vase. The most successful work was done in the final years of the Archaic period (*c.* 500–*c.* 480 BC) when the style of the figures, with their formal and elaborate patterns of drapery, was still decorative rather than naturalistic. Monotony was avoided through the use of a

wide variety of poses and simple devices for rendering character and mood. Besides the old heroic and Dionysiac themes, many scenes from daily life (especially orgiastic banquets) were now being used.

Classical period (c. 480–c. 330 BC). This period saw a progressive decline in Attic vase painting. Because of the limitations imposed by the pot surface, the vase painter could no longer keep pace with the rapid advance toward naturalism in the major arts; the occasional attempts at perspective and depth of grouping simply detracted from the shape of the vessel (a mistake repeated in some painting on Italian maiolica in the late 16th century AD). Furthermore, in contrast with the earlier wares, much of the later Attic vase painting shows a saccharine sentimentality and triviality in both the choice of subject and its treatment. Distinguished exceptions are the funerary lekythoi of the late 5th century, decorated in subdued mat colours on a white background. The figures on these vases, isolated and statuesque, share the serenity and restraint of the Parthenon sculptures and suggest something of the grandeur of classical free painting, nearly all of which is now lost. In the 4th century, the figured decoration of pottery had become a degenerate art, and by *c.* 320 BC it had died out in Attica.

In addition to their black- and red-figure vases, the Athenians manufactured plain black-painted wares in great quantity; these follow the shapes of the figured pottery.

Hellenistic period (c. 330–c. 30 BC). After the end of red-figure, Greek pottery is undistinguished. Painted decoration is virtually limited to festoons of ivy, laurel, and a vine in white or yellow over a black ground; the black pigment loses its lustrous sheen and assumes a dull metallic texture. A class of hemispherical bowls, known as Megarian, was made in molds and bears relief decoration in imitation of metal bowls. More remarkable are the contemporary terra-cotta figurines; among the most accomplished are the draped women from Tanagra in Boeotia, whose artistic value is sometimes marred by excessive sentimentality.

ETRUSCAN AND ROMAN

Etruria. At the beginning of the Iron Age (*c.* 900 BC), the most characteristic vessel of the Villanovan culture is the cremation urn. It is usually biconical in shape but sometimes takes the form of a primitive hut, decorated with quasi-architectural ornament in relief.

The first pottery of importance is the Etruscan ware called *bucchero*, which was fired in a reducing kiln. The earliest examples of the 8th century BC, for which the wheel was rarely used, were decorated with incised or engraved geometric patterns. By the 6th century lively and stylized birds and animals were engraved, modelled, or applied in friezes or in conjunction with such geometric patterns as re-entrant (coiling inward) spirals. Later, relief ornament was often executed by rolling a cylinder with design recessed in intaglio over the soft clay, the principle being the same as that used to make Babylonian cylinder seals. Vases with covers in the form of a human head, with arms slipped through fixed ring handles, were made for funerary purposes until about the mid-6th century.

In the late Archaic period the Etruscans excelled in life-size terra-cotta sculptures, of which the outstanding examples are the menacing figure of Apollo, from his temple at Veii, and the large sarcophagi from Caere, with couples of banqueters reclining on the lid. Figures, heads, and busts continued to be produced in the Hellenistic period.

Greek influence

Proto-Corinthian ware was copied with great exactness by Greek colonists as early as 700 BC at Cumae, near Naples. The Etruscans soon learned to use the Greek black pigment, and stylized human and animal figures appear in red, black, and white on a light clay or on the *bucchero* surface. Copies of the black-figure vases were soon so accomplished that it is not always easy to tell exactly where a specimen was made. The red-figure class, however, is rarely difficult to separate from Greek work. The decoration is much more complex and elaborate, and the reverse is often carelessly executed. (Long after the red-figure style had fallen into disuse in Greece, it lingered on in Italy, particularly in the south.)

Roman Empire. The characteristic and most widely dispersed type of pottery of the Roman Empire was the red, polished Arretine ware, so called because manufacture was at first concentrated at Arretium (modern Arezzo). It is sometimes also misleadingly termed Samian ware, from a supposed connection with the island of Samos. The body was generally formed in a mold and was frequently decorated with raised designs. These were

achieved by using a mold that had itself been impressed with several stamps arranged in the desired pattern. This decorative technique—which gave the ware yet another name, terra sigillata (clay impressed with designs)—was borrowed from metalwork. The patterns, too, were often influenced by metalwork and include floral and foliate motifs, mythological scenes, and scenes from daily life. The potteries at Arretium, which were organized on factory lines, operated between about 30 BC and AD 30. Their products were highly prized and widely exported.

Lead glazing perhaps originated or was rediscovered (the Assyrians having used it) in Egypt. Certainly it was established in the Near East by the 1st century BC. The glazes were generally stained with copper to yield a greenish colour and were sometimes used over relief decoration which, like the designs on Arrentine ware, betrays the influence of metalwork. The technique reached Italy and France by the 1st century AD.

Of the other varieties of Roman pottery, lamps made either in a buff or a dark gray clay are exceptionally common and usually have an impressed or molded design. A few depicting Christian motifs or gladiatorial combats are prized a little more highly than most specimens, but, generally, they are of little value, monetarily or otherwise. Molded terra-cotta plaques with reliefs of mythological and other subjects borrowed from Greece were often used to decorate buildings.

ISLAMIC

Influence of Islāmic pottery on Europe

In quality, the Islāmic pottery of Syria, Egypt, Mesopotamia, Persia, Afghanistan, and Anatolia rivals even the wares of the Far East, and its influence on the development of European pottery was more profound than that of any other region except China. In China, too, Islāmic innovations were adopted, while the Islāmic potter, in his turn, owes an incalculable debt to the Chinese.

Near and Middle Eastern pottery was at its best between the 9th and 13th centuries, and its history is closely linked to the fortunes of the caliphate (the dominion of the temporal and spiritual head of Islām). Each dynasty was surrounded in its capital by a wealthy and beauty-loving court that patronized artists and artisans. When one dynasty fell and another established itself elsewhere, it seems that the finest potters emigrated to the new capital, carrying with them their special, and often secret, skills. At first the principal centres of manufacture were Baghdad, al-Fusṭāṭ (old Cairo), and Samarkand; later they shifted to Raqqah on the Euphrates and to Rāy (Rhagae) and Kāshān, both in northern Iran.

Most of the extant pottery has been excavated and consequently is fragmentary. Little made before the 14th century has survived above ground; and tombs, often rich depositories of undamaged wares in other regions of the world, are fruitless because Muslims did not bury pottery with their dead. Only one or two discoveries of undamaged wares have been made: for example, at Gurgan, Iran, entire specimens were found carefully packed in large earthenware jars. They had probably formed part of the stock of merchants, who buried them and fled before the invading Mongols in 1221. Because of deterioration through burial, much Islāmic pottery (like Roman and Near Eastern glass) is iridescent.

Umayyad. There is little pottery of merit from the period of the Umayyad caliphate (661–750). At this time the capital was at Damascus, and the chief interest of the pottery lies in its mingled Mediterranean and Middle Eastern derivation; for example, attempts were made to synthesize the formal repetitive style derived from the ancient Babylonian and Assyrian civilizations with naturalistic ornament in the Greco-Roman style. When the ʿAbbāsids overthrew the Umayyads and moved the capital to Baghdad, the European influence on ornament waned. Good use continued to be made of Western techniques, however, particularly of lead glazes that had been employed by Greek and Roman potters since the 3rd century BC.

ʿAbbāsid. An event that had a profound effect on the development of the Middle Eastern pottery was the presentation of a number of T'ang porcelain bowls to the caliph Hārūn ar-Rashīd about AD 800 (see below *China: T'ang dynasty*). Shortly after this, the first fine pottery was produced in Baghdad and elsewhere in the caliphate. Thus, it seems possible that it was through the example of the Chinese that pottery came to be regarded as an artistic medium instead of a purely utilitarian one. This supposition is borne out by the fact that T'ang wares were in great demand and were imported in large quantities after this date: they and early Islāmic imitations, particularly of the dappled T'ang glazes, have been found in various parts of Mesopotamia and as far apart as Egypt and eastern Persia. Unlike their contemporaries in China, however, Islāmic potters aimed primarily at richness of colour and decoration rather than beautiful shapes and textures. Nearly all their pottery is glazed and is painted with elegant, rather stylized motifs. Floral and foliate ornaments predominate, although complex geometrical patterns are also characteristic. In theory there was a religious ban, formulated in the Ḥadīth (traditions of the Prophet), on all representations of animal life, which were thought to encourage idolatry. In practice, particularly in Persia, the limitation was often disregarded except in the decoration of mosques. The animal figures on pottery are spirited and rhythmical, while the human ones tend to be stiff, resembling those in contemporary miniatures. Arabic calligraphy was commonly and effectively used as an element of design.

Islāmic technical innovations

The Islāmic potters were responsible for a number of important technical innovations, the most influential of which was the rediscovery of tin glaze in the 9th century AD. Though tin was first used by the Assyrians and according to some authorities was discovered as early as 1100 BC, it had fallen into disuse. The ʿAbbāsid potters first used it in an attempt to imitate the texture of T'ang wares, but soon it became the vehicle for characteristically Middle Eastern decoration. From Mesopotamia and Persia the technique was later taken to Moorish Spain and then to Italy and other parts of Europe, where it was employed for a number of important wares—maiolica, faience, and delft (see below *European: to the end of the 18th century*).

Like that of tin glazing, the technique of lustre painting was perfected (and probably invented) by Islāmic potters. Again, like tin-glazing, it later passed to Muslim Spain but not to the Far East. Lustre on pottery probably was first used to cover entire vessels, thus simulating vessels made of precious metals that were proscribed by sumptuary laws laid down in the Ḥadīth, which sought to preserve the earlier simplicity of Muslim life. The metallic pigments employed in lustre painting were probably silver and copper in combination, although an occasional ruby glint suggests that gold may sometimes have been included. After firing, the painting may be dull yellow, golden brown, or olive, tinged with green or red.

Extensive use was made of slip. Wares such as the early Gabrī type of the 11th century and later have a reddish body washed over with white slip. Designs were executed by scratching through the slip to the body beneath (sgraffito). On some later specimens the background was cut away to leave a raised design in white slip or the design was incised through the white slip, as in the earlier specimens, and then was itself covered with green and brown glazes. The usual motifs are large floral forms, animals, and bold inscriptions. Sgraffito ware became common throughout the Middle East and appears in Egypt and Syria in the 13th century.

Many fragments of Chinese pottery and porcelain have been found at the site of Sāmarrāʾ, on the Tigris, where the ʿAbbāsids built their summer palaces in the 9th century (see below *China: T'ang dynasty*). Among the native wares are some made in a buff body decorated in relief under a green glaze; others with monochrome green, white, and yellow glazes or with glazes in imitation of a well-known type of T'ang decoration; and those painted with cobalt blue (perhaps the earliest use of underglaze blue) and further embellished with lustre of various colours.

Sāmānid. To the northeast, beyond the Oxus (modern Amu Darya) River, the Sāmānid dynasty (874–999) be-

came practically independent of the caliphate at Baghdad and fostered a national artistic and literary revival. Sāmānid pottery, which has been found chiefly at Samarkand and Nīshāpūr, differs from the pottery of more westerly regions in technique and style. The best pieces have a reddish body covered with a white, vivid red-brown, or purplish-black slip that was then painted and fired under a lead glaze. The function of the slip, besides providing colour, was to prevent the pigments of the painting from running when the lead glaze was applied. The colours used in painting were the same as those of the slips, with the addition of yellowish green and browns. The designs often consist of the angular Arabic Kūfic characters or stylized birds and floral motifs. The shapes are plain—usually either plates or rather shallow bowls—and the total effect is both bold and elegant.

Egyptian. Egyptian pottery of the Islāmic period was at its best during the Fāṭimid dynasty (969–1171). Wares were at first coarser than those of Mesopotamia because of the poor quality of local materials, and the shapes were less refined, since Chinese influence was absent. Lustre painting (probably introduced in mid-10th century) was nevertheless, excellent in quality. A typical feature is the painting on the backs of dishes, a practice derived from Baghdad and later copied by the Moorish potters of Spain. Signed specimens of lustre ware and tin-glazed wares are known, the best coming from a potter named Sa'd.

Painting on the backs of dishes

Toward the end of the period a much whiter type of ware, with a compact body, came into use and thereafter became common throughout the Middle East. Another widespread group of wares, popular until the 14th century, has decoration carved and incised into the body and is covered with transparent glazes. The patterns suggest the influence of some of the Sung wares of China.

Mesopotamia and Persia, 11th to 15th century. In the 11th century the Seljuq Turks overran Persia and Mesopotamia, and their ascendancy lasted until the advent of the Mongols during the 13th century. As the Seljuqs had no capital, the most flourishing cities during this time were those on the trade routes. In the 12th century very fine pottery was made in the new white body recently developed in Egypt; it was decorated with bold carving, occasional piercing, and translucent glaze. Most of these wares are said to have been found at Rāy near Teheran, where many other beautiful wares have been excavated. Wares with a sandy body and a clear glaze were painted with a golden-brown lustre, often in conjunction with blue. These seem not to have been made after the city was sacked by Genghis Khan in 1220. Especially associated with Rāy are examples of *minai* painting of uncommon quality. The *minai* technique, a Persian discovery of the 12th century, was a method of decoration in which colours were painted onto a glazed and fired bowl and then fixed by refiring the bowl at a comparatively low temperature. The advantage of the process was that many colours that would not have withstood the heat of the first firing could now be used. The technique may perhaps have influenced the rare examples of overglaze decoration on late Sung or Yüan wares from Tz'u-chou, although it did not come into common use in China until the early part of the 15th century (see below *China: Ming Dynasty*).

At Rāy the glaze is cream or turquoise, and the *minai* palette included blue, turquoise, purple, red, green, and white, with the addition of gold leaf. All these colours, except the blue, are mat in appearance, and the style strongly recalls that of Persian manuscript illumination of the 13th century.

Another technique employed at Rāy was the use of silhouette decoration, a kind of sgraffito. The pot was covered with a thick black or blue and black slip, and the design was carved out with a knife. The glazes were applied without colour or stained with copper to yield a brilliant turquoise.

Raqqah was a prosperous trading city until it was sacked by the Mongols in 1259. Most of its pottery, which can be dated between the 9th and 14th centuries, is rougher and the designs bolder than those of Rāy. The body is white, inclining to buff, and is covered with a siliceous glaze. Some of the Raqqah fragments are painted with a brownish lustre. Others have designs in relief, sometimes covered with an opaque turquoise glaze or with a bluish-green translucent glaze. In the 12th and early 13th centuries bold designs were executed in black under pale-blue glazes and, more frequently, in blue and black under a clear glaze. Occasionally the glazes were stained purple with manganese.

Kāshān tiles

Kāshān is chiefly famous for its tiles, in fact the words *kāshī* or *kāshānī* ("of Kashan"), are commonly used as synonyms for tile (and have been incorrectly applied to tilework from India). Lustre-painted tiles had been made since at least the 9th century and were used mostly on the walls of mosques and public buildings. Those of Kāshān, particularly in the 13th and 14th centuries, are distinguished by their fine workmanship, brilliance, and intricacy of design. In shape they are square, rectangular, or of interlocking cross or star shapes, each carrying a small part of the total design. The relief inscriptions are frequently picked out with blue pigment.

Also associated with Kāshān are the *lakabi* ("painted") wares made in the 12th century. The term, a misnomer, refers to a variation of the sgraffito silhouette technique mentioned above: an incised design was decorated with different coloured glazes (blue, yellow, purple, and green), which were kept apart by intervening threads of clay. Although a number of *lakabi* wares were also made at Raqqah, the technique was soon abandoned at both places, as the glazes always tended to run out of their compartments during firing, giving a smudged effect.

Both the original site of Solṭānābād and the nature of the wares that may have been made there are extremely uncertain. Principally associated with it are wares decorated with relief molding under a turquoise or dark-blue glaze or painted in black slip under a clear turquoise glaze. They date from the second half of the 13th century onward. Toward the end of the 12th century the glaze material was frequently mixed with the white-burning clay then in use. In the more highly fired specimens the product is not unlike a primitive soft porcelain, and occasional specimens are slightly translucent. These wares probably inspired the attempts to make porcelain at Florence (see below *European pottery to the end of the 18th century*). Neither stoneware nor true porcelain was ever made in Persia.

Persian tankard with decoration cut through a black slip and covered with a turquoise glaze, 12th century, found at Soltānābād (modern Arāk, Iran). In the Victoria and Albert Museum. Height 12.7 cm.

After the Mongol conquests of the 13th century the production of pottery practically ceased, except at Kāshān. A slow revival began about 1295, and, although pottery in the Near and Middle East never again reached its former height, some fine wares were made at Solṭānābād in the 14th century. Good use was made of the rich sombre colours beloved by the Mongols, particularly dark blues, grays, and blacks.

Later Persian. Since the whole of Central Asia now lay under the Mongol domination, overland trade with

China greatly increased. By the 15th century Chinese influence, particularly that of Ming blue-and-white, was predominant, and the older styles were tending to die out (see below *China*: *Ming dynasty*). A group of blue-and-white wares belonging to the 15th and early 16th century are known as Kubachi wares because large numbers of them survived above ground in this town in the Caucasus. They have a very soft body, a brilliant crackled glaze, and rhythmical and spontaneous designs. The later Kubachi blue-and-white is closer to the Chinese originals.

Polychrome appears about 1550, and the palette includes a red related to, though lighter than, the Armenian bole introduced about the same time in Turkey (see below *Turkish pottery*). The best polychrome painting was done on tiles. Tabriz has been suggested as the real centre of manufacture, but although it seems likely that Tabriz was a manufacturing town in view of its tiled mosques and the fact that Tabriz potters were famous abroad (and indeed were either invited or carried off to Turkey on two occasions), no kiln sites have been found there.

One of the later kiln sites in Persia is Kerman, which was the leading pottery centre in the 17th century. Its wares are characterized by a very strong bright blue and a wavy, rather bubbly, glaze. Pseudo-Chinese marks were frequently added to the blue and white. The most usual colours on Kerman polychrome wares are blue, green, browns, and a bright red similar to Armenian bole. The quality of production declined considerably during the 18th century.

Lustre painting

Lustre painting, which had almost ceased in the 13th century, was revived during the second half of the 17th century and perhaps lasted into the 18th century. Its place of manufacture is not known. Most of the objects decorated in this manner are small bottles or spittoons, and their cramped designs are timid and fussy. The lustre is warm brown, often with a strong red tinge, and was sometimes used in conjunction with blue glaze. Another early technique revived at the same time was piercing, formerly practiced in the Seljuq era. There are a number of delicate pierced white wares covered with a colourless glaze, which were imitated in China during the reign of Ch'ien-lung. Pierced pottery and porcelain of this kind was often known in Europe as Gombroon ware, the name of the port (now Bandar ʿAbbās) from whence it was shipped.

Chinese celadon was imitated, not very successfully, from the 14th century. In the 16th century other monochrome glazes were produced at Kerman and elsewhere. These and the celadon were frequently decorated with painted or incised ornament—the former a practice quite foreign to Chinese Sung dynasty wares.

During the 18th century most of the pottery produced in Persia was inferior blue-and-white. In the 19th century the standard declined still further with the adoption of the Chinese-inspired *famille rose* palette (see below *China*: *Ch'ing dynasty*), and only a group of wares made at Teheran between 1860 and 1890 can command any respect. Some excellent peasant pottery with a buff body and lead glaze was made in Turkistan, however.

Syrian. The potters from al-Fusṭāṭ and Raqqah may have migrated to Damascus after their potteries were destroyed by the Mongols, for lustre painting continued in Syria throughout the 13th and 14th centuries after it had ceased elsewhere in the Middle East. The lustre ranges in colour from silver to yellow and dull brown and is often used in conjunction with a blue glaze on big, heavy jars and albarellos (a jar with an incurving waist, used for dry drugs and ointments). Characteristic are gold designs arranged in panels with much use of inscriptions and heraldic devices. The body material is coarse and grayish, and the glaze sometimes has a wide crackle. Lustre painting fell into disuse in Syria about 1400 and might have died out altogether had not the secret meantime been carried from Egypt to Spain (see below *European pottery to the end of the 18th century*). The commonest type of Syrian pottery in the 14th century is a blue-and-black style similar in shape and design to the lustre ware. Rather uncertainly drawn animals appear on some of the vessels.

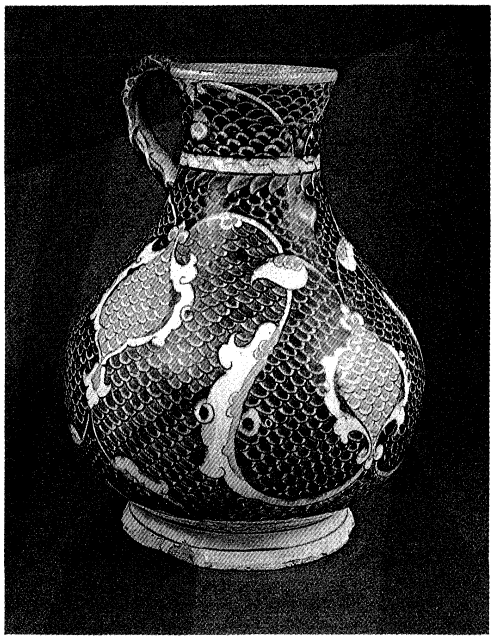
The earliest known Middle Eastern copies of Chinese blue-and-white were made in Syria at the end of the 14th century. Blue-and-white became commoner on both vessels and tiles in the first half of the next century. Later, the potteries seem to have fallen into disuse until the new mosque built in Damascus by the Turkish ruler Süleyman I (the Magnificent) in the mid-16th century provided a fresh impetus for the industry. The polychrome tiles of the 16th century at first have designs with a hard black outline; later, a more flowing foliate style was developed. A soft purple replaces the Armenian bole of Iznik (see below *Turkish pottery*). Vessels and tiles, gradually declining in quality, continued to be made in Damascus until the end of the 18th century.

Turkish. A branch of the Seljuq Turks occupied Anatolia from 1078 to 1300 and was succeeded by the Ottoman Turks, who first extended their lands westward, conquering Byzantium in 1453 and in the 16th century becoming masters of much of southeastern Europe and the lands lying to the east and south of the Mediterranean. The first notable pottery wares from Turkish lands were the tiles and bricks covered with coloured glazes made in Anatolia for architectural purposes in the 13th century. Mosques in particular were decorated in this way. (Persian influence in decoration suggests the presence of potters from that region.) The art of tilework apparently died out after 1300 and was not reintroduced until about 1415, when Persian craftsmen were brought from Tabriz to decorate the mosques at Bursa and Edirne. Apart from tilework, pottery appears to have received little encouragement until the late 15th century, by which time the chief centre of production was firmly established at İznik (earlier called Nicaea).

The great era of Turkish pottery

The great era of Turkish pottery (*c.* 1500–*c.* 1580) coincides with the expansion of Ottoman power. Decoration was at first influenced by 15th-century Ming blue-and-white porcelain. The earlier designs were probably taken at second hand from Persian sources, since a distinctly Persian flavour is usually evident. This is indicated by the intricacy of the designs and their arrangement in bands, and by the shapes of some of the vessels, which suggest the influence of metalwork. At one time the wares in this style, which lasted until about 1525, were thought to come from Kütahya in central Anatolia and are still sometimes known by that name.

At this and later periods the body of Iznik pottery was soft and sandy. It was made from grayish-white clay covered with a thin slip that was usually white, although occasionally red or blue was used as a ground on later wares. Decoration was carried out in underglaze colours under a transparent siliceous glaze. The commonest shapes are flat dishes, but jugs, dishes with a high foot, and bowls are also found. Cylindrical vessels with small rectangular handles set halfway down are flower vases, not tankards, as one might think. A rare form is a pottery version of a mosque lamp.



During the next period (*c.* 1525–50), some wares of which have been erroneously attributed to Damascus, Iznik pottery was at its finest. Ming blue-and-white was now copied directly; for example, the central motif of grapes on a dish in the Victoria and Albert Museum, London, is an almost exact imitation of a well-known mid-15th century Chinese motif. On the same dish is a characteristic border pattern, which was called the Ammonite scroll border because it was thought to resemble the coiled shell of the fossil ammonite but which is certainly a debased version of the Ming Rock of Ages pattern. This scroll border appears often; a slightly later and even more debased version, which incorporates large S-shaped scrolls, is sometimes known as the dollar pattern.

The palette was gradually expanded to include turquoise, sage green, olive green, purple, and black. Most of the blue and turquoise specimens are painted with flowers. The Chinese flora motifs were almost entirely replaced by tulips, poppies, carnations, roses, and hyacinths in the form of fairly symmetrical sprays springing from a single point. The earliest flowers are often rather more stylized than the later, perhaps because the representation of living things was prohibited by Qur'ānic

(Koranic) tradition. Even on comparatively late examples, floral designs are sometimes stylized to the point of abstraction, suggesting that decorators might have suited their patterns to the religious susceptibilities of their customers. An effective abstract pattern is formed from a series of overlapping scales that are usually carefully

Scale pattern

drawn. The same ground was later employed in Italy on maiolica and at the Berlin porcelain factory and may have indirectly inspired the series of wares with scale grounds made at Worcester, England.

After about 1550 Iznik pottery enters its third stage. The most notable technical innovation is the use of Armenian bole (sealing-wax red), a thick pigment that stands out in slight relief from the surface of the vessel.

The other great change is that tiles, which had previously been made in small numbers, became all important and remained so until the early 17th century. They were used to provide lavish decoration for the new mosques built at Constantinople by Süleyman I. Once again potters were brought from Tabriz to begin the work. Much use is made of copper green and the new red, the colours very brilliant on the glossy white ground. The tiles, usually square, make up flowing repeating patterns or long high pictures with elaborate borders.

On pottery, symmetrical sprays of flowers continued to be used as decoration until about 1600. Paintings of animals and birds are found occasionally, probably executed by Persian workmen since their resemblance to Persian wares is strong. The rare specimens with human figures were probably painted by Greeks or Armenians for export to the West. Turkish sailing vessels sometimes appear as a decorative motif.

In the 17th century the quality of Iznik wares declined, and by 1800 manufacture had ceased. At Kütahya, pottery making had begun by 1608 and continued into the middle of the 20th century. The wares, though inferior, have some resemblance to those of Iznik with the addition of a yellow pigment.

EUROPEAN: TO THE END OF THE 18TH CENTURY

European wares made before the 19th century fall into six main categories: lead-glazed earthenware, tin-glazed earthenware, stoneware, soft porcelain, hard porcelain, and bone china.

Lead-glazed earthenware was made from medieval times onward and owes little to outside influences. The body is generally reddish buff in colour; the glazes are yellow, brown, purplish, or green. The wares are usually vigorous in form but often crudely finished. Lead-glazed wares fell out of favour when tin glaze became widely known toward the end of the 15th century, but they returned to popularity with the advent of Wedgwood's creamware shortly after the middle of the 18th century. The body of this later lead-glazed earthenware is drab white or cream, the glaze clear and transparent like glass, and the forms precise.

The first important tin-glazed wares came from Italy during the Renaissance, and these colourful examples of the painter's art exerted a profound influence on later work elsewhere. Manufacture spread rapidly, first to France, then to Germany, Holland, England, and Scandinavia. Under the name of maiolica, faience, or delft, it enjoyed immense popularity until the advent of Wedgwood's creamware, after which the fashion for tin-glazed ware declined rapidly.

Stoneware is first commonly seen in Germany during the 16th century; its manufacture was developed in England during the 18th century, culminating in the unglazed ornamental jaspers and basaltes of Wedgwood.

Two other types of ware, less common than those already discussed, are slipware and lustreware. Slip was applied both as a covering over an earthenware body and in the form of decoration, for example on the sgraffito wares of Italy (which owe a good deal to similar wares from Byzantium) and the dotted and trailed slips of 17th- and 18th-century England. Lustre pigments were used in Spain, where they are the principal decoration on the magnificent series of wares referred to as Hispano-Moresque; in Italy, where they supplement other modes of decoration; and much later, in England—although in the last case they are no longer artistically important.

The manufacture of soft porcelain was essayed in 16th-century Italy under the patronage of Francesco de' Medici, grand duke of Tuscany. Similar attempts were made elsewhere in Italy about the same time, and manufacture is supposed to have been continued at Pisa and at Candiana, near Padua (Padova). The first production of soft porcelain on a considerable scale did not take place, however, until toward the end of the 17th century in France.

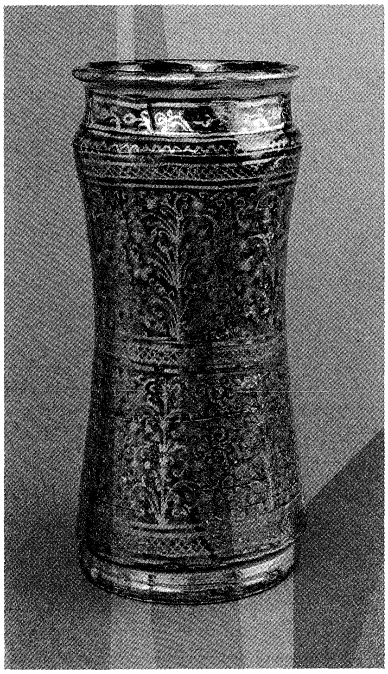
Porcelain and bone china

In Saxony about 1675 Ehrenfried Walter von Tschirnhaus started experiments to make porcelain from clay mixed with fusible rock. Almost certainly he had made hard porcelain by the end of the century, but manufacture did not become a practical commercial proposition until the year of his death, in 1708. Experiments were continued by his assistant, an alchemist named Johann Friedrich Böttger, who is sometimes credited with von Tschirnhaus' discovery. The factory was established at Meissen about 1710, and the first porcelain sales of any consequence took place at the Leipzig Fair in 1713.

Later, at the end of the 18th century, Josiah Spode the Second added bone ash to the hard porcelain formula to make bone china.

Byzantium. In AD 330 Byzantium became the imperial capital of the Roman Empire and was renamed Constantinople. The term Byzantine, however, is applied to the period that ended in 1453, when Constantinople was captured by the Ottoman Turks (and renamed Istanbul).

Since it was not a Christian custom to bury pottery with the dead, few wares survive, and chronology is difficult. Most of the surviving wares fall into two classes: one is a red-bodied type, sometimes with stamped relief decoration under a clear glaze; the other, a sgraffito type with human figures, animals, birds, monograms, foliate designs, the Greek cross, and the like, engraved through a white slip and covered with yellow and green glazes. The latter is the commonest type after the 12th century. Both styles were fairly widespread and have been recovered in fragmentary form from excavations at Istanbul, and in Greece, Cyprus, and the Crimea.



Spain. The earthenware of Spain falls into two classes: lustreware and painted tin glazed ware.

Lustreware. The lustre technique spread to Moorish Spain by way of Egypt, but it is impossible to say exactly when it arrived.

Hispano-Moresque pottery

The body of Hispano-Moresque pottery is usually of fairly coarse clay, which has burned to a pinkish buff, covered with a tin glaze containing lead in varying proportions. The lustre, added overglaze, varies in colour from golden to a pale straw, and a coppery lustre almost invariably indicates at least a 17th century date. Many dishes were additionally painted in blue and, less often, with manganese.

By courtesy of the trustees of the British Museum

Hispano-Moresque albarello painted with lustre on a blue ground, Valencia, *c.* 1460. In the British Museum. Height 27.6 cm.

Most surviving wares of the early period are dishes of various shapes. Less common are albarellos, waisted drug jars based on a Middle Eastern form. Vases based on the old Iberian Amphora but with two massive wing handles (the Alhambra type) are very rare. The decoration on wares of this early period is predominantly Moorish. Fine specimens of this kind are unlikely to be later than 1525. Subsequently, Spanish artists repeated the Moorish designs, but these often degenerate in their hands; and Arabic and the Kūfic script, frequently used by Moorish potters, becomes meaningless. The early designs are, for the most part, plant forms and arabesques, both the vine leaf and the bryony leaf being used. A little later there are magnificently drawn animals in heraldic form, principally lions and eagles. Still later there are deer and antelope, which may owe something to Persian sources. Dishes with coats of arms of noble families surrounded by vine- and bryony-leaf ornament are unusually fine. Many of them were made in Valencia and the neighbouring village of Manises for Italian families. A feature of many of the dishes is the lustre decoration on the reverse. Although often no more than a series of concentric circles, occasionally there are superb eagles and other animals found on dishes from Valencia that are even finer than the obverse designs.

In the 17th century much lustred pottery was made for the cheaper markets and for export to England. The painting is executed in a lustre pigment of deep coppery hue. While this ware is not important in comparison with the early wares, it is often decorative.

Other tin-glazed ware. Although the influence of Valenician lustre pottery on later Italian maiolica is obvious, the wares of Paterna, near Valencia, were hardly less influential in the 14th century. They were decorated in green and manganese, often with motifs taken from Moorish sources; this combination of colours is to be seen in early Italian pottery from Orvieto and elsewhere.

Much tin-glazed pottery of excellent quality was made at Talavera de la Reina, in New Castile, during the 17th and 18th centuries. The palette is characteristic of much Spanish tin-glazed ware; green and manganese play a distinctive part, frequently combined with touches of orange-red and gray. The *istoriato* style of Urbino (see below *Italy*) was copied here, and the Italian painter and engraver Antonio Tempesta (1555–1630) provided a source of inspiration for some of the painting. Alcora, in Valencia, made much faience of excellent quality during the 18th century.

Kinds of tilework

Tilework was particularly common in Spain from the earliest period; according to one proverb, only a really poor man had "a house without tiles." At first tilework was made with a typically Persian technique by which thin slabs of tin-glazed pottery were sawn into pieces and embedded in a kind of mortar (tile mosaic). The *cuerda seca* method of making tiles followed about 1500: outlines were drawn on the surface in manganese mixed with a greasy substance that prevented the coloured glazes used from mingling. Tiles made by the *cuenca* technique had deeply impressed patterns the compartments thus formed being filled with coloured glazes. Tiles were also decorated with lustre pigments.

Porcelain. The early porcelain made at Buen Retiro, near Madrid, in the 1760s, had been justly compared to that of Saint-Cloud. The quality of the ware was good, and some skillful figure modelling was done by Giuseppe Gricci, who had previously worked at Capodimonte (see below *Italy*).

Italy. The pottery of Italy is extremely important not only in itself but for its subsequent influence in other European countries. Indeed, its influence may have spread even farther afield: a few specimens of Ming porcelain have motifs that may have been inspired by it.

There are two well-defined classes of Italian earthenware: maiolica, or tin-glazed ware, and pottery decorated in the sgraffito technique.

Maiolica. Tin-glazing was introduced in the 13th century from the Middle East through the Muslim civilization in southern Spain, wares being shipped from there to Italy by Majorcan traders. The term maiolica was at first applied to this Hispano-Moresque lustreware, but in the 16th century it came to denote all tin-glazed ware.

Italian maiolica is principally noteworthy for its painted decoration, which excelled in technical competence anything produced in Europe since classical times. The painting was executed in several colours on the dry but unfired tin glaze. Great skill was needed, since the surface absorbed the colour as blotting paper absorbs ink, and erasures were therefore impossible. The best wares were given a final coating of clear lead glaze called *coperta.* The range of colours was comparatively limited: cobalt blue, copper green, manganese purple, antimony yellow, and iron red formed the basic palette, while white was provided by the tin-glaze material. When white was used for painting, it was applied onto a bluish-white glaze (*bianco sopra bianco*, or "white on white"), or on a light-blue (*berettino*), or dark-blue ground.

Lustre pigments

Lustre pigments were introduced from Spain. The lustre of Italian wares is often the golden-yellow colour derived from silver, and sometimes it is ruby, suggesting the use of gold. The silver lustre often developed a nacreous effect known as mother-of-pearl (*madre perle*).

The forms of maiolica are few and comparatively simple. For the most part they were dictated by the need for a surface on which the painter could exercise his skill; thus, dishes form the greater part of surviving wares. It is doubtful whether most maiolica was ever intended for general use. Dishes, for instance, were displayed on sideboards and buffets far more often than they were placed on the table. Gaily coloured drug jars were a fashionable decoration for pharmacies and include the albarello shape, copied from Spain, for dry drugs, and a spouted jar for wet drugs. Ewers (pitchers) with a trefoil (leaf-shaped) spout, derived from the Greek oenochoe, were made, as well as the massive jars representative of Florentine work of the 15th century.

The earliest maiolica, beginning in the 13th century, is decorated in green and manganese purple in imitation of

the Spanish Paterna ware. Much work of this kind was done at Orvieto, in Umbria, where the characteristic form was a jug with a disproportionately large pouring lip. Orvieto ware has almost become a generic term for anything in this style, although similar vessels were made at Florence, Siena, and elsewhere. It was current in the 14th century and continued in the 15th century, when other colours were added to the palette. The decorative motifs —masks, animals, and foliage—are Gothic, with some traces of Eastern influence.

From Florence came a series of wares painted in a dark, inky, impasto (or very thick) blue. These, too, have Gothic ornament, particularly oak leaves, which came into use sometime before 1450. Heraldic animals also appear on some specimens. This kind of decoration was obviously inspired by Spanish pottery, and a few examples are hardly more than copies. Soon after 1500, Florentine production was concentrated in the castle of Caffagiolo, in Tuscany, and came under the patronage of the Medici family, whose arms appear frequently. A notable addition to the palette here was a bright red pigment, a most difficult colour to attain and one not often used.

Gothic ornament was gradually displaced by classical motifs, such as grotesques, trophies, and the like, which, early in the 16th century, themselves gave way to the *istoriato* style. This style, no doubt inspired by the achievements of contemporary painting, imitates the easel picture closely. Its realism, including the use of perspective, is quite unlike any previous ceramic decoration. The subjects were often classical, but biblical subjects, some taken from the woodcuts of Bernard Salomon (*c.* 1506–61), are frequently represented. Maiolica was often called Raffaelle ware, a tribute to the influence of the painter Raphael (1483–1520), although he, in fact, never made any designs for pottery. In particular the maiolica painters copied his *grotteschi* (grotesques), motifs adapted from those rediscovered in the grottoes of the Golden House of Nero soon after 1500 and so-called in consequence. They are usually fantastic combinations of human, animal, and plant forms. The works of Albrecht Dürer and Andrea Mantegna were also borrowed, often through engravings made by Jacopo Ripanda (Jacopa da Bologna and Marcantonio Raimondi); some examples are almost exact copies, others are freer interpretations. The paintings sometimes occupy the centre of the dish with a border of formal ornament surrounding them, but in many instances, notably those from Urbino, they cover the entire surface. It is often impossible to regard the pottery body as anything more than a support for the painting, its pictorial or narrative subject having been executed with little or no consideration for the nature of the object it decorated. Although pottery decoration is rarely successful unless it is designed to enhance, or at least not to detract from, the shape of the body, an exception must be made for some of these colourful wares: at their best they are highly ornamental.

Istoriato style

The *istoriato* style probably developed at Faenza (Emilia) in about 1500. One of the earliest and most important centres of production, it had been manufacturing maiolica since before 1450. Almost as early are some examples from Caffagiolo. Castel Durante adopted the same style, and it is particularly associated with the name of Nicola Pellipario (died *c.* 1542), the greatest of the maiolica painters. He also painted grotesques similar to those of Deruta, in Umbria, which are rather more stylized than the grotesques introduced later in the 16th century at Urbino that are humourous and full of movement. The former are often used as a surround to an interior medallion in the *istoriato* style. Urbino was probably the largest centre for the manufacture of maiolica at the time. The industry there was under the patronage of the Della Rovere family, whose name, meaning "oak tree," led to the adoption of the oak-leaf motif in wreathed form.

The Deruta factory

Among the early factories, that of Deruta (which may have been under the patronage of Cesare Borgia) is of considerable importance. Maiolica has been made there from medieval times, and manufacture continues in the mid-20th century. Deruta potters about 1500 were the first to use lustre pigment, which was of a pale-yellow tone, and they also adopted the Spanish practice of painting designs on the reverse of dishes. They also often covered only the obverse with tin glaze and applied a lead glaze to the reverse—again, a typically Spanish practice. The best work was done before 1540.

"Death of the Virgin," maiolica plaque painted in the *istoriato* style by an unknown Italian artist often referred to as the Master of the Death of the Virgin, Faenza, Italy, *c.* 1510. The composition is taken from Martin Schongauer's engraving of the same subject. In the British Museum. Diameter 26.7 cm.
By courtesy of the trustees of the British Museum

The use of lustre pigments at Gubbio, in Umbria, probably started soon after it began at Deruta. The quality of the work was such that maiolica was sent from Castel Durante, Faenza, and even from Deruta itself for this additional embellishment. An interesting series of dishes is that painted with the portraits of young women, often with the addition of a terse and appreciative comment such as "*Bella*," which were made at Deruta, and also apparently at Gubbio.

Maiolica was manufactured in Venice between the 16th and 18th centuries. As might be expected in an important seaport with worldwide trade, its maiolica often shows Eastern influence. The designs of Iznik were sometimes copied (as they were, in fact, on other Italian wares of the period), and imitations of Chinese porcelain of the Ming period gave rise to a style known as *alla porcellana* ("in the manner of porcelain").

Of the later potteries, that of Castelli, near Naples, did excellent work from the 16th century onward, although its later wares tend to become pedestrian. *Istoriato* painting was revived there in the 17th century in a palette paler in tone than that of early work in this style. Much maiolica survives from Savona, in Liguria, a good deal of which is painted in blue in Oriental styles.

Although hardly to be classified as pottery, sculptured reliefs were made by Luca della Robbia (died 1482) in terra cotta and covered with maiolica glazes. He was followed by his nephew, Andrea, and the latter's sons. Giorgio Vasari's suggestion that Luca invented the maiolica glaze is erroneous.

Sgraffito wares. Sgraffito wares are comparatively rare. The technique was derived from Byzantine sources by way of Cyprus which was under Venetian rule from 1472 to 1570. Manufacture was confined to northern Italy, the largest centre being at Bologna. The body of the sgraffito ware was covered with a slip of contrasting colour, the decoration then being scratched through to the body beneath and the whole covered with a lead glaze, which has a yellowish tone. Often the incised designs were first embellished with underglaze colours (blue, green, purple, brown, and yellow) that tended to run during firing. This technique died out finally at the end of the 18th century, but some important work of the kind was done in the late 15th and 16th centuries.

Porcelain. There are only about 50 surviving pieces of the soft-paste porcelain made in Florence at the time of the Medicis, and little is known of its actual production. The earliest definite date for manufacture is 1581. Painting is nearly always in blue with manganese outlines. Most decorative motifs are derived from China, Persia, or Turkey, and the forms usually copy those of Urbino maiolica.

No hard porcelain was made in Italy until Francesco and Giuseppe Vezzi's factory was established in Venice in 1720. It made fine hard porcelain the body of which has a slightly smoky colour. The style is Baroque, and the palette is notable for a brownish red. Another factory, that of Geminiano Cozzi, started in 1764, was the one where most Venetian porcelain was made. Cozzi worked in the Meissen and Sèvres styles and produced some good figures.

Ginori and Capodimonte

The porcelain factory at Doccia, near Florence, still in production in the 1970's, was founded by Marchese Carlo Ginori in 1735. Coffeepots in the Baroque style, sometimes painted with coats of arms, are characteristic of the early period. Equally fine figures were made during the 18th century. Porcelain with figure subjects in low relief was made only at Doccia, although it has been repeatedly and erroneously attributed to the soft-porcelain factory established in the royal palace of Capodimonte by Charles III of Naples in 1743. As well as extremely well painted service ware, Capodimonte is renowned for its figures. The factory was transferred to Buen Retiro, near Madrid, in 1759, when Charles became king of Spain (see above *Spain*).

France and Belgium. The medieval pottery of France is difficult to date and classify with accuracy, but lead glaze was in common use by the 13th century at the latest. Proficient sgraffito decoration was done at Beauvaisis (Oise) and at La Chapelle-aux-Pots (Charente-Inferieure).

Palissy rustic ware

Lead-glazed wares of the 16th century. Bernard Palissy began to experiment with coloured glazes about 1539 and, after much difficulty, succeeded in producing his rustic wares in 1548. For the most part these are large dishes made with wavy centres intended to represent a stream, with realistically modelled lizards, snakes, and insects such as dragonflies grouped thereon. They are decorated on the obverse with blue, green, manganese purple, and brown glazes of excellent quality, while the back is covered with a glaze mottled in brown, blue, and purple. Palissy later turned his attention to classical and biblical subjects, which he molded in relief. After his death in 1589, work in his style was continued at the Avon pottery, near Fontainebleau.

Almost contemporary with Palissy's rustic ware is a type of pottery made in the style of the metalwork of the period. It was made at Saint-Porchaire and is sometimes called, erroneously, *Henri Deux* ware, or *faience d'Oiron.* The body is ivory white and covered with a thin glaze. Before firing, designs were impressed into the clay with metal stamps like those used by bookbinders, and the impressions were then filled with slips of contrasting colours. This technique resembles the *mishima* technique of decoration in Korea (see below *Korea*).

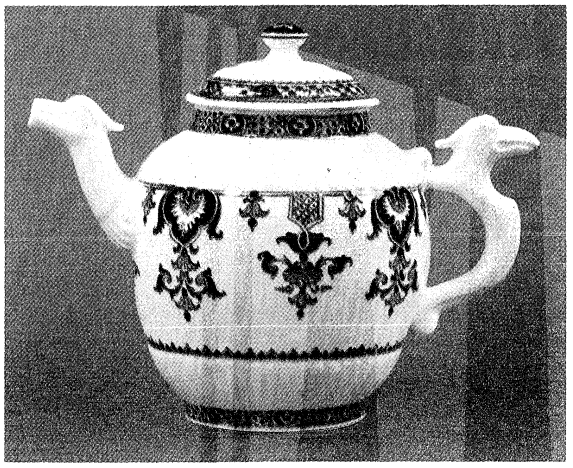
Faience, or tin-glazed ware. The technique and the designs of Italian maiolica influenced the development, in the early 16th century, of French faience. There were Italian potters at Lyon in 1512, and, by the end of the 16th century, painting in the manner of Urbino was well established there. Faience was also made at Rouen, probably as early as 1526, and at Nevers toward the end of the 16th century.

A new factory, established at Rouen about 1656 by Edme Poterat, introduced a decoration of *lambrequins,* ornament with a jagged or scalloped outline based on drapery, scrollwork, lacework ornament, and the like. *Lambrequins* were extremely popular and were copied at other porcelain and faience factories. The faience of Nevers, too, is extremely important and shows the Baroque style at its best. In the second half of the 17th century the porcelain of both China and Japan became increasingly well known in Europe, and many designs were borrowed from Chinese sources by potters at Nevers and elsewhere.

The factory of Moustiers in the Basses-Alpes was founded by Pierre Clérissy in 1679. During the early period frequent use was made of the engravings of Antonio Tempesta (1555–1630) as well as biblical scenes. Later came a series of dishes decorated with designs after Jean I Bérain (1637–1711), whose work greatly influenced French decorative art at the time. These designs usually include grotesques, baldacchini (canopies), vases of flowers, and the like, linked together by strapwork in a typically Baroque manner.

In 1709, when Louis XIV and his court melted down their silver to help pay for the War of the Spanish Succession, the nobility looked for a less expensive medium to replace it. In consequence, faience gained in popularity and importance. A great deal was manufactured in the region of Marseilles, the factory of the Veuve Perrin being particularly noted for overglaze painting in the Rococo style. Perhaps the most influential factory was that of Strasbourg, in Alsace (which had officially become part of France in 1697), founded by C.F. Hannong in 1709. The wares—painted in blue, in other faience colours, and in overglaze colours—were much copied elsewhere. Overglaze colours were introduced about 1740, their first recorded use in France. (For the first use in Europe, see below *Germany and Austria.*) Brilliant *indianische Blumen* (flower motifs that were really Japanese in origin but that were thought to be Indian because the decorated porcelain was imported by the East India companies) were painted in a palette that included a carmine similar to the Chinese overglaze rose ("purple of Cassius"). A characteristic copper green was also used. *Deutsche Blumen* ("German flowers") were introduced, perhaps by A.F. von Löwenfinck, about 1750, and inspired similar painting elsewhere. Figures by J.W. Lanz, who also worked in porcelain here and at Frankenthal, are to be seen. Much work was done in the fashionable Rococo style, including objects, such as clock cases and wall cisterns, and tureens in the form of fruit and vegetables. Both faience and porcelain in a variety of decorative forms were used for the banqueting table. Such table decoration, which in the 17th century had been supplied by confectioners who worked in sugar, had become very fashionable in Europe.

Faience and porcelain as table decoration



The wares of Niderviller, in Lorraine, were much influenced by those of Strasbourg. The later figures were probably modelled by the sculptor Charles Gabriel Sauvage, called Lemire (1741–1827), and some were sometimes taken from models by Paul-Louis Cyfflé (1724–1806). At Lunéville, not far away, Cyfflé worked in a pleasant but sentimental vein and used a semiporcelain biscuit body known as *terre-de-Lorraine,* which was intended to resemble the biscuit porcelain of Sèvres. The work of both Sauvage and Cyfflé is extremely skillful.

Faience was made at Tournai (now in Belgium) and at Brussels during the 17th century. Their styles were mainly derivative, but Brussels made some excellent tureens in forms such as poultry, vegetables, and fruits during the Rococo period.

After 1800 most French pottery factories concentrated on the manufacture of faience-fire (creamware).

Porcelain. In the second half of the 17th century much interest was taken in both faience and porcelain, although the technique of making soft-paste porcelain (*pâté tendre*) had yet to be mastered, and the secret of hard-paste porcelain manufacture was not discovered until the 18th century.

A factory at Saint-Cloud, founded by Pierre Chicaneau in the 1670s, made faience and a soft-paste porcelain that were yellowish in tone and heavily potted. Much use was made of molded decoration, which included sprigs of prunus blossom copied from the *blanc de Chine* of Tehua (see below *China: Ming dynasty*). Particularly common was a molded pattern of overlapping scales. Most examples are small, but there are some large jardinières (flowerpot holders) that are extremely handsome. The early painted wares were decorated in underglaze blue with typically Baroque patterns, including the *lambrequins* introduced at Rouen. Motifs derived from the

Porcelain teapot with decoration in underglaze blue, Saint-Cloud, France, *c.* 1720. In the Museum of Fine Arts, Boston. Height 13.9 cm.
By courtesy of the Museum of Fine Arts, Boston

designs of Jean Bérain are also to be seen. Polychrome specimens, some of which were decorated in the style of Kakiemon, (see below *Japan: Edo period*), date from about 1730.

At Chantilly, the first soft-paste porcelain was decorated almost entirely in the Kakiemon style, and the body was invariably covered with a tin-glaze. The Japanese period ended about 1740. For some years thereafter simple Meissen styles were copied, in particular the German flowers. In 1753 an edict in support of the newly established factory at Vincennes forbade all other factories to manufacture porcelain or to decorate faience in polychrome; much Chantilly porcelain of the later period, therefore, is creamy white, decorated only with slight flower sprigs in blue underglaze. A transparent glaze was introduced in 1751 and replaced the very unusual practice of covering porcelain with a tin-glaze.

A factory at the Rue de Charonne, in Paris, was started by François Barbin in 1735 and removed to Mennecy in 1748. The early productions were in the manner of Saint-Cloud and Rouen. Later, some excellent flower painting was done, and figure modelling was excellent in quality. Small porcelain boxes from Mennecy, often in the form of animals, are much sought in the 20th century.

Vincennes and Sèvres

The most important of the French factories was established at Vincennes about 1738 and removed to a new building at Sèvres in 1756. Louis XV was a large shareholder in the original company and the factory eventually passed to the crown in 1759. It became state property in 1793, and has so remained.

The factory did not succeed in its attempts to make a practicable soft-paste porcelain until 1745. Much of the work at Vincennes consisted of naturalistic flowers with bronze stalks and leaves, sometimes in vases elaborately mounted in gilt bronze by the court goldsmith, Claude Thomas Duplessis, and others. Meissen was also copied for a short period, but the factory soon evolved its own style, which remained partly dependent on the use of high quality gilt-bronze mounts. A few glazed and painted figures were made, but these gave place in 1751 to figures of biscuit porcelain. In 1757 the sculptor Étienne-Maurice Falconet was appointed to take charge of modelling, a position he retained until 1766. Designs by the painter François Boucher were frequently used by Falconet and others; Boucher's influence is particularly strong during the lifetime of Louis XV's mistress, Mme de Pompadour, who took much interest in the factory. Later, some excellent work in this medium was done by the sculptors Augustin Pajou and Louis-Simon Boizot.

Both at Vincennes and Sèvres much use was made of coloured grounds in conjunction with white panels, which were used for decorative painting of the highest quality. These panels were surrounded by rich and elaborate raised gilding, which was engraved and chased (toolen). The most usual ground colours were a dark underglaze blue (*gros bleu*) and a brighter, overglaze (*blue de Roi*); also used were turquoise blue, yellow, green, and *rose Pompadour* (often miscalled *rose du Barry* in England).

The porcelain of Sèvres was made to harmonize with the exotic and luxurious style of interior decoration that characterized French court circles. The soft-paste body was of superb quality; and, because the extremely fusible glaze partly remelted in the enamelling kiln, the colours sank into the glaze in a way hardly seen elsewhere.

Hard porcelain of Sèvres

The factory prosecuted the search for the ingredients of hard porcelain with vigour. They were found after a prolonged search at Saint-Yrieix-la-Perche, near Limoges, in 1769. The new body was first manufactured soon after 1770, although for some years it was only used for biscuit figures. Later, it was employed for dishes and vases decorated in a severe but luxurious classical style. In 1800 the manufacture of soft porcelain was discontinued.

A large number of smaller factories making hard porcelain sprang up, chiefly in and around Paris, in the second half of the 18th century. Some were patronized by members of the royal family, including Louis XVI's wife, Marie Antoinette. A number of provincial factories were also engaged in the same manufacture.

The Tournai factory, in Belgium, which began to make porcelain in 1751, enjoyed the patronage of the empress of Austria, Maria Theresa. Here, and in the associated factory at Saint-Amand-les-Eaux, the work of Sèvres was imitated on a considerable scale.

Germany and Austria. While Germany is principally noted for its superb porcelain, the stoneware of the Rhineland is no less noteworthy. A great deal of faience was also made, though this was less important.

The earliest type of ware made in Germany (*c.* 1350) was the *Hafnergeschirr* ("stove maker vessel"). Originally the term referred to tiles, molded in relief and usually covered with a green glaze, which were built up into the large and elaborate stoves needed to make mid-European winters tolerable. Jugs and other vessels made by these stove makers, however, came to be called Hafner ware by extension when their manufacture began about the mid-16th century. The work of Paul Preuning of Nürnberg is

Hafner ware

an example of this kind of ware. He decorated his pottery with coloured glazes kept apart by threads of clay (the cloisonné technique). In Silesian Hafner ware, on the other hand, the design is cut out with a knife, the incisions preventing the coloured glazes from mingling. The earliest German stove tiles are lead glazed. Tin glazes came into use about 1500.

After these beginnings, German pottery developed in two distinct classes: stoneware and tin-glazed earthenware.

Stoneware. The stoneware (*Steinzeug*) came mainly from the Rhineland and, in particular from Cologne, Westerwald, Siegburg, and Raeren (the latter now in Belgium). Manufacture probably began in Cologne about 1540. The body of the stoneware is extremely hard and varies from almost white (Siegburg) to bluish gray

(Westerwald); a brown glaze over a drab body is also to be seen (Raeren). The surface is glazed with salt—no more than a smear glaze, pitted slightly, like orange peel. A smooth, though still very thin, glaze was achieved by mixing the salt with red lead. Particularly popular at Cologne in the late 16th century was the "bearded-man jug" (*Bartmannkrug*), a round-bellied jug with the mask of a bearded man applied in relief to the neck. This type was sometimes called a "Bellarmine" in England; the mask was thought to be a satire on the hated Cardinal Robert Bellarmine (Bellarmino), but there is no authority for this assumption. In England, where they were imported in large quantities, they were also known as graybeards. The term tigerware was also used for the mottled brown glaze over a grayish body.

Some of the earliest German stoneware is notable for its remarkably fine relief decoration in the Gothic style. Oak-leaf and vine-leaf motifs were common, as were coats of arms on medallions. The applied relief and stamped decoration was, at times, most elaborate, and the thin glaze lent it additional sharpness and clarity. Reliefs of biblical subjects appear on tall, tapering tankards (*Schnellen*), which were provided with pewter or silver mounts. The *Doppelfrieskrüge* were jugs with two molded friezes (usually portraying classical subjects) around the middle. They and the tankards were made in Raeren brownware by Jan Emens, surnamed Mennicken, in the last quarter of the 16th century. Emens also worked in the gray body that was used at Raeren at the turn of the century, employing blue pigment to enhance the decoration. At a later date, blue and manganese pigments were used together, and this practice continued throughout the 17th century. Figures were sometimes set in a frame reminiscent of Gothic architectural arcades, and inscriptions of one kind or another are fairly frequent.

The style of the stonewares gradually fell into line with the prevailing Baroque style, particularly toward the end of the 17th century. At Kreussen, in Bavaria, a grayish-red stoneware was covered with a brown glaze, and the molded decoration was often crudely picked out with opaque overglaze colours that had a tin-glazed base. The earliest dated specimen is 1622, which was the first time overglaze colours had been used on pottery in Europe. The technique, learned from Bohemian glass enamellers, was to have some influence in France as well as in Germany.

Germany stoneware was extremely popular abroad; during the 17th century, for instance, Sieburg even exported to Japan.

Meissen stoneware

An extremely important type of stoneware was first made shortly before 1710 at a factory at Meissen that was under the patronage of Augustus the Strong, elector of Saxony and king of Poland. It was discovered by E.W. von Tschirnhaus (1651–1708) and J.F. Böttger (1682–1719) during their researches into the secret of porcelain manufacture. It usually varies from red to dark brown and is the hardest substance of its kind known. An almost black variety was termed *Eisenporzellan* ("iron porcelain"), and a black glaze was devised by Böttger to cover specimens of defective colour. Decoration is usually effected by means of applied reliefs, although the black-glazed specimens were sometimes decorated with lacquer colours, as well as with gold and silver. Silvering was not uncommon and was also practiced in other German centres during the early part of the 18th century on both stoneware and porcelain.

A particular feature of Meissen stoneware is the incised decoration done by lapidaries on the engraving wheel. Many specimens were engraved with coats of arms, and grinding into facets (the *Muscheln* pattern) was also practiced. The same methods were used to give a plain surface a high polish. Metal mounts, common Rhenish stoneware, also were sometimes accompanied by insetting precious and semiprecious stones.

Because of the vogue for porcelain, stoneware manufacture declined and was finally abandoned about 1730.

Tin-glazed ware. Faience factories were so numerous that it is only possible to mention the most important of them. Perhaps the earliest tin-glazed wares other than stove tiles are the amusing jugs in the form of owls (with detachable heads to be used as cups) that came from Brixen (Bressanone), in the Tirol. Their shape and style no doubt inspired the later owl and bear jugs, with similarly versatile heads, made in England during the 18th century. These owl jugs (*Eulenkrüge*) were, at first, used as prizes in archery contests and were sometimes repeated in Rhenish stoneware.

The first manufacture of faience on a considerable scale took place at Nürnberg, and some dishes in the Italian style still survive. Much more is known, however, of the productions of Kreussen, which is chiefly of interest for its blue-and-white faience jugs. The outline of flowers painted in blue is almost cross-sectional in style and terminates in a small spiral—hence the name spiral family.

A factory of Hanau, near Frankfurt am Main, was started in 1661 and remained in operation until 1806. Many of the early wares were decorated with Chinese motifs. A type of jug with a long narrow neck, the *Enghalskrug*, was made in Hanau. Some have a globular body (sometimes copied in China and Japan in blue painted porcelain); others, a spirally fluted body and a twisted handle. Pewter or, less often, silver covers were common. The painting includes coats of arms, landscapes, and biblical subjects. Groups of dots amid strewn flowers (*Streublumen*) are characteristic. Realistically painted German flowers appear shortly before mid-18th century. Most painting is in blue, manganese, and the other less often used faience colours. Overglaze colours do not seem to have been used.

A factory in Frankfurt am Main itself was founded in 1666. Imitations of Chinese motifs as well as biblical subjects were very popular. The blue is brilliant, and the surface usually suggests the use of a transparent overglaze. Narrownecked jugs were commonly made and are some-

times difficult to distinguish from those of Hanau. This centre closed about 1740. At Nürnberg a later factory was established about 1712, continuing until about 1840. Most of the subjects used at Frankfurt and Hanau were repeated at Nürnberg, as well as designs based on the the Rococo engravings of J.E. Nilson (1721–88), which were also popular at many of the porcelain factories. The Rococo style, which spread from France to Germany about the second quarter of the 18th century, is reflected both in the forms and the decoration.

Wares of Bayreuth

The wares of Bayreuth are particularly interesting. Early products were painted with a misty blue, but overglaze colours were speedily adopted. "Leaf and strapwork" (*Laud-und-Bandelwerk*) was a much used type of motif, and excellent work was done by A.F. von Löwenfinck (who is known particularly for his work on porcelain) and Joseph Philipp Danhofer. Perhaps the finest 18th-century faience was made by the factory at Höchst, near Mainz, which also manufactured porcelain. Decoration was usually in overglaze colours, and landscapes, figure subjects, German flowers, and chinoiseries (European delineations of the Chinese scene with a strong element of fantasy) are of a much higher quality than elsewhere. Faience thus decorated with colours applied over the glaze, as on porcelain, was termed *Fayence-Porcellaine* during the 18th century.

An important aspect of both faience and porcelain decoration in Germany is the work of the studio painters, or *Hausmaler*, who brought undecorated faience and porcelain from the factories and painted it at home, firing the decoration in small muffle kilns. For this reason, their work was done in overglaze pigments. At first they mostly used the *Schwarzlot* technique—decoration in a black, linear style that was nearly always based on line engravings. Faience thus decorated dates from about 1660 and is the work of Johann Schaper (died 1670), who had been a Nürnberg glass painter, J.L. Faber, and others. Polychrome enamel decoration was developed by another glass painter, Abraham Helmhack (1654–1724), who mastered the technique as early as 1690, many years before it was adopted by the factories. The more important studio painters are Johann Aufenwerth and Bartholomäus Seuter of Augsburg, J.F. Metzsch of Bayreuth, the Bohemians Daniel and Ignaz Preussler, and Ignaz Bottengruber of Breslau. The work of the latter is particularly esteemed.

Toward the end of the 18th century a number of German factories, including some already making faience, made lead-glazed earthenware (*Steingut*) in imitation of Wedgwood, while a factory at Königsberg (now Kaliningrad) imitated Wedgwood's black basaltes body.

Porcelain. The earliest hard porcelain, produced by the factory at Meissen, is smoky in tone, but some improvements were made in 1715 and others in the following decade. Many early specimens were painted with a limited range of overglaze colours of good quality, including a pale violet lustre derived from gold that remained in use until about 1730. In 1720 a painter from Vienna, Johann Gregor Höroldt, was appointed chief painter (*Obermaler*) to the factory; he was responsible for introducing a new and much more brilliant palette, as well as some ground colours (*Fond-Porzellan*). The earliest ground colour to be noted is a coffee brown termed *Kapuzinerbraun,* which was invented by the kilnmaster Samuel Stölzel. The use of blue underglaze proved difficult, and little work of the kind was done. Overglaze painting, on the other hand, was of fine quality and includes topographical subjects, figure subjects based either on harlequin, pierrot, and other characters of the Italian comedy or on the style of the painter Jean-Antoine Watteau and his followers, and flowers in the Oriental style (called *indianische Blumen*) as well as native flowers (*deutsche Blumen*) taken from books of botanical illustrations. A series of harbour scenes from engravings of Italian ports were mostly executed by C.F. Herold (cousin to the *Obermaler*) and J.G. Heintze. Perhaps the most important early wares are the chinoiseries, which appear in great variety. The first work of the kind, much of it painted by the *Hausmaler* Bartholomäus Seuter, is in gold silhouette followed by polychrome painting after designs by the *Obermaler.* The figures are painted in three-quarter length. *Indianische Blumen* motifs were used, and Arita decorations, particularly those of Kakiemon (see below *Japan: Edo period*), were closely copied.

Figure modelling

Little figure modelling was done until about 1727, when the sculptor Johann Gottlob Kirchner was appointed *Modellmeister* and asked to make some colossal figures of animals for the Japanische Palais, the building that housed Augustus the Strong's porcelain collection. Because the medium was unsuited to work of this kind, most of the surviving examples are spectacular and magnificent failures. After the death of Augustus the Strong in 1733 large-scale modelling was practically discontinued, and the new *Modellmeister,* Johann Joachim Kändler, turned his attention to small figures suitable for decorating the dining table.

Assisted by other modellers, Kändler soon made the figures of Meissen fashionable throughout Europe. The first important Rococo work in porcelain appears in Saxony after 1737 when Kändler started to make the Swan service—perhaps the best known of all porcelain services. It is decorated with such motifs as swans, nereides, and tritons. Rococo Meissen was widely sought.

Meissen was the most influential European factory until the beginning of the Seven Years' War in 1756, when it was taken by the Prussians. From then until 1763 it was operated by nominees of Frederick the Great, who virtually looted the factory. By the end of the war, leadership had passed to Sèvres, and the work of Meissen for the next 50 years is much less important than formerly. The transitional Louis XVI style of c. 1763–74, the Neoclassical style was increasingly used, and is typified by the figure modelling of Michel Victor Acier, who came to the factory to share the position of *Modellmeister* with Kändler in 1764. From 1774–1814 the designs of Sèvres and of Wedgwood (Wedgwoodarbeit) were copied.

Few marks have been so consistently abused as that of the crossed swords of Meissen. Since the 18th century, it has been added to all kinds of unlikely specimens.

The other German factories of the period were, for the most part, established with the aid of runaway workmen from Meissen and Vienna, where Claudius Innocentius du Paquier had started a factory in 1719 with the aid of two men who were themselves from Meissen. Early Vienna hard-porcelain wares are highly prized. Much use was made of leaf and strapwork patterns, and excellent work was done in black monochrome (*Schwarzlot*). The factory passed to the state in 1744, and its later work is competent without being distinguished. Between 1784 and 1805 it became noted for elaborate gilding and coloured grounds, with minutely detailed painting, after Angelica Kauffmann and others, in reserved white medallions.

The Vienna factory provided a number of wandering arcanists (men who possessed the *arcanum,* or "secret," of hard-porcelain manufacture), two of whom helped to establish the Höchst factory, which began manufacture about 1752. This factory is principally noted for excellent figures in the Neoclassical style by Johann Peter Melchior and for the work of Simon Feilner.

A factory in Berlin, started in 1761 and acquired by Frederick in 1763 when he relinquished his hold on Meissen, produced wares with painted decoration of high quality. The decoration made much use of mosaic patterns—detailed diapers (small repeated motifs connecting with one another or growing out of one another with continuously flowing or straight lines) painted over a coloured ground. A large service made in 1819 for presentation to the Duke of Wellington and decorated with scenes from his battles is now in Apsley House, London.

Nymphenburg figures

There is much interest in the figure modelling of Franz Anton Bustelli, who worked at Nymphenburg, a suburb of Munich. The factory, which is still in operation, was started about 1753. Bustelli became *Modellmeister* in 1754 and retained the position until his death in 1763. His magnificent series of figures based on the Italian comedy are the most important expression of Rococo in German porcelain. The painted wares of the factory were also of fine quality.

Some excellent figures were made at Fürstenberg, where hard porcelain was first manufactured in 1753, and at Frankenthal by such notable modellers as J.W. Lanz, the cousins J.F. and K.G. Lücke, and Konrad Linck. Ludwigsburg, started in 1758, produced porcelain that was grayish in colour and more suitable for figure modelling than for service ware. The figures of artisans by an artist known as the Modeller der Volkstypen (modeller of folk-types) are original and pleasing, and the sculptor, Wilhelm Beyer, did good work in the Neoclassical style.

The Netherlands. During the 17th century, red stoneware was made by Ary de Milde of Delft and others in imitation of the wares of I-hsing (see below *China: Ming dynasty*). Creamware was manufactured at several places at the end of the 18th century. Most Dutch pottery of the period, however, is tin glazed.

Italian potters had settled in Antwerp by 1525, and surviving examples of tin-glazed ware from this period are in the Italian style. Manufacture was concentrated to a great extent in Delft soon after the beginning of the 17th century. By about 1650 the large brewing industry began to decline, and the old buildings were taken over by potters who retained such names as The Three Golden Ash-Barrels, The Four Roman Heroes, and The Double Jug for their potteries. The craftworkers of the town were organized into the Guild of St. Luke, which exercised a considerable amount of control over apprenticeships and established a school of design.

In the 17th century the Dutch East India Company, chartered in 1602, imported Chinese and Japanese wares in great quantities, and the taste for Eastern decoration rapidly ousted Italian fashions. For the greater part of the 17th century decoration was in blue, and Chinese porcelain was closely imitated. In wares of the best quality this imitation is so exact that, without a fairly close inspection, it is possible to mistake them for the originals. Western decorations—biblical and genre scenes, landscapes and seascapes—were carried out in styles similar to Dutch paintings of the period. Tilework was frequently undertaken; many individual tiles have survived, although large panels made up of many tiles are very rarely complete. Blue painting was followed by the use of the usual underglaze faience colours, the outline (known as *trek*) being first drawn with blue or manganese and then filled in. Before firing, the object was covered with an additional transparent lead glaze known as *kwaart,* which made the surface more brilliant. Red was a difficult colour; often when it was to be used, an unpainted space was left during the first firing, and the red was applied afterward and fired at a lower temperature. Gilding is found on the finer specimens and required a further firing. Overglaze colours were introduced by Zacharias Dextra about 1720, and the Chinese *famille rose* patterns were frequently imitated. Among the rarer and more showy examples of delft may be numbered the *Delft dorée,* on which gilding is lavish, and the *Delft noir,* which has a black ground (suggested by Chinese lacquer work) in conjunction with polychrome decoration. Work of this kind is often attributed to Adriaen Pijnacker.

Delft tiles

Marks on Dutch delft are extremely unreliable, for many later copies were given the earlier marks of important potteries, especially during the 19th century.

Britain. The medieval pottery of England was affected little by outside influences. Moreover, poor communications prevented the industry from concentrating in any one place; most wares, therefore, are made of local clay by local craftsmen. The potters worked alone or in extremely small groups, and their tools were few and simple. The clay used for the body ranges from buff to red, or, when fired in a reducing atmosphere, from gray to almost black. As with much Japanese pottery, little effort was made to disguise the method by which the vessel was formed, so that pronounced ridges are frequently visible. Both relief and inlaid decoration are found, especially on tiles, and brushed slip was also used to add simple patterns.

Unglazed ware was common, especially in the early period, but a soft lead glaze came into more general use later, the knowledge probably being derived from France. The early glaze varied between yellow and brown according to the iron content of the clay, although a group having a particularly rich brown glaze was made by first washing the pot with slip containing manganese. The use of copper oxide to give a rich green of variable colour dates from the 13th century. During that period, the green, buff, and brown glazes were used in conjunction. Cistercian wares, made in the monasteries before their dissolution in 1536–39, are more precisely finished. They have a dark-brown glaze over a stoneware body and are sometimes decorated with white slip or incised. By far the greatest number of surviving specimens are jugs and vessels for storing liquids; since they have almost always been excavated, a reasonably perfect specimen is a rarity.

Tin-glazed ware. Lead-glazed wares tended to die out after tin glaze reached England via the Netherlands about 1550. At first it was called gallyware, but, with the rise of the Dutch manufacturing centre at Delft, the ware came to be called delft. Its popularity was due to the fact that it could be painted in bright colours. The earliest surviving examples are the Malling jugs, so called because an early specimen of the kind was preserved in the church at West Malling, Kent. These were almost certainly made in London. The colour varies from turquoise to black; a variety with a blue ground flecked with orange was probably suggested by the tigerware from the Rhineland. The jugs usually have silver or pewter mounts. Similar mounts, often of English manufacture, are to be seen on Rhenish jugs imported into England and occasionally on Turkish jugs of about the same period.

Malling jugs

By 1628 a flourishing factory had been established at Southwark, London. Influenced by some Chinese blue-and-white porcelain of the Ming reign of Wan-li (1573–1620), some surviving specimens are decorated in blue, with birds amid floral and foliate motifs. Almost contemporary are some large dishes painted in polychrome colours. The earliest (1600), which is in the London Museum, bears the following couplet: "The rose is red the leaves are grene/God Save Elizabeth our Queene." The dish has a border of blue dashes and is a forerunner of the so-called blue-dash chargers that were popular later in the century. These were decorated with biblical scenes (Adam and Eve being a special favourite), crude portraits of the kings of England, ships, armorial bear-

ings, and the like. The influence of Italian maiolica and Chinese porcelain can be seen in the border designs.

Many wine bottles are extant, often with the name of the wine (Sack, Claret, etc.) painted in blue and a date. Others are more elaborately decorated, a few are in polychrome.

Toward the end of the 17th century service ware became more frequent (although tea ware was now scarce). Blue-and-white was still made in large quantities, but a polychrome palette was more in evidence, and the influence of Dutch potters is often obvious.

Chinese influence, which had been particularly strong in the early part of the 18th century, tended to persist, particularly at Bristol. The Rococo style was used to a limited extent. Later, some not very successful attempts were made to utilize The Neoclassical forms. Overglaze colours on tin-glazed wares appear after mid-century. These colours, a special pallet now called Fazackerly colours, were probably used only at Liverpool.

The main centres of production of tin-glazed ware were in London (Southwark and Lambeth), Bristol, and Liverpool, although there were smaller potteries elsewhere. One of them—Wincanton in Somerset—made frequent use of manganese, which produces purple and purplish-black colours. The tin glaze fell into disuse about the turn of the 18th century, its place having been taken by Wedgwood's creamware. (In the mid-20th century manufacture has been successfully revived at Rye, Sussex.)

17th-century slipware. Wares decorated with dotted and trailed slip were made at Wrotham, Kent, and in London during the first half of the 17th century. Wrotham is noted principally for drinking mugs with two or more handles, known as tygs; and London for dishes with such pious exhortations as "Fast and Pray," obviously inspired by the Puritans. Manufacture was also started in Staffordshire, and many surviving examples were signed by the potter in slip. The work of Thomas Toft is particularly valued. The best work of this kind was done before the end of the 17th century, and although it may fairly be described as peasant ware, many of the earlier specimens are vigorously decorated and amusing. Manufacture continued until the end of the 18th century.

Stoneware. The popularity of Rhineland stonewares in England, as well as that of the newly imported Chinese stoneware teapots from I-hsing kilns (see below *China*: *Ming dynasty*), led to attempts to imitate both kinds. The first patent for making copies of porcelain and Cologne ware known to have been exercised was awarded to John Dwight (*c.* 1637–1703) of Fulham in 1671. In addition to German stoneware, he made a brown-glazed stoneware decorated with stamped ornament that was continued at Fulham after his death and has been extensively reproduced since. He probably never made any porcelain, but he mentions red china, which can only refer to imitations of the I-hsing stoneware.

The brothers John Philip and David Elers, of German origin, made red stoneware at a factory in Staffordshire. It is difficult to separate their work from that of Dwight (at Fulham), on the one hand, and that of their Staffordshire imitators, on the other. Most wares are decorated with stamped reliefs, the Chinese prunus blossom being comparatively common. The tendency to utilize patterns from silverwork, which is apparent on some examples, may be connected with the fact that the Elers had been silversmiths. The Elers' migration to Staffordshire perhaps can be regarded as the starting point for the large modern industry that has grown up in that area. Certainly from this time onward Staffordshire wares tend to lose their peasant character and to approach a factory-made precision that was to be general by the end of the 18th century.

Salt-glazed stoneware

The earlier red- and brown-glazed stonewares were replaced about 1690 by a salt-glazed stoneware that was regarded as an acceptable substitute for porcelain. It varies in colour from drab to off-white, the glaze on later specimens often having a richer, more glassy appearance due to the addition of red lead to the salt. One of the earliest varieties is decorated with reliefs stamped from pads of clay that were applied to the surface.

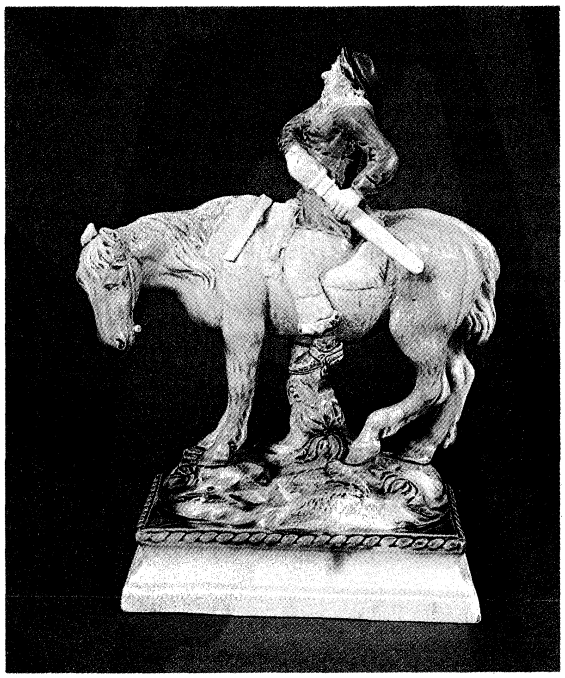
18th-century developments. The "scratched-blue" class of white stoneware dates from about 1730 and is decorated with incised (sgraffito) patterns, usually touched with blue. Decoration is floral, and inscriptions and dates are fairly frequent. Its manufacture continued until about 1775.

From the 1730s molded patterns in relief were popular, the clay being pressed into molds of metal, wood, or fired clay. The introduction of plaster of paris molds around 1745 gave much greater scope and led to the development of intricate shapes in the finer varieties of white stoneware. The patterns greatly increased in sharpness and elaborate piercing is to be seen.

Transfer printing was first used about 1755, possibly at Liverpool, which produced wares of all kinds, including tiles, using this decorative technique.

The earliest use of overglaze colours belongs to the same period—previously, white wares had been sent to Holland for decoration. The Englishman who first mastered the technique was William Duesbury. Established as a decorator in London by 1751, he concentrated on painting porcelain, but he also seems to have overglaze-painted stoneware from Staffordshire. Some extant brilliantly painted figures are probably from his studio. A little earlier than Duesbury's overglaze-painted figures are the uncoloured pew groups, which consist of two or three figures seated on a high-backed settle or pew, modelled in a primitive and amusing fashion. A rich blue overglaze ground, often called Littler's blue after William Littler, who is thought to have invented it, was much used on the salt-glazed stoneware, as well as the porcelain, made at Longton Hall, a factory that operated in Staffordshire from about 1750 to 1760 and that was also associated with Sittler.

John Astbury is particularly associated with a type of brown-glazed ware decorated with stamped pads of white clay. Some of the earliest Staffordshire figures in brown and white clay covered with a lead glaze have been attributed to Astbury.



Agateware

Thomas Whieldon (1719–95) of Fenton Low, Staffordshire, manufactured agateware—that is, ware made by combining differently coloured clays or by combing together different colours of slip. In the former method the clays were usually laid in slabs, one on the other, and beaten out to form a homogeneous mass in which the colours were inextricably mingled. Agatewares seem to have been made in Staffordshire between 1725 and 1750, the earlier specimens being salt glazed, while the later ones were covered with a colourless lead glaze. Whieldon is most famous for his use of coloured glazes that were mingled to give a clouded or tortoiseshell effect and were used on an earthenware body, sometimes over molded decoration. A few naïvely modelled figures with this type of glaze are attributed to him. From 1754 to 1759 he was in partnership with Josiah Wedgwood, who developed the fine green and yellow glazes to decorate molded wares in the form of pineapples, cauliflowers, and the like.

Coloured glazes were also used by Ralph Wood I (1715–72) of Burslem, Staffordshire, for decorating an excellently modelled series of figures in a creamware (lead-glazed earthenware) body, the finest, perhaps, a mounted Hudibras in the Victoria and Albert Museum. Many of these figures are attributed to the modeller Jean Voyez, who was much influenced by the work of P.L. Cyfflé at Lunéville (see above *France*). Ralph Wood I is also noted for the typical English Toby jug (first made soon after 1700), which is a beer jug in the form of a man, usually seated and holding a pipe and a mug, the hat (where present) forming a detachable lid. Very popular, they continued in production for many years. Enoch Wood, another member of the family, joined Ralph Wood II in partnership as Enoch Wood & Co., which lasted until 1790. They made most of the wares current in Staffordshire at the time, as well as some excellent figures decorated with overglaze colours.

Work of Wedgwood

Josiah Wedgwood (1730–95), the most famous of all the Staffordshire potters and the most important exponent of Neoclassicism in the field of pottery, is chiefly celebrated for his fine jasper and black basaltes stone-

wares, but his creamware was undoubtedly the more influential in the 18th century. It was well finished and clean in appearance, with simple decoration in good taste, often in the popular Neoclassical style. His wares appealed particularly to the rising bourgeois class, both in England and abroad, and porcelain and faience factories suffered severely from competition with him. Surviving factories switched to the manufacture of creamware (*faience fine* or *faience anglaise*), and the use of tin glaze almost died out.

Wedgwood secured the patronage of Queen Charlotte (wife of King George III) for his creamware in 1765 and renamed it Queen's ware. Much of it was transfer printed by John Sadler and Guy Green at Liverpool. Evidence of its popularity and importance is provided by the enormous service of 952 pieces made for Catherine the Great's palace of La Grenouillière, in St. Petersburg.

The basaltes ware, also called black porcelain or Egyptian ware, was a type of stoneware introduced about 1768. Like the jasper that followed, it was used almost entirely for ornamental work—vases, ewers, candlesticks, plaques, medallions, and tea and coffee ware. Some of it was painted in what Wedgwood called encaustic enamel in imitation of Greek red- and black-figure vases, but most of the decoration was either molded and applied or incised by turning on a lathe.

Jasperware

Jasper, introduced about 1775, is a fine-grained white unglazed stoneware, slightly translucent when thinly potted or fired above the normal temperature. Undoubtedly it was inspired by the biscuit porcelain of Sèvres. Its name derives from the fact that it resembles the natural stone in hardness. At first the body was stained blue (with applied decoration in white). Other colours, such as sage green, lilac, black, and yellow, followed speedily. Like basaltes, jasper was used mainly for ornamental wares, but perhaps the most interesting products are the portrait medallions of contemporary notables. Vases do not appear to have been made until after 1780. In 1790 Wedgwood produced the first copies of the Portland vase, a magnificent Roman cameo glass vase of dark-blue glass decorated with white figures, at that time owned by the Duke of Portland but now in the British Museum. The vase was reproduced in later years, particularly in Victorian times both by Wedgwood in jasper and by Northwood in glass. Wedgwood's jasperwares were imitated in biscuit porcelain at Sèvres, and Meissen produced a glazed version called Wedgwoodarbeiten. Less influential was the red stoneware (*rosso antico*), which sometimes had an enamelled decoration of classical subjects, and caneware, a buff stoneware.

Lustre pigments introduced into England toward the end of the 18th century, were used in a manner quite different from the earlier styles of other countries (see below *Spain and Islāmic pottery*). To simulate silverwork, wares were completely covered with platinum lustre, which remains unchanged in colour after firing (silver itself yields a pale straw colour); the amount of metal used was extremely small. Such wares were known as poor man's silver. Wares were also painted or stencilled with lustre patterns. The most valuable type commercially were the resist lustres, which have a lustred background and the pattern reserved in white. They were made by painting or stencilling the pattern on the glaze with shellac, which resisted the subsequent application of the metallic pigment. Silver lustre was rarely used, but gold lustre, which gives variable colours from pink to purple, was fairly common. (Copper, whose colour remains more or less unchanged in its lustre form, was used throughout the 19th century for common wares.)

Poor man's silver

Porcelain. A factory for porcelain manufacture, using a soft-paste body similar to that of Saint-Cloud, was established in Chelsea, London, about 1743 by Charles Gouyn and Nicolas Sprimont, the latter a silversmith. The rare surviving specimens include jugs molded in the form of goats and further decorated with an applied bee, obviously based on a silver prototype that no longer exists. (Extant examples of the latter are 19th-century forgeries.) These goat and bee jugs are often marked with an incised triangle, which was then the mark in use. About 1750 a new body was adopted, together with the familiar mark of an anchor, which was raised on a small medallion until about 1752, painted in red until about 1756, and executed in gold thereafter. The work of the Chelsea factory was extensively influenced by Meissen until about 1756, the styles of Sèvres superseding it in the gold-anchor period. Wares marked either with the raised or the red anchor are the most highly valued; the painting of these is excellent in quality. Some of the best wares were painted by an Irish miniaturist, Jeffrey Hamet O'Neal. The gold-anchor-marked wares are noted for rich gilding and some

fine coloured grounds that, on occasion, rivalled those of Sèvres. The figures in the later Rococo style are generally inferior to those of the earlier red anchor period. Some Chelsea porcelain from 1760 onward was painted in the

studio of James Giles of Clerkenwell. The factory was bought by William Duesbury of Derby (see below) in 1770 and entered a phase known as the Chelsea-Derby period. The Neoclassical style was introduced together with the figure in biscuit porcelain made fashionable by Sèvres. It closed finally in 1784.

A group of figures, the best known examples of which are those portraying a girl in a swing, were made in the 1750s—possibly at Chelsea but more probably at a short-lived factory staffed by workmen who had seceded from Chelsea. A class of figures characterized by an apparent retraction of the glaze from the base—dry-edged figures—are attributed to a factory established at Derby about 1750. This enterprise apparently petered out and another factory in Derby was started in 1756 by Duesbury (who was later to buy the Chelsea factory). It advertised itself as the second Dresden and is noted toward the end of the century for the excellence of its painting by Zachariah Borman, William Billingsley, and others.

Longton Hall in Staffordshire made figures and a good deal of service ware molded in the form of leaves. A rich blue ground (Littler's blue) was used on porcelain and salt-glazed wares alike. Its wares are rare and much sought.

The Bow factory (London) was started as early as 1744 with the aid of clay brought from Virginia by the American settler Andrew (André) Duché, who had discovered the secret of manufacture quite independently some years before (see below *Colonial America*). An amusing and primitive class of Bow figures was executed by an anonymous artist known as the Muses Modeller, because the most typical figures portray the Muses. Generally speaking, Bow wares are unsophisticated, and the factory obviously catered to prosperous tradesmen, a market ignored by Chelsea. An important technical innovation took place at Bow in 1750, when calcined bones were added to the porcelain body. This was the first major departure from the French soft-porcelain formula, which was fundamentally a mixture of clay and ground glass. Bone ash was added to soft porcelain by Chelsea about 1755, by Lowestoft (which mainly copied Bow styles) in 1758, and by Duesbury to Derby porcelain in 1770, when he purchased the Chelsea factory. About 1800 at his factory at Stoke-upon-Trent, Staffordshire, Josiah Spode the Second added calcined bones to the hard-porcelain formula to produce the standard English bone-china body (see below *19th century*).

Development of English bone china

Another variation on the original soft-porcelain body was introduced at a factory in Bristol started by Benjamin Lund about 1748. Clay was mixed with a fusible rock called steatite (hydrous magnesium silicate), the principle being similar to that used in the manufacture of hard porcelain. This factory was transfered to Worcester in 1752 and still manufactures fine porcelain. In the 18th century, scale grounds, which consisted of patterns of overlapping scales in various colours, were particularly popular. Transfers taken from engraved plates were also extensively used for decoration. After 1783 wares show a progressive decline in taste. A second factory was established at Worcester by Robert Chamberlain in 1786 (see below *19th century*).

William Cookworthy discovered the secret of hard porcelain independently after many years of experiment. In 1768 he opened a factory at Plymouth (which was transferred to Bristol in 1770) that made figures in the style of Bow and Longton Hall. Richard Champion acquired the patent for hard porcelain in 1772 and manufactured tableware Neoclassical in style and excellent in quality. The patent was bought by a syndicate that established a factory at New Hall, Staffordshire, in 1782 and made a humble variety of wares for about 40 years.

Scandinavia. The faience industry spread to Scandinavia mainly because of migratory workmen from Germany. A number of factories in Denmark, Norway, and Sweden during the 18th century made faience and creamware in the English manner. A distinctive Scandinavian production was that of bowls, made in the shape of a mitre, for a kind of punch called bishop. The most important factories are those of Rörstrand and Marieberg (Koja) in Sweden. A typical Rococo concept to come from Marieberg is a vase standing at the top of a winding flight of steps. Called a terrace vase it is often decorated with a rabbit or some other animal.

In 1774 a factory at Copenhagen directed by Louis Fournier, a modeller from Vincennes and Chantilly, began the manufacture of true porcelain. The factory was acquired in 1779 by King Christian VII of Denmark and Norway. In 1789 the factory started work on an enormous service, originally intended for Catherine the Great, each piece of which was painted with a detailed picture of a Danish flower. This service, the "Flora Danica," is now in Rosenborg Palace, Copenhagen. Numerous skillfully made figures were also produced. The factory continues to produce fine porcelain.

Service for Catherine the Great

Switzerland and Russia. A factory started near Zürich in 1763 and directed by Adam Spengler made both faience and porcelain and, after 1790, creamware. Delicate figures, some modelled by J.V. Sonnenschein from Ludwigsburg, and good-quality service ware were produced.

The factory of St. Petersburg was established about 1745. Later production was on a fairly large scale, and the work of Sèvres and Meissen was freely copied. Some good original work was also done, and well-modelled figures of Russian peasants were made toward the end of the century. Even better figures were made at a factory in Moscow founded about 1765 by an Englishman named Francis Gardner. Many factories at Moscow and elsewhere in Russia were established during the 19th century.

Colonial America. There is little detailed information about the pottery made by the early European settlers in North America. Most of it was manufactured locally for local needs and from the clays that were nearest to hand. Since most of these contained iron in varying quantities, the pottery body burned to colours between buff and red. Until kilns capable of reaching a high temperature were constructed, manufacture was limited to earthenware. Lead glazes were commonly used. Slips, both as a wash and as trailed decoration, were employed, and sgraffito decoration is known. Most of this pottery

was made for practical rather than decorative purposes. A few potteries were established in the 17th century in Virginia, Massachusetts, and New Jersey; and in eastern Pennsylvania, German settlers started work as early as 1735 making slip-painted and sgraffito earthenware in their own traditions.

Perhaps the most important development in colonial America took place in Savannah, Georgia, where Andrew Duché started a pottery about 1730. He interested himself in the manufacture of porcelain and discovered the china clay and feldspathic rock necessary to its manufacture. By 1741 he appears to have made a successful true porcelain but failed to gain adequate financial assistance to develop it. He therefore travelled to London, arriving in 1744, and tried to sell the secret to the founders of the Bow factory in London. Their interest is certain, since the patent specification subsequently filed specifically mentions *unaker*, said to be the Cherokee name for china clay. Duché returned to Virginia by way of Plymouth and there spoke with William Cookworthy, later to be the first manufacturer of true porcelain in England. It is still not known to what extent Duché actually manufactured porcelain; but since the *Bristol Journal* for November 24, 1764, refers to the import of some specimens of porcelain said to have been made in Georgia there is little doubt that the first porcelain to be made in an English-speaking country came from North America. The Cherokee clay was shipped to England from time to time during the 18th century. Wedgwood imported several tons of it to use in the development of the jasper body.

Hard porcelain in America

By 1765 potteries were being established on a sufficient scale to warrant an attempt to recruit workmen from Staffordshire. Wedgwood wrote at the time: "They had a agent amongst us hiring a number of our hands for establishment of new Pottworks in South Carolina."

The manufacture of tin-glazed ware began in Mexico soon after the Spanish Conquest in the first half of the 16th century. Spanish styles predominated, especially that of Talavera, but Chinese influence occurs in the 18th century. The wares became a kind of inspired folk pottery in the 19th century.

19TH CENTURY

There is a fundamental difference between work done before the Industrial Revolution, the effect of which began to be felt in the pottery industry before 1800, and that done subsequently. A student of the older wares, particularly those of the East, may find much of the later work difficult to accept because of its machine finish. When an object is made by hand it is never exactly the same as any other object, nor are the processes by which it has been formed and decorated disguised. Consider, for example, a Sung dynasty pot or a specimen of Japanese tea ceremony ware, whose imperfections of finish by factory standards are an integral part of their beauty and character, or the glaze of a *Kuan* vase, which would lose its individuality if it possessed the smooth finish of a factory-made specimen. The technical precision of the 19th century, which made its products indistinguishable from one another, and the careful concealment of the means by which the end had been achieved, were both unprecedented and deleterious. Style and craftsmanship degenerated steadily in the factories. The situation was aggravated by the Great Exhibition of 1851, which encouraged manufacturers throughout Europe to vie with each other in producing wares displaying virtuosity unhampered by questions of taste; for example, from as far afield as St. Petersburg, hitherto outside the mainstream of European development, came some particularly colossal and hideous vases in a debased Neoclassical style—which were described by a contemporary writer as "second to few of the productions of Dresden and Sèvres for beauty of outline and perfection of finish."

Those who bought these wares—as well as those who produced them—contributed to the degeneration of taste. Before the advent of mass communications in the 20th century, new fashions originated in the wealthiest stratum of society (which was usually also the most cultivated) and filtered downward. As a result of the political and economic effects of the Seven Years' War (1756–63), combined with the beginning of the Industrial Revolution, the European bourgeoisie prospered, and their wealth enabled them to become patrons and arbiters of taste. Primarily interested in the arts as a method of display or as status symbols, they demanded an excess of intricate and expensive ornament. In the Far East the same process of degeneration began at the same time, at least partly as a result of the large number of export orders received. This pernicious influence was kept at bay for awhile by the emperor Ch'ien-lung, who stigmatized the English as cultural barbarians, but became much more pronounced in the 19th century. Similar tendencies may be seen in Japanese pottery after 1853, when many factories worked almost entirely in styles demanded by their customers in the West.

Britain. *Porcelain.* The Neoclassical style, which had been popular during the middle years of the 18th century, gradually lost its earlier simplicity. In France, the rise of Napoleon brought in its train the ostentatious Empire style (copied, for the most part, from the decorative art of imperial Rome), which had much influence in England during the Regency period (1811–20). It is noticeable on the porcelain vases made at such factories as Worcester, Derby, and Rockingham. They were often decorated with well-painted topographical subjects that were no longer confined by frames but ran around the vase as a continuous landscape. Flower painting was often of excellent quality and was much influenced by the work of William Billingsley, a flower painter who worked at Derby toward the end of the 18th century.

At Worcester a factory established by Robert Chamberlain in 1786 produced porcelain decorated in a debased Japanese style. Because of their gaudy colour—iron red and underglaze blue coupled with lavish gilding—some Japan patterns are called thunder-and-lightning patterns. Similar Japan patterns were being employed at Derby and at an older Worcester factory, although much of the work of the latter was more restrained. Some of the best painting at the old factory was executed by Thomas Baxter, who used marine shells as a subject.

It has been said, unfairly, that Josiah Wedgwood, by developing the factory system, was largely responsible for the degradation of the pottery art; but Wedgwood wares have usually been in good taste even if they have not always been particularly adventurous. A far more malign influence was that of John Rose of Coalport (Salop). Rose admired the work of Sèvres and imitated it, buying or borrowing specimens to copy and using such ground colours as the *rose Pompadour.* He was one of the first English exponents of the revived Rococo style, which appeared about 1825, and made much porcelain encrusted with applied flowers. His work has been erroneously regarded as a close copy of old Sèvres. Coalport flower painting, however, is very fine in quality and much in the style of Billingsley, who actually worked at the factory for some years.

Spode and Minton

Josiah Spode the Second, who invented the standard English bone china about 1800, at first made good use of it. Some of his later wares, however, became increasingly pretentious copies of French styles, with highly coloured grounds, lavish gilding, and an excess of applied ornament. The factory was taken over in 1833 by William Taylor Copeland, Jr. and was amalgamated with Wedgwood in 1964.

The firm of Minton's was founded at Stoke-upon-Trent in 1793 by Thomas Minton, a Caughley engraver said to have devised for Spode the Broseley Blue Dragon and Willow patterns that are still in use. Like Coalport, the factory was much occupied in copying the work of Sèvres. From 1848 to 1895 they employed a Frenchman, Joseph-François-Léon Arnoux, as art director, and under his tutelage French artists were brought to England; for example, the sculptor Albert Carrier-Belleuse and also Marc-Louis Solon, who was responsible for introducing *pâte-sur-pâte* decoration into England (see below *The European continent*).

The Derby tradition of fine painting was carried into the

19th century, during which time the flower designs became somewhat overblown, although landscapes remained on a high level. The sets of so-called Campaña vases (more properly Campagna), distantly derived from Italianate copies of the Greek krater, were often decorated with landscapes by the brothers Robert and John Brewer and others. The Brewers were pupils of the topographical painter Paul Sandby.

About 1840 Parian ware, an imitation of Sèvres biscuit porcelain, was introduced by Copeland & Garrett (formerly Spode), and a great many figures, some of them extremely large, were made in this medium. Most of them are either sentimental subjects or quasi-erotic nudes, which were popular subjects of Victorian art. Parian ware had some success in America, where it was manufactured by Norton and Fenton.

Stoneware and earthenware. Production of earthenware and stoneware for the cheaper market continued on an ever-increasing scale. Lustre decoration, which had been revived in the preceding century, was used more frequently than before. A type of stoneware obviously inspired by Wedgwood's jasperware was made at Castleford, Yorkshire. Ironstone china, a type of opaque stoneware sometimes called opaque porcelain, was introduced early in the 19th century. Pseudo-Chinese and Japan patterns were frequently used to decorate it.

Ironstone china

By 1830 new underglaze colours had been pressed into service for transfer printing. These new colours were particularly used by Ridgway & Co. of Hanley, Staffordshire. Transfer-printed earthenware in blue, which became increasingly popular after 1810, was soon being produced in enormous quantities. It was much used by Spode, who often employed American subjects for wares exported to the United States. Polychrome transfer printing, essayed tentatively at Liverpool during the 1760s, was also mastered.

Earthenware figures were made in large quantities in Staffordshire and elsewhere, the best associated with Enoch Wood. They were intended as chimney ornaments, and the subjects range from bullbaiting to sentimental shepherdesses. Many of them are copied more or less directly from Derby porcelain figures, and they are a sad but accurate reflection of the times during which they were made.

The Great Exhibition of 1851 completed the degeneration started by the revival of the Rococo style. Technical progress allowed the manufacturers ever-increasing elaborations with which they bludgeoned the few remaining sensibilities of their customers. Past styles were indiscriminately and ignorantly copied. Minton's, for example, made an earthenware decorated with coloured glazes that they miscalled maiolica. It was used not only for decorative wares but for domestic articles—such as umbrella stands—and for architectural purposes.

The Paris exhibitions of 1867 and 1878 brought Japanese pottery and porcelain once more to the attention of European manufacturers, but it was not the superb porcelain of Arita that had had so much influence in the previous century. This time the Japanese exported cream-coloured earthenware with a closely crackled surface and lavish painting of poor quality, judging that it would appeal to Western taste. It became extremely popular under the name of Satsuma and was copied avidly at Worcester and elsewhere (see below *Japan: 19th and 20th centuries*).

By 1860 a few people had become profoundly disturbed by the level to which popular taste had sunk. Among them was the English poet and designer William Morris, who founded a firm of interior decorators and manufacturers in 1861. One of his pupils, William de Morgan, started a pottery at Fulham (London) in 1888 that made dishes and tiles inspired by Persian, Hispano-Moresque, and Italian wares. De Morgan used brilliant blues and greens and a coppery red lustre. His designs are a great improvement on those of the factories, although they, too, are derivative.

After about 1860 Doultons of Lambeth (London) copied 18th-century brown stoneware, making small figures and repeating earlier designs. The incised decoration by Hannah Barlow is both pleasant and competent. From a Fulham pottery owned by the Martin brothers came grotesque and often amusing stoneware vases that were sometimes decorated with coloured slips.

The European continent. In the 19th century Meissen and Sèvres continued to be the two principal factories and leaders of fashion, although at both places, as elsewhere, artistic standards declined considerably.

Meissen and Sèvres in the 19th century

In the first half of the 19th century Meissen adopted the revived Rococo style, and a large export trade with England was renewed. This was the period of the sentimental Dresden shepherdess, formerly much admired in England and the United States. Later productions include large and ornate candelabra, overdecorated mirror frames, clock cases, and the like, as well as vases and tureens based on the old Rococo models.

From about 1870 styles altered somewhat and are afterward referred to as those of *die Neuzeit* ("the New Period"). Some of the figures and groups illustrating contemporary subjects throw an amusing sidelight on manners and customs of the time.

At Sèvres, as a result of Napoleon's campaign in Egypt and the newly aroused interest in that country, the Empire style of the first decades of the 19th century incorporated many Egyptian motifs, which were somewhat incongruously translated into porcelain. Also, many porcelain plaques with minutely detailed overglaze painting in imitation of easel pictures were executed.

Technical improvements include the introduction, in about 1855, of *pâte-sur-pâte*, a process later popular in England, particularly at Minton's. The design was painted in white slip onto a surface of coloured, lightly fired clay. After each coat of slip dried another superimposed upon it, until the desired degree of relief had been attained. Finally, it was scraped, smoothed, and incised by metal tools and the whole object glazed and fired.

The sculptor Auguste Rodin was employed at Sèvres for a short time but does not seem to have left any enduring marks of his presence. Artistically speaking, Sèvres porcelain has not been very distinguished since the 18th century.

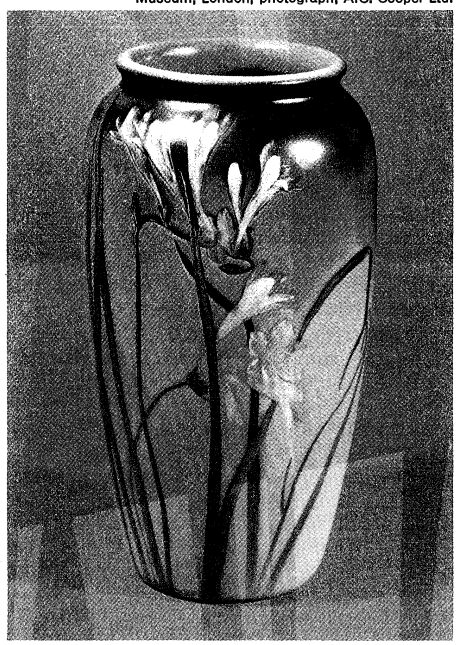
The Royal Porcelain works at Copenhagen has made a great deal of porcelain with simple patterns in underglaze blue derived from Chinese sources by way of Meissen. Molded fluted shapes are characteristic. Production of the well-known biscuit figures after the sculptor Bertel Thorvaldsen (1768–1844) began in 1867. The factory later introduced a slightly amber-coloured biscuit that was used for figure modelling. Painting on a grayish-toned crackled glaze led to experiments with celadons since, technically, the two have much in common (see below *China: Han Dynasty*). Other glazes inspired by early Chinese work followed. The firm of Bing and Gröndahl was established in 1853 and has done excellent and imaginative work.

Royal Copenhagen

The United States. Although Andrew Duché had succeeded in making porcelain as early as 1741, the first man to produce porcelain in any quantity was William Ellis Tucker of Philadelphia. At first he was a decorator of whiteware but started to manufacture both creamware and bone china about 1826. Judge Joseph Hemphill became a partner in 1832, and workmen were imported from Europe. Copies of Sèvres porcelain and other European wares were made about this time in a fine white porcelain body. The first factory at Bennington, Vermont, founded by Capt. John Norton in 1793, made domestic wares, including salt-glazed stoneware. The factory was removed to Bennington Village by his son, Judge Luman Norton, in 1831, and creamware and a brown-glazed ware were produced. In 1839 the factory became Norton and Fenton, and about 1845 the manufacture of Parian ware began. This unglazed near-white porcelain named after Parian marble had been made first in England by Copeland & Garrett (see above *Britain*). John Harrison of Copeland's was hired by Norton and Fenton and brought with him a number of molds. An ironstone china called graniteware or white granite was also made.

The East Liverpool, Ohio, industry was established in 1838 by James Bennett, an English potter. The first prod-

ucts made there were Rockingham and yellow-glazed ware. In the decade following the Civil War, William Bloor, Isaac W. Knowles, and others introduced the production of whiteware. By the last decade of the 19th century, production had grown until it was the largest pottery-producing area in the world.



At about the same time, Zanesville, Ohio, was also developing as a pottery centre. First production was salt-glazed and slip-decorated stoneware. At a later date much artware was produced in Zanesville plants operated by Samuel Weller, J.B. Owens, George Young, and others. This artware established the basis for a sizable modern interest in collecting. Another important centre during the 19th century was at Trenton, New Jersey, where the first factory was established in 1852. Connected with it was William Bloor, who had some responsibility for putting the industry on a successful footing in East Liverpool. Trenton, like East Liverpool, produced fine, skillfully decorated whiteware.

Study of pottery manufacture at universities

A close study of the technical side of manufacture was not undertaken until Edward Orton, Jr., succeeded in getting support for the establishment of a department of ceramics at Ohio State University in Columbus in 1894. The New York State College of Ceramics at Alfred, New York, was started soon afterward, with Charles F. Binns as its director. Binns was a member of an English family connected with the manufacture of porcelain at Worcester and Derby during the 19th century and had himself held a supervisory position at Worcester. Similar departments were added to other universities soon afterward, and in 1898 Orton took the lead in forming the American Ceramic Society. In this way knowledge was put on a more scientific basis, and the trained potters who soon became available to the industry were responsible for many technical improvements. Nevertheless, the artistic direction of the factories did not reach a high standard.

Toward the end of the century it became fashionable for American women to study the art of painting on European pottery, and the Cincinnati Art Pottery Company was founded in 1879 to promote sound pottery design. As a result of its work, the Rookwood Pottery was established in 1880 by Maria Longworth Storer. Rookwood wares show a distinct Japanese influence and have excellent red and yellowish-brown glazes.

20TH CENTURY

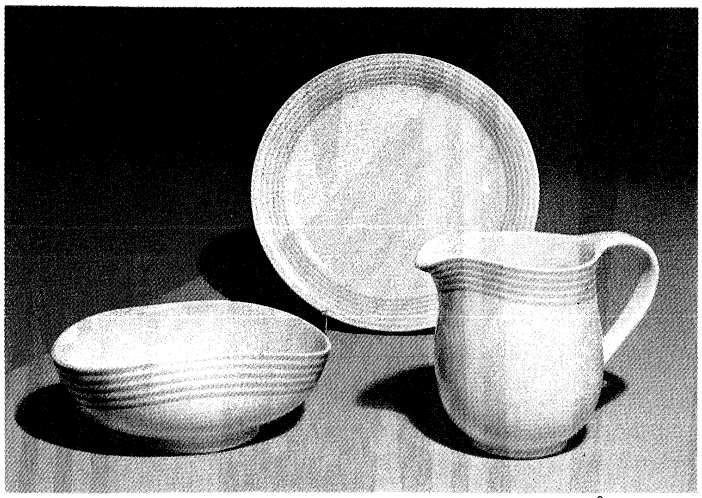
Pottery factories. At the beginning of the 20th century the Wedgwood factory, whose work has always remained at a high level, extended its already considerable business in the United States, and a service of nearly 1,300 pieces was supplied to the White House during the presidency of Theodore Roosevelt (1901–09). In 1940 the factory began to move to its present site at Barlaston, Staffordshire, when the historic site at Etruria, Staffordshire, was progressively abandoned; the new plant is one of the most modern in the world.

Designs of Dorothy Doughty

A new development in decorative porcelain is to be seen in the designs of Dorothy Doughty for the Worcester Royal Porcelain Company, in England, and in those of Edward Marshall Boehm, at Trenton, New Jersey. Characteristic of this kind of work are the American birds of Dorothy Doughty issued in limited editions by the Worcester Company. They are especially remarkable for technical advances in preparing the article for firing, which allow the material to be treated with much greater freedom than hitherto. Porcelain becomes very soft when it reaches the point of vitrification, but, using an elaborate series of props to support free-floating parts, the Worcester technicians succeeded in firing designs that would have been completely impossible earlier. Associated with these models are exact reproductions of natural flowers that also excell in complexity and verisimilitude anything made in the past.

In the early part of the 20th century, Bernard Moore experimented with Chinese glazes, producing some successful flambé and *sang-de-boeuf* glazes on a stoneware body at his small factory in Stoke-upon-Trent (see below *China*: *Ch'ing dynasty*). He worked in association with William Burton of Pilkington pottery in Manchester, which made experimental decorative ware of all kinds.

After World War I, figure modelling worthy of the old Meissen tradition was done by Paul Scheurich, Max Esser, Paul Börner, and others. The early red stoneware was also revived. This renaissance was halted temporarily by World War II, but production had been resumed by 1950. In the 1970s the wares exported from the German Democratic Republic into western Europe were excellent in quality.



A factory that has preserved its traditional reputation for fine porcelain is Nymphenburg, at Munich, now the Staatliche Porzellan-Manufaktur Nymphenburg. At the beginning of the 20th century it began to use a wider range of underglaze colours with the aid of colour chemists from Sèvres and, about the same time, reissued some of the old figures and services of Bustelli and Auliczek (appropriately marked). Attention was soon turned to services of fine quality in the modern idiom, and excellent figures by Resl Lechner and others were produced. Lechner succeeded in adapting the 18th-century styles to 20th-century purposes in a manner that is an object lesson to those manufacturers who insist, even today, on adding the scrolls and flourishes of the Rococo.

Such factories as Rörstrand and Gustavsberg in Sweden and Arabia Oy in Finland have achieved a growing reputation for excellent design in the modern idiom. The emphasis on form in present-day pottery is to a great extent due to the import of Chinese wares of the Sung dynasty (see below) during the 1920s.

The pottery of the United States in the 1970s bears comparison with that of any other country, and standards are constantly improving. Technically, the U.S. is perhaps ahead of the rest of the world. The growing appreciation of good pottery design has led national, state, and local governments to sponsor pottery making as an art. There is also a pottery experimental station in the Tennessee Valley.

Government-sponsored pottery making

The artist-potter. The artist-potter has had an important influence on modern design from the time that Bernard Leach (1887–) established the St. Ives Pottery in 1920. Leach spent many of his early years in the Far East and learned the art of making *raku* and stoneware in Japan (see below *Japan*: *Kamakura and Muromachi periods*). He began working at a time when interest in early Chinese wares had greatly increased, and much of his work is obviously influenced by the work of Tz'u-chou (see below *China: Sung dynasty*) as well as that of Japan. It is, nevertheless, strongly individual. One of Leach's

pupils, Michael Cardew, has done good work in stoneware, which he often decorates with vigorous patterns drawn with a pleasing economy of outline. William Staite Murray, at one time the head of the ceramic department of the Royal College of Art, has made some important and interesting stoneware and has influenced many younger potters. Excellent work has been done by continental potters working in England, among them Lucie Rie from Vienna and Hans Coper from Germany. Amusing figures have come from Marion Morris, who was trained in Budapest.

The artist-potters on the Continent tend to be less conservative than their English counterparts, and many new and interesting developments have occurred. The modern fashion for abstraction in art is particularly favourable to development, since the potter understood its principles long before the 20th-century painters and sculptors came to it. By the 1970s many art schools included pottery making in their curriculum, and students were rapidly increasing in numbers.

Somewhat outside the mainstream of pottery tradition, and a markedly individual production related to their work in other media, is the pottery of such well-known artists as Pierre-Auguste Renoir, Paul Gauguin, Joan Miró, Henri Matisse, Ernst Barlach, and Pablo Picasso. A good many of these wares are unique, although some have been repeated by factory production methods.

III. East Asian and Southeast Asian pottery

CHINA

Nowhere in the world has pottery assumed such importance as in China, and the influence of Chinese porcelain on later European pottery has been profound.

It is difficult to give much practical assistance on the question of Chinese marks. Most of the Chinese marks give the name of the dynasty and that of the emperor; however, many of them have been used so inconsequentially that, unless the period can also be assigned with reasonable certainty by other means, it is better to disregard them. The dating of Chinese pottery is further complicated by the fact that there were traditional and persisting types that overlapped; quite often, therefore, dynastic labels cannot be regarded as anything more than an indication of the affinities of the particular object under discussion.

Chinese symbolic decoration

Chinese decoration is usually symbolic and often exploits the double meaning of certain words; for instance, the Chinese word for bat, *fu*, also means "happiness." Five bats represent the Five Blessings—longevity, wealth, serenity, virtue, and an easy death. Longevity is symbolized by such things as the stork, the pine, and the tortoise, the *ling chih* fungus, and the bamboo, all reputed to enjoy long life. The character *shou*, which also denotes longevity, is used in a variety of ornamental forms. Together, the peach and the bat represent *fu-shou*, long life and happiness. The "Buddha's hand" citron, a fruit with fingerlike appendages, is a symbol of wealth, and each month and season is represented by a flower or plant. The *pa kua*, consisting of eight sets of three lines, broken and unbroken in different combinations, represent natural forces. They are often seen in conjunction with the Yin-Yang symbol, which represents the female–male principle, and which has been well described by the pottery scholar R.L. Hobson as resembling "two tadpoles interlocked." The dragon generally is a mild and beneficent creature. It is a symbol of the emperor, just as the phoenix-like creature (*feng-huang*) symbolizes the empress.

There are three principal religious systems in China: Confucianism, Taoism, and Buddhism. Taoist figures, in particular, appear frequently on porcelain as decoration. The most important, Lao-tzu, has a large and protuberant forehead. He is usually accompanied by the "eight immortals" (*pa hsien*), and these are sometimes modelled as sets of figures. The eight horses of the emperor Mu Wang (Chou dynasty) are also frequently represented. The Buddhist goddess Kuan-yin and the eighteen lohan, disciples of Buddha, were also modelled. The "eight Buddhist emblems" appear fairly frequently, as do the "eight precious things" and a collection of instruments and implements used in the arts and known as the "hundred antiques." The "lions of Buddha" (often miscalled dogs) are frequently represented, as is the kylin (properly the *ch'i-lin*), which is a composite animal, not unlike a unicorn, that has a fierce appearance but gentle disposition.

Most of these symbols were not used in pottery decoration before the Ming dynasty, although both the dragon and a phoenix-like creature (probably the Chinese pheasant), as well as some floral motifs, are earlier. The *lei-wen*, however, which resembles the Greek key fret (an ornament consisting of small, straight bars intersecting one another in right angles) and is sometimes used on the later ceramic wares, appears on bronzes as early as the Shang and Chou dynasties, where it is called the cloud-and-thunder fret. The *t'ao-t'ieh*, a grotesque mask of uncertain origin, also appears on early bronzes and on later pottery and porcelain. Decorations based on Chinese literary sources are usually extremely difficult to trace to their origin.

The earliest Chinese pottery is of the Neolithic period and has been discovered in the provinces of Honan and

Earliest Chinese pottery

Kansu. Perhaps the best known of these wares is a series of large urns of red polished pottery with geometric decoration found in the Pan-shan cemetery and at Mach'ang, both in Kansu Province. These were made by hand, the latest specimens with perhaps some assistance from a slow wheel, and are at least as early as 2000 BC.

Shang (or Yin) and Chou dynasties (c. 1766–221 BC). The only known complete specimen of a fine white stoneware dating from *c.* 1400 BC (Freer Gallery of Art, Washington, D.C.) is decorated with chevrons (linked V-shapes) and a key-fret pattern, the shoulder motifs being reminiscent of those seen on contemporary bronze vessels. This ware is much better in quality than most other surviving pottery of the Shang period (*c.* 1766–1122 BC) or of the following Chou dynasty (*c.* 1122–221 BC). Much Chou pottery is decorated with rudimentary incised ornament, some of which resembles the impress of coarse textiles referred to as mat markings. The shapes used for these pieces were often inspired by bronze vessels.

The development of glazing in China may have started with the application of glass paste to some of the later Chou wares. Stoneware vessels of about the 3rd century BC have a glaze that is little more than a smear but one that has obviously been deliberately applied. This type persisted for several centuries.

Han dynasty (206 BC–AD 220) and the period of the Six Dynasties (AD 221–589). The first pottery to survive in appreciable quantities belongs to the Han dynasty; most of it has been excavated from graves. Perhaps the commonest form is the *hu*, a baluster-shaped vase copied from bronze vessels of the same name and sometimes decorated with relief ornament in friezes taken directly from a bronze original. The hill jar, which has a cover molded to represent the Taoist "Isles of the Blest," is another fairly frequent form, and many models of servants, domestic animals, buildings, wellheads, dovecots, and the like also have been discovered in graves. Some of this pottery is unglazed or decorated with cold (*i.e.*, unfired) pigments, but much of it is covered with a glaze that varies from copper green to yellowish brown; often the colours have become iridescent from long burial. The body is usually a dark red and approaches stoneware in hardness.

Han glaze is more glasslike than that of the Chou period and is of an excellent quality. It contains lead and was frequently coloured green with copper oxide.

Celadon glazes

Yüeh *yao* ("Yüeh ware") was first made at Yüeh-chou, Chekiang Province, during the Han dynasty, although all surviving specimens are later, most belonging to the Six Dynasties. They have a stoneware body and an olive or brownish-green glaze and belong to the family of celadons, a term that looms large in any discussion of early Chinese wares. It is applied to glazes ranging from the olive of Yüeh to the deep green of later varieties. These colours were the result of a wash of slip containing a high proportion of iron that was put over the body before glazing. The iron interacted with the glaze during firing and coloured it.

T'ang dynasty (AD 618–907). Chinese pottery reaches an important stage in its development during the T'ang dynasty.

Nearly everything that has survived has been excavated from tombs, many of them found accidentally by railway engineers and latterly by more systematic excavations. Excavations at Sāmarrā' on the Tigris, a luxurious residence built by the caliph al-Mu'taṣim (son of Hārūn ar-Rashīd) in AD 836 and abandoned in 873, have uncovered many fragments of T'ang wares of all kinds. Perhaps the most important finds from a historical viewpoint are the fragments of what is undoubtedly porcelain. An Islāmic record of travels in the Far East, written in 851, records "vessels of clay as transparent as glass." There can be little doubt, therefore, that translucent porcelain was made in the T'ang period, although it was not until the Yüan dynasty (1279–1368) that it began to resemble the type with which the West is most familiar.

Early porcelain

Perhaps the most important single development was the use of coloured glazes—as monochromes or splashed and dappled. The T'ang wares commonest in Western collections are those with either monochrome or dappled glazes covering a highly absorbent, buff, earthenware body. The dappled glazes were usually applied with a sponge, and they include blue, dark blue, green, yellow, orange, straw, and brown colours. These glazes normally exhibit a fine crackle and often fall short of the base in an uneven wavy line, the unglazed surface area varying from about one-third to two-thirds of the vessel.

Dappled glazes are also found on the magnificent series of tomb figures with which this period is particularly associated. Similar figures were made in unglazed earthenware and were sometimes decorated with cold pigment. Although the unglazed specimen or those covered only with the straw-coloured glaze are occasionally modelled superbly, many are crude and apparently made for the tombs of the less affluent and influential. Most of the glazed figures are much better in quality and occasionally reach a large size; figures of the Bactrian camel, for instance, are particularly impressive, some being nearly three feet high. The Bactrian pony, introduced into China about 138 BC, is to be found in many spirited poses. This

fashion for tomb figures fell into disuse at the beginning of the Sung dynasty (AD 960–1279) but was revived for a short while during the Ming period (1368–1644), when T'ang influence is noticeable.

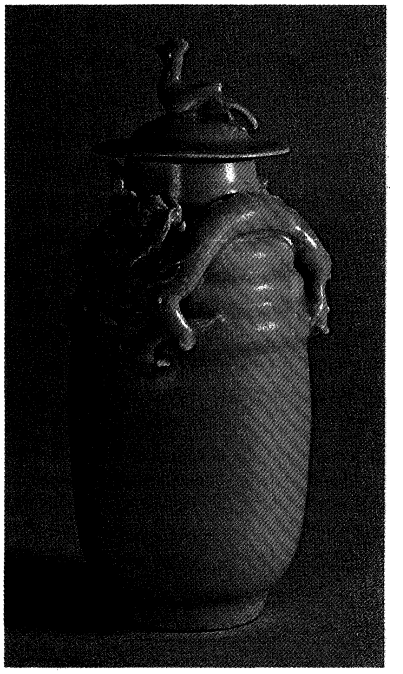
Marbled wares are seen occasionally. The effect was achieved either by combing slips of contrasting colours (*i.e.*, mingling the slips after they had been put on the pot, by means of a comb) or by mingling differently coloured clays. Another type of T'ang ware (probably from Honan) had a stoneware body with a dark-brown glaze streaked by pale blue. Most vessels stand on a flat base; although later T'ang wares sometimes were given a foot ring, for the most part this can be regarded as evidence in favour of a Sung dating.

Sung dynasty (AD 960–1279). The wares of the Sung dynasty are particularly noted for brilliant feldspathic glazes over a stoneware body and their emphasis on simplicity of form. Decoration is infrequent but may be incised, molded, impressed, or carved; a certain amount of painted decoration was done at Tz'u-chou in Chihli (now called Hopeh) Province (*see* below). The esteem accorded to the Sung wares accounts for the relatively large number that have survived. The principal varieties are Ju, *kuan*, Ko, Ting, Lung-ch'üan, Chün, Chien, Tz'u-chou, and *ying-ch'ing*.

Ju ware has a buff stoneware body and is covered with a

dense greenish-blue glaze that sometimes has a fine crackle. It was made in Honan at an Imperial factory that apparently had a life of about 20 years, starting in 1107.

Kuan ("official") is another Imperial ware that is also exceedingly scarce. It was probably first made in the north, the kilns being re-established at Hangchow in Chekiang Province about 1127, when the court fled southward to escape the Chin Tatar invaders. The body is of stoneware washed with brown slip. The glaze varies from pale green to a lavender blue, with a wide-meshed crackle emphasized by the application of brown pigment. Chinese references to "a brown mouth and an iron foot" can be identified with the colour of the rim and the foot ring.

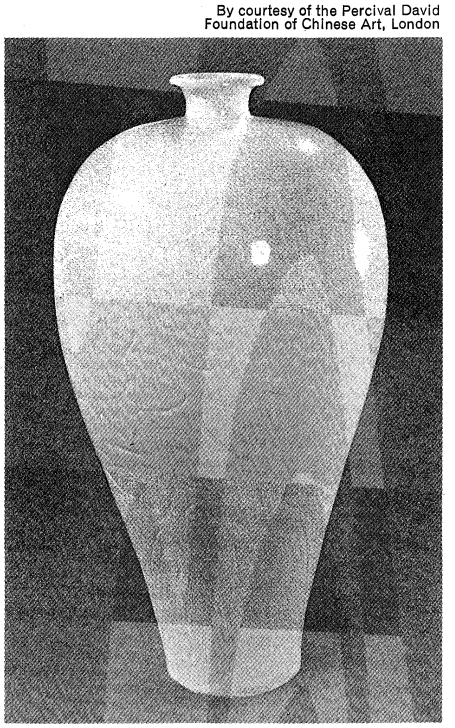


Ko ware is closely related to *kuan* ware. It has a dark stoneware body and a grayish-white glaze with a well-marked crackle, which was induced deliberately for its decorative effect.

Ting wares are white. Some exhibit an orange translucency, while the coarser varieties are opaque. The finest examples are called "white" (*pai*) Ting. On the exterior of bowls and similar vessels the glaze of white Ting is apt to collect in drops, called teardrops. Many articles, particularly bowls, were fired mouth downward, leaving an unglazed rim that was afterward bound with a band of copper or silver. (Bands appear occasionally on other Sung wares, notably *ying-ch'ing*, and were sometimes used to conceal damage rather than an unglazed rim.) Coarser varieties are known as "flour" (*fen*) Ting and "earthen" (*t'u*) Ting, and there are also a few examples of black Ting. As in the case of *kuan* ware, the kilns are said to have been removed southward in 1127, but it has so far proved impossible to differentiate between the northern and southern varieties. Other white wares made elsewhere during the period include those of Tz'u-chou and a variety covered with a white slip over a grayish body from Chü-lu Hsien (both in present Hopeh Province).

Lung-ch'üan

The celadons of Lung-ch'üan are, perhaps, the most common of the classic Sung wares. The town is in the province of Chekiang, near the capital of the southern Sung emperors at Hangchow. The kilns probably date back to the 10th century. The glaze, which is superb in quality, is a transparent green in colour. It is thick and viscous, usually with a well-marked crackle. (The glaze on early specimens is less transparent and more dense.)



By courtesy of the Victoria and Albert Museum, London

Lung-ch'üan celadon ware wine jar and cover, with light bluish-green glaze, Sung dynasty, 12th century. In the Victoria and Albert Museum, London. Height 25.4 cm.

The body is gray to grayish white, best seen at the rim, where the glaze tends to be thin. By far the most frequent surviving examples of Lung-ch'üan celadon are large dishes, for which there was a thriving export trade, due in part to the superstition that a celadon dish would break or change colour if poisoned food were put into it. Bowls and large vases, both of which are scarce, were also made with this glaze. Decoration is usually incised, but molded decoration is also found. On some pots the molding was left unglazed, so that it burned to a dark reddish brown —an effective contrast to the colour of the glaze. The more finely potted wares are the scarcest and often the oldest. The heavier varieties were intended to withstand the rigours of transport to overseas markets, and probably most of them belong to the Yüan dynasty (1279–1368), when the export trade was considerably extended.

Ting ware vase, white porcelain with an ivory-white glaze covering carved design of peony flowers and foliage, Sung dynasty (AD 960–1279). In the Percival David Foundation of Chinese Art, London. Height 36.8 cm.

Chün ware comes from the K'ai-feng district of Honan Province. The body is a grayish-white, hard-fired stoneware covered with a thick, dense, lavender-blue glaze often suffused with crimson purple. This is the first example of a reduced copper, or flambé, glaze. Conical bowls are especially numerous, and dishes are not unusual, but the finer specimens are usually flowerpots, sometimes said to have been made for Imperial use. Characteristic are barely perceptible channels or tracks caused by the parting of the viscous glaze; these are called earthworm tracks by the Chinese. The kilns probably continued to produce this ware until the 16th century, and it is difficult to separate some of the later productions from the earlier.

Chien ware is called after the original place of manufacture, Chien-an, in Fukien Province. Manufacture was later moved to nearby Chien-yang, probably during the Yüan period. The glaze is very dark brown, approaching black, over a dark stoneware body, and it usually stops short of the base in a thick treacly roll.

There are many variations in the colour of the glaze. Streaks in lighter brown are referred to by the Chinese as hare's fur. Silvery spots on the glaze are called oil spots. The most usual surviving form is the teabowl; these were much esteemed by the Japanese under the name of *temmoku* and were used in the tea ceremony (see below *Japan: Kamakura and Muromachi periods*).

The Tz'u-chou ware

The kilns of Tz'u-chou, formerly in Honan, are now in Hopeh Province. The earliest surviving examples are referable to the T'ang dynasty. In the Sung period, vases, wine jars, and pillows (which are more comfortable than they appear) were the most usual products. The body is usually a hard-fired, grayish-white stoneware that was first covered with a wash of white slip and then with a transparent glaze. For the first time painted decoration appears under the glaze, perhaps as a result of influence from the Middle East (see above *Islāmic pottery: 11th to 15th century in Mesopotamia and Persia*). Decoration is nearly always in brown or black; the motifs are usually floral and display a singular freedom of line that is very attractive. (The inclusion of human and animal figures suggests a Yüan or a Ming dating, at the least.) The slip covering was sometimes carved away, leaving a pattern in contrasting colour, a technique also used in conjunction with a dark brown glaze. A hare's-fur glaze, similar to that of Chien wares, was also employed. A blue glaze with painted decoration in black beneath it was obviously inspired by contemporary Persian pottery decorated in the same way. Another innovation, perhaps derived from the same source, is the use of colours applied over the glaze. These are limited to primitive reds and greens and yellows.

Ying-ch'ing ware

An important and not uncommon ware is *ying-ch'ing* ("shadowy blue"). It was manufactured both in the south (Kiangsi) and the north (Hopeh). Moreover, it was extensively exported and has been found as far west as the ruins of al Fusṭāṭ (old Cairo). The body is pale buff in colour, usually translucent, and thinly potted, breaking with a sugary fracture. Most genuine examples seem to belong to the Sung and Yüan periods, but it is probable that, in the north at any rate, manufacture started late in the T'ang dynasty and lasted well into the Ming period. Bowls of conical form are the commonest survival, and many are decorated with incised floral and foliate motifs. Lightly molded decoration occurs, as does combing of the clay. The *mei p'ing* vase is found with this glaze; it has a tall body with straight sides, high, rounded shoulders, and a short narrow neck and was intended to hold a single spray of prunus blossom. Stem cups, deep bowls, and ewers were also produced. Bowls sometimes have the rim bound with copper.

Yüan dynasty (1279–1368). The Yüan, or Mongol, dynasty is often regarded as being no more than transitional between Sung and Ming types. This is not entirely true. Undoubtedly, many Sung types were continued, just as the T'ang types were continued at the beginning of the Sung dynasty, but there are other wares that represent a new departure. The manufacturing centre of Ching-te-chen increased in importance and first manufactured the white translucent porcelain that was to have a revolutionary effect on Chinese wares. The use of painted decoration, begun during the Sung period at Tz'u-chou, also became much more widespread, and the two techniques were combined in a manner that later affected the course of porcelain manufacture throughout the world.

The *Ko ku yao lun* of 1387 refers to *shu fu* ware, a type of white porcelain. The base is unglazed. Decoration in relief, painted in slip or engraved, is to be seen on some surviving examples of porcelain. It appears to be a development of the earlier *Ting ch'ing*. Much more unusual is the appearance of a few specimens of Yüan date that are painted with reduced copper red under the glaze. As mentioned above, the potters of Chün-chou had achieved this colour, but only in the glaze.

The use of underglaze blue was introduced from the Middle East, where it had been employed at least as early as the 9th century, specimens thus decorated having been recovered at Sāmarrā' (see below *Islāmic pottery: 'Abbāsid*). The best known example of Yüan porcelain decorated in this manner, which is usually referred to as blue-and-white, is a pair of vases in the Percival David Foundation of Chinese Art in London. They bear a date equivalent to 1351. The peony scroll, carved or in applied relief, appears on some of these blue-and-white wares.

Blue-and-white ware

Ming dynasty (1368–1644). The Mongol emperor Shun Ti was defeated in a popular uprising, and the Hung-wu emperor, founder of the Ming dynasty, succeeded him in 1368. When the country had recovered from these internecine struggles, pottery art took a new lease of life, though under somewhat changed conditions. The Sung wares went out of favour, and the old factories sank into obscurity, while the fame and importance of the great porcelain town of Ching-te-chen, near the P'o-yang Hu in Kiangsi Province, overshadowed all the rest. The Imperial factory there was rebuilt and reorganized to keep the court supplied with the new porcelain. The staple product of Ching-te-chen was the fine white porcelain that made "china" a household word throughout the world; and as this ware lent itself peculiarly well to painted decoration, the vogue for painted porcelain rapidly replaced the old Sung taste for monochromes.

"China" ware

The reign of the Yung-lo emperor (1402–24) is remarkable for some extremely thin-walled pieces, referred to as "bodiless" (*t'o t'ai*) ware. Engraved examples are known, and Chinese commentaries refer to specimens decorated in red.

After this early period, Ming wares generally are fairly easily recognizable. Porcelain replaced stoneware as the usual medium, and polychrome decoration became widely employed. The largest single group of Ming porcelain is that painted in blue underglaze. Much of the pigment used was imported from Middle Eastern sources. Supplies of this so-called Mohammedan blue (*hui-hui ch'ing*), which came from the Kashān district of Persia, were not always obtainable and were interrupted on more than one occasion. The quality of the blue-painted wares, however, remained to a great extent dependent on its use until the end of the 16th century, when methods of refining native cobalt were devised.

Flask decorated with a dragon and wave scrolls in underglaze blue, Ming dynasty, 14th century. In the Victoria and Albert Museum, London. Height 36.8 cm.

The wares lack much of the precision of the porcelain made during the following Ch'ing period (1644–1911), when a kind of factory system grew up that divided the work into a large number of repetitive operations. Little trouble was taken to smooth over imperfections of manufacture, and foot rings are often finished summarily. The glaze, too, frequently has minor defects, and articles, such as vases, are sometimes slightly distorted and carelessly finished. The shape of many examples can fairly be described as massive, in spite of the fact that most of them were made for export, and the difficulties of transporting them must have been considerable. None of these factors evinces a lack of skill, especially as the potters were quite capable of technical virtuosity when they wished to dis-

play it—some of the most thinly potted of all Chinese porcelain belongs to this period. It seems that the Ming potters disdained the attitude of mind that treated blemishes as important; occasional distortions, in fact, were regarded as lending interest to an object. The Chinese did not carry this aesthetic creed to the same lengths as the Japanese (see below *Japan*), but the difference seems to be largely one of degree. Ming wares can fairly be described as masculine, in contrast to the more feminine, more precisely finished wares of the later Ch'ing period.

Reign of the Hsüan-te emperor (1425–35). In this period the arts were particularly fostered and a high level of achievement attained. The blue painting is blackish in colour, with dark spots at intervals where thick blobs of pigment were deposited by the brush—the so-called heaped and piled effect. The motifs are floral and foliate, with the occasional use of fish and waterfowl. Sometimes vessels are bordered by a pattern of conventional rock amid waves—the Isles of Immortality—often referred to as the Rock of Ages pattern. The pattern appears frequently throughout the Ming period and later.

Heaped and piled effect

Contemporary Chinese commentaries refer to the use of underglaze copper red—often called sacrificial red for uncertain reasons. To a great extent sacrificial red was abandoned later in the dynasty in favour of overglaze iron red, although it was used again during the reign of the Ch'ing dynasty K'ang-hsi (1661–1722) and Yung-cheng (1723–35) emperors and appears in a rather primitive form from some provincial kilns. Both copper red and blue were used as monochromes and, occasionally, together; but since these pigments required a slightly different firing temperature, one or the other is usually deficient in quality.

The use of overglaze colours was rare, and the technique had by no means been fully mastered.

Reign of the Ch'eng-hua emperor (1464–87). Much overglaze decoration can be attributed with a reasonable measure of certainty to the reign of Ch'eng-hua, the finest examples being, perhaps, the chicken cups, so-called because they are decorated with chickens. Their decoration is outlined in underglaze blue and filled in with soft overglaze colours called "contending colours" (*tou ts'ai*). Ch'eng-hua overglaze colours were thin, subdued in colour, and pictorial in effect.

The practice of enamelling directly onto unglazed, or biscuit, porcelain instead of onto a glazed and fired body is sometimes thought to have begun in this reign, though that of the Chia-ching emperor (1521–66) is the more likely. Ming specimens are, in any case, extremely rare; most belong to the reign of the K'ang-hsi emperor (1661–1722) in the Ch'ing dynasty.

Reigns of the Hung-chih and Cheng-te emperors (1487–1521). The first use of a coloured overglaze ground can be attributed to the reign of the Hung-chih emperor (1487–1505), when a yellow of variable shade first appears. In the reign of the Cheng-te emperor (1505–21) the influence of the Muslim palace eunuchs who supervised the Imperial kilns is seen in such blue-and-white motifs as the Mohammedan scroll, which is composed of somewhat formal flowers joined by S-shaped stems, with scroll-like leaves at intervals along them. Mohammedan blue was again available. The earliest versions of this theme, which seems orginally to have come from a textile pattern, are the least stiffly drawn. The linear style of painting characteristic of earlier porcelain altered to one in which outlines were filled in with flat ungraduated washes.

Muslim influence

Reign of the Chia-ching emperor (1521–66). This reign is notable for a deterioration in the quality of the porcelain body, offset by the use of rich dark blue. Wares painted overglaze, too, were executed in good colours, with well-marked outlines. A characteristic colour, the opaque iron red (*fan hung*), sometimes called tomato red, was used as a monochrome with gilt traceries over it on bowls that sometimes had interior decoration in underglaze blue. Various wares have decoration in red and green, a palette that became more familiar later. A yellow glaze is found in conjunction with incised decoration (usually a dragon) in green. Very rarely was a green or blue monochrome used.

Reigns of the Lung-ch'ing and Wan-li emperors (1566–1620). The styles of Chia-ching were, to some extent, continued in the following reigns of the Lung-ch'ing (1566–72) and Wan li (1573–1620) emperors. A palette containing underglaze blue in conjunction with green, yellow, aubergine purple, and iron red (the precursor of the later Ch'ing *famille verte* palette) was known as "Wan-li five-colour" ware (Wan-li *wu ts'ai*). The red and green Chia-ching decoration was also used, and vast quantities of blue-and-white porcelain were produced for export. The body is quite unlike that used earlier in the dynasty, being thin, hard, crisp, and resonant. It is the commonest of all Ming wares in the West. During the reign of the Wan-li emperor, much pierced work (*ling lung*) was done. Pierced objects range from small brush pots to vases with coloured glazes sometimes termed *fa hua*.

The Ming dynasty ended in 1644. The wares of the last three emperors, for the most part, followed styles already established; perhaps an exception can be made for blue-and-white, which shows a number of new departures in both form and decoration. Many of the vases are without a foot-ring and stand on a flat, unglazed base. Forms based on European wares were obviously made for export.

Provincial and export wares. Most of the wares hitherto discussed were made in the Ching-te-chen area; it remains to consider the other wares of the period. The export of celadons went on, not only to the countries west of China but also to Japan, where they were much esteemed. Most celadons attributable to the Ming period have incised under the glaze floral and foliate decoration of a kind that also appears on blue painted wares.

The fine porcelain of Te-hua in Fukien Province was first made, perhaps, in the early part of the dynasty. Most of this porcelain was left undecorated, and received the name in Europe of blanc de chine. The glaze is exceptionally thick and lustrous, and early examples are often slightly ivory in tone. Overglaze painting is infrequent; virtually all early coloured specimens, figures or vessels, have been decorated in Europe, usually in the Netherlands. Figures especially were produced at the Te-hua kilns, with the Buddhist goddess Kuan-yin being a favourite subject.

Blanc de chine porcelain

The stoneware of I-hsing in Kiangsu Province was known in the West as boccaro ware and was copied and imitated at Meissen, at Staffordshire, and in the Netherlands by Ary de Milde and others. Its teapots were much valued in 17th century Europe, where tea was newly introduced. The wares of I-hsing are unglazed, the body varying from red to dark brown. The molding is extremely precise and was often sharpened by grinding on a lapidary's wheel. The body was sometimes polished in the same way.

Most of the Ming stoneware ridge tiles and roof finials were made at kilns near Peking. Many of them are decorated in green, yellow, turquoise, and aubergine-purple glazes, recalling the wares of the T'ang dynasty. A Ming date is exceedingly optimistic for most of them. To this group belong, it is thought, a few large figures that have sometimes been somewhat doubtfully awarded a T'ang date.

The provincial tile kilns also manufactured "three-coloured" (*san ts'ai*) wares, perhaps originally a product of the Tz'u-chou kilns. These were decorated with coloured glazes that were often kept from intermingling by threads of clay (cloisonné technique) or were used in conjunction with the pierced technique (*fa hua*). Others have engraved designs under the glazes. Most existing specimens are large vases, barrel-shaped garden seats, and the like. The best are extremely handsome and imposing, turquoise and dark-blue glazes being particularly effective.

Ch'ing dynasty (1644–1911). With the Ch'ing dynasty came the beginning of the immense vogue for porcelain in Europe that was to reach its height during the first half of the 18th century. Many varieties of Ch'ing ware are common in the West. Its wares differ, for the most part, from those of the Ming period in a fairly distinctive manner. Potters had their medium under almost complete control, and their products are much more precisely finished. Their finesse contrasts sharply with the struggles

Difference between Chinese and European pottery making

of potters in Europe, where porcelain manufacture did not emerge from the purely empirical stage until the 19th century. Letters written in 1712 and 1722 by a Jesuit missionary who spent some years at Ching-te-chen record that some Ch'ing pieces were handled by as many as 70 men, each contributing a small part to the total effect, and this is one of the reasons why many Ch'ing wares are found to lack the freshness and the spontaneity of Ming decoration.

The Imperial kilns of Ching-te-chen were fortunate in the support they received from the palace during the reigns of the K'ang-hsi (1661–1722), Yung-chen (1723–35), and Ch'ien-lung (1736–96) emperors. The K'ang-hsi emperor, in particular, was a patron of the arts on a considerable scale.

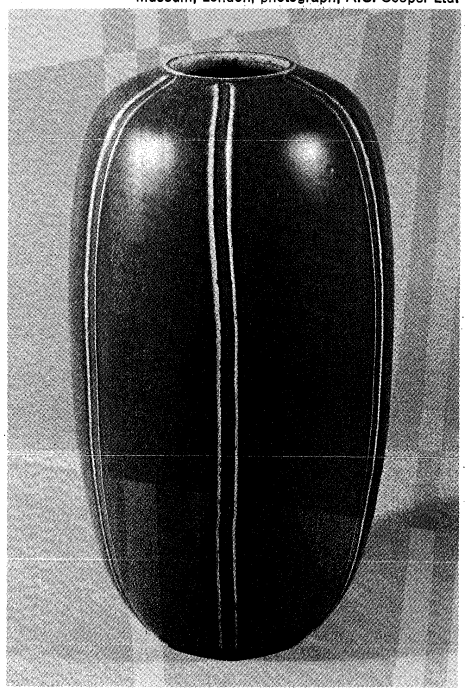
Underglaze blue and red. The blue-painted porcelain of the Ch'ing dynasty has been somewhat neglected in the 20th century. This is probably due to the ridiculously high value placed on it during the latter years of the 19th century, when it was called Nanking ware. Even the best, which belongs to the reign of the K'ang-hsi emperor, hardly bears comparison with the finer Ming wares, though its influence on European porcelain was far-reaching. Blue-and-white porcelain was exported to Europe in vast quantities, and many of the forms were especially made for export; the condiment ledge on plates and dishes, for instance, which first appeared in the reign of the Wan-li emperor (Ming dynasty), had been added for Western customers (the Chinese used the saucer dish). The blue-and-white of the K'ang-hsi period has an extremely white body, and the blue is exceptionally clear and pure. It is variable in shade, and the design is executed in graduated washes within lightly drawn outlines, a point of difference from Ming wares. Many of the designs of the Ming period were in use, and, of the later patterns, those illustrating literary and historical themes are probably of the highest quality.

Ginger jars decorated with prunus blossom reserved in white on an irregular blue ground, intended to represent the cracked ice of spring and sometimes described as pulsating, were once valued highly; in the mid-20th century a more realistic attitude was taken toward them.

Underglaze copper red was also used during the 18th century. The stem cups of the Yung-cheng period with three fruit or three fish in silhouette, which imitate those of Hsüan-te, are much better known than the wares they copied. Copper red also appears in conjunction with underglaze blue, and a greenish-toned glaze is common with pieces thus decorated.

Underglaze blue was sometimes used as a monochrome ground colour. It was blown on the surface in powder form before glazing; a bamboo tube, closed with gauze at one end, was employed for the purpose. It is thus called powder blue, or, in Chinese, *ch'ui ch'ing* ("blown blue"), and is distinct from the sponged blue grounds of the Ming dynasty. It was subsequently used at several of the porcelain factories in Europe. Clair du lune (*yüeh pai*, "moon white"), a cobalt glaze of the palest blue shade, was also used.

Use of powder blue



Coloured glazes. Copper red, called oxblood (*sang-de-boeuf*) by the French, appears in monochrome form as Lang *yao*. This glaze was also known to the Chinese as "blown red" (*ch'ui hung*). It was certainly used as a monochrome in early Ming times and possibly even earlier, and is the direct ancestor of the showy flambé glazes (*yao pien*) of the Ch'ien-lung period that are often vividly streaked with unreduced copper blue.

Another variation, no doubt at first accidental, is the glaze known in the West as "peach bloom," a pinkish red mottled with russet spots and tinged with green. The Chinese have various names for it, but perhaps the commonest is "bean red" (chiang-tou *hung*). It is used on a white body. Most objects glazed in this way are small items for the writer's table.

Monochromes of all kinds are a distinct and important section of Ch'ing wares, and many reproductions of Sung monochromes were made. The use of iron as a pigment can be seen in a revival of the celadon glaze. The Ching-te-chen celadons have, generally, a pale-green glaze over white porcelain, the foot-ring being given a wash of brown to simulate the old ware. Meanwhile, celadons of the Lung-ch'üan type were still being made. In addition to the celadon glaze, iron was used to produce colours varying between café au lait and pale yellow and also "dead-leaf" brown.

Sometimes panels were reserved in white and painted in overglaze colours. Specimens thus glazed appear in the old Dutch catalogues as Batavian ware, because the wares were imported via the Dutch centre of trade and trans-shipment at Batavia (modern Djakarta), in Java. They are also related to "mirror black" (*wu chin*), a lustrous colour obtained by the addition of manganese, and sometimes decorated with gilding or even, as in at least one extant specimen, with both gilding and silvering. Imperial yellow, a lead glaze often used over engraved dragons and similar designs, was again employed during the 19th century.

Vase with *flambé* glaze *(yao pien)* of reduced copper, Ch'ing dynasty, reign of the Ch'ien-lung emperor, 1736–96. In the Victoria and Albert Museum, London. Height 32.4 cm.

Brilliant turquoise glazes derived from copper have been produced up to the mid-20th century, although later examples seldom have the quality of the earlier ones. The glaze is usually covered with a network of fine crackle, and in some examples there is engraved decoration under the glaze. Related glazes are the copper greens—for example, leaf green and cucumber green, the latter being speckled with a darker colour. Apple green is an overglaze colour used as a ground and applied over a crackled gray glaze. Most greens are relatively late.

Purple, or aubergine, glazes derived from manganese are seen occasionally. Brinjal bowls, decorated with engraved flowers, have an aubergine ground in conjunction with dappled green and yellow glazes. (Brinjal, in fact, means aubergine, or eggplant, which is a favourite food in parts of the East.) Bowls with engraved dragons and a combination of only two of these colours are somewhat better in quality.

Overglaze colours. Overglaze colours were sometimes used as monochromes; for example, iron red or, as it is sometimes called because it varies a little in shade, coral red. The surface is usually glossy but occasionally mat. The rose colour, discussed below, was used both as a monochrome and as a ground colour.

The wares enamelled on biscuit are a much sought after group. They are a development of the Ming *san ts'ai*

wares, which were still being made during the Ch'ing period. The effect of painting directly on biscuit was to produce a soft and distinctive colouring that is extremely attractive. The outlines were first painted directly on the unglazed surface in brownish black; some of the colours were then painted within these outlines and others were washed over them; however, red or blue overglaze colours, when they appear, are usually provided with a patch of glaze underneath them. The practice seems hardly to have survived the K'ang-hsi period, except for deliberately made later copies.

Famille verte overglaze

During the reign of the K'ang-hsi emperor the wares decorated overglaze were painted in the *famille verte* palette, usually over a white glaze. The name *famille verte* ("green family") is derived from the dominant distinctive green employed, but the wares are in fact a development of the Wan-li five-colour ware, the most important difference being the replacement of the earlier underglaze blue by an overglaze blue. On most genuine examples it is possible to see a distinct halo around the overglaze blue, but its absence does not necessarily condemn the piece as not genuine. The *famille noire* has the *verte* palette in conjunction with a black ground; the *famille jaune* uses the same colours, but is used in conjunction with a yellow ground. In each case the white porcelain disappears under the colours.

Trumpet-shaped vase with floral decoration on background of green enamel, *famille verte*, Ch'ing dynasty, reign of the K'ang-hsi emperor, 1661–1722. In the Victoria and Albert Museum, London. Height 61 cm.

By courtesy of the Victoria and Albert Museum, London

Toward the close of the reign of the K'ang-hsi emperor (*c.* 1685) an opaque overglaze rose colour appears. This and its related colours were called "foreign colours" (*yang ts'ai*). It soon formed the characteristic colour of a group of wares, referred to as the *famille rose*, which was particularly developed during the reign of the Yung-cheng emperor. It more or less replaced the *verte* palette. The translucent overglaze colours of the earlier period tended to become opaque, and painting has a more feminine quality to its style.

During the 18th century the white wares of Ching-te-chen were made mostly for the home market, though a few were exported. They included examples of the bodiless ware and the *an hua* (literally "secret language"). The latter, copied from a traditional Yung-lo (1402–24) type, has designs lightly incised or painted with white slip. The body is white, and the whole is covered with clear glaze. The decoration can only be seen plainly if light is allowed to shine through it. Pierced work was revived in certain rare pieces inspired by jade; the use of piercing that was filled with glaze was derived from Persian Gombroon ware.

European influence and the export trade. Before mid-18th century, some European wares had found their way to China, as witness certain copies of early Meissen porcelain. The taste of the European trader, though hardly representative of the more cultured section of Western civilization, also began to have considerable influence at this time.

Much decoration was done in studios in and around the port of Canton, white porcelain being sent from Ching-te-chen for the purpose. Enormous quantities of *famille rose* porcelain were painted there, including most of the "ruby-backed" dishes, which are completely covered on the reverse, except for the interior of the foot ring, with a ground of overglaze opaque rose. They often have an elaborate arrangement of minutely delineated border patterns around the central subject (usually pretty women), demonstrating the new, and later widespread, idea that the beauty of an object is directly proportional to the amount of decoration on it. This theory was to be one of the causes of the degeneration of later Chinese and Japanese wares; it was, however, by no means confined to the Orient and can be seen in most 19th-century European porcelain.

The Yung-cheng painters were the first to carry foliate decoration over on to the back of the dish, usually as a prolongation of the stem. This was repeated later during the reign of the Tao-kuang emperor (1821–50). The European tendency to draw flowers in a naturalistic manner also appears in China from the Yung-chen period onward, although the practice was not carried to the same lengths.

An attempt to imitate the European method of overglaze painting, in which colours were applied in flat washes that partly sank into soft porcelain glazes, can be seen in the "ancient moon pavilion" (*ku yüeh hsüan*) wares. These will sometimes have a European subject, for example, a Watteau shepherdess, but Chinese subjects were also used.

Oriental Lowestoft

Of the wares more directly due to European intervention perhaps the best known is Chinese export porcelain, still sometimes known as Oriental Lowestoft. The name is due to an error on the part of William Chaffers (the author of a book on pottery marks), who persisted in attributing these wares to the small English factory at Lowestoft. If this porcelain is important at all, it is as a curiosity; the artistic value is nearly always negligible. The styles are usually based on those of European pottery or metalwork or on a combination of Western and Oriental motifs in an unpleasing jumble. The designs were provided by Western traders, and coats of arms are comparatively common.

Other wares connected with the export trade are those decorated with the Mandarin patterns; these came from Cantonese studios and were introduced toward the end of the 18th century. They have figure subjects in panels that are surrounded with coloured grounds and an excess of floral and other ornament in unprepossessing combinations of colours.

Much white porcelain was sent to Canton to be decorated, but much, too, was shipped to Europe for the same purpose. Many examples were painted by German studio

painters, by Dutch enamellers, and by English "outside decorators."

Europe, of course, was not the only export market open to the Chinese. Much blue-and-white was exported to the traditional markets in Persia and the Near East (Arabic inscriptions can be seen on some specimens) and elsewhere—India, Thailand, Burma, and Tibet.

Other Chinese kilns

The wares discussed so far have been principally those of Ching-te-chen. Those of Te-hua in Fukien Province, however, are also important. Figures of the Buddhist goddess Kuan-yin in particular were exported in enormous quantities, and the *an hua* and pierced decorations often came from Te-hua. Vessels, such as libation cups with applied prunus sprigs, were copied by European factories in the 18th century, notably by those at Meissen, Chelsea and Bow, and Saint-Cloud. The body is usually white, sometimes with an ivory tone, and the glaze is thick, rich, and lustrous. European forms are to be seen occasionally, and most coloured examples have been decorated in the West. The kilns of I-hsing also continued making the traditional wares.

19th and 20th centuries. The 19th century has little to offer that is new or of good quality. Snuff bottles painted with miniature designs were first made toward the end of the 18th century, but most belong to the reign of the Chia-ch'ing (1796–1820) and Tao-kuang (1821–51) emperors. Bowls with circular medallions painted in overglaze colours with yellow or rose grounds are, perhaps, among the finer wares. Also of good quality are bowls covered with an opaque ground, rose or yellow, with designs engraved into it. These were first made in the 18th century and extend to the reign of the Tao-kuang emperor.

Most of the wares of Tao-kuang are poor in quality, although some examples in the style of Yung-cheng are better. The glaze has a musliny texture similar to that seen on some early Ming wares and on Japanese porcelain from Arita. Translucent overglaze colours over underglaze blue are a Yung-cheng type that had a revival at this time. In addition, the *rose-verte* palette was commonly used.

In 1853 the Taiping Rebellion led to the destruction of the kilns at Ching-te-chen, which were not rebuilt until 1864. The reign of the T'ung-chih emperor (1862–75) is principally notable for poor copies of earlier monochromes, including the peach-bloom glaze. Nearly all wares from this time onward are slick copies of older work.

KOREA

Because Korea lies to the north of China and close to the islands of Japan, it has usually formed a cultural link between the two countries. During the Japanese invasion of 1592, for instance, many Korean potters were taken to Japan, where they were set to work making tea ceremony wares, which had hitherto been imported, and they later helped to found the porcelain industry.

Silla dynasty (57 BC–AD 935). It is difficult to distinguish some Korean wares from those made in the northern provinces of China during the contemporary Han to T'ang period. The wares of the Silla period include some reminiscent of those of the Chou dynasty. Specimens of stoneware obviously based on metalwork are distantly related to some of the Han bronzes. Patterns on these wares are geometric and incised into the clay before firing.

An olive-green glaze was introduced later in the Silla dynasty, probably about the 9th century. Roof tiles and finials have a brown or a green glaze and may be contemporary with the Han dynasty.

Koryŏ dynasty (918–1392). The wares of the Koryŏ dynasty (roughly corresponding to the Chinese Sung and Yüan dynasties) exhibit a much greater diversity and fall into rather more clearly defined groups. The attribution of certain black-glazed *temmoku* types (see above *China: Sung dynasty*) is controversial, but it seems that at least some were made in Korea. Many celadons, too, have typical Korean lobed forms, based on the melon or the gourd. These are also to be seen in porcelain, much of which has a bluish-white glaze. Some lobed boxes, usually circular, are decorated with impressed designs and are probably always Korean.

One of the difficulties in the study of Korean pottery is that practically everything has been recovered from tombs; few actual kiln sites have been discovered. Nevertheless, one such excavation at Yuch'ŏn-ni has disclosed shards of both the celadon glaze and of white porcelain from which it seems evident that white porcelain resembling both the *ying-ch'ing* and Ting types was made (see above *China: Sung dynasty*). The earliest vessels were probably fairly close copies of Chinese styles, while the distinctive Korean style followed rather later. A crazing of the glaze and a certain amount of flaking are characteristic. A mere handful of specimens, some fragmentary, of inlaid white porcelain have survived. They are best represented by a vase in the Duksoo Palace Museum of Fine Arts in Seoul that has panels of black-and-white inlay beneath a celadon glaze. Decoration on much Korean porcelain of the period is either incised (foliage being a frequent motif), combed, or molded in shallow relief.

White porcelain

Korean celadons have a stoneware body covered with a glaze varying from bluish green to a putty colour; some are obviously analogous to the celadons of Yüeh-chou (see above *China: Han dynasty*). Characteristic of Korean pots are the stilt or spur marks to be seen on the otherwise glazed base; these are the points on which the pots rested in the kiln. Many of the forms are lobed. Perhaps the most important divergence from the usual Chinese celadon is the presence of inlaid decoration beneath the glaze of many specimens, later examples of which are often referred to as *mishima*.

Mishima decoration

The designs were first incised into the clay, and the incisions were then filled with black and white slip. The inlaid patterns are diverse, but most of the subjects are floral; birds are to be seen occasionally. Isolated flowers with symmetrically radiating petals are also found, principally on boxes.

Korean bottle with a celadon glaze and *mishima* (inlaid decoration), Koryŏ dynasty, 13th century. In the Victoria and Albert Museum, London. Height 34.6 cm.

Yi dynasty (1392–1910). While most Korean wares of this period are distinctly rougher than those of China in the Ming and Ch'ing periods, the decoration is often magnificent in quality. Most can be clearly distinguished

from Chinese wares by their forms, which show distinct differences in almost every case. Lobed forms suggested by the melon are very characteristic, and the pear-shaped bottle differs in its proportions from that of the Chinese. The large rugged jars with high shoulders are not so precisely potted as similar jars from China, often showing a marked degree of asymmetricality. Twisted rope handles are also peculiar to Korea. Many of the ewers are obvious adaptations from metalwork.

Painting in brownish black beneath a celadon glaze, which had begun in the Koryŏ dynasty, continued in the Yi dynasty. Inlaid decoration was also executed during the early part of this period, the pattern often being engraved by stamps rather than incised freehand. Sgraffito decoration, in which patterns were incised through a grayish-white slip, is also seen occasionally.

Some excellent painted designs in an underglaze blue of variable colour but usually distinctly grayish in tone were executed on a rough procelain body that is almost stoneware. The designs are particularly notable for great economy of brushwork and superb drawing. Their affinities are much more with Japanese pottery than with contemporary Chinese wares. A typical Japanese technique, "brush" (*hakeme*), or brushed slip, is used in conjunction with painted decoration in the early part of the dynasty, but later it is used alone. Korean influence on Japanese pottery was probably at its strongest during the ascendancy of the Japanese warrior Hideyoshi (1536–98), who invaded Korea. It is unlikely that much important work was done in Korea itself after this invasion.

JAPAN

Since Japan is a well-wooded country, wood has always been used for domestic utensils of all kinds, either in a natural state or lacquered. Until recent times, therefore, pottery and porcelain were not employed extensively for general domestic use but were reserved for such special purposes as the tea ceremony (see below). In pottery the Japanese especially admire accidental effects that resemble natural forms. Objects that appear misshapen and glazes that exhibit what would normally be regarded as serious imperfections in the West are admired by the Japanese connoisseur. The Japanese potter liked his work to reveal the impress of the hand that had made it. Marks, such as the ridges left by the fingers in a newly-thrown vessel, were frequently accentuated instead of being obliterated, and marks made by tools were often left untouched.

Accidental effects

Hand modelling was practiced long after the wheel was known, and asymmetries and irregularities of form were purposely sought. Similar accidental effects were encouraged in glazing: coloured glazes were allowed to run in streaks and were irregularly applied. They were often thick, with many bubbles, and with a semifluid or treacly appearance. Crackled glazes and those deeply fissured (the latter called dragon skin or lizard skin) were deliberately induced. Painted decoration, frequently blue, brown, or iron red, is often summary and almost calligraphic in its simplicity. The aim was to give an overall effect that resembled such natural objects as stones, in being largely uncontrived.

From the 15th century onward, the art of the potter was also affected by the elaborate tea ceremony (the *cha-no-yu*). In its original form it was probably introduced from China by Zen priests, but at the court of the shogun (military governor) Yoshimasa (1435–90), in Kyōto, it developed into a fixed ceremonial pattern. Possibly the ceremony was first exploited as a means of settling feudal disputes. It is held in a small room or pavilion, usually surrounded by a carefully designed garden. When the guests are summoned they enter a sparsely furnished room through a very low doorway. The fact that guests must crawl into the room is thought to have served the purpose of preventing them from concealing a sword under their robes.

In a recess called the tokonoma, a picture mounted on brocade or silk is hung, and the guests bow to this in appreciation. The tea master puts a little powdered tea in a bowl and pours on it water that has been heated over a charcoal brazier. The tea is whipped to a froth with a bamboo whisk and then passed from hand to hand. The various utensils (the teabowl, tea caddy, water container, boxes, plates, and iron tea kettle) have been carefully selected by the tea master and are often of great age. The tea drinking is followed by a discussion and appreciation of the qualities of the utensils. The bowls are valued for their heat-retaining properties and the way in which they fit the hand as well as for their appearance. Sometimes a newly acquired work of art is produced by the host for the delectation of his guests. Since the tea masters were the aesthetic arbiters, their influence on Japanese pottery was profound.

Early history. The early history of Japan is considerably more obscure than that of China. The first Japanese pottery belongs to the Jōmon period (*c.* 2500–250 BC). It has a black body, and the decoration is usually an impressed representation of coiled rope or matting (*jōmon* means "coiled"). *Jōmon-shiki* ("pottery") is widely distributed throughout the islands, but complete specimens are very rare. It was followed by Yayoi pottery, specimens of which have been excavated throughout Japan. The body is somewhat finer in quality than Jōmon pottery and is usually red or gray. Decoration is simple, and forms will sometimes show the influence of Korean pottery of the period. It ceased to be produced about the 6th century AD.

Jōmon pottery

Meanwhile, from about the 3rd to the 6th century AD, large tombs were constructed in the form of oval or circular tumuli from whose bases have been recovered the *haniwa* ("clay circle") figures of warriors, women, horses, and so forth. They are hollow, and, though vigorously modelled, they are more primitive than analogous tomb figures from China.

In the Asuka or Sueki period (AD 552–710) that followed, wares are much more sophisticated. Unlike the preceding types, they were made with a wheel, and firing took place in a rudimentary kiln at a much higher temperature than previously. Widespread manufacture continued through the Nara period (710–794) and the early part of the following Heian, or Fujiwara, period (794–1185). Some examples have a smear glaze, no doubt at first caused accidentally by wood ashes coming into contact with the surface. Three colours of glaze—green, yellowish brown, and white—were used either alone or in combination and resemble those of T'ang earthenware. Pottery of this kind has been found around Ōsaka and Kyōto. The principal pottery productions of the period were vases, dishes, bowls, and bottles of various descriptions.

The influence of Korea and of T'ang China is noticeable. Toward the end of the Heian period contacts with China were severed, and there was a corresponding decline in the art of pottery; even the traditional Sueki ware disappeared.

Kamakura and Muromachi periods (1192–1573). A revival in the Kamakura period (1192–1333) followed the visit of the potter Katō Shirōzaemon (Tōshirō) to China in 1227, where he learned the secrets of pottery making. He established himself at Seto, Owari (now Aichi Prefecture), which speedily became a large centre of manufacture. There were soon about 200 kilns in the vicinity making a variety of wares, some of which were glazed in black in imitation of the *temmoku* wares of China (see above *China: Sung dynasty*). The early wares were mainly for ritual purposes, but by the beginning of the Muromachi, or Ashikaga, period (1338–1573) teabowls, plates, jars, and saucers of domestic utility were also being made. Wares of the Kamakura period are decorated with incised designs or with impressed or applied ornament. The Muromachi wares are much plainer as the result of the growing influence of the tea ceremony, especially the *wabi* school of the cult, which concentrated on rustic simplicity. The wares of both of these periods have a feldspathic glaze, but the Muromachi glaze is more even in quality than the Kamakura, which has a tendency to run in rivulets. A transitional type has a soft-yellowish glaze or a dark-brown glaze sometimes called Seto *temmoku*.

A large number of kilns were in existence, the more important known as the "six pottery centres of ancient Japan." These were Seto; Tokoname (also in Aichi Prefecture), which may have exceeded Seto in the size of its production; Bizen (Okayama Prefecture), which has produced an excellent unglazed stoneware from the Heian period to the 20th century; Tamba (Kyōto Prefecture); Shigaraki (Shiga Prefecture); and Echizen (Fukui Prefecture). The wares of Seto, especially those made for Buddhist ceremonies, were regarded as the finest pottery of this period.

Seto–Mino wares

Momoyama period (1574–1600). Production had been interrupted during the civil wars of the 15th and 16th centuries. Toward the end of the 16th century the Seto kilns were removed for a time to the Gifu Prefecture of Mino Province, where they received the protection of the feudal baron (daimyo) of Toki. The Mino pottery was founded by Katō Yosabei, whose sons started other potteries in the vicinity, notably that under the aegis of the tea master Furuta Oribe Masashige. New kilns were also built elsewhere, and pottery, while retaining its importance in the tea ceremony, became much more widely used for ordinary purposes. The inspiration for most of its shapes and designs came from the Mino region. The later wares of these kilns are much less austere than those attributed to the Muromachi period, since the cult of the tea ceremony, now widespread, had lost something of its earlier simplicity. Characteristic tea ceremony wares of the early years of the 17th century are Shino, which has a thick, crackled glaze and is sometimes summarily painted in blue or brown; yellow Seto (*ki-Seto*), whose crackled yellow glaze covers a stoneware body; and, at Narumi, in the adjoining Owari region, a ware of the kind associated with Oribe (which had become a generic term for pottery influenced by the tea master of that name), which is glazed in white, straw colour, yellowish green, and pinkish red, with sometimes the addition of slight painting in brown.

Toward the end of the 16th century the tea ceremony was reformed by Sen Rikyū (1521–91), the tea master to the military dictator of Japan, Toyotomi Hideyoshi. Sen Rikyū was principally responsible for the replacement of the hitherto much admired *temmoku* bowls from China by others patterned after unsophisticated Korean wares; his influence has persisted to the 20th century. In the 1590s Hideyoshi twice invaded Korea, and as a result of these wars many Korean potters were taken to Japan, where their influence was considerable.

Raku ware water jar and cover, Tokyo, Edo period, 18th century. In the Museum of Fine Arts, Boston. Height 20.3 cm.

Raku ware

A tilemaker named Ameya, who is said to have been a Korean, introduced a new type of ware that was covered with a lead glaze and fired at a comparatively low temperature. His son Tanaka Chōjirō and his family extended this technique to the tea ceremony bowl, and, about 1588 their wares were brought to the notice of Hideyoshi, who awarded them a gold seal engraved with the word *raku* ("felicity"). The *raku*, made in Kyōto, are among the most famous of all Japanese wares. The shape of the vessels is extremely simple: a wide straight-sided bowl set on a narrow base. At first the glaze was dark brown, but a light orange red was developed later, to be followed in the 17th century by a straw colour. Still later, green and cream and other colours were introduced. Teabowls attributed to the first Chōjirō are greatly valued in Japan.

Kakiemon ware decorated with iron red and coloured enamels, Hizen Province, Japan, Edo period, 17th century. In the Metropolitan Museum of Art, New York. Diameter 24.4 cm.

Karatsu ware

The kilns of Karatsu, a district in the north of Hizen Province, may have been established by Korean potters, since the influence of Korea is perceptible in some of them. The term Karatsu ware encompasses a great variety of shapes and styles: "undecorated" (*muji*), "painted" (*e*), "speckled" (*madara*), in the Korean style (Chosen), which has a thick opaque glaze, and in the style of Seto (Seto), which has a white glaze. The earliest Karatsu ware belongs probably to the end of the 16th century, although it is sometimes awarded a still earlier date. Most surviving examples belong to the 17th century. The most valued pieces are those made for the tea ceremony.

Edo Period (1603–1867). According to tradition, the first Japanese porcelain was made at the beginning of the 16th century after Shonzui Goradoyu-go brought back the secret of its manufacture from the Chinese kilns at Ching-te-chen. Another account claims that a Korean potter called Ri Sampei, who was brought to Japan by Hideyoshi, discovered porcelain clay in the Izumi Mountain, near Arita (Saga Prefecture); this version is feasible, since no porcelain made before the end of the 16th century has been identified.

The first Arita manufacture was decorated in blue underglaze, simple and excellent in quality. Specimens soon found their way to Europe in Dutch ships, and the Dutch were awarded a trading monopoly in 1641. Some of these early Japanese export wares are based on contemporary European metalwork and faience.

The family of Sakaida is especially connected with the Arita kilns. The first recorded member, born about 1596, worked in underglaze blue until the family learned the secret of using overglaze colours. According to tradition, it was told to them by a Chinese met by chance in the port of Nagasaki. This overglaze technique was perfected soon after the middle of the 17th century. It was continued by the family, and, since many of them were called Kakiemon, the style has become known by that name. The palette is easily recognized—iron red, bluish green, light blue, yellow, and sometimes a little gilding; many examples have a chocolate-brown rim. Octagonal and

Kakiemon porcelain

square shapes are especially frequent. Themes of decoration are markedly asymmetrical, with much of the white porcelain surface left untouched. This technique and style spread rapidly to other provinces, and its influence on porcelain that was manufactured in Europe during the first half of the 18th century was at least as great as that of Chinese porcelain. A later Kakiemon development in which "brocade" (*nishikide*) patterns in compartments were used (at the suggestion of Dutch traders) prove to be less pleasing. These later coloured wares from Arita became known as Imari, after the port from which they were shipped.

Like 18th-century Chinese white porcelain, Japanese white wares were shipped to Europe, where they were subsequently decorated by Dutch and other European enamellers.

Kutani porcelain

Of considerable importance but more rarely seen in Europe is the porcelain called Kutani. The kilns at Kutani-mura (Ishikawa Prefecture) were founded about 1652 and operated for approximately 60 years. Greatly valued, old-Kutani or *ko*-Kutani, porcelain is among the finest of the Japanese wares. The body is heavy, approaching stonewares, and the designs are executed boldly and in rich colours.

The Mikawachi kilns under the protection of the prince of Hirado made porcelain principally for his use. The delicate, very white body is usually decorated in miniature style with underglaze blue. Kyōto imitated Sung celadons and the Ming green and red wares. Seto made no porcelain until about 1807; the first production was decorated in underglaze blue (*sometsuke*). Overglaze colours date from about 1835.

The manufacture of earthenware was continued during the 17th and 18th centuries, and much of it is notable for its decoration. Toward the end of the 17th century Ninsei (Nonomura Seisuke) began work at Kyōto and was responsible for much finely enamelled decoration on a cream earthenware body covered with a finely crackled glaze. Also at Kyōto, the work of Kenzan, who used rich and subtly coloured slips often as a background for plant motives, and of the Dōhachi family, famous for their overglaze decoration, are among the wares which are much sought in Japan.

19th and 20th centuries. Japanese productions during the 19th century, in common with those in most other parts of the world, greatly deteriorated in taste. A typical product of the period is the so-called Satsuma pottery, most of which was not made at Satsuma, but at Kyōto, and was then sent to Tokyo to be decorated especially for export. The designs are overcrowded and debased, and its popularity undoubtedly retarded an appreciation of work in the true Japanese taste among Western students and collectors.

Like Western pottery manufacture in the mid-20th century, Japan's is largely industrialized, and most products are derivative, but the Japanese tradition of pottery making in small and private kilns continues.

THAILAND AND ANNAM

Pottery was made in the old Siamese capitals of Sukhothai and Sawankhalok. It is also thought that potteries persisted at Ayutthaya until the 18th century. Little is known of the early history of the region, and definite information on its pottery is almost nonexistent. Dating of the pottery from these regions for the most part has been by analogy with related Chinese wares, which greatly influenced Siamese work.

Kilns have been excavated on the site of old Sawankhalok, about 200 miles (320 kilometres) north of Bangkok. The principal type of ware is a grayish-white stoneware covered with a translucent celadon glaze, usually grayish green in colour. The glaze is commonly crackled; this appears to be fortuitous, since little trouble was taken to achieve a precise finish. A particularly common decoration consists of roughly scored vertical flutes, with incised circles at the shoulder to accentuate the form. Decoration of a more definite kind is always incised under the glaze and is usually floral. Flowers are stylized, sometimes with combed lines on the petals. Covered bowls, dishes, ewers, and bottles with two small loop handles at the neck are the most common forms.

Another type of ware, with similar forms, has a rather treacly-brown glaze. Some well-modelled animals are found with this glaze. There are also tiles and bricks with crudely modelled figures in relief on them. They are analogous in form and technique to Chinese pottery of the Sung dynasty and are generally regarded as being contemporary with the Sung or Yüan period. Some small covered jars of a gray porcelaneous ware, summarily decorated with stylized floral and foliate patterns, appear to have been made at Sawankhalok (the date is probably equivalent to that of the early Ming period). These Martabani wares were widely exported throughout the East during this period.

Annam. Little is known of wares made in Annam, but some brownish celadons are regarded as likely to have been made there, as well as some small covered jars painted in a poor underglaze blue.

IV. American Indian pottery

The American Indians are of Asiatic descent; their route to the New World was from Siberia into Alaska across the Bering Straits. The usually quoted period of their migration is between 40,000 and 10,000 years ago. Since they were nomadic peoples, it is unlikely that they brought the knowledge of pottery making with them. When pottery making did begin, it was fundamentally unlike any known work from the Old World, and the few remote resemblances to Oriental motifs are almost certainly fortuitous. The wheel remained unknown until the arrival of Europeans, although there is reason to think that a turntable, or slow wheel, may have been used occasionally. Most of the pottery was made by coiling, some by molding—both are techniques that could have arisen spontaneously. It is likely that most of the work was done by women rather than by the men. This is nearly always the case with primitive potters when the wheel is not used, and Pueblo Indian women still do this kind of work.

Slips were used to cover the body, and coloured slips provided the material for much of the painted freehand decoration. Glazes are rare, although examples can be found among the Pueblo Indians of New Mexico from about AD 1300 onward, on a few vessels from the Chimú area in the Andes, and occasionally in Central America. The effect of a reducing atmosphere was understood, so that gray and black pots are found as well as the red and brown ones fired in an oxidizing flame. Undecorated surfaces were often highly polished.

NORTH AMERICA

The most important North American pottery was made in the southwest—an area including Arizona, New Mexico, and also parts of Utah and Colorado. The people who inhabited the plateau land from about 100 BC are often referred to as the Anasazi, a Navaho Indian word meaning ancient people. They are the ancestors of the Pueblo, who began to emerge about AD 700. The Anasazi were nomadic hunters; although they did not at first make pottery, they did make excellent baskets. Fixed dwellings appear about AD 50, and this probably marks the beginning of pottery manufacture. The earliest pots appear to have been baskets that were smeared with clay and then dried in the sun.

Next came basket-shaped wares coiled in a gray body, used principally for cooking. They were followed by more decorative bowls and pots, with striking black and white geometric designs that seem to have been executed about AD 700. Slightly later there is another type of ware that has black decoration on a red slip. After the 12th century the earlier types began to disappear and were replaced by polychrome wares decorated with stylized birds, feathers, animals, and human figures amid the geometric patterns. The principal colours are yellow and red. A small quantity of glazed ware was made in the Zuñi area of New Mexico.

The Hohokam tribes (a Pima word meaning "those who have gone"), who lived in the desert of southern Arizona

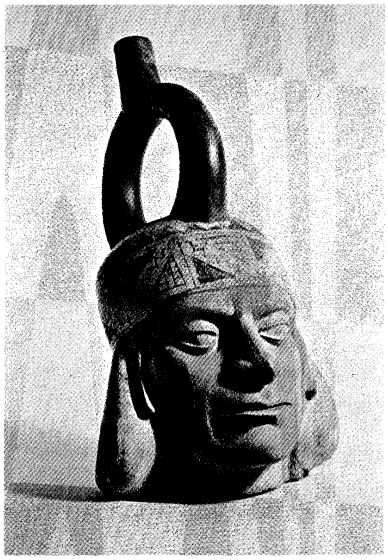
Pottery figures for religious purposes

and were approximately contemporary with the Anasazi, made pottery figures for religious purposes, usually of crudely modelled naked women. Some of this pottery is a gray ware, but most of it is buff, with decoration in iron red that has a quality lacking the stiffness of the Pueblo designs.

The Mogollon culture of New Mexico produced, during the Mimbres period of the 11th and 12th centuries, a ware remarkable for its lively black and white decoration depicting human, animal, and insect forms in a much less stylized manner than the paintings on most other wares from the southwest.

There is little pottery of importance from other parts of the United States. Primitive pots have been found on the Atlantic coast, in Georgia and Florida, on the Gulf Coast, and elsewhere, some of which are based on basketwork. Geometric decoration, usually incised, is the rule. Eskimo pottery, which is generally rather crude, bears some resemblance to early Asiatic types.

CENTRAL AMERICA



The pottery of Mexico and the rest of Central America is of considerable interest, but the wares are so diverse that it is impossible to summarize them adequately. They probably date from the 2nd millennium BC onward and were made by the Mayas, the Zapotecs, the Toltecs, and the Aztecs. Generally speaking, geometric patterns are common, and slips in black, brown, white, or red were frequently used. A curiosity of Central America (possibly adopted from South America) is a technique that resembles to some degree the batik method of dyeing textiles.

Maya, Zapotec, Toltec, and Aztec pottery

The surface of the pot was coated either with wax or gum. This was then scraped away in part to form a predetermined pattern, and the whole surface of the pot was covered with pigment. In firing, the gum burned away, leaving only the scraped parts in colour. Ornament carved in low relief after firing is to be seen occasionally and has few parallels outside the Americas. An unusual technique from the Mexican highlands consisted of covering the whole surface of the pot with a kind of thick slip, most of which was then scraped away, leaving only thin partitions. These compartments were filled with slips of a contrasting colour. The commonest shapes are bowls and wide-mouthed vases; many of these were made with legs, usually three, so that they could be set down on uneven ground. Figurines, some of which are painted, have also been found.

Between about 600 BC and AD 1000, the Mayas were making an excellent polychrome pottery in which designs in red and black were painted on a cream or orange slip.

Stirrup spout vessel in the form of a portrait head, Mochica culture, Peru (100 BC–AD 900). In the British Museum. Height 21.6 cm.

Between roughly the 4th and the 10th centuries AD, the Zapotecs, whose chief ceremonial site was Monte Albán in Oaxaca State, made striking urns in the forms of their gods. An orange-coloured pottery decorated in a great diversity of styles is associated with the Toltecs, as is a dark-coloured pottery with a glossy appearance and incised ornament (plumbate ware). Both of these types were widely distributed throughout Central America from the 11th to 14th centuries. Little is known of the Aztecs until about 1325, the date of the foundation of Tenochtitlán (Mexico City). Much of their later pottery utilizes an orange-burning clay that was painted with black curvilinear geometric motifs, in contrast to their earlier rectilinear style. During the period of Montezuma I in the 15th century, designs became more naturalistic, and birds, fish, and plant forms were freely utilized. European motifs first appear after the conquest, and such techniques as tin glazing were used from the 17th century onward.

SOUTH AMERICA

Most South American pottery was made at centres in the Andes and on the west coast, particularly in Bolivia and Peru. Pottery of lesser importance comes from Ecuador, Colombia, northwest Argentina, and northern Chile. In some places a very high degree of skill was attained, especially in the central Andes, where the earliest wares seem to date from the end of the 2nd millennium BC. Much of the pottery was made in molds. The stirrup-shaped spout on many jars is a characteristic feature. The batik type of decoration already mentioned was also used. Vessels were modelled in the shape of animal or human figures, which were also used as motifs for painted decoration. The puma god worshipped by the early peoples appears in many forms. Depictions of erotic themes also appear in South American pottery, particularly in the Mochica and Chimú cultures.

Mochica culture

The work of the Mochica culture, which flourished around the northern coast of Peru, is at its best about the 7th century AD. Jars in the form of human heads, some of which may be portraits, are remarkable both for the naturalism of the treatment and the skill of the potter. These have the stirrup spout. Painted decoration is often stylized although with a considerable degree of realism, and the subjects are nearly always ceremonial or religious nature.

The pottery of the Nazcas, who lived on the southern coast of Peru at much the same period, is noted for its painting. A varied palette included several shades of red and blue, yellow, orange, green, brown, black, gray, and white. The stirrup spout here becomes two spouts joined by a flat bridge. The earliest painting is on a red ground, white grounds becoming more common later. Geometric patterns are to be seen in conjunction with stylized birds, human heads, and the like. The naturalistic portrait jars of the Mochica do not appear, but there are some vessels in the form of figures modelled in a much more conventional style and similarly painted. Puma's heads occur in relief, with the body of the animal completed in brushwork. The centipede god is a motif that does not appear elsewhere.

The people of Tiahuanaco, who lived in the region around Lake Titicaca, were influenced by the Nazca wares, though painted decoration, often carried out on a red slip ground, is more limited in colour than the Nazca. The puma head was used as a motif. In general, decoration is extremely stylized with a very strong geometric flavour.

Chimú culture

The Chimú culture succeeded the Mochica in the northern area and lasted until the arrival of the Incas. The most familiar ware is in a body that varies from gray to black, although a red polished ware, sometimes painted in white slip, was also made. The influence of the Mochica tradition can be seen in the retention of the stirrup spout on some jars; others have the double spout connected by a flat bridge. The modelled wares of the Mochica culture were also revived but are of a generally inferior quality.

The Incas originally settled in Cuzco, the old capital of

Peru, at the end of the 11th century. During the 15th century they established themselves firmly over a wide area, including the territory of the Chimús. They were principally soldiers and administrators with small inclination toward luxury; and their pottery, of excellent quality particularly in the 15th century, is designed in good taste without an excess of decoration. Most Inca pottery is red polished ware. It is usually painted with geometric designs in red, white, and black, although relief decoration is also to be seen on black ware, especially from the Chimú region.

The commonest surviving form has been called an aryballos, although its resemblance to the Greek form is remote and fortuitous. It has a conical base, and the neck finishes in a flaring mouth. Two loop handles are set low on the body. The assumption that this vessel was made for carrying water on the back seems a little doubtful in view of its shape and the disposition of the handles. Little fine pottery was made after the arrival of the Spaniards in the 16th century.

BIBLIOGRAPHY. Books on pottery are fairly numerous, but many have been written in recent years for the popular market and are not always reliable or duplicate information. The following titles may be regarded as standard or major works.

General works: Two good introductory surveys are GEORGE SAVAGE, *Pottery Through the Ages* (1963) and *Porcelain Through the Ages*, 2nd ed. (1963). ROBERT J. CHARLESTON (ed.), *World Ceramics* (1968), is a lavishly illustrated history of ceramics written by many noted specialists in Europe and the United States. Highly recommended is W.B. HONEY, *European Ceramic Art, from the End of the Middle Ages to about 1815*, 2nd ed., 2 vol. (1963), which has a comprehensive list of marks and an excellent bibliography. Also useful is EMIL HANNOVER, *Keramisk Haandbag*, 2 vol. (1919–24; Eng. trans., *Pottery and Porcelain*, 3 vol., 1925); and WARREN COX, *The Book of Pottery and Porcelain* (1944). GEORGE SAVAGE, *The Dictionary of Antiques* (1970), includes information about continental wares on a less comprehensive scale, but its extensive bibliography has been brought up to date. It also differentiates between works in print and those available only in libraries or secondhand. For the technical side of pottery, see BERNARD LEACH, *A Potter's Book* (1940); W.B. HONEY, *The Art of the Potter* (1946); and PAUL RADO, *An Introduction to the Technology of Pottery* (1969). Factory marks are discussed and listed in W.B. HONEY and JOHN P. CUSHION, *Handbook of Pottery and Porcelain Marks*, 3rd rev. ed. (1965); Cushion has also published separate handbooks on *English Ceramic Marks and Those of Wales, Scotland, and Ireland* (1959), on *German Ceramic Marks and Those of Other Central European Countries* (1961), and on *French and Italian Ceramic Marks* (1965). GEOFFREY GODDEN, *Encyclopaedia of British Pottery and Porcelain Marks* (1964), is another recommended source. WILLIAM CHAFFERS, *Marks and Monograms on Pottery and Porcelain*, 14th ed. (1931), formerly the standard work, has now been superseded and is sometimes inaccurate. More specialized is ARTHUR BEHSE, *Deutsche Fayencemarken–Brevier* (1955), which should be consulted for German wares. Ceramic terms are defined by GEORGE SAVAGE and H. NEWMAN in the *Illustrated Dictionary of Ceramic Terms* (1973).

Ancient Near East and Egypt: Books dealing specifically with the pottery of this area and period are scarce. See WALTER ANDRAE (ed.), *Coloured Ceramics from Assur* (1925); and HENRY WALLIS, *Egyptian Ceramic Art* (1898). More information will be found in books dealing with the arts of the ancient Near East and Egypt.

Ancient Aegean, Greece, and Italy: Works on ancient pottery from these regions are fairly numerous. A comprehensive selection is listed below. HENRY B. WALTERS, *A History of Ancient Pottery*, 2 vol. (1905, reprinted 1971); CHARLES T. SELTMAN, *Attic Vase-Painting* (1933); VINCENT D'ARBA DESBOROUGH, *Protogeometric Pottery* (1952); G.M.A. RICHTER, *A Handbook of Greek Art*, 6th ed. (1969); *Ancient Italy* (1955); *Attic Red-Figured Vases: A Survey*, 2nd ed. (1958); and *The Craft of Athenian Pottery* (1923); ARTHUR LANE, *Greek Pottery*, 3rd ed. (1971); ROBERT M. COOK, *Greek Painted Pottery* (1960); T.B.L. WEBSTER, *Greek Terracottas* (1951); ROBERT J. CHARLESTON, *Roman Pottery* (1955); JOHN D. BEAZLEY, *Etruscan Vase Painting* (1947).

Islāmic pottery: There are few works easily available. The best are ARTHUR LANE, *Early Islamic Pottery*, rev. ed. (1958) and *Later Islamic Pottery*, 2nd ed. (1972); see also MAURICE S. DIMAND, *A Handbook of Muhammadan Art*, 3rd ed. rev. (1958); and ROBERT L. HOBSON, *A Guide to Islamic Pottery of the Near East* (1932).

Western pottery: Where they exist, the titles of English works on continental pottery are given below. Those listed in other languages are illustrated works that will supplement the deficiency of works in English. In the case of porcelain, English works that discuss the wares of individual factories are given only in special cases since they are extremely numerous and most general works on the subject include a bibliography. (*Spain*): ALICE W. FROTHINGHAM, *Catalogue of Hispano-Moresque Pottery in the Collection of the Hispanic Society of America* (1936); *Talavera Pottery, with a Catalogue of the Collection of the Hispanic Society of America* (1944); *Lustreware of Spain* (1951); ALBERT VAN DER PUT, *Hispano-Moresque Ware of the XVth Century* (1904). (*Italy*): JOSEPH CHOMPRET, *Répertoire de la Mojolique Italienne*, 2 vol. (1949); BERNARD RACKHAM, *Guide to Italian Maiolica* (1933); *Catalogue of Italian Maiolica*, 2 vol. (1940); and *Italian Maiolica* (1952)—Rackham's books are the best source of information in English; ARTHUR LANE, *Italian Porcelain* (1954); GIUSEPPE MORAZZONI, *Le Porcellane Italiane* (1935). (*France and Belgium*): CHARLES DAMIRON, *La Faïence artistique de Moustiers* (1919) and *La Faïence de Lyon* (1926); JEANNE GIACOMOTTI, *Faïences françaises* (1963; Eng. trans., *French Faïence*, 1963); HANS HAUG, *Les Faïences et porcelaines de Strasbourg* (1922); ARTHUR LANE, *French Faïence*, 2nd ed. (1970), the best introduction to the subject; FRANCOIS PONCETTON and GEORGE SALLES, *Les Poteries Françaises* (1928); PAUL ALFASSA and JACQUES GUERIN, *Porcelaine française du XVII^e au milieu du XIX^e siècle* (1932); EMILE BOURGEOIS, *Le Biscuit de Sèvres au XVIII^e siècle*, 2 vol. (1909); W.B. HONEY, *French Porcelain of the 18th Century* (1950); EUGENE J. SOIL DE MORAIME, *La Manufacture impériale et royale de porcelain de Tournay*, 3rd ed. of his *Céramique tournaisienne* by LUCIEN DELPLACE DE FORMANOIR (1937); GEORGE SAVAGE, *Seventeenth and Eighteenth Century French Porcelain* (1960); PIERRE VERLET, SERGE GRANDJEAN, and MARCELLE BRUNET, *Sèvres* (1953). (*Germany and Austria*): KARL KOETSCHAU, *Rheinisches Steinzeug* (1924); HANS MEYER, *Böhmisches Porzellan und Steingut* (1927); GUSTAV E. PAZAUREK, *Deutsche Fayence und Porzellan-Hausmaler*, 2 vol. (1925, reprinted 1970) and *Steingut: Formgebung und Geschichte* (1921); O. RIESEBIETER, *Die deutschen Fayencen des 17. und 18. DIXON, *English Porcelain of the Eighteenth Century* (1952); ENGLISH CERAMIC CIRCLE, *English Pottery and Porcelain: Commemorative Catalogue of an Exhibition Held at the Victoria and Albert Museum* (1949); STANLEY W. FISHER, *The Decoration of English Porcelain* (1954) and *English Blue and White Porcelain of the 18th Century* (1947); GEOFFREY GODDEN, *An Illustrated Encyclopaedia of British Pottery and Porcelain* (1966); W.B. HONEY, *Old English Porcelain* (1948); WILLIAM KING, *English Porcelain Figures of the Eighteenth Century* (1925); GEORGE SAVAGE, *18th-Century English Porcelain*, new ed. (1964); CYRIL COOK, *The Life and Work of Robert Hancock* (1948); *William Duesbury's London Account Book, 1751–1753*, with an introduction by MRS. DONALD MCALISTER (1931); WILLIAM H. TAPP, *Jefferyes Hamett O'Neal, 1734–1801* (1938). (*American Indian pottery*): G.H.S. BUSHNELL and ADRIAN DIGBY, *Ancient American Pottery* (1955). (*United States*): JOHN RAMSAY, *American Potters and Pottery* (1939); EDWIN A. BARBER, *Tulip Ware of the Pennsylvania-German Potters* (1903); WARREN COX, *The Book of Pottery and Porcelain*, vol. 2 (1944).

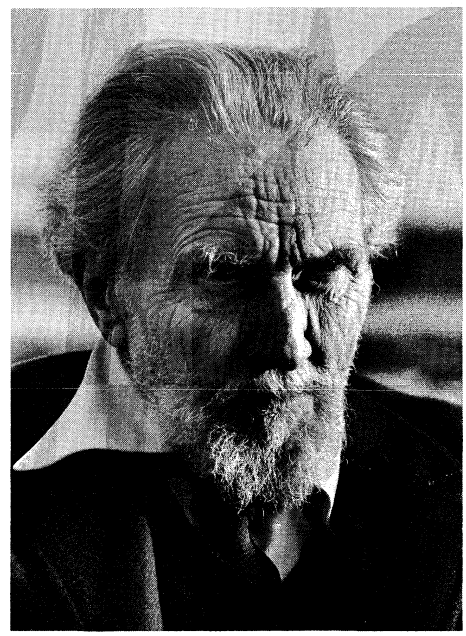
Non-Western pottery: (*China*): The best general work is still W.B. HONEY, *The Ceramic Art of China, and Other Countries of the Far East* (1945); but ROBERT L. HOBSON, *Chinese Pottery and Porcelain*, 2 vol. (1915), is often consulted. Hobson's *Wares of the Ming Dynasty* (1923) and *Later Ceramic Wares of China* (1925), are scholarly works, well illustrated for their period. *Chinese Art*, 4 vol. (1960–65), by a number of internationally known experts, covers the whole field of Chinese art, including pottery and porcelain, and is of considerable value to the student. The earliest Chinese wares are discussed in English by CHIN-TING WU in *Prehistoric Pottery in China* (1938). Wares till the Sung dynasty are discussed by BASIL GRAY in *Early Chinese Pottery and Porcelain* (1952); and by ARTHUR L. HETERINGTON in *Early Ceramic Wares of China* (1922) and *Chinese Ceramic Glazes*, 2nd rev. ed. (1948). For wares of the Ming dynasty and subsequently, see ROGER SOAME JENYNS, *Ming Pottery and Porcelain* (1953) and *Later Chinese Porcelain*, 2nd ed. (1959). (*Korea*): G. ST. G.M. GOMPERTZ, *Korean Celadon, and Other Wares of the Koryŏ Period* (1963); and CHEWON KIM, *The Ceramic Art of Korea* (1961); W.B. HONEY, *Corean Pottery* (1947). (*Japan*): Japanese porcelain is better documented than the pottery of that country. ROGER SOAME JENYNS, *Japanese Porcelain* (1965), is the definitive work in English on the subject. See also TAOANARI MITSUOKA, *Ceramic Art of Japan* (1949); and ROGER SOAME JENYNS, *Japanese Pottery* (1971). (*Chinese and Japanese export porcelain*): This includes works on the erroneously termed Oriental Lowestoft. MICHEL BEURDELEY, *Porcelaine de la compagnie des Indes* (1962; Eng. trans., *Porcelain of the East India Companies;* U.S. title, *Chinese Trade Porcelain;* 1962); SIR HARRY M. GARNER, *Oriental Blue and White*, 3rd ed. (1970), discusses early blue-and-white export wares; JOHN A. LLOYD HYDE, *Oriental Lowestoft* (1954); JEAN MCCLURE MUDGE, *Chinese Export Porcelain for American Trade, 1785–1835* (1962); JOHN G. PHILLIPS, *China Trade Porcelain* (1956); WALTER A. STAEHELIN, *The Book of Porcelain* (1966), a book of Chinese illustrations relating to the export trade in the 18th century; SIR A. TUDOR CRAIG, *Armorial Porcelain of the Eighteenth Century* (1925); T. VOLKER, *Porcelain and the Dutch East India Company* (1954), an examination of the records in relation to the import of Chinese and Japanese porcelain in the 17th century.



(Ge.S)

Pound, Ezra

One of the most important poets and critics of his time, as well as a supremely discerning and energetic entrepreneur of the arts, Ezra Pound did more than any other single figure to advance a "modern" movement in English and American literature by promoting—and also by occasionally helping to shape—the work of such widely different poets and writers as W.B. Yeats, James Joyce, Ernest Hemingway, Robert Frost, D.H. Lawrence, and T.S. Eliot.

Ezra Loomis Pound was born on October 30, 1885, in the small mining town of Hailey, Idaho, the only child of a Federal Land Office official, Homer Loomis Pound of Wisconsin and Isabel Weston of New York City. About 1887 the family moved to the eastern states, and in June 1889, following Homer Pound's appointment to the U.S. Mint in Philadelphia, they settled in nearby Wyncote, where Pound lived a normal middle class childhood. After two years at Cheltenham Military Academy, which he left without graduating, he attended a local high school. From there he went for two years (1901–03) to the University of Pennsylvania, where he met his lifelong friend, the poet William Carlos Williams. He took his Ph.B. (bachelor of philosophy) degree at Hamilton College, New York, in 1905 and returned to the University of Pennsylvania for graduate work. He received his M.A. in June 1906 but withdrew from the university after working one more year toward his doctorate. He left with a knowledge of Latin, Greek, French, Italian, German, Spanish, Provençal, and Anglo-Saxon, as well as of English literature and grammar.

Ezra Pound.

In the autumn of 1907, Pound became professor of Romance languages at Wabash Presbyterian College, Crawfordsville, Indiana. Although his general behaviour fairly reflected his Presbyterian upbringing, he was already writing poetry and was affecting a bohemian manner.

His career came quickly to an end, and in February 1908, with light luggage and the manuscript of a book of poems that had been rejected by at least one American publisher, he set sail for Europe.

He had been to Europe twice before, once with his great aunt in 1898 and once again in the summer of 1906, when he had gathered the material for his first three published articles: "Raphaelite Latin," concerning the Latin poets of the Renaissance, and "Interesting French Publications," concerning the troubadours (both published in the *Book News Monthly*, Philadelphia, September 1906); and "Burgos, a Dream City of Old Castile" (October issue).

Now, with little money, he sailed to Gibraltar and southern Spain, then on to Venice, where in June 1908 he published, at his own expense, his first book of poems, *A lume spento*. About September 1908 he went to London, where he was befriended by the writer and editor Ford Madox Ford (who published him in his *English Review*), entered William Butler Yeats's circle, and joined the "school of images," a modern group presided over by the philosopher T.E. Hulme. In England, success came quick-

Success in London

ly to Pound. A book of poems, *Personae*, was published in April 1909; a second book, *Exultations*, followed in October; and a third book *The Spirit of Romance*, based on lectures delivered in London (1909–10), was published in 1910.

After a trip home—a last desperate and unsuccessful attempt to make a literary life for himself in Philadelphia or New York—he returned to Europe in February 1911, visiting Italy, Germany, and France. Toward the end of 1911 he met an English journalist, Alfred R. Orage, editor of the Socialist weekly *New Age*, who opened its pages to him and provided him with a small but regular income during the next nine years. In 1912 Pound became London correspondent for the small magazine *Poetry* (Chicago); he did much to enhance the magazine's importance and was soon a dominant figure in Anglo-American verse. He was among the first to recognize and review the poetry of Robert Frost and D.H. Lawrence and to praise the sculpture of the modernists Jacob Epstein and Henri Gaudier-Brzeska. As leader of the Imagist movement of 1912–14, successor of the "school of images," he drew up the first Imagist manifesto with its emphasis on direct and sparse language and precise images in poetry and edited the first Imagist anthology, *Des Imagistes* (1914). Though his friend Yeats had already become famous, Pound succeeded in persuading him to adopt a new leaner style. In 1914, the year of his marriage to Dorothy Shakespear, daughter of Yeats's friend, Olivia Shakespear, he began a collaboration with the then unknown James Joyce. As unofficial editor of *The Egoist* (London) and later as London editor of *The Little Review* (New York), he saw to the publication of Joyce's *Portrait of the Artist as a Young Man* and *Ulysses*, thus spreading Joyce's name and securing financial assistance for him. In the same year he gave T.S. Eliot a similar start in his career as poet and critic.

Editor of *Des Imagistes*

In the years following he continued to publish his own poetry (*Ripostes*, 1912; *Lustra*, 1916) and prose criticism (*Pavannes and Divisions*, 1918). From the literary remains of the great Orientalist Ernest Fenollosa, which had been presented to Pound in 1913, he published highly acclaimed English versions of early Chinese poetry, *Cathay* (1915), and two volumes of Japanese Nō plays (1916–17).

Unsettled by the slaughter of World War I and the spirit of hopelessness he felt was pervading England after its conclusion, Pound decided to move to Paris, publishing before he left two of his most important poetical works, "Homage to Sextus Propertius," in the book *Quia Pauper Amavi* (1919), and *Hugh Selwyn Mauberley* (1920). "Propertius" is a comment on the British Empire in 1917, by way of Propertius and the Roman Empire; *Mauberley*, a finely chiselled "portrait" of one aspect of British literary culture in 1919, is one of the best and most praised poems of the 20th century.

Meeting with Hemingway

In Paris (1921–24) Pound met and helped the young American novelist Ernest Hemingway; wrote an opera, *Le Testament*, based on poems of François Villon (performed in Paris in 1926 and by the BBC, London, in 1931 and 1962); assisted T.S. Eliot with the editing of his long poem *The Waste Land*; and acted as correspondent for the New York literary journal *The Dial*. In 1924 he tired of Paris and moved to Rapallo, Italy, which was to be his home for the next 20 years. In 1925 he had a daughter, Maria, by the expatriate American violinist Olga Rudge, and in 1926 his wife, Dorothy, gave birth to a son, Omar. The daughter was brought up by a peasant woman in the Italian Tirol, the son by relatives in England. In 1927–28 Pound edited his own magazine, *Exile*, and in 1930 brought together, under the title *A Draft of XXX Cantos*, various segments of his ambitious long poem "The Cantos," which he had begun in 1915.

The 1930s saw the publication of further volumes of "The Cantos" (*Eleven New Cantos*, 1934; *The Fifth Decad of Cantos*, 1937; *Cantos LII-LXXI*, 1940) and a collection of some of his best prose (*Make It New*, 1934). A growing interest in music caused him to arrange a long series of concerts in Rapallo during the 1930s; and, with the assistance of Olga Rudge, he played a large part in the rediscovery of the 17th-century Italian composer Antonio Vivaldi. The results of his continuing investigation in the areas of culture and history were published in his brilliant but fragmentary prose work *Guide to Kulchur* (1938).

Following the worldwide depression of the 1930s, he turned more and more to history, especially economic history, a subject in which he had been interested since his meeting in London in 1918 with C.H. Douglas, the founder of Social Credit, an economic theory stating that maldistribution of wealth due to insufficient purchasing power is the cause of economic depressions. Pound had come to believe that a misunderstanding of money and banking by governments and the public, as well as the manipulation of money by international bankers, had led the world into a long series of wars. He became obsessed with monetary reform (*ABC of Economics*, 1933; *Social Credit*, 1935; *What Is Money For?*, 1939), involved himself in politics, and declared his admiration for the Italian dictator Benito Mussolini (*Jefferson and/or Mussolini*, 1935). The obsession affected his "Cantos," which even earlier had shown evidence of becoming an uncontrolled series of personal and historical episodes.

As war in Europe drew near, Pound returned home (1939) in the hope that he could help keep the peace between Italy and the United States. He went back to Italy a disappointed man, and between 1941 and 1943, after Italy and the U.S. were at war, he made several hundred broadcasts over Rome Radio on subjects ranging from James Joyce to the control of money and the U.S. government by Jewish bankers and often openly condemned the U.S. war effort. He was arrested by U.S. forces in 1945 and spent six months in a prison camp for army criminals near Pisa. Despite harsh conditions there, he translated Confucius into English (*The Great Digest & Unwobbling Pivot*, 1951) and wrote *The Pisan Cantos* (1948), the best and most moving section of his long poem. Returned to the U.S. to face trial for treason, he was pronounced "insane and mentally unfit for trial" by a panel of doctors and spent 12 years (1946–58) in St. Elizabeth's Hospital for the criminally insane in Washington, D.C. During this time he continued to write and publish "The Cantos" (*Section: Rock-Drill*, 1955; *Thrones*, 1959), translated ancient Chinese poetry (*The Classic Anthology*, 1954) and Sophocles' *Trachiniai* (*Women of Trachis*, 1956), received visitors regularly, and kept up a voluminous and worldwide correspondence. Controversy surrounding him burst out anew when, in 1949, he was awarded the important Bollingen Prize for his *Pisan Cantos*. When on April 18, 1958, he was declared unfit to stand trial and the charges against him were dropped, he was released from St. Elizabeth's. He returned to Italy, dividing the year between Rapallo and Venice. For a while he wrote and worked but soon lapsed into silence; he died in Venice on November 1, 1972.

Anti-American broadcasts

Out of his 60 years of publishing activity came 70 books of his own, contributions to some 70 others, and more than 1,500 articles.

MAJOR WORKS

POEMS: *A lume spento* (1908); *Personae* (1909); *Exultations* (1909); *Provença* (1910); *Canzoni* (1911); *Ripostes* (1912); *Lustra* (1916); *Quia Pauper Amavi* (1919); *Hugh Selwyn Mauberley* (1920); *Umbra* (1920), collected early poems; *Poems 1918–1921* (1921); *A Draft of XVI Cantos* (1925); *Personae (The Collected Poems)* (1926); *A Draft of the Cantos 17–27* (1928); *A Draft of XXX Cantos* (1930); *Eleven New Cantos* (1934); *The Fifth Decad of Cantos* (1937); *Cantos LII-LXXI* (1940); *The Pisan Cantos* (1948); *The Cantos* (collected edition, 1948); *Section: Rock-Drill*, cantos 85–95 (1955); *Thrones, 96–109 de los cantares* (1959); *Redondillas, or Something of That Sort* (1967), unpublished long poem of 1911; *The Cantos* (1970).

PROSE: *The Spirit of Romance* (1910); *Gaudier-Brzeska* (1916); *Pavannes and Divisions* (1918); *Instigations* (1920); *Indiscretions* (1923); *Antheil and the Treatise on Harmony* (1924); *Imaginary Letters* (1930); *How to Read* (1931); *ABC of Economics* (1933); *ABC of Reading* (1934); *Make It New* (1934); *Social Credit: An Impact* (1935); *Jefferson and/or Mussolini* (1935); *Polite Essays* (1937); *Guide to Kulchur* (1938); *What Is Money For?* (1939); *"If*

This be Treason . . ." (1948); *Literary Essays* (1954); *Pavannes and Divagations* (1958); *Impact* (1960), economic, political, and cultural essays.

TRANSLATIONS: *The Sonnets and Ballate of Guido Cavalcanti* (1912); *Cathay* (1915); *Certain Noble Plays of Japan* (1916); *"Noh" or Accomplishment* (1917, dated 1916); *Dialogues of Fontenelle* (1917); *The Natural Philosophy of Love*, from Remy de Gourmont's *Physique de l'amour* (1922); *Ta Hio: The Great Learning* (1928); *Guido Cavalcanti Rime* (1932); *Confucius: Digest of the Analects* (1937); *The Classical Anthology Defined by Confucius* (1954); *Sophokles Women of Trachis* (1956); *Moscardino*, first volume of Enrico Pea's four-volume novel, *Il romanzo di Moscardino* (1956); *Love Poems of Ancient Egypt*, with Noel Stock (1962).

ITALIAN PROSE: (translated into English by John Drummond)—*Carta da Visita* (1942; *A Visiting Card*, 1952); *L'America, Roosevelt e le cause della guerra presente* (1944; *America, Roosevelt and the Causes of the Present War*, 1951), *Oro e lavoro* (1944; *Gold and Work*, 1952); also, trans. by Carmine Amore, "Introduzione alla natura economica degli S.U.A." (1944; Money Pamphlets by £, No. 1, "An Introduction to the Economic Nature of the United States," 1950).

BIBLIOGRAPHY. A complete listing of Pound's works may be found in DONALD GALLUP, *A Bibliography of Ezra Pound* (1963, revised reissue 1969), thorough and accurate; and MARIE HENAULT, *Checklist of Ezra Pound* (1970). Most of the writing on which his fame now rests may be found in *Personae (The Collected Poems)* (1926, new ed. 1949), a selection of poems Pound wished to keep in print in 1926, plus a few earlier and later poems added 1949; *The Cantos* (1970), cantos 1–117, a collection of all the segments published to date; *The Spirit of Romance* (1910, new ed. 1953; paperback with new prefatory note by Pound, 1968); *Literary Essays* (1954), the bulk of his best criticism, ed. with introduction by T.S. ELIOT; *Guide to Kulchur* (1938, new ed. 1952); *The Letters of Ezra Pound, 1907–1941*, ed. by D.D. PAIGE (1950), an excellent introduction to Pound's literary life and inimitable epistolary style.

Biographical studies: NOEL STOCK, *The Life of Ezra Pound* (1970); CHARLES NORMAN, *The Case of Ezra Pound* (1968); *Pound/Joyce: The Letters of Ezra Pound to James Joyce*, ed. with commentary by FORREST READ (1967); JULIEN CORNELL, *The Trial of Ezra Pound* (1966); HARRY MEACHAM, *The Caged Panther: Ezra Pound at Saint Elizabeths* (1967); MARY DE RACHEWILTZ, *Discretions* (1971).

SULLIVAN (ed.), *Ezra Pound: A Critical Anthology* (1970). *On the Cantos:* NOEL STOCK, *Reading the Cantos* (1967); J.H. EDWARDS and W. VASSE, *Annotated Index to the Cantos of Ezra Pound* (1957).

(N.St.)

Poussin, Nicolas

Nicolas Poussin has been regarded by artists and connoisseurs in France as the greatest French painter of the 17th century, and perhaps in the history of French art, though he in fact lived and worked in Rome—except for the year and a half he spent at the Royal Court of France (1640–42)—from his 30th year to his death. His celebrity began during his lifetime—even the great sculptor Gian Lorenzo Bernini, who was the leading Baroque artist in Rome, was one of his fervent admirers—and his fame and influence were kept alive by such artists as Jacques-Louis David during the 18th century and in the 19th century by Eugène Delacroix, Jean-Auguste-Dominique Ingres, and Paul Cézanne, who proclaimed his own art an attempt to "do Poussin over again after nature."

Childhood and early travels. Poussin was born in 1594 in the hamlet of Villers near the small town of Les Andelys, on the River Seine, north of Paris. He was the son of very poor parents who earned a scanty living as small farmers, although his father once had been a soldier. Poussin spoke of the good education he received at Les Andelys, yet it seems that he was not even instructed in a trade or craft until his 16th year. He apparently did not show any interest in the arts until the painter Quentin

Poussin, self-portrait, oil painting, 1650. In the Louvre, Paris.
Giraudon

Varin (1570–1634) visited Les Andelys in 1612 to produce several paintings for the church of Le Grand Andely. Poussin's interest in the arts was awakened, and he decided to become a painter. As this was impossible in Les Andelys, he left his home, going first to Rouen and then to Paris to find a suitable teacher. His poverty and ignorance made this search very difficult. He found no master who appeared satisfactory and studied at different times under several minor painters who were either Mannerists in the Dutch tradition or portraitists. In another respect Poussin was more successful. A young nobleman from the French province of Poitou asked Poussin to come to his château and paint several pictures for him. But the nobleman's mother tried to use Poussin as an ordinary servant, so the young artist secretly left the estate to return to Paris. Travelling on foot and without any means, Poussin endured, according to his own statement, the greatest hardship and fatigue. He did not reach Paris but had to return to his paternal home, where he arrived not only very ill but much humiliated.

Early influences and training

Recovering after a year, Poussin again set out for Paris, not only to continue his studies but also to pursue another aim. While previously resident in the French capital, he had met a chamberlain of the Queen Mother, Marie de Médicis, an amateur of high rank who introduced him to the art of the Italian High Renaissance through reproductions of Raphael's paintings. These engravings, according to his biographer Passeri, inspired him with "that light he had ever longed for." He yearned, therefore, to go to Rome, which was then the centre of the European art world. Only after three attempts was he successful in reaching the Papal City. His first attempt to reach Rome met with disaster in Florence, the second at Lyon where he was stopped by police because of debts he had left unpaid in Paris. His third and final attempt to get to Rome was aided by cavalier Giambattista Marino, the Italian court poet to Marie de Médicis.

Journey to Rome

Marino, then a sick elderly man, took a liking to the young Poussin and ordered him to make a series of mythological drawings illustrating the *Metamorphoses* by the ancient Roman poet Ovid. He discussed with him the theoretical fundamentals common to poetry and painting, as they were seen at that time, and tried to pave his way to Rome, recommending him to Cardinal Francesco Barberini, a nephew of the reigning pope, Urban VIII. Marino had also intended to introduce Poussin personally to several Roman connoisseurs, as he was himself about to go to Rome (1623). But his plan failed; he fell ill and had to leave for Naples before Poussin arrived from Paris. The painter was left to rely on his own abilities and again underwent a time of severe privation.

Before Poussin's journey to Rome, most art historians are inclined to insert a visit that he is supposed to have paid to Venice in 1624. This journey is refuted by other scholars for three reasons. First, it is not considered logical that a man of limited means, journeying from Paris to Rome, would, after his arrival in Italy, first travel east rather than going directly south. Second, the principal source for this supposed Venetian journey is a note of questionable reliability written by Giulio Mancini, physician of Pope Urban VIII. Third, the paintings Poussin produced immediately after his arrival in Rome, such as the battle scenes (Leningrad, Moscow, and Rome), show no influence of Venetian colourism but imitate compositions of ancient Roman sarcophagi. Yet the so-called Venetian style of some of the pictures Poussin painted in Rome during the following years was probably inspired by three relatively early pictures painted by the Venetian Titian, which then hung in the Villa Ludovisi and were greatly admired by many Roman artists: "The Feast of the Gods," "The Bacchanal," and "Bacchus and Ariadne." This evidence was first cited by the Italian art theorist and biographer Giovanni Pietro Bellori (1615?–96), who knew Poussin personally.

First Roman period. Between Poussin's arrival in Rome in 1624 and his departure for France in 1640 he came to know many of Rome's most influential people. Perhaps the most important of his new acquaintances was the commendatore Cassiano dal Pozzo, secretary to Cardinal Barberini, who had a decisive influence upon his art. Pozzo was a well-known antiquarian who owned a rich collection of antique artifacts. According to Poussin's own testimony, these antiquities taught him most of what he came to know about classical art. Through Pozzo, who became Poussin's patron, the French painter became a fervent admirer of ancient Roman civilization. Voluntarily exiled from his native country, he developed an unreasonable hatred of French culture and an artistic style that, by its thoroughly Roman character, markedly contrasted with that of the other French artists then living in Rome or France.

Poussin continued the vagrant life of a bachelor, often changing his Roman address for unknown reasons. Toward the end of the 1620s he contracted a serious illness (according to Passeri, syphilis) that forced him to change his life-style. Suffering intense pain and socially abandoned, he was finally looked after by the family of a French confectioner and his Italian wife. Possibly impelled by a sense of gratitude after his recovery in 1630 or perhaps for mere convenience, he married their daughter, Anne-Marie Dughet, who was 18 years younger than himself. With Anne-Marie he lived in a childless marriage until she, passionately lamented by the painter, died a few years before his own death. He then began to lead a modest, silent, almost hidden petit bourgeois life, in a small house to which hardly anybody was admitted.

Marriage and retirement from artistic life of Rome

Although his art was much appreciated and he was known as one of the great painters in Rome, Poussin retired from active participation in artistic circles, as well as from the French community. His retirement from the artistic life of Rome did not result from fear nor from doubts about his artistic talent; on the contrary, it was based on an enormous self-confidence. While other artists followed the general movement of the Roman Baroque with the intention of attaining a certain significance in the general trend of the day, Poussin endeavoured to overcome the fashionable style on a higher level, inspired by Roman pre-Christian architecture and Latin books on moral conduct as well as by the nobility and greatness of Raphael's works, which, as he believed, had renewed the spirit of antiquity.

Painter to Louis XIII. Between 1638 and 1639, his achievements in Rome attracted the attention of the French court. Louis XIII's powerful minister Cardinal Richelieu tried to persuade Poussin to return to his homeland and become a member of the Académie Royal de Peinture et de Sculpture that he was trying to establish. In spite of a long preliminary correspondence, including an official invitation and a personal letter written by the King, Poussin showed no intention of following the summons. For a year and a half he made all sorts of excuses, knowing only too well how little the atmosphere of the French court would be compatible with the life he was used to and with the art he produced. But he finally yielded to the continued intense pressuring of Richelieu, Louis XIII, and Fréart de Chambray, a connoisseur of high rank and a collector, who was sent to Rome to conduct the negotiations. On October 28, 1640, Poussin sailed for France with several assistants. He left his wife in Rome, a fact that shows how much he distrusted his future appointment as a *peintre du roi*, "Painter to the king."

Received with great honours, Poussin nevertheless soon found himself in trouble with the ministers of the King as well as with the French artists, whom he met with the utmost arrogance. He was offered commissions for kinds of work he was not used to nor really qualified to execute: altarpieces, book covers, designs for tapestry and for the decoration of the Grande Galérie of the Louvre palace. What he produced did not elicit the praise he expected, so he left Paris in September 1642, not triumphantly as he had arrived but defeated, alone, in the *Coche de Lyon* (*i.e.*, ordinary stagecoach), and perhaps more humiliated than ever before. Unfortunately he did not live to see his personal style glorified by the French Academy in the late 17th century.

Second Roman period. During Poussin's second Roman period his personal appearance and behaviour changed. How he wished to be seen is evident from his two self-portraits, painted 1649 (Staatliche Museen Prussischer Kulturbesitz, Berlin) and 1650 (Louvre, Paris): a noble man with an assertive air that stemmed from his self-esteem. He could be met taking walks in the gardens of the Pincio followed by a number of admirers to whom he uttered his ideas concerning art and life, which increasingly became a kind of pagan philosophy. It is only during this period of his life that he really assumed the identity of the "painter-philosopher" for which he is generally known. During this last creative period Poussin concentrated his efforts on highly sophisticated themes of classical mythology as well as on biblical subjects.

Appearance and behaviour during second Roman period

Growing rather pessimistic with respect to human existence in general, he followed only from a great distance the events of Roman life and the political difficulties of his native land. His health declined, but, the more his body decayed, the more his spiritual and artistic faculties rose. From 1660 onward Poussin's complaints about his declining health became more numerous, and continuous pain interrupted his activities. Early in 1665 he ceased to paint. He died on November 19 and was buried in San Lorenzo in Lucina, his Roman parish church.

MAJOR WORKS

"The Triumph of David" (*c.* 1626; Dulwich College Picture Gallery, London); "The Assumption of the Virgin" (*c.* 1626; National Gallery of Art, Washington, D.C.); "The Martyrdom of St. Erasmus" (1628–29; Vatican Museum, Rome); "The Plague at Ashdod" (1630–31; Louvre, Paris); "The Adoration of the Magi" (1633; Gemäldegalerie, Dresden); "The Rape of the Sabine Women" (*c.* 1635; Louvre, Paris); "The Triumph of Neptune" (*c.* 1635; Philadelphia Museum of Art, Philadelphia); "The Adoration of the Shepherds" (*c.* 1637; National Gallery, London); "The Rape of the Sabine Women" (*c.* 1637; Metropolitan Museum of Art, New York); "The Seven Sacraments" (first series; 1642; Belvoir Castle near Grantham, Leicestershire, England; also one panel, National Gallery, Washington, D.C.); "The Seven Sacraments" (second series, 1644–48; The Duke of Sutherland Collection, on loan to the National Gallery of Scotland, Edinburgh); "Holy Family on the Steps" (1648; National Gallery of Art, Washington, D.C.); "Landscape with Diogenes" (1648; Louvre, Paris); "Self-Portrait" (1650; Louvre, Paris); "Christ and the Woman Taken in Adultery" (1653; Louvre, Paris); "The Exposing of Moses" (1654; Ashmolean Museum, Oxford); "The Arcadian Shepherds" (*c.* 1655; Louvre, Paris); "The Four Seasons" (1660–64; Louvre, Paris); Apollo and Daphne" (1664; Louvre, Paris).

BIBLIOGRAPHY. SIR ANTHONY BLUNT, *Nicolas Poussin*, 3 vol. (1966–67), is the most comprehensive account of Poussin's life and art. KURT BADT, *Die Kunst des Nicolas Poussin*, 2 vol. (1969), is an interpretation of the originality of Poussin's artistic achievements.

(K.Ba.)

Poverty

Poverty is the condition that is said to exist when people lack the means to satisfy their basic needs. In this context, the identification of poor people, then, first requires a determination of what constitutes basic needs. These may be defined as narrowly as "those necessary for survival" or as broadly as "those reflecting the prevailing standard of living in the community." The first criterion would cover only those people near the borderline of starvation or death from exposure; the second would extend to people whose nutrition, housing, and clothing, though adequate to preserve life, do not measure up to those of the population as a whole.

Poverty in industrial and underdeveloped nations

The immediately apparent differences between the living standards of the poor of the past or the poor of today's underdeveloped nations on the one hand, and those of the poor of modern, industrial societies, who may actually own automobiles, television sets, and washing machines, on the other, have led some authorities to suggest that it is unreasonable to call the latter group "poor." Others point out in response that people behave in accord with community standards, expectations, and aspirations in addition to absolute physiological needs. The problem of definition is further compounded by the noneconomic connotations that the word poverty has acquired. Poverty has been associated, for example, with poor health, low levels of education or skills, an inability or an unwillingness to participate in society, high rates of disruptive or disorderly behaviour, and improvidence. While all of these attributes have often been found to exist with poverty, their inclusion in a definition of poverty would tend to obscure the relation between them and the inability to provide for one's basic needs.

Whatever definition one uses and whatever correlates one adds to one's definition, authorities and laymen alike commonly assume that the effects of poverty are harmful both to individuals and to society. The assumption has considerable justification: in the United States in the 1950s an infant boy had a life expectancy of 66 years; in the underdeveloped nations the expectation was much lower—India, 42; Guatemala, 44; Colombia, 44; Guinea, 26. A similar differential could also be observed within countries. In the United States, for example, the infant mortality rate for urban blacks was roughly twice as high as that for whites.

TYPES OF POVERTY

Poverty can be classified according to a number of dimensions: time or duration (long- or short-term or cyclical), distribution (widespread, concentrated, individual), attitudes toward the poor (sympathetic or hostile), and presumed causes. The latter two dimensions are particularly important because of their relation to the kinds of efforts that are used in the attempt to ameliorate poverty.

Cyclical poverty. Cyclical poverty refers to poverty that may be widespread throughout a population, but the occurrence itself is of limited duration. In nonindustrial societies (present and past) this sort of inability to provide for one's basic needs rests upon temporary food shortages caused by natural phenomena or poor agricultural planning.

In industrialized societies the level of life is related to fluctuations in the ability of business, industry, and government to sustain high levels of employment at adequate wages. This ability, in turn, is dependent on, among other factors, fiscal policy, international trade balances, and, in capitalist countries, the optimism or pessimism of investors. Throughout the 19th and early 20th centuries the industrialized nations of the world experienced business panics and recessions. The United States' experience in the Great Depression of the 1930s, though unique in some of its features, exemplifies this kind of poverty. The Depression was rooted in the war debts of U.S. allies, reparations payments by Germany, and the tariff policies following World War I, as well as in runaway stock market speculation. Its effects, like those of prior depressions, included high unemployment rates, lowered wholesale prices, and reduced national production and income. Although business depressions affect all segments of society, their impact is most severe on people of the lowest strata, because of their marginal resources.

Effects of panics and depressions

For many years, poverty resulting from business fluctuations was accepted as an inevitable consequence of a natural process of market regulation. Relief (either in the form of temporary public works projects or provision of food) was granted reluctantly to tide people over until the business cycle again entered an upswing. As the causes of business depressions came to be more clearly understood, relief and public works were replaced in importance by programs intended to avert business depressions or to hasten recovery from them through manipulation of fiscal policy, regulation of the stock market, and international trade agreements. The general assumption today is that these measures minimize poverty by maintaining a healthy economy.

Collective poverty. In contrast to cyclical poverty, which is temporary, "collective" poverty involves a relatively permanent insufficiency of means to secure basic needs—a condition that may be so general as to describe the average level of life in a society, or that may be concentrated in relatively large groups in an otherwise prosperous society. Both generalized and concentrated collective poverty may be transmitted from generation to generation, fathers passing their poverty on to their sons.

Generalized collective poverty. Poverty is relatively general and lasting in much of Asia, the Middle East, most of Africa, and large parts of South and Central America. Life for the bulk of the population in these societies is at a minimal level. Death from starvation is not unusual. Nutritional deficiencies cause disease seldom seen by doctors in the West. Low life expectancy, high levels of maternal and infant mortality, and poor health characterize life in these societies. The magnitude of the problem is indicated by the probability that some 1,500,000,000 of the world's population are malnourished, in contrast to 450,000,000 who are well fed.

This type of poverty is usually related to economic underdevelopment. The total resources of many of these nations would be insufficient to support the population adequately, even if they were equally divided among all of the citizens. Proposed remedies are twofold: expansion of the gross national product through improved agriculture or industrialization, or both, and population limitation. Thus far, both population control and induced economic development have proved difficult and disappointing in their results.

Problems in developing countries

Increase of the gross national product does not necessarily lead to an improved standard of living for the population at large—for a number of reasons. (1) The most apparent of these is that, in the short run, as the food supply increases, the population generally increases at a higher rate. (2) Most of the underdeveloped nations are also characterized by a long-standing system of highly unequal rewards—a system likely to continue despite marked increases in the gross national product. Some authorities suggest that for some time to come, a larger portion of any increase will be siphoned off by persons who are already wealthy or in comfortable circumstances than will trickle down to the larger part of the population living at the near-starvation level. This, for instance, has often been the fate of aid from advanced nations. (3) The problem of financing agricultural and industrial improvements is one that cannot be met through the resources of the underdeveloped nations themselves but is dependent on investments from outside. It can be anticipated that a sizable portion of any increase in productivity will be paid as interest on these investments, again reducing the surplus available to the masses of poor in these countries. Industrializing nations are also especially vulnerable to the effects of poverty due to crop failures created by droughts, floods, or other natural afflictions. Their development plans have often been aborted because they have been forced to take funds earmarked for investment and use them instead for the purchase of food from other nations.

Concentrated collective poverty. In many industrialized, relatively affluent countries, particular demographic groups are vulnerable to long-term poverty. In city ghet-

tos, in regions bypassed or abandoned by industry, and in areas where agriculture or industry is inefficient and cannot compete profitably, there are found victims of concentrated collective poverty. These people, like those afflicted with generalized poverty, have high mortality rates, poor health, and so forth, when compared with the more affluent members of society. Although concentrated poverty is discussed in greater detail later in this article, briefly it may be said here that efforts at amelioration focus on ways to bring the deprived groups into the mainstream of economic life by attracting new industry, introducing improved agricultural methods, and raising the level of skills of the employable members.

Ghetto poverty

Case poverty. Similar to collective poverty in relative permanence but different from it in terms of distribution, case poverty refers to the inability of an individual or family to secure basic needs even in social surroundings of general prosperity. This inability is generally related to the lack of some basic attribute that would permit the individual to maintain himself. How severe the physical or mental handicap or how deficient the education and skill must be to make one unemployable depends on the range of jobs available in the society. Physical strength and endurance are crucial in countries depending more on labour than on capital, whereas in industrialized societies skill, education, and social adaptability have become more important. Those who have handicaps in social adaptability have long been associated with improvidence, a label covering such behaviour as the inability to manage money, laziness, drunkenness, and producing too many children.

Physical and mental handicaps are usually regarded sympathetically, as being beyond the control of the people who suffer from them. Efforts to ameliorate poverty stemming from physical causes focus on education, sheltered employment, and, if needed, economic maintenance. The *socially* handicapped, as can be judged from the language used to identify them, are stigmatized. Their handicaps are felt, in many instances, to be within the control of the individual, if he chooses to control them, and his poverty, then, is regarded as the outcome of the individual's own failures. The person is often dealt with punitively, given financial aid only reluctantly, and pressed to accept casework services to help him change his ways. Two attitudes toward the poor—sympathy and hostility—have permeated the literature on poverty.

TRADITIONAL ATTITUDES TOWARD POVERTY

Early efforts to cope with poverty up to the latter part of the 19th century had a common undercurrent: relief should involve at most only a *minimal* provision for basic needs, reflecting the idea that poverty offers an incentive to better one's self and that a guarantee of the means of survival removes that incentive. In Scotland the Rev. Thomas Chalmers expressed the belief of many when he declared in 1823 that the "four fountains of charity" were "frozen or locked up by the hands of legislation." These fountains were the frugality of the poor themselves, the kindness of relatives, the sympathy of the wealthy for the poor, and the sympathy of the poor for one another.

Laissez-faire and Malthusian views

Laissez-faire theory added economic justifications to the attitudes of those who favoured only minimal assistance. It proclaimed that if progress were to occur, economic life should be regulated only by the natural market processes of supply and demand. Adam Smith pointed out in 1776 that the propertied classes must ultimately pay wages high enough to assure the subsistence and reproduction of the labour force. Failure to do this would lead to the downfall of the system. This process, however, would eliminate only utter destitution, not poverty. Although Smith was not unsympathetic to the plight of the destitute, he was pessimistic about the results of efforts to improve their condition through relief. Smith assumed a finite wage supply and argued that any amount removed from this supply to relieve destitution without paying for work could only reduce the amount available to those who did work, making their subsistence more difficult. In his view interference with the natural process would lead to eventual intensification of the problem of poverty.

Thomas Malthus' *Essay on the Principle of Population*, published in 1798, furthered this general attitude. Malthus contended that since any increase of a population's food supply is more than consumed by the consequent increase in population, the only antidote was the limitation of population by war, disease, and famine. Without these controls he felt that the economic growth of his time would never be reflected in improved living conditions for a large part of the population. Later economists took up Malthusian ideas and declared flatly that attempts to interfere with "natural" processes by helping the poor could only lead to perpetuating destitution by maintaining them in too large numbers.

Existence at or below the subsistence level on the part of substantial numbers of people was accepted as the necessary price for economic growth and progress. As Joseph Townsend, a clergyman, had written in his *Dissertation on the Poor Laws* (1786):

> It seems to be a law of nature that the poor should be to a certain degree improvident, that there may always be some to fulfill the most servile, the most sordid, and the most ignoble offices in the community. The stock of human happiness is . . . much increased [when] the more delicate are not only relieved from drudgery . . . but are left at liberty . . . to pursue those callings which are suited to their various dispositions.

Townsend had forecast the union of laissez-faire economic theory and some theologies.

Much of late-18th- and early-19th-century Protestant theology was dominated by the concept of predestination. Material success and the accumulation of wealth were indications that one was favoured in God's eyes. Personal attributes associated with material success, such as thrift and sobriety, were valued highly, and the failure to succeed was seen as the "will of God" that ought not to be interfered with. When it was accompanied by improvidence and drunkenness, surely the victims of poverty deserved the consequences of their folly. To protect them from the consequences of their behaviour could only encourage profligacy.

Thus economics and religion combined to create a fear of the effects of alleviating poverty. Yet the repercussions of failure to alleviate poverty were also severe: famine, disease, theft, riots, and intense suffering. The common resolution of this quandary was to take relief measures sufficient to remove only the worst and most visible of the risks.

Social Darwinism

The justifications for the minimal relief of poverty were reinforced in the late 19th century by the advent of social Darwinism, an application of the principles of biological evolution to the social sphere. Biological evolution had occurred through the unregulated competition of individual organisms and species for the scarce necessities of life. Unfit individuals and unadaptable species died or became extinct, leading to vigorous species and the eventual emergence of man. In just such a manner, reasoned the English sociologist Herbert Spencer, who coined the phrase "survival of the fittest," unregulated competition among men had led to social and economic progress and the rise of the most able to positions of power and eminence. For progress to continue, unregulated competition must continue. Those at the bottom of the social ladder were there because they were inferior or unfit to engage in social life. To aid them would retard their extinction, hence retard progress itself.

Changing attitudes in the late 19th and early 20th centuries. Something, then, had to happen to break down the biases against the poor so that public provision for them and direct financial assistance in their own homes (outdoor relief, in contrast to workhouses and almshouses) became more acceptable. Religious and economic assumptions were gradually changing. The late 19th century saw an accelerating rejection of religious dogma regarding predestination in favour of a theology that emphasized the perfectability of man. This resulted in increased expression of a view that the poor need not be relegated to the poorhouse—that both they and their situations were capable of improvement.

Furthermore, almost simultaneously with the advent of

Progressive liberalism

social Darwinism, there came those who questioned not only its conclusions but the assumptions of laissez-faire economics as well. Critics asked whether the upper classes occupied their favoured status as a result of their own fitness in the struggle for survival or through their power to regulate competition in their own interest. Those who accepted the second alternative began to propose means through which the basis for competition by the poor could be improved while reducing what they saw as the unfair advantage of the rich. This did not represent a total rejection of the laissez-faire model as an ideal. Rather it was an attempt to make it function more adequately. The changes in attitude and their conversion into practice reflect the changing experiences of people in a rapidly industrializing society. Increased exposure of the conditions and consequences of poverty and a fear of the consequences played a part in the adoption of new programs.

Exposure of poverty problems. A number of investigations of public welfare practices were undertaken in the mid-19th century, when even though society in most industrialized countries was generally prosperous, expenditures for welfare had risen sharply. Suspicions of mismanagement and charges that able-bodied people were being cared for were common. Thus, most investigations were geared to reducing public expense. Contrary to expectations, these studies revealed that almshouses and relief rolls included the mentally and physically ill, the aged, and women with children, with a very low proportion of employable persons. The almshouses were particularly reprehensible, for they were dirty and crowded, and no special treatment was afforded the insane. By the end of the 19th century there were several successful efforts to set up specialized institutions for the indigent insane, ill, and children.

The "friendly visitors"

Public outdoor relief received no such spur as a result of these investigations. Relief given to recipients in their own homes, though cheaper than almshouses, was viewed suspiciously. The policy makers of private agencies stressed that continued dependence on financial support from any source was demoralizing to the recipients and damaging to society. Therefore, the help that they were prepared to give was preventive and, in the early stages particularly, geared to removing defects of character. (Only in cases in which urgent need forestalled other efforts at improvement did they offer temporary financial assistance.) Associations designed to improve the condition of the poor utilized the services of volunteer "friendly visitors," who attempted to help the poor lift themselves up from poverty through education, kindly example, and moral suasion.

Private agencies restricted their services to those believed able to improve their own condition. Despite the reiterated policy "that it is worse to debase by alms than to withhold them; that the physical must be subservient to the moral, and the moral receive the attention its paramount importance demands" (quoted in R.E. and M.W. Pumphrey, *The Heritage of American Social Work;* Columbia University Press, 1961, p. 110), the friendly visitors were often faced with situations in which they gave priority to financial assistance. The idea of the vicious circle of poverty was born in these confrontations with the poor. Hardworking people whose income was insufficient to meet their needs, the involuntarily unemployed whose wages had been so low that they couldn't "save for a rainy day," workers felled by illness or industrial accidents, unmarried women, widows, and children whose limited employment opportunities at low wages gave little hope that they could ever become self-supporting: none of these situations could be alleviated by moral suasion. And, given such a start, the children of the poor were doomed to repeat the lives of their parents. Even in situations not so clearly outside the control of the poor, should children be penalized for their parents' failures? The voluntary agencies could not help any of these individuals. They did not deserve the label "paupers." Yet all of them were worthy of help beyond the minimal provisions of public relief. Though in practice, charity organizations often provided the necessities of life for their clients, their resources, derived from contributions, were totally inadequate to meet the need they found. It became apparent to many of the visitors, if not to their supervisors, that new means for relieving and preventing poverty were necessary.

Settlement work

Settlement houses, such as Toynbee Hall in England, Hull House in Chicago, and the Henry Street Settlement in New York, were founded to educate the poor and to provide places for social gatherings. College-educated workers from comfortable homes lived in the settlement houses located in the slums. They found that, in addition to their original purposes, their new-found knowledge—as Jane Addams, founder of Hull House, said—made these workers see the needs of their neighbourhoods as a whole and furnish data for, and use their influence to secure, legislation.

In addition to the personal experiences of the friendly visitors, settlement house workers, and journalists, other sources of information became available from 1890 to the beginning of World War I. These were the scientific social surveys starting in England with Charles Booth's *Life and Labour of the People in London* and B. Seebohm Rowntree's *Poverty: A Study of Town Life.* As Booth remarked, "a large portion of the population are ill-nourished to the point of being inefficient, but that for very many of these it is impossible that it should be otherwise; the remuneration of unskilled labour, the cost of food, and the needs of the human body being what they are."

Although, admittedly, the sentiments and findings of friendly visitors, settlement workers, journalists, and social surveyors were recorded throughout the 19th century, it is in the period 1890–1910 that they intensified and began to affect social policy. In terms of the classification of types of poverty mentioned earlier, the conception of concentrated poverty, with its presumed causes and effects, had begun to replace that of case poverty.

Discontent and protest. The change of attitudes about the poor was a significant factor in bringing about reform. Reform, however, does not necessarily follow a change of attitude alone. Another set of circumstances made it seem expedient, as well as moral, to deal with the poor in a different way. Although the period up to the outbreak of World War I in Western countries was one of tremendous economic growth and prosperity, there were large parts of the population who did not share in the growth and who were cruelly affected by the periodic business panics. Farmers vigorously protested low prices. Factory labourers working 10 to 12 hours a day for wages barely sufficient to support themselves expressed similar dissatisfaction. In times of financial depression, discontent grew as thousands of employable persons found themselves facing unemployment or reduced wages.

Radical reform movements

Discontent was expressed in many ways: third parties and movements proliferated, efforts to unionize intensified, and looting and rioting occurred. Marxist and anarchist thought provided much of the rhetoric, stressing the conflict of class interests and the eventual triumph of the workers over the capitalists. Some of the means advocated for furthering the interest of the workers alarmed the more prosperous. An anarchist, Johann Most, from Germany, wrote in 1885, "Dynamite! Of all the good stuff, that is the stuff! . . . place this in the immediate vicinity of a lot of rich loafers who live by the sweat of other people's brows, and light the fuse. A most cheerful and gratifying result will follow." (Quoted in S.H. Holbrook, *Dreamers of the American Dream;* Doubleday & Co., Inc., 1957, p. 295). Isolated acts of violence during labour disputes or political rallies, regardless of their provocation or doubt about responsibility, seemed to confirm the danger from radicals and the poor.

Measures for the relief of poverty in the late 19th and early 20th centuries. Effective change was slow in coming. Often long periods elapsed between the first proposal and discussion of a measure and its actual implementation. The first programs to be adopted bore either an indirect relation to poverty or were conceived of as preventing poverty. They did not put money into the hands of the poor. Compulsory education, better housing, improved public health facilities, and the regulation of wa-

Preventive, insurance, and direct-relief plans

ges and hours of women and children appeared to be measures that would break up the vicious circle of poverty. Advocates of public health and tenement housing regulation were relatively successful in securing early legislation. Unfortunately, the tenement laws did not alleviate the poverty-perpetuating crowding and bad sanitation, because of poor enforcement and the connection between low rent and poor housing. Child labour laws were slow to appear. Minimum-wage and minimum-hour legislation for women also proceeded slowly.

Unemployment insurance, workmen's compensation, and health insurance were planned to give money to the poor while avoiding the implication of pauperism. Proponents of workmen's compensation stressed that it would avoid prolonged litigation to establish liability and would be a means of avoiding industrial accidents, as well as providing money for injured workers. Benefit scales for all programs were initially very low for the wage earner and his dependents.

A substantial group of widows and children were not covered by insurance programs geared to previous employment, and some form of direct, government-financed assistance was required to avoid destitution and the separation of family members. Mothers' allotments were proposed to provide an adequate income. These programs were accompanied by supervision and regulation of the families' lives, however, in order to discourage dependence on public money. Allowances were small in the expectation that families would supplement them through earnings. Even so, laws permitting the allotments could not assure that local governments would implement the programs. Agitation for direct financial aid to the indigent aged began in the late 19th and early 20th centuries, leading to the German and British systems of compulsory contributory insurance. In the United States, federal programs of unemployment insurance and old-age assistance were introduced in the 1930s.

None of the plans—preventive, insurance, or direct assistance—gave sufficient money to meet the needs of the poor, and in many instances no money actually became available to them despite permissive legislation. Mothers' allotments and, to a lesser extent, old-age pensions were not granted with an eye to long-term maintenance, and the emphasis of the efforts was on making the recipients self-supporting. Nonetheless, significant changes had occurred. The undifferentiated almshouse had been rejected, issues regarding the legitimacy of various forms of aid to the poor and their financing had been settled, and a number of programs were in operation in most Western countries by the beginning of World War II. For further description of such programs, see WELFARE AND SECURITY PROGRAMS.

INDUSTRIAL POVERTY IN THE LATTER HALF OF THE 20TH CENTURY

Rediscovery of poverty amid affluence. To say that something has been "rediscovered" is to suggest that the phenomenon was virtually dormant, overlooked, neglected, or lost sight of for a period of time. This was the situation with respect to attention to poverty in affluent nations from the end of World War II to the late 1950s and beyond. Some observers contend that social scientists, social workers, and various other professionals retained a high level of interest in poverty, but that it was masked by a new frame of reference that did not use the labels "poor" and "poverty." Rather they spoke in terms of "lower class," "low-income group," and "multiproblem family." When viewed more closely, however, the situation clearly involved more than a particular set of terms falling into disrepute and disuse. No matter what the label, the interest of social scientists, professionals, and laymen in poverty dropped off markedly after the Great Depression of the 1930s and remained at a lower level for nearly two decades. Throughout most of the 1950s, social research and popular literature were concerned with such topics as the changing mores and mass culture. The lure of these subjects was enhanced by what is probably the most important single reason for the deflection of interest in the poor: most social thinkers shared with the general public the commonly held belief that the postwar prosperity of industrial nations was eliminating large-scale poverty. The few references to poverty in sociological literature, for example, portrayed the poor as comprising a small percent of population. As will be seen, this conception had little basis in reality. Nonprofessionals in the United States, most notably Michael Harrington in *The Other America* (1962), helped to shatter these illusions and redirect public attention to the paradox of extensive poverty coexisting with affluence.

The "new" poverty

After such a long period of neglect, poverty was rediscovered and action was deemed necessary because of a number of events. In the United States a set of social and economic disorders began to accelerate in the 1950s and increasingly fed into each other until their overall impact was inescapable. Among the factors involved, the most crucial were the rising costs of welfare, the belief that crime rates were soaring, and, in some countries, the sharp increase in unemployment.

Poor minorities, youth, and unskilled workers

The political consequences of the climbing rate of unemployment or partial employment were immediate and far-reaching because of the composition of the unemployed or underemployed group. Three categories posed particularly sensitive problems: minority groups, such as the nonwhites in the U.S. and Britain, whose rate was over that of the overall figure; the young, who were similarly overrepresented; and the semiskilled workers who had, until that time, been continuously employed. In the United States the increasingly large numbers of Negroes and young persons joining the ranks of the jobless represented potentially volatile forces. Equally important were the workers who had regarded themselves as having a secure claim in the job market. The "respectable working class," from which upwards of one-third of the unemployed were drawn, reacted strongly to its sudden impoverishment and began to exert political and social pressure. Through unions and informal networks of relationships, the message and implications of their discontent and anxieties got through to politicians and community leaders. Their addition to the already high welfare rolls made it impossible to continue to perceive the poor as a residual group of the old, disabled, and otherwise unemployable. A similar pattern can be detected in the rediscovery of poverty in other affluent nations, although the timetable has been somewhat different.

Life of the poor and its effects. Descriptions of the way of life and behaviour of the poor in modern industrial society are remarkably similar to depictions of the poor in industrial societies of the past. A vignette of the poor in Charles Booth's London could as well be that of a black family in a Harlem hovel, an Algerian family in the slum outskirts of Paris, an Italian family in a Naples slum, a family in the wastelands of Appalachia, or a poor Japanese family crowded in the hovels of Tokyo. The general picture that emerges, despite variations in cultural setting, is that of severe sociocultural and personality impoverishment together with pervasive family and personal disorganization. Numerous studies among the poor have documented the high incidence of family instability, emotional illness, and various types of deviant behaviour such as crime and delinquency. Indifference, apathy, fatalism, resignation, and related traits are terms typically used to describe the outlook of the poor and are at the core of what is often referred to as the "culture of poverty." Family life may be fraught with fear and violence and exhaustion and bitterness. The children typically grow up emotionally and physically stunted—a situation conducive to repeating the cycle of their parents' lives.

Anxieties of the poor

One need not seek far for an explanation of these characteristics of the poor. The chronic insufficiency of basic needs—poor nutrition, bad housing, and inadequate medical care—and the anxiety that accompanies a precarious existence are the roots of the common deterioration of personal and social behaviour of those living in poverty.

This contemporary poverty amid affluence belongs to the concentrated collective type, in that various demographic groupings in the population (*e.g.*, the aged, the unskilled, the incapacitated, the minority groups, large families) have a high incidence of relatively permanent

poverty. A common approach to explaining the sources of such poverty is to list a set of factors and characteristics associated with the poor and to suggest that the cause of poverty is to be found in some combination of these factors. A report issued by the U.S. Chamber of Commerce, for instance, uses this approach in holding that "poverty is largely a product of ignorance, changing industrial technology, prejudices that limit opportunity, worn out farms and depressed communities, inability or unwillingness to move where jobs are, lack of motivation, curable physical or mental abilities" (*The Concept of Poverty*, 1965). There is nothing untrue about this statement: all the "causes" cited do play some role in poverty. Many observers would contend, however, that this is a useless, even misleading position; that it does not isolate the salient variables; that it mixes personal attributes such as ignorance, unwillingness to move, and lack of motivation with attributes of the social structure such as changing technology, worn-out farms, and depressed communities; and that it does not say whether individual and structural attributes are to be treated equally as sources of poverty or, if not, how each should be weighed.

Any approach focussing on the poor's attitudinal characteristics (*e.g.*, motivation) or even demographic characteristics (*e.g.*, occupational status) as a *point of departure* for assessing the causes of poverty can lead to serious errors. In particular, a line of reasoning that moves from individual psychological attributes to group attributes and then to the complex phenomena of socioeconomic poverty confuses cause and effect. To be sure, lack of adequate job skills and education carry high risks for poverty, and families resigned to remaining in a depressed area and possessed of too many children are also likely candidates for poverty. Such characteristics, however, are as much the consequences of poverty as they are causes, if not more so.

Social structure of the poor

The more plausible approach may be in seeing that the social structure is the ultimate source of the bulk of poverty. This orientation allows one to encompass structural factors (for instance, technological change) that most authorities agree are implicated in poverty as well as to account for the ambiguous role of most of the personal and group attributes usually dealt with.

The key feature of the social structure pertinent to a discussion of the causes of poverty is the economic institution, with an emphasis on the relations between unemployment, employment and poverty, and the increasing impact of automation in changing the nature of these relations. (Other relevant factors in a capitalist society are its monetary and fiscal policies.) Historically, poverty and unemployment have been closely connected, but they are no longer. Admittedly, changes in the unemployment rate do still figure importantly in changes in the number of the poor today. For example, an unemployment rise of 1 percent in a labour force of over 80,000,000 could mean the addition of 1,000,000 or more (including dependents) to the ranks of the poor, with pronounced effects upon certain disadvantaged groups. But large-scale unemployment is not a prominent feature of contemporary poverty. In most industrial countries the unemployment rate in recent times has remained below 4 to 7 percent. More to the point, most of today's poor families have at least one employed person, and in the majority of instances the wage earner is the family head. The employment situation is not too different for unattached individuals under 65: the great majority of persons in this group have jobs.

Thus, although there is no denying that unemployment is important in considering such poverty groups as the aged, the incapacitated, the illiterate, the minorities, and the female-headed family, it is more important to direct attention to the bulk of the poor who are employed. Overwhelmingly, the jobs that poor persons hold in industrial society require minimal skills and bring in marginal wages. The low income from such employment, together with the high incidence of "short weeks" and periodic brief layoffs, largely explains how a situation of nominally full employment can coexist with widespread poverty.

The changed relation between unemployment and poverty seems due largely to the progressive shrinkage of job opportunities in the lower ranges of the occupational structure. Among other things, automation may be steadily reducing the need for workers doing repetitive tasks of the type required in mass production. The long-range ramifications of automation are uncertain, but for the foreseeable future it appears that the supply of workers with limited skills and education is increasingly outstripping the demand for them, with a consequent lack of pressure for a livable wage scale.

Coping with the problem of poverty. From early times, direct financial aid to the poor has been regarded as a temporary, but necessary, evil. Only the aged and severely disabled have been assured of uninterrupted, though often inadequate, income. It has been assumed that if one is of working age, reasonably healthy, and willing to work, he can locate a job that will provide for his needs. As suggested above, in recent years there has been greater awareness that this assumption is not justified. Consequently, plans to cope with poverty are increasingly geared to meeting the needs of the employed poor and those for whom there are no jobs.

Guaranteed income and job-training plans

This is the basic rationale underlying a variety of income maintenance plans falling into the category of "guaranteed annual income." Under such programs a minimum income figure is set, based on family size, and the difference between this figure and actual income is made up by a government subsidy. The problem centres obviously on determining a proper figure. If it remains too low, there will be scarcely an elimination of the welfare and relief costs. Setting the minimum appreciably higher, on the other hand, raises other problems. As the income of the unemployed, underemployed, or lowly paid poor begins to approach that of employed persons just above the minimum level, it creates a growing potential for resentment of the system. Furthermore, many observers contend that the incentive to work is reduced in both groups. Other critics argue that a guaranteed income to people who are primarily employed in jobs demanding low skills will remove pressure on employers to pay higher wages for these jobs. This would have the added effect of depressing the earnings of those who are not quite eligible for subsidies.

A number of programs, either proposed or operative in some countries, focus on semiskilled and unskilled workers, trying to upgrade their skills through education or retraining. Such relatively short-term job-training programs, however, have tended to be highly selective and to eliminate those very persons most in need of training. When programs have indeed included these persons, considerable time has had to be spent on such basic skills as reading, writing, and arithmetic, which alone do not improve employability. In short, job training as a means of eliminating poverty has been most successful only with those workers who have not required massive upgrading of skills.

Another program that has attracted many supporters is the children's allotment, which would pay a specified amount for each child to all families regardless of need. Such a program exists in such countries as France, Sweden, and the U.S.S.R. Although such a scheme neglects the childless poor, it is argued that money thus spent has the greatest impact on future poverty—improving, as it does, the future of the present generation of youth. Some critics of the plan fear that it would encourage an increase in the birthrate in a world that is already overpopulated, although this has not been the case in any Western nation granting children's allotments.

Expansion of welfare programs

Overall, there has been in most Western countries a considerable expansion of all varieties of programs aimed at equalizing incomes and reducing poverty. Sweden is a notable example. It has one of the world's most highly developed systems of labour-management mediation and conciliation, controls over incomes and production, and welfare programs. One-third of the nation's annual budget goes to welfare, financed by relatively high progressive taxes that have appreciably narrowed the gap between "rich" and "poor".

BIBLIOGRAPHY. Any account of the history of English poor laws is heavily indebted to SIDNEY and BEATRICE WEBB, *English Poor Law History*, 2 vol. (1927–29). A detailed account of the treatment of the poor in medieval times may be found in B. TIERNEY, *Medieval Poor Law: A Sketch of Canonical Theory and Its Application in England* (1959). The debate surrounding Speenhamland and the Poor Law Reform of 1834 is central to J.R. POYNTER, *Society and Pauperism* (1969). B.D. COLL, *Perspectives in Public Welfare* (1969), offers a good, brief history of changing forms of public welfare from medieval to modern times. M. ORSHANSKY describes the most commonly used standard for determining the extent and distribution of poverty in "How Poverty is Measured," *Monthly Labor Review*, 92:37–41 (1969). Information on the extent, distribution, and perpetuation of poverty in the U.S. may be found in A.B. BATCHELDER, *The Economics of Poverty* (1966); L. FISHMAN (ed.), *Poverty Amid Affluence* (1966); H. LUMER, *Poverty: Its Roots and Its Future* (1965); and H.H. MEISSNER (ed.), *Poverty in the Affluent Society* (1966). Proposals for new means of alleviating poverty, such as children's allotments and the guaranteed annual income, are discussed in A.L. SCHORR, *Explorations in Social Policy* (1969); and in J.C. VADAKIN, *Children, Poverty and Family Allowances* (1968). Problems in reducing poverty in the nonindustrial nations are dealt with in G. MYRDAL, *Asian Drama: An Inquiry into the Poverty of Nations* (1968); G.A. BORGSTROM, *The Hungry World: The Modern World at the Edge of Famine* (1967); and in G.M. MEIER, *Studies in International Poverty*, 2nd ed. (1970). "The Dimensions of World Poverty," *Scient. Am.*, 219:27–35 (1968), by D. SIMPSON, deals with the measurement, extent, and severity of world poverty and also comments on the prospects for its alleviation; as does D. HOROWITZ in *The Abolition of Poverty* (1969). J. BHAGWATI, *The Economics of Under-developed Countries* (1966), sets forth an internation framework for the relief of poverty and discusses the incidence of squalor, the economic and social structures of underdeveloped countries, and the types of domestic programs that have been undertaken. T. BALOGH, *The Economics of Poverty* (1966), concentrates on the problems, policies, and proposals for relief of poverty in the newly independent nations.

Pragmatism

In its broadest and most familiar sense, "pragmatism" refers to the usefulness, workability, and practicality of ideas, policies, and proposals as criteria of their merit and claims to attention. Achieving results, "getting things done" in business and public affairs is often said to be "pragmatic." There is a harsher and more brutal connotation of the term in which any exercise of power in the successful pursuit of practical and specific objectives is called "pragmatic." The character of American business and politics is often so described. In these cases "pragmatic" carries the stamp of justification: a policy is justified pragmatically if it is successful. The familiar and the academic conceptions have in common an opposition to invoking the authority of precedents or of abstract and ultimate principles. Thus in law, judicial decisions that have turned on the weighing of consequences and probable general welfare rather than on being deduced from precedents have been called pragmatic.

The word pragmatism goes back to the Greek πραγμα ("action," "affair"). The Greek historian Polybius (died 118 BC) called his writings "pragmatic," meaning thereby that they were intended to be instructive and useful to his readers. In his introduction to the *Philosophy of History*, Hegel commented on this "pragmatical" approach as the second kind of reflective history, and for this genre he cited Johannes von Müller's *History of the World* (Eng. trans. 1840). As the psychologist and leading Pragmatist William James remarked, "the term is derived from the same Greek word πραγμα meaning action, from which our words 'practice' and 'practical' come." Charles Peirce, another pioneering Pragmatist, who may have been the first to use the word to designate a specific philosophic doctrine, had Kant's German term rather than the Greek word in mind: *Pragmatisch* refers to experimental, empirical, and purposive thought "based on and applying to experience." In the philosophy of education the notion that children learn by doing, that critical standards of procedure and understanding emerge from the application of concepts to directly experienced subject matters, has been called "pragmatic." In semiotics, the general theory of language, that part that studies the relation of the user to the words or other signs that he uses is called pragmatics (as distinct from semantics and syntax).

MAJOR THESES OF PHILOSOPHIC PRAGMATISM

During the first quarter of the 20th century, Pragmatism was the most influential philosophy in America, exerting an impact on the study of law, education, political and social theory, art, and religion. Six fundamental theses of this philosophy can be distinguished. It is, however, unlikely that any one thinker would have subscribed to them all; and even on points of agreement, varying interpretations mark the thought and temper of the major Pragmatists. The six theses are:

1. Responsive to Idealism and evolutionary theory, Pragmatists have emphasized the "plastic" nature of reality and the practical function of knowledge as an instrument for adapting to reality and controlling it. Existence is fundamentally concerned with action, which some Pragmatists exalted to an almost metaphysical level. Change being an inevitable condition of life, Pragmatists have called attention to the ways in which change can be directed for individual and social benefit. They have consequently been most critical of moral and metaphysical doctrines in which change and action are relegated to the "merely practical," on the lowest level of the hierarchy of values. Some Pragmatists anticipated the more concrete and life-centred philosophy of Existentialism by arguing that only in acting—confronted with obstacles, compelled to make choices, and concerned to give form to experience—is man's being realized and discovered.

2. Pragmatism is a continuation of critical Empiricism in emphasizing the priority of actual experience over fixed principles and a priori reasoning in critical investigation. For James this meant that the Pragmatist

> turns away from abstraction and insufficiency, from verbal solutions, from bad *a priori* reasons, from fixed principles, closed systems, and pretended absolutes and origins. He turns towards concreteness and adequacy, towards facts, towards action. . . . It means the open air and possibilities of nature, as against . . . dogma, artificiality, and the pretence of finality in truth.

3. The pragmatic meaning of an idea, belief, or proposition is said to reside in the distinct class of specific experimental or practical consequences that result from the use, application, or entertainment of the notion. As Peirce commented: "Our idea of anything is our idea of its sensible effects." Two propositions for which no different effects can be discerned have merely a verbal appearance of dissimilarity, and a proposition for which no definite theoretical or practical consequences can be determined is pragmatically meaningless. For Pragmatists "there is no distinction of meaning so fine as to consist in anything but a possible difference of practice." Meaning thus has a predictive component, and some Pragmatists came close to identifying the meaning of a term or proposition with the process of its verification.

4. While most philosophers have defined truth in terms of a belief's "coherence" within a pattern of other beliefs or as the "correspondence" between a proposition and an actual state of affairs, Pragmatism has, in contrast, generally held that truth, like meaning, is to be found in the process of verification. Thus truth *is* the verification of a proposition, or the successful working of an idea. Crudely, truth is "what works." Less crudely and more theoretically, truth is in Peirce's words, the "limit towards which endless investigation would tend to bring scientific belief." For John Dewey, founder of the "Instrumentalist" school of Pragmatism, these are beliefs "warranted" by inquiry.

5. In keeping with their understanding of meaning and truth, Pragmatists have interpreted ideas as instruments and plans of action. In contrast to the conception of ideas as images and copies of impressions or of external objects, Pragmatist theories have emphasized the functional character of ideas: ideas are suggestions and anticipations of possible conduct; they are hypotheses or forecasts of what will result from a given action; they are ways of organiz-

ing behaviour in the world rather than replicas of the world. Ideas are thus analogous in some respects to tools; they are efficient, useful, and valuable, or not, depending on the role that they play in contributing to the successful direction of behaviour.

6. In methodology, Pragmatism is a broad philosophical attitude toward the formation of concepts, hypotheses, and theories and their justification. To Pragmatists man's interpretations of reality are motivated and justified by considerations of efficacy and utility in serving his interests and needs; the molding of language and theorizing are likewise subject to the critical objective of maximum usefulness according to man's various purposes.

HISTORY OF PRAGMATISM

Idealism, Empiricism, Kantianism

Antecedents in modern philosophy. Pragmatism was a part of a general revolt against the overly intellectual, somewhat fastidious, and closed systems of Idealism in 19th century philosophy. These boldly speculative Idealists had expanded man's subjective experience of mind till it became a metaphysical principle of cosmic explanation. To the Idealist, all of reality was one fabric, woven from parts that cohered by virtue of the internal relations that they bore to one another; and this reality was often interpreted in abstract and fixed intellectual categories. The theory of evolution, then still new, seemed to the Pragmatists, on the other hand, to call for a new, non-Idealist interpretation of nature, life, and reason—one that challenged the long-established conceptions of fixed species. The new emphasis was on the particular variations and struggles of life in adapting to the environment. Philosophically, the fact of growth and the development of techniques for instituting changes favourable to life became the significant factors rather than the Idealist's ambitious rationalistic account of human goals and of the universe in general, and important developments in natural science and logic also encouraged a critical attitude toward earlier systems.

There were two main influences on the early formation of Pragmatism: One was the tradition of British Empiricism in the work of John Stuart Mill, Alexander Bain, and John Venn, which had stressed the role of experience in the genesis of knowledge—and particularly their analyses of belief as being intimately tied in with action and, indeed, as definable in terms of one's disposition and motive to act. The work of George Berkeley, an important 18th-century empirical Idealist, which presented a theory of the practical and inferential nature of knowledge, of sensations as signs (and thus predictive) of future experience, led Peirce to refer to him as "the introducer of Pragmatism." The other major influence came from modern German philosophy: from Kant's analysis of the purposive character of belief and of the roles of will and desire in forming belief and his doctrine of "regulative ideas," such as God or the Soul, which guide the understanding in achieving systematic completeness and unity of knowledge; from Romantic Idealists, for whom all reason is "practical" in expanding and enriching human experience; and from Hegel's historical and social conception of changing and developing subject matters. In sum, Peirce was profoundly impressed by Kant and by the Scottish philosophy of common sense, James by British Empiricism and by the voluntarisms (stressing the role of choice or will) of the genetic epistemologist James Ward and the relativistic French Personalist Charles Renouvier, Dewey by Coleridge's version of Kant's active conception of mind and by neo-Kantian and Hegelian Idealism.

Finally, to these influences must be added that of American social experience in the 19th century: the rapid expansion of industry and trade and a popular optimism, with its roots in Puritan theology, holding that hard work and virtue are bound to be rewarded. Both the precariousness of frontier life, however, and the rapidly expanding economy weakened the prevailing Calvinistic belief in a predestined future and encouraged the emergence of inventiveness, a sense of living still in the New World experiment, and adoption of the ideal of "making good."

The Metaphysical Club. It was in the critical group discussions of the "Metaphysical Club" in the 1870s in Cambridge, Massachusetts, that Pragmatism first received philosophic expression. In addition to Peirce and James, membership in the club included Chauncey Wright, F.E. Abbot, and Justice Oliver Wendell Holmes, Jr. A version of Peirce's now classic paper "The Fixation of Belief" (Nov. 1877) seems to have been presented at the club. But James also published a paper in 1878, "Spencer's Definition of Mind as Correspondence," in which his Pragmatism and analysis of thought and belief are clearly discernible. It was in a lecture delivered 20 years later, however, that James introduced Pragmatism, then fully crediting the idea to Peirce. It was primarily James's exposition that became famous and was received by the world at large.

Peirce's Pragmatism

The classical Pragmatists. The Pragmatic philosophy of Charles Sanders Peirce was part of a more general theory of thought and of signs. Thought, or "inquiry," it was held, results from doubt, a state in which habitual actions are blocked or confused and from which organic irritation and irresolution result. Resolution, unobstructed conduct, on the other hand, are products of belief, which is a form of stability and satisfaction. It is the function of scientific thought to produce true beliefs. In a prolonged effort to embed this analysis of doubt and inquiry within a more comprehensive theory of signs in which communication, thought, knowledge, and intelligent conduct could be fully understood, Peirce achieved a wealth of original insights. A sign is a socially standardized way by which something (a thought, word, object) refers man (the community of sign users) to something else (the interpretant), which, in turn, is itself another sign. Peirce's Pragmatism is thus a method for translating certain kinds of signs into clearer signs in order to surmount linguistic or conceptual confusion. Getting at the interpretant involves determining the "effects" or consequences of the signs or ideas in question.

Peirce's Pragmatism is therefore primarily a theory of meaning that emerged from his first-hand reflections on his own scientific work, in which the experimentalist understands a proposition as meaning that, if a prescribed experiment is performed, a stated experience will result. This method has two different uses:

(1) It is a way of showing that when disputes permit no resolution, the difficulties are due to misuses of language, to subtle conceptual confusions. Such questions as whether the physical world is an illusion, whether man's senses always mislead him, or whether his actions are fated are "not real problems."

(2) The method may be employed for clarification. As Peirce wrote:

> Consider what effects, that might conceiveably have practical bearings, we conceive the object of our conception to have. Then our conception of these effects is the whole of our conception of the object.

To say, for example, that an object *O* is hard means that if the operation of scratching *O* is performed, *O* will not be scratched by most substances. One thus achieves clarity when one can supply a conditional statement of this kind.

Similarly, in his theory of truth, one means by truth of belief that if a certain operation is the subject of continuous scientific inquiry by the community of investigators, assent to the belief would increase and dissent decrease "in the long run." Consequently, not only is thought purposive but meaning carries a reference to the future. Peirce's concept of the community of sign users and inquirers also has social and moral relevance, for it is nothing less than the ideal of rational democracy.

Witnessing his doctrine undergo a medly of dubious interpretations, Peirce eventually dissociated himself from these by calling his own view "Pragmaticism," a term he called so ugly as to be safe from uninformed use. Parts of the work of Dewey, of the social Pragmatist G.H. Mead, and of the conceptualistic Pragmatist C.I. Lewis are a further development of the logical Pragmatism of Peirce. The English logician F.P. Ramsey and the Italians Giovanni Vailati and Mario Calderoni also undertook significant extensions of Peirce's Pragmatism.

An alternative, though not wholly different, version of Pragmatism was developed by William James. It took a

psychological and moral form largely unforeseen and unintended by Peirce.

James's Pragmatism

A basic difference between Peirce and James is discernible in their respective conceptions of the direction to be taken by Pragmatic analysis. While Peirce construed meaning in general, conditional schema, and interpretants, James focussed upon the distinct contributions that ideas and beliefs make to specific forms of human experience on the living level of practical wants and purposes. Between the two close friends there persisted a fundamental philosophical difference in outlook that affected even their styles. While James was a Nominalist, holding that the full significance of ideas, meanings, and actions lies in their particular concrete existent occurrence, Peirce—as a scholastic Realist—sharply criticized him at this point, arguing that "a thing in general is as real as in the concrete."

The most conspicuous feature of James's writings on Pragmatism is the dominant place given to considerations of value, worth, and satisfaction—consequences of his teleological (purposive) conception of mind (*cf.* his *Principles of Psychology*). James maintained that thought is adaptive and purposive but also suffused with ideal emotional and practical interests—"should-be's"—which, as conditions of action, work to transform the world and create the future, even to "make the truth which they declare." Consequently, truth and meaning are species of value: "*The true is the name of whatever proves itself to be good in the way of belief.*"

James took meaning to be an intimate part of the use of ideas for expediting action. The notion of the difference that a proposition makes in experience was fundamental in James's Pragmatic methodology. He remarked that "it is a good rule in physiology, when we are studying the meaning of an organ," to look to the specific function that it performs. In like manner, the special difference that the presence of mind makes in observable cases, reflected in its unique functioning, defines the use of "mind": "In particular, the pursuance of future ends and the choice of means . . . are thus the *mark and criterion of the presence of mentality*."

With his training in medicine and psychology and the influence of Darwin in the background, James considered that the main function of thought is to help us establish "satisfactory relations with our surroundings." Thus man helps to mould the character of reality according to his needs and desires. Indeed, this is fundamental in James's defense of the right to believe in his famous essay "The Will to Believe" (1897). James argued that we may have a reasonable right to hold a religious or metaphysical belief (*e.g.*, that there is a perfect, eternal, and personal aspect of the universe) when the belief in question would supply a vital psychological and moral benefit to the believer, when evidence for and against the belief is equal, and when the decision to believe is forced and momentous. In James's functional conception of truth, the "working," and hence the truth, of ideas is their role in opening up valuable possible directions of thought and action—"a leading that is worth while."

James's "working" view of truth and of a reality that man in part makes by acting out and real-izing ideas, and especially his essay "The Will to Believe," were enthusiastically received by F.C.S. Schiller in England and by Giovanni Papini in Italy, and these doctrines became a cause célèbre for Pragmatists and their critics.

Schiller's Pragmatism

An admirer and friend of James, Schiller, now nearly forgotten, was once the most famous Pragmatist in England and Europe. Schiller was initially a humanist in the sense that, for him, both reality and knowledge are reflections of human activity—"the taken" rather than "the given." He first came to appreciate James's "The Will to Believe" in 1897 and subsequently acknowledged its impact on his thinking in an early and important paper, "Axioms As Postulates" (1902). He was a tireless critic of the "closed" systems of Idealism of F.H. Bradley, J.M.E. McTaggart, and Bernard Bosanquet and an advocate of the intellectual freedom that consists in "open," plural, changing, and to some extent never finished philosophical theorizing. According to Schiller, reality and truth are "man-made" rather than eternal verities. The true and the false are basically forms of good and bad and are relative to the private purposes of some particular person. He attempted to describe and analyze the "logic" of the experimental "trying" through which such needs are satisfied. For Schiller, reality is wholly plastic; and, starting out from initial postulates, one proceeds to construct his schemes for achieving a satisfactory outcome of desire, finally rendering his unformed possibilities (*hylē*) into a common world of language and action. On this view, all of science derives from and is inescapably guided by the psychological process of human thought; man is the measure of all things.

Dewey's Instrumentalism

John Dewey once noted that "Peirce wrote as a logician and James as a humanist." This distinction characterizes not only the course of Pragmatism but also the shaping of Dewey's own thought. Dewey first felt the influence of James in the 1890s while struggling to free himself from the hold of Hegelian Idealism. Later, he recognized the value of Peirce's work, which clearly prefigured certain ideas that he had developed independently.

With indefatigable effort and care Dewey reformulated Pragmatism, critically readjusting some of its conflicting doctrines, drawing upon his own work in psychology and education, and finding stimulation in the social Pragmatism of his friend George Herbert Mead. The resulting construction was Instrumentalism, which Dewey conceived as a single coherent theory embracing both the logical and humanistic currents of Pragmatism and thus integrating the methods and conclusions of scientific knowledge with beliefs about values and purposes.

While scientific, moral, and social experiences may differ in subject matter, the method of thought functioning "in the experimental determinations of future consequences" remains the same for all inquiry. Initially provoked by doubtful or problematic conditions, intelligent conduct is addressed to a resolution and settling of these conditions and to a "warranted assertion"—Dewey's version of "truth." Such is the "mediative function" of reason. "Truth" is thus identified with the outcome of competent inquiry. Actions occurring on the organic level, if they be at first confused and obstructed, can then become organized, coherent, and liberated through such inquiry.

Dewey's analysis of the organic, cultural, and formal conditions of intelligent action implies that all reflective conduct issues in an evaluation of a situation with respect to future action and consequences: thus inquiry is essentially an evaluative procedure. This method, most impressively applied in the sciences, is nonetheless a paradigm of moral activity as well. In ethics, "the action needed to satisfy" the situation is not to be found simply by the application of moral codes. The meaning

> has to be searched for [since] there are conflicting desires and alternative apparent goods. . . . Hence inquiry is exacted. . . . The good of the situation has to be discovered, projected and attained on the basis of the exact defect and trouble to be rectified.

In general, for Instrumentalism, moral ideals and "ends" function as means and hypotheses in guiding the deliberative process directed to controlling experience and attaining future goods.

> Not health as an end fixed once for all, but the needed improvement in health—a continual process—is the end and good. . . . Not perfection as a final goal, but the ever-enduring process of perfecting, maturing, refining is the aim of living . . . . Growth itself is the only moral 'end.'

Inquiry possessed a genuine religious significance for Dewey, and in its functioning as a critical, self-corrective social process of human growth he envisaged the working ethic of democracy.

Other American Pragmatists. Two important contributions to American Pragmatism, which have not yet received the attention that they deserve, came from Mead and Lewis.

Mead's orientation was social psychology. He had studied physiological psychology in Germany, had earlier worked under James and Josiah Royce at Harvard, and was also familiar with Peirce's analyses of thought and

signs. Dewey regarded him as one of the most fertile minds in American philosophy.

Mead's social and Lewis' conceptualistic Pragmatism

Mead developed the most comprehensive of the Pragmatist theories of mind. He depicted the evolution of mind and self-consciousness as emerging from social interactions and the use of gestures and "significant symbols" such as words. In contrast to other creatures, an individual regarded as having mind, engaging with others in social acts, can respond to his own gestures as others respond to them—thus taking on social roles and becoming an "other" in respect to himself. It is therefore by means of language, the use of "significant symbols," that mind emerges.

Fundamental to Mead's philosophy is his conception of the social act, in which individuals modify and direct one anothers' activities, work out their purposes, and accordingly transform their environments. In the social act the future controls present conduct, and this is distinctive of consciousness. Since the function of intelligence is to render the world "favourable for conduct," Mead viewed the development of scientific knowledge and the evolutionary process as coinciding.

Lewis's theory of "conceptualistic Pragmatism" was derived partly from his study of modern logic and partly from the influence of Royce and the classic Pragmatists. The critical results of a careful study of Kant are traceable in his work.

Lewis's Pragmatism focusses upon concepts, categories, and principles through which experience is interpreted. Though the sensuously given is "unalterable," how it is taken, how conceptually interpreted, depends on the purposes and initiatives of the mind—the a priori element in knowledge, which, functioning as categorical criteria of reality, is "true no matter what." It is by means of these that a systematic interpretation of reality is developed. However,

> there may be alternative conceptual systems, giving rise to alternative descriptions of experience, which are equally objective and equally valid. . . . When this is so, choice will be determined . . . on pragmatic grounds.

In stressing the purposive character of conceptualization, Lewis is thus in the main course of American Pragmatism.

Pragmatism in Europe. In his preface to *Pragmatism*, James commented that the Pragmatic movement was the focal expression of a number of philosophic tendencies suddenly becoming conscious of themselves and of "their combined mission." He mentioned the French thinkers Maurice Blondel, Édouard Le Roy, and B. de Sailly and the Italian, Giovanni Papini. Blondel was the author of *L'Action* (1893) and spokesman for a voluntaristic and activistic theory of knowledge. He was a founder of the "school of action," a liberal Catholic group that was part of the modernist movement (which employed the new historico-critical approach to the Bible and promoted a rationalistic interpretation of the faith). As early as 1888, Blondel appropriated the term *Pragmatisme*, only to abandon it when he learned of American Pragmatism, which was a more naturalistic philosophy than his own. Le Roy, closer to James than other French thinkers, also called his views Pragmatism. In broad respects he was like James in holding that the truth and the full significance of beliefs is found in acting them out. Le Roy was a disciple of Henri Poincaré, who had argued that scientific theories are not mere summaries of data, nor deduced from axioms, but are creative constructions, products of human thought and ingenuity, "conventions." To the question of what limits are imposed on otherwise arbitrary conventions, of what justifies them, Le Roy suggested their convenience in use. James saw similar forms of Pragmatism in Ernst Mach, Wilhelm Ostwald, Pierre Duhem, and Théodore Ruyssen in "the notion that no theory is absolutely a transcript of reality" and that "their great use is to summarize old facts and lead to new ones" so that they are a "man-made language, a conceptual shorthand . . . in which we write our reports of nature."

Blondel, Le Roy, Papini, and others

Another French thinker, Georges Sorel, undertook to reformulate James's Pragmatism into a "useful" doctrine of social criticism. Mussolini later cited Sorel and James as two of his philosophic mentors. He claimed to find in James "that faith in action, that ardent will to live and fight, to which Fascism owes a great part of its success." To the democratic James, no lesson could have been more badly learned.

A more immediate and direct form of James's Pragmatism occurred in Italy with its centre in the journal *Leonardo*, under the leadership of the iconoclastic critic Giovanni Papini. James referred to Papini as "a brilliant, humorous and witty writer." He called him a genius and was addressed in turn by him as "the Master." Papini's Pragmatism, derived from James's "The Will to Believe," became a theory of the will to action. In action, through creative power and passion, man achieves a kind of divinity. This romantic exaltation of action was appealing to artists but also to fanatics. Papini and his associate Giuseppe Prezzolini comprised the "magical" school of Pragmatism (in the sense of seeking "divinely-creative" power) in contrast to the "logical" school inspired by Peirce of G. Vailati and M. Calderoni.

Later tendencies. Certain extensions and applications of Pragmatism are to be found in current American philosophy. Sidney Hook has directed some of the critical techniques of analysis against a number of ideologies. In the tradition of the scientifically oriented Pragmatisms of Peirce and Dewey, he has explored the relation between the logic of experimental inquiry and the ethic of democracy. A converging of Pragmatism and Logical Positivism resulted in the movement of "logical empiricism" which, in addition to Dewey and Lewis, included the top-rank philosophers of science P.W. Bridgman, Rudolf Carnap, and Ernest Nagel, and the philosophical semanticist Charles W. Morris, all of whom were responsive to the Pragmatisms of Peirce, James, and Dewey. More recent and detailed studies of the structure of science, the nature of theories and explanation, by Carnap, Lewis, and Nagel, and a new interest in Instrumentalism deriving from the work of F.P. Ramsey, Ludwig Wittgenstein, W.H. Watson, and Gilbert Ryle (as well, of course, as from Dewey) exhibit a further continuation of Pragmatism.

Positivists and Nominalists

Maintaining a "more thorough Pragmatism" than that of Carnap and Lewis, who viewed choices made within scientific frameworks as pragmatic decisions, the prominent logician W.V. Quine has argued against the alleged boundary between analytic and synthetic truths. No portion of the conceptual scheme of science is exempt (as analytic truths were supposed to be) from possible revision in the flux of experience and in the light of pragmatic interests in efficacy and comprehension in predicting future experience. In important respects Quine's view of the evolution, organization, and function of the conceptual structure of science is close to that of Schiller, James, and Dewey.

Quine has also defended a methodological Pragmatism and relativism on ontological questions on the nature of being or reality. This position, also taken by another contemporary philosopher of science and language, Nelson Goodman, recalls the earlier Pragmatists' notion of the "plastic" character of reality, now seen as conceptually plastic in the sense of being expressible in a variety of systems of symbols and languages. It is conceptually misguided to seek *the* nature of objects, since what there *is* is not describable *in abstracto* from the particular language in which an ontological question has been put. Objects declared to be real, be they classes, numbers, atoms, or stones, may differ widely. But differences between the "theoretical" and the "factual" entities are basically differences of degree and purpose in evolving conceptualization. Hence reality is anything that it is truly said to be —in any of many linguistic and symbolic systems; and where differences in ways of speaking about objects call for choices, the ensuing adjudications will be pragmatic.

EVALUATION OF PRAGMATISM

Pragmatism has been vulnerable to certain criticisms. It has often been portrayed as a rationalization of the American business ethos—a portraiture perhaps inspired, but not by any scrutiny of the writings of the philosophers themselves. Similarly, the Pragmatic theory of truth has

been assailed. Concerning an idea or belief, James had held that one can say: " 'It is useful because it is true' or that 'it is true because it is useful.' " "Both phrases," he added, "mean the same thing." Most scholars, however, have denied this equivalence. His position may seem, moreover, to allow for an idea to be true (*i.e.*, useful or expedient) for one person and false (inexpedient) for others. Finally, James was accused of reducing truth to a subjective play of opinions that one happens to relish or find useful to believe. To these charges James replied that "what immediately feels most 'good' is not always most 'true' when measured by the verdict of the rest of experience." He also warned: "Woe to him whose beliefs play fast and loose with the order which realities follow in his experience."

As a single movement, Pragmatism is no longer extant; but as a body of ideas it contributes a heritage that is destined for future analysis and development. Chief among these are the interpretation of thought and meaning as forms of purposive behaviour, of knowledge as evaluative procedure in which normative and descriptive materials are integrally related, and of the logic of scientific inquiry as a norm of intelligent conduct in the affairs of men. Finally, Pragmatism has succeeded in its critical reaction to the 19th-century philosophy from which it emerged. It has influenced the current conception of philosophy as a critical method of investigating problems and clarifying communication rather than as a universal synthesis of knowledge. Pragmatism thus has certain affinities with the critical philosophizing of G.E. Moore and Bertrand Russell, as well as with the thought of the French intuitionist and vitalist Henri Bergson and his disciple Édouard Le Roy, of Blondel, of the early Positivists Mach and Duhem, of the fictionalist Hans Vaihinger, of the Vienna Circle and the philosopher of logic and language Ludwig Wittgenstein, and also of the founder of Phenomenology, Edmund Husserl, and some of the continuing forms of Phenomenology and Existentialism. It has recognized the relative, contingent, and fallible (yet still authentic) character of human reason, rather than perpetuating the dubious ideal of philosophy as a system of eternal truths. In so doing, and in thus altering the philosophical scene, Pragmatism has become vitally implicated in the practices of current intellectual life; and in the light of this fact, a more pragmatic justification of Pragmatism is difficult to imagine.

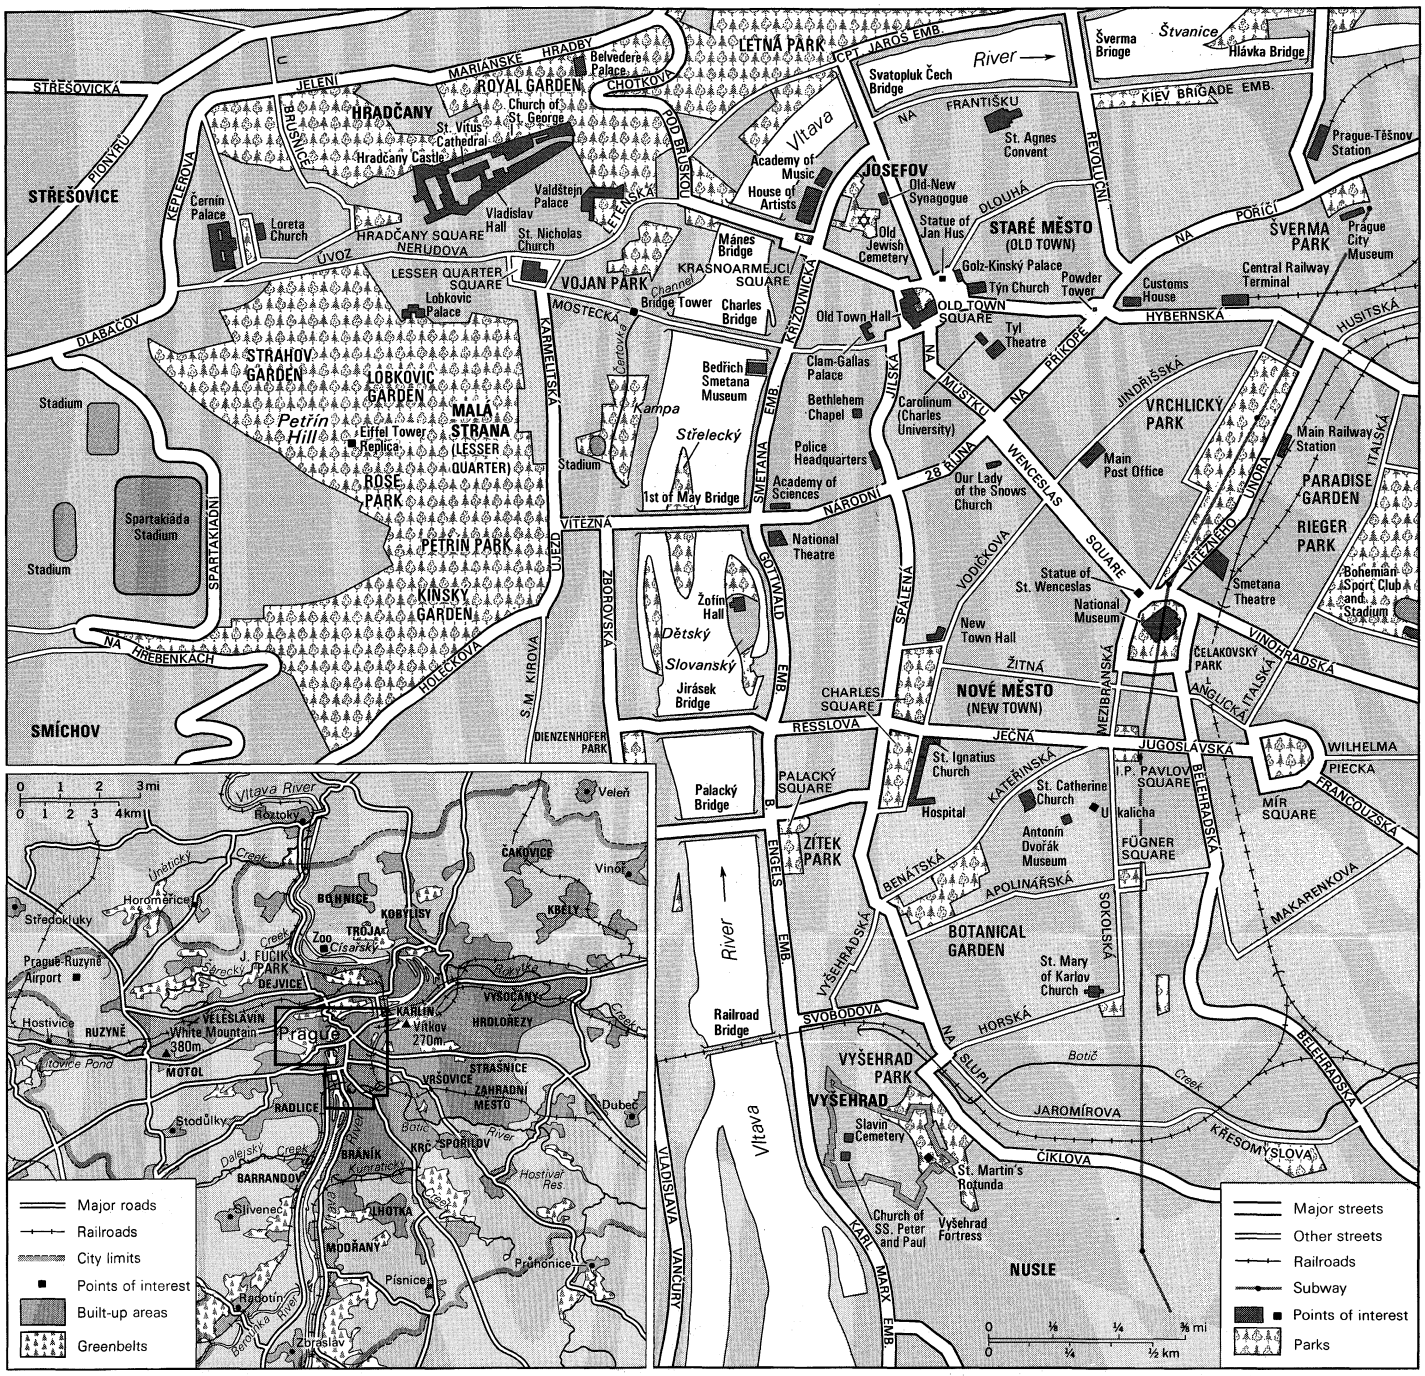
Prague

One of the finest cities of Europe, Prague (Czech Praha), the capital of Czechoslovakia and that nation's major economic and cultural centre, lies at the heart of the continent and was the home of some 1,173,000 people by the mid-1970s. Spread like Rome on seven hills, the city has a rich architectural heritage that reflects both the uncertain currents of history in Bohemia and an urban life extending back more than a thousand years. The physical attractions of the city are many. The winding course of the Vltava River, with its succession of bridges and changing vistas, contrasts with the ever-present backdrop of the great castle of Hradčany (or Prague Castle), which dominates the left-bank region of the city from behind massive walls set high on a hill. The narrow streets and little taverns and restaurants of the older quarters contrast with the broad sweep of Václavské náměstí (Wenceslas Square) and modern parks and housing developments, while the great 18th-century Baroque palaces have their own elegance and splendour. Seen from the surrounding hills, the many church towers make up a unique perspective, giving Prague its description as the "city of a hundred spires." This architectural harmony has been enhanced by post-1945 planning, which has preserved the ancient core of the city as one major monument and has carefully supervised all modern building.



The character of the city

Prague is also famous for its cultural life: Wolfgang Amadeus Mozart lived there, and his *Prague Symphony* and *Don Giovanni* were first performed there; the lyric music of the great Czech composers Bedřich Smetana, Antonín Dvořák, and Leoš Janáček is commemorated each year in the spring music festival. In literature, the *U kalicha* ("At the Chalice") beer parlour, still popular with local residents and tourists alike, provided the setting for the humorously anti-authoritarian activities of Schweik, immortalized by the novelist Jaroslav Hašek in *The Good Soldier Schweik;* the writings of Franz Kafka, dwelling in a different way on the dilemmas and predicaments of modern man, also seem indissolubly linked with life in this city. For related information see BOHEMIA AND CZECHOSLOVAKIA, HISTORY OF; and CZECHOSLOVAKIA.

THE HISTORY OF PRAGUE

The foundation of the city. For thousands of years that portion of the Vltava's course where Prague was to rise was crossed by trade routes linking northern and southern Europe. The region is replete with Paleolithic relics, and Neolithic farmers inhabited the region from around 5000 to 2700 BC. Celts had settlements in the region from about 500 to 200 BC, including the fortified Závist, to the south of Prague. From the 4th century AD to the 6th, Slavs appeared on the Vltava banks, followed by the Avars.

The first settlement at what is now Prague has been traced to the second half of the 9th century. The oldest building was Vyšehrad Castle (*hrad*, "castle"), set on a commanding right-bank hill. It was soon followed by what was to become Hradčany Castle, set on an equally commanding left-bank site a little downstream. Legend (stirringly told in Smetana's opera *Libuše*) ascribes the foundation of Prague to a Princess Libuše and her husband Přemysl, a plowman and founder of the Přemyslid dynasty; legend notwithstanding, the Přemyslids, in power from *c.* 800 to 1306, consolidated a political base centred on Prague that was to be the nucleus of the Bohemian state and that enabled the natural trade advantages of the city site to develop under defensive protection. The dynasty included St. Wenceslas (Václav), who was murdered by his brother Boleslav *c.* 936 and whose statue now looks down upon the square to which his name was

Central Prague and (inset) its metropolitan area.

later given; and Boleslav I, whose reign (*c.* 936–967) witnessed the consolidation of power against a German threat. The little community began to flourish, and in the year 965 the Arab merchant and traveller Ibrāhīm ibn Yaʿqūb was able to describe it as a "busy trading centre." In 973 the bishopric of Prague was founded.

Medieval growth. The economic expansion of the community was soon reflected in the topography of the city. A market centre on the right bank, opposite Hradčany Castle, developed into the Staré Město (Old Town), particularly after the construction of the first stone bridge over the river in 1170. By 1230 the Staré Město had been given borough status and was defended by a system of walls and fortifications. On the opposite bank, under the walls of Hradčany, the community known as Malá Strana (Lesser Quarter; literally, Small Side) was founded in 1257. Following the eclipse of the Přemyslids, the House of Luxembourg came to power when John of Luxembourg, son of the future emperor Henry VII, became king of Bohemia. His son, Charles IV, Bohemian king and Holy Roman emperor, had his capital at Prague from 1346 to 1378 and took considerable personal interest in the development of the city. In 1348 he founded the Charles University (Universita Karlova), the first in central Europe, which was later to attract scholars and students from all over the Continent. His reign also saw the growth of the planned Nové Město (New Town) adjacent to the Staré Město; construction of the Karlův most (Charles Bridge; 1357, reconstructed in 1970) linking the Staré Město and the Malá Strana; and the beginning (1344) of the great St. Vitus' Cathedral, which was not completed until 1929. Other buildings included the Carolinum (the central hall of the university), the town hall (destroyed in 1945), and several churches and monasteries in Nové Město. The Jewish ghetto was also developed, and the bishopric was raised to an archbishopric in 1344.

The role of Charles IV in planning the city

By the 14th century Prague had become a major central

European city, with the Czech money minted at nearby Kutná Hora serving as the hard currency of the entire region. Foreign merchants, notably Germans and Italians, became economically and politically powerful in uneasy alliance with the kings. The social order, however, became less stable because of the emergent guilds of craftsmen, themselves often torn by conflicts between masters and journeymen. The town paupers added a further volatile element.

The Reformation and the Thirty Years' War. Prague played a significant role in the Reformation. The sermons of Jan Hus, a scholar at the university, begun in 1402 at the now-restored Bethlehem Chapel and carrying forward the criticisms of the church developed by the English reformer John Wycliffe, endeared him to the common people but brought him into conflict with Rome; he was burned at the stake in the town of Constance (Konstanz, West Germany) in 1415. Popular uprisings in 1419, led by the Prague priest Jan Želivský, included the throwing of city councillors from the windows of the New Town Hall in the incident known as the first Defenestration of Prague. The next year Hussite peasant rebels, led by the great military leader Jan Žižka, joined forces with the Hussites of Prague to win a decisive victory over the Catholic king (later emperor) Sigismund at nearby Vítkov Hill.

During the next 200 years, the rich merchants became ascendant once more, and the late Gothic architectural style flourished in many churches and buildings, reaching a peak in the fine Vladislavský sál (Vladislav Hall) of Hradčany Castle. In 1526, however, the Catholic Habsburgs became rulers of Bohemia and attempted to crush Czech Protestantism. The second Defenestration of Prague (1618), when the governors of Bohemia were thrown from the windows of the council room in Hradčany Castle—one of the major events precipitating the Thirty Years' War—was followed by the decisive defeat of Protestant forces at the Battle of the White Mountain (Bílá Hora), near the city, in 1620. Twenty-seven Prague commoners and Czech noblemen were executed on the Staroměstské náměstí (Old Town Square) in 1621; the city ceased to be the capital of the empire, was occupied by Saxons (1631) and Swedes (1648), and went into a decline hastened by two outbreaks of plague.

The modern period. *The 18th century.* The return of more settled conditions in central Europe was marked by renewed economic growth, and Prague's population grew from 40,000 in 1705 to more than 80,000 by 1771. In 1784 the Staré Město, the Nové Město, the Malá Strana, and the Hradčany Castle complex were administratively united into one city. The merchants and the mostly German, Spanish, and Italian nobility who were active in and around Prague in this period had an enormous effect on both architecture and cultural life. Outstanding architects created magnificent palaces and gardens, often in the shadow of the castle, and churches in the Prague version of the Baroque style sprang up throughout the city.

Effects of the Industrial Revolution

The 19th century. The onset of the Industrial Revolution had major effects in Prague. The first suburb (Karlín) was established in 1817, and in the next 20 years many factories sprang up, often in association with the coal mines and ironworks at Kladno and Králův Dvůr, not far away. The population passed 100,000 by 1837, and expansion continued after the city received its first railway eight years later. The rise of a working class and of strong nationalistic sentiments had a profound effect on the city; students, artisans, and workers took to the barricades against the ruling Austrians when revolution flared briefly in 1848. Within 20 years Czechs had won a majority on the City Council, and Czech cultural life was experiencing a renascence centred on Prague. The Neoclassical building of the National Museum and the National Theatre are only two examples of the building that took place in this period. By the 1890s the first electric streetcars (trams) were running in the city, urban services were being reorganized, and a replica of the Eiffel Tower in Paris overlooked the city from Petřín Hill.

The 20th century. In 1918 Prague became the capital of the newly independent Czechoslovak republic, and a Greater Prague of 19 districts had been established within two years. By 1930 the population had reached 850,000. The city suffered a severe setback following the surrender of large parts of Bohemia and Moravia to Germany under the Munich Agreement of 1938. The citizens rose in revolt on May 5, 1945, and held the city until the Red Army arrived four days later. The post-World War II period was marked by economic reconstruction and by careful planning with a view to restoring and preserving the historic monuments of the city centre. There is also an increasing emphasis on the development of new satellite communities. The city continued to grow (although most of its recent population growth is attributable to annexation rather than to natural growth or immigration), reaching 1,173,000 inhabitants by the mid-1970s. In spite of the political vicissitudes of the 20th century, Prague had established a growing international reputation and had become a major tourist centre.

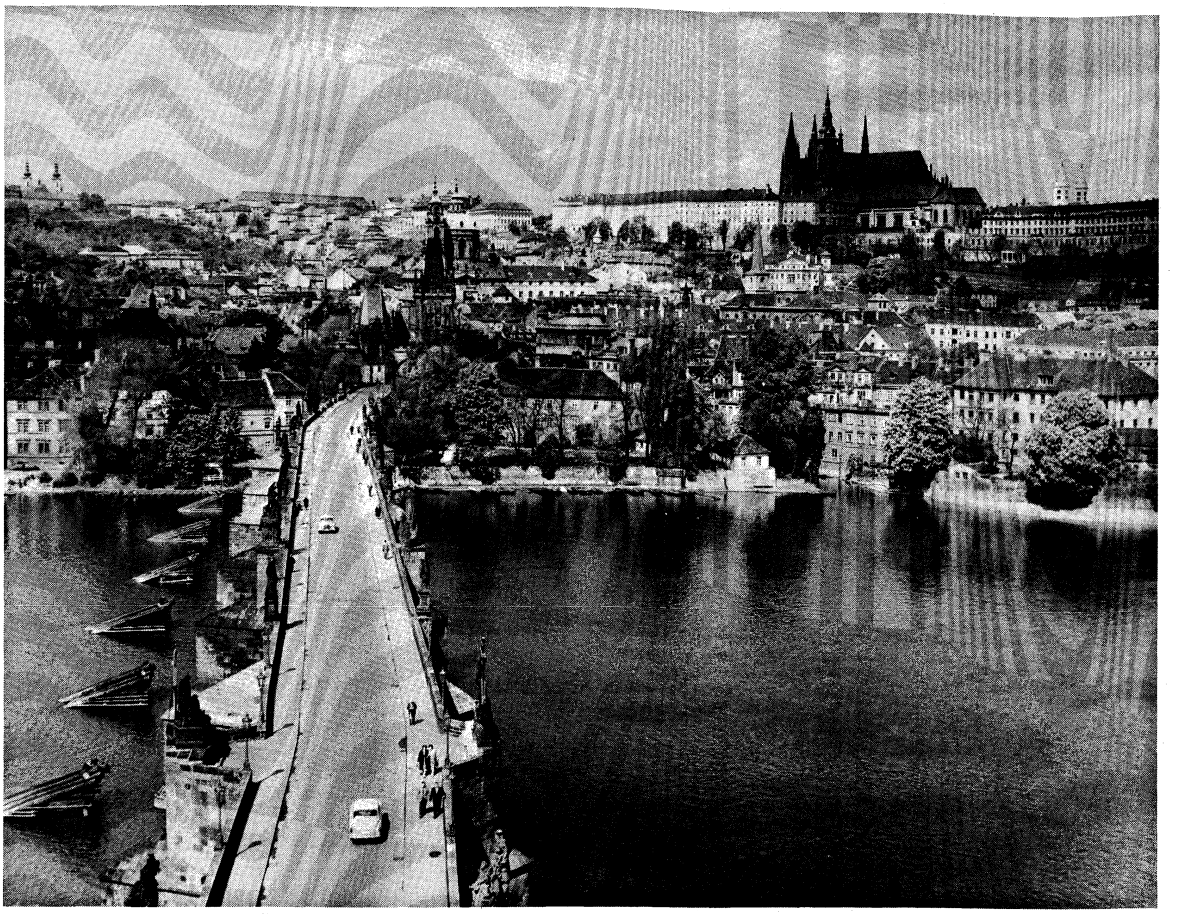
After World War II

THE CONTEMPORARY CITY

Topography and environment. From its original small riverside settlements, Prague has spread over its seven or more hills and also up tributary valleys and along riverside terraces. By the mid-1970s, the whole administrative area had grown to 191 square miles (496 square kilometres).

The lowest point in the city is 623 feet (190 metres) above sea level and the highest is 1,247 feet (380 metres), on the White Mountain. The climate of Prague is typically midcontinental, with the July average reaching 67° F (19.5° C), while that of January falls to 31° F (−0.5° C).

Demography. Prague has a number of demographic peculiarities stemming mainly from the effects of World War II. The basic problem is that there are more women than men (53.4 percent to 46.6 percent by the mid-1970s), and a sizable proportion of the female population is past the age of fertility; for example, 26 percent of the women but only 19.6 percent of the men were over 60 years of age by the mid-1970s. The natural rate of increase is very small—2.3 per 1,000 in 1975, from a birth rate of 16.5 and a death rate of 14.2 per 1,000.



A tendency toward smaller families reflects both difficulties in housing and increased participation by both parents in the work force. Out of every 100 births in Prague by the early 1970s, about 65 percent were of a first child, 29 percent of a second child, and only 4 percent and 2 percent, respectively, of a third or later child. Future trends in the city population will depend critically on the rate of in-migration, but it appears that increase will continue through the 1970s and beyond.

Economic life and administration. Though Prague is justly renowned for its cultural life and monuments, it has played a very important role in the economic life of Czechoslovakia since the early and intensive development in the 19th century of such industries as those producing textiles and machinery. About 28 percent of the total labour force of more than 640,000 is employed in manufacturing, about 14 percent in construction, 12 percent in trade, 8 percent in education and culture and in transport and communications, and 7 percent in science and research. Nearly half the labour force is female, the proportion of women reaching 44 percent in manufacturing, 57 percent in education and culture, 66 percent in trade, and no less than 80 percent in the health field.

Women in the labour force

In manufacturing, production of machinery occupies the majority of workers, followed, in about equal numbers, by food production (including brewing of the famous Prague beer), textiles, and printing. By the end of the 1960s, 38 percent of manufacturing production was of consumer goods—a 50 percent increase over the beginning of the decade.

Since 1945 the municipal administration has been carried out by the 150-member National Committee of Prague, with power residing in an 18-member council headed by a mayor with cabinet rank in the national government. The mayor has three deputies in charge of city planning, scientific development, and cultural life. A dozen or so specialized committees deal with particular aspects of city administration and services. A similar ad-

View of Prague (Malá Strana district) across Charles Bridge and the Vltava River, with Hradčany Castle at upper right and the spires of St. Vitus' Cathedral rising behind it.
H. Armstrong Roberts

ministrative structure operates, on a smaller scale, in each of the 10 city districts, which range in size from the smaller inner-city districts—which are losing population to the suburbs but nevertheless maintain a high population density and hold most of the employment opportunities—to the much larger outer residential districts.

Municipal services. The standard municipal services—the supply of gas, electricity, and water—have been consolidated under state control since World War II and have been considerably modernized and expanded as part of overall urban planning. The high percentage of employed women has caused the authorities to turn their attention toward the provision of nurseries for the children of working mothers; there were 138 of these by the mid-1970s, supplying places for more than 7,400 children. Other facilities include swimming pools, often run in conjunction with sports organizations. On the river, the city provides mooring positions for pleasure boats.

Housing shortage

The housing problem continues to cause difficulties in the city, in spite of a building program. Of the more than 380,000 separate housing units in the city by the beginning of the 1970s, about a quarter had been built since 1945. Tourist accommodation has also expanded, and more than a million people a year (half of them from abroad) now visit the city.

As in other cities of the Communist bloc, all retail establishments—food stores, department stores, and self-service establishments—are publicly owned and part of the municipal system. There are numerous small restaurants and taverns, many of which—especially in the Malá Strana—have an intimate and historic atmosphere and offer fine views over the city and the winding river.

Public transportation is handled by buses and streetcars, or trams. More than 1,800,000 people are carried daily on this system, which is cheap and subsidized; only 12 to 15 percent of commuters use their own cars. The defects of this long-established public system have been evident for some time, and in 1966 construction started on a subway system, very deep in places; the first section was opened in 1974. Under a related reorganization, two of the large Prague railway stations were to be abolished and the main station reconstructed and enlarged to handle all rail traffic entering the city. The international airport at nearby Ruzyně, because of its favourable location in the centre of the continent, has become of major significance. A fleet of passenger boats on the Vltava is also an element in transportation.

Health services

Health services in the city are provided by some 270 health districts, each serving some 3,500 people. The 13 major hospitals in the mid-1970s (including a new hospital complex in the Motol district) had about 8.5 beds per 1,000 inhabitants.

Education and cultural life. There are nine institutions of higher education in Prague, including two universities with more than 34,000 students, but by far the most famous is the Charles University, founded in 1348, the oldest in central Europe. The Academy of Arts and the Academy of Music (with a conservatory founded in 1811) are also important. The other notable university institution is for foreign students, the University of the 17th of November (a reference to the killing of a number of Czech students by occupying forces on that date in 1939), founded in 1961, which has about 4,000 students from more than 90 countries, many of them from the developing world. The activity of the Academy of Sciences is supplemented by many specialized institutions; the academy sponsors an increasing number of international congresses. Higher education in the city benefits from a tradition that can count among its scholars and teachers the great 17th-century astronomers Tycho Brahe and Johannes Kepler and the noted modern physicist Albert Einstein, who taught in Prague in 1911–12.

Prague has a renowned and active musical life, which reaches a high point each year in the internationally

known spring music festival. The city's fine orchestras —the Prague Symphony and the Prague Philharmonic— have won reputations abroad. Theatrical traditions are also strong, with about 15 well-attended theatres in the city. There are also many museums and galleries.

Architecture

Perhaps the greatest treasures of the city, however, are the more than 1,700 officially recognized architectural and artistic monuments, ranging in period from the Romanesque through the Gothic to the Baroque, Rococo, Classical, and Neoclassical. The interiors of these buildings, which often house major art collections, have been restored since 1945. The most notable Romanesque monument is probably the simple but striking 10th-century Church of St. George, behind the north wall of Hradčany Castle. To the west of it is its more massive successor, the basically Gothic St. Vitus' Cathedral, the twin spires of which dominate the city skyline. Other Gothic monuments include the Týn Church on Old Town Square; the elegant Prašná brána (Powder Tower), marking the former city walls in what is now the busy Příkopy shopping area; the restored Bethlehem Chapel, where Hus preached; and the St. Agnes Convent, built in 1234 and notable for its collection of 14th-century paintings. The Old-New Synagogue and the tumbling, crowded gravestones of the Old Jewish Cemetery—Europe's oldest—serve as a reminder of the strong Jewish tradition in Prague life.

Baroque buildings are the city's greatest single artistic treasure, among them the splendid Valdštejn and Clam-Gallas palaces, St. Nicholas Church, and the Antonín Dvořák Museum. The geometric tiling of the Golz-Kinský Palace facade provides a distinctive glimpse of the Rococo style. Classical buildings include the Bedřich Smetana Museum on the riverside and the elegant Belvedere Palace (the former Royal Summer Palace). The National Museum and the National Theatre are the main Neoclassical buildings.

The beauty of the city is enhanced by its many parks and gardens, including a major cultural and entertainment centre in the park named for Julius Fučík (a slain resistance leader of World War II) and a large zoo in suburban Troja.

Recreational facilities also include the vast Strahov sports complex—containing three stadiums, the largest of which, Spartakiáda Stadium, holds 250,000 spectators and is used for the mass gymnastic display known as the Spartakiáda—as well as a number of other sports and cultural centres, with emphasis on facilities for youth. The film studios at Barrandov, on the city outskirts, have produced a number of high-quality motion pictures and there is a museum of modern sculpture at Zbraslav.

PROSPECTS FOR THE FUTURE

The 1976–80 Five-Year Plan, approved at the 15th Congress of the Czechoslovakian Communist Party in 1975, is primarily a long-term plan, dealing with developmental problems of the city (through the year 2000 in some respects, although for the most part only through 1980 or 1990). Housing is a matter of critical concern, and the plan calls for construction of some 58,000 new apartments to be completed by 1980. These are to be built as 11 new residential developments on the outskirts of Prague; remodelling and reconstruction are planned for the older, more historic parts of the city. The other areas of strongest concern are public services, especially health care, education, public buildings, and transportation. It

Hospitals

was expected that by 1980 major new hospital facilities would be completed at Bulovka and Motol, the Vysočany Hospital would have been reconstructed, and 10 lesser facilities would be built or expanded. Some 32 schools, mostly in the newer, outlying districts of the city where the younger population is concentrated, were to be built. Among the projects involving public buildings, two of the most important are the new Czechoslovak Palace of Congresses and a modernized National Theatre. The principal transportation projects include completion of some 12 miles (20 kilometres) of new subway lines and the construction of the first links in a major system of circular and radial roads.

BIBLIOGRAPHY. BOHUMIL LANDISCH, *Praha* (1970) and *Praha, matka měst*, 3rd ed. (1970), are annotated (in Czech, German, English, and French) photographic publications dealing with Prague's history. JIRI DOLEZAL and EVZEN VESELY, *Památky staré Prahy* (1966), is a popularized photographic survey of historical Prague, with brief commentary. EUGEN VASILIAK, *Nad Prahou (Prague Seen from Above)* (1966), is a book of aerial photographs of old and new Prague with accompanying text. JOSEF CIBULKA, *The Crown Jewels of the Bohemian Kingdom* (Eng. trans. 1969), provides a description of the Czech coronation jewels (well illustrated), discussing their history and artistic value. EMANUEL POCHE, *The Golden Lane on Prague Castle* (Eng. trans. 1969), describes the picturesque street of Hradčany Castle. See also JAROMIR NEUMANN, *The Picture Gallery of Prague Castle* (1967). ALOIS SVOBODA, *Prague* (1968), is a guide for the tourist (in English). JOSEF JANACEK (ed.), *Dějiny Prahy* (1964), is a comprehensive collective publication covering the detailed development and history of the city from the earliest times to 1960.

(Ja.K./R.H.O.)

Prayer

Prayer is an act of communication by man with the sacred or holy—God, the gods, the transcendent realm, or supernatural powers. Found in all religions in all times, prayer may be a corporate or personal act utilizing various forms and techniques. Prayer has been described in its sublimity as "an intimate friendship, a frequent conversation held alone with the Beloved" by St. Teresa of Ávila, a 16th-century Spanish mystic.

NATURE AND SIGNIFICANCE

Prayer is a significant and universal aspect of religion, whether of primitive peoples or of modern mystics, that expresses the broad range of religious feelings and attitudes that command man's relations with the sacred or holy. Described by some scholars as religion's primary mode of expression, prayer is said to be to religion what rational thought is to philosophy; it is the very expression of living religion. Prayer distinguishes the phenomenon of religion from those phenomena that approach it or resemble it, such as religious and aesthetic feelings.

Prayer as the primary mode of expression in religion

Historians of religions, theologians, and believers of all faiths agree in recognizing the central position that prayer occupies in religion. According to the American philosopher William James, without prayer there can be no question of religion. An Islāmic proverb states that to pray and to be Muslim are synonymous, and Sadhu Sundar Singh, a modern Christian mystic of India, stated that praying is as important as breathing.

Of the various forms of religious literature, prayer is considered by many to be the purest in expressing the essential elements of a religion. The Islāmic Qur'ān is regarded as a book of prayers, and the book of Psalms of the Bible is viewed as a meditation on biblical history turned into prayer. The *Confessions* of the great Christian thinker St. Augustine (354–430) are, in the final analysis, a long prayer with the Creator. Thus, because religion is culturally and historically ubiquitous, if prayer were removed from the literary heritage of a culture, that culture would be deprived of a particularly rich and uplifting aspect.

From its primitive to its mystical expression, prayer expresses a desire on the part of men to enter into contact with the sacred or holy. As a part of that desire, prayer is linked to a feeling of presence (of the sacred or holy), which is neither an abstract conviction nor an instinctive intuition but rather a volitional movement conscious of realizing its higher end. Thus, prayer is described not only as meditation about God but as a step, a "going out of one's self," a pilgrimage of the spirit "in the presence of God." It has, therefore, a personal and experiential character that goes beyond critical analysis.

Prayer is also linked to sacrifice, which seems to support prayer as a cultic—as well as a personal—act and as a supplement to the bare word of man in his attempts to relate to the sacred or holy. In any case, the sacrificial act generally precedes the verbal act of prayer. Thus, the presentation of an offering often prolongs prayer and is viewed as a recognition of the sovereignty and benefi-

cence of the deity or supernatural powers. The word of man (in prayer), however, apart from a concomitant sacrificial act, is itself viewed as the embodiment of sacred action and power.

When prayer becomes dominating and manipulative in its intent, it becomes magic. With words and songs, man thus believes that he can ask, conjure, and threaten the sacred or supernatural powers. Imprecation and incantation become, in effect, "oral talismans" (charms). The effectiveness of such magical prayer is believed to depend on the recitation of a precise formula, or rhythm, or on the saying and repeating of the divine name. Manipulation by magic, however, is neither the explanation nor the essence of prayer but rather its deviation and exploitation, a tendency that is to be noticed whenever prayer departs from its basic and essential meaning—*i.e.*, the expression of a desire to enter into contact with the sacred or holy.

ORIGIN AND DEVELOPMENT

Theories of the origin of prayer

During the 19th century, when various evolutionary theories were in vogue, prayer was viewed as a stage in the development of religion from a magical to a "higher" stage. Such theories, which saw in prayer no more than a development of magic or incantation, failed to recognize the strictly personal characteristics of prayer. Even if a scholar could prove the chronological precedence of magical incantations to prayer—which has thus far not been done—he would be derelict in his scholarly duty if he saw in such a precedence the only explanation of prayer. The origin of prayer is to be found—essentially and existentially—in the recognition and invocation of the creator-god, the god of heaven.

Though some scholars, such as Costa Guimaraens, a French psychologist in the early 20th century, have attempted to trace prayer back to a biological need, the attempt, on the whole, has been unsuccessful. If sometimes —especially with exceptional subjects or subjects with fragile nervous systems—the act of prayer is accompanied by corporal phenomena (*e.g.*, bleeding, shaking), such phenomena can accompany it without having provoked it and without explaining its deep inspiration. In order to analyze normal prayer psychologically it is especially important to choose normal subjects. Affective sources such as fear, joy, and sadness doubtless play a role in prayer. Such affectations are expressed in prayers recorded in various religions and particularly in the Psalms of the Bible; but they do not explain the recourse to prayer itself, which is explained by a motivation deeper than affective elements. The cause and occasion of prayer must not be confused.

Moral sentiments also are integrating elements, but they are accidental to the development of prayer; virtue is not necessarily expressed in the act of praying because there exist atheists of incontestable morality. Morality is more a consequence than a cause of prayer; and it follows more than it prepares for the development of the religious man.

William James and psychologists such as Joseph Segond describe prayer as a "subconscious" and "emotional effusion," an outburst of the mind that desires to enter into communication with the invisible. Experiences of prayer very often, in fact, do include "cries from the heart," "inexpressible laments," and "spiritual outbursts." The psychological explanation has the advantage of probing the subconscious, of describing the various forces that act within men's psyches; but the emergence of the subconscious in the act of prayer is not the essence of prayer since it minimizes the role of intelligence and the will. Among what are called the higher religions (*e.g.*, Judaism, Christianity, Islām, Hinduism, Buddhism), divine action, which is the object of the human action of prayer, violates neither man's consciousness nor his freedom.

Sociologists often explain prayer in terms of the religious environment, which plays an indubitable role in spiritual behaviour. Though prayer supposes a personal belief, that belief is, to a great extent, provided by society. Society creates and regulates social and religious rites and liturgies to express its beliefs, but to explain the origin of prayer solely in terms of an environmental context would be to neglect the inner, personal origins of prayer. That belief is transmitted by society is incontestable, but the channel is not to be viewed as the source. Society itself is, so to speak, a tributary of beliefs that are both received from and given to the collective whole and also from and to each of its members. The collective forms may influence personal prayer, but they do not explain it.

The vertical (divine–human) as well as horizontal (social) dimension of prayer is also expressed in the alternation between speech and silence. Whereas magical formulas are used to coerce the supernatural, liturgical language, even when incomprehensible to the congregation, seeks to lead the participants into an apprehension of the mystery of the divine. In the presence of the mystery of the divine, man often discovers that he can only stammer or that his speech often falters. When this occurs, he frequently expresses his "fear and love" (Luther) or "*tremendum et fascinans*"—*i.e.*, fear and attraction (according to Rudolf Otto, a modern German historian of religion), in apophatic (negative) formulas. Speech with the divine is, in such cases, followed by silence before men, as one apprehends the inexpressible (*i.e.*, the sacred or holy). Religious language, like silence, thus expresses the distance and inadequacy of man in relation to the divine mystery.

TYPES OF PRAYER

Because the various types of prayer are connected and permit a flow from one type to another, it is difficult to conceive of them in terms of rigid classifications. They are enumerated here more on the basis of psychology than on history.

The central position of request in religion

Petition. The role of the request in religion has played such a central part that by metonymy (using a word for another expected word) it has given its name to prayer. However contestable this may sometimes be, it is impossible to refuse to recognize the importance of request, whether it be for a material or spiritual gift or accomplishment. The requests that occur most often are for preservation of or return to health, the healing of the sick, long life, material goods, prosperity, or success in one's undertakings. Request for such goals may be tied to a magical invocation; it may also be a deviation from prayer when it takes the form of a bargain or of a request for payment due: "In payment of our praise, give to the head of the family who is imploring you glory and riches" (from the Ṛgveda, a sacred scripture of Hinduism). Christianity has never condemned material requests but rather has integrated them into a single providential order while at the same time subordinating them to spiritual values. Thus, in essence though not always in practice, requests are only on the fringe of prayer. As a religion adopts more spiritual goals, the requests become more spiritual: in the *Choephori*, a play written by Aeschylus (a Greek tragic poet of the 6th–5th centuries BC), Electra, the daughter of King Agamemnon, prays, "Grant that I may be a more temperate and a more pious wife than was my mother." Other examples of the transformation to spiritual goals may be seen in the prayers of the ancient Babylonian and Assyrian kings who asked for the fear of God, rather than material benefits, and that of a priest of the Ewe (a West African people) who even asks of his god "That I remain near you and that you remain near me."

Confession. The term confession expresses at the same time an affirmation of faith and a recognition of the state of sin. In Mazdaism (Zoroastrianism and Parsiism), as in ancient Christianity, the confession of faith accompanies the renunciation of demons. The *Confessions* of St. Augustine also illustrate this dual theme. In a similar fashion, ancient and primitive men recognize that their sins unleash the anger of the gods. To counter the divine wrath, a Ewe, for example, throws a little bundle of twigs —which symbolizes the confessor's sins—into the air and he says words symbolizing the deity's response, "All your sins are forgiven you."

The admission of sin cannot be explained only by anguish or by the feeling of guilt; it is also related to what is deepest in man—*i.e.*, to what constitutes his being and his

action (as noted by Karl Jaspers, a 20th-century philosopher). The awareness of sin is one of the salient features of religion, as, for example, in Hinduism: "Varuṇa is merciful even to him who has committed sin" (Ṛgveda). Confession is viewed as the first step toward salvation in both Judaism and Christianity; in Buddhism, monks confess their sins publicly before the Buddha and the congregation two times every month.

Situated at the most personal level of man, sin places him directly before God, who alone is able to grant pardon and salvation. The Miserere ("Lord, have mercy," Psalm 51) of the ancient Israelite king David expresses repentance for sin with an intensity and depth that has a universal value. One of the results of such a dialogue with God is the discovery of the dark depths of sin.

Intercession. Members of primitive societies have a clear sense of their solidarity in the framework of the family, the clan, and the tribe. This solidarity is often expressed in intercessory prayer, in which the needs of others are expressed. In such societies, the head of the family prays for the other members of the family, but his prayers also are extended to the whole tribe, especially to its chief; the primitive may pray even for those who are not members of his tribe (*e.g.*, strangers or Europeans).

The purposes of prayer

Intercessory prayers are also significant in Eastern and ancient religions. In the hymns of the Ṛgveda, the father implores the god Agni (god of fire) for all of those who "owe him their lives and are his family." In the Greek play *Alcestis* by Euripides (5th century BC), the mother, on her death, entrusts the orphans she is about to leave to Hestia, the goddess of the home. Among the Babylonians and the Assyrians, a priesthood was established primarily to say prayers of intercession.

Prayers of intercession to the divine are supported by mediatory minor gods or human protectors (alive or dead), marabouts (dervishes, or mystics, believed to have special powers) in Islām, or saints in Christianity, whose mediation ensures that the prayer will be efficacious.

In biblical religion, intercession is spiritualized in view of a consciousness of the messianic (salvatory) mission. Moses views himself as one with his people even when they fail in their duty: "Pardon your people," he prays, "or remove me from the Book of Life." Such solidarity finds its supreme form in the prayer of Christ on the cross —"Father, forgive them, for they know not what they do"—which St. Stephen (the first recorded Christian martyr) and other martyrs repeated in the course of their sufferings.

Praise and thanksgiving. Praise, in the prayer of primitive peoples, can be traced to salutations, such as in the prayer of the Hottentots (of South Africa) to the New Moon—"Welcome." Praise among most of the ancient peoples was expressed in the hymn, which was primarily a prayer of praise (whether ritual or personal) for the gift of the created world. Israel praises its Creator for "his handiwork," as does the Qur'ān. Contemplation of the majesty of the universe thus often gives rise to a prayer that is not always completely free from pantheism (the divine in all things) and that can be found all the way from the nature hymns of Oriental religions to the effusions of J.-J. Rousseau, the 18th-century French moralist, embracing the trees and contemplating the sunrise.

Praise—in addition to concerns for the created world—plays an important role in the prayer of mystics, for whom it is a form of adoration. Praise in this instance constitutes an essential element of the mystic experience and celebrates God, no longer for his works, but for himself, his greatness, and his mystery.

When the great deeds of God are the theme of praise, it becomes benediction and thanksgiving. Even when words denoting thanksgiving are not present, the substance of thanksgiving is manifest, even, for example, for the Pygmy of Central Africa, who says to his god, "Waka (meaning God), you gave me this buffalo, this honey, this wine." Mealtime prayers, frequently enunciated in both ancient and modern religions, give thanks for the goods of the earth and are linked to the giving of an offering.

In Christianity, Christ is discovered as the gift of God and in his mission the economy (or mode of operation) of salvation. Thus, the giving of thanks is viewed as man's response, as a spiritual reaction to the benefit received—*i.e.*, the mediatory work of Christ. Because of the cultivation of this expected response, praise and thanksgiving occupy a central position in Christian prayer and in the liturgy, so much so that its name is given to the Eucharistic Prayer (*i.e.*, the Prayer of Thanksgiving).

Adoration. Adoration is generally considered the most noble form of prayer, a kind of prostration of the whole being before God. Even if the prayer of request is predominant among primitives, they are seized with the feeling of fear and trembling before the numen (spiritual power) of all that is mana (endowed with the power of the sacred or holy) or taboo (forbidden because of association with the sacred). Names given to the divinity in prayers of adoration express dependency and submission, as, for example, in the prayer of the Kekchí Indians of Central America: "O God, you are my lord, you are my mother, you are my father, the lord of the mountains and the valleys." To express his adoration man often falls to the ground and prostrates himself. The feeling of submissive reverence also is expressed by body movements: raising the hands, touching or kissing a sacred object, deep bowing of the body, kneeling with the right hand on the mouth, prostration, or touching the forehead to the ground. The gesture often is accompanied by cries of fear, amazement, or joy; *e.g.*, *has* (Hebrew), *hū* (Islām), or *svāhā* (Hindu).

Motivation behind adoration

Adoration takes on its fullest meaning in the presence of the transcendental God who reveals himself to man in the religions of revelation (Judaism, Christianity, and Islām). In the Old Testament prophet Isaiah's vision of the holy (Isa. 6:3), the seraphim (winged creatures) chant to Yahweh: "Holy, holy, holy is the Lord of hosts; the whole earth is full of his glory." This hymn of adoration became a part of the Christian liturgy. The supreme form of adoration, however, is generally considered to be holy silence, which can be found in primitive religion and in ancient religions, as well as in the "higher" religions, and among mystics it expresses the most adequate attitude toward the immeasurable mystery of God: "I am in a dark sanctuary, I pray in silence; O silence full of reverence" (Gerhard Tersteegen, an 18th-century Protestant mystic). Silent adoration is often viewed as the introduction or the response to an encounter with the sacred or holy.

Unitative: mystical union or ecstasy. Ecstasy is literally a departure from, a tearing away from, or a surpassing of human limitations and also a meeting with and embracing of the divine. It is a fusion of being with being, in which the mystic experiences a union that he characterizes as a nuptial union: "God is in me and I am in him." The mystic experiences God himself in an inexpressible encounter because it is beyond the ordinary experiences of man. The mystical union may be a lucid and conscious progression of contemplative prayer, or it may take a more passive form of a "seizing" by God of the one who is praying.

Prayer as an expression of the mystical experience

The mystic, by his goals and actions, is removed from both the world and himself. He discovers in the light and majesty of the divine his own poverty and nothingness and is thus torn between the contemplation of the greatness of God and his own meagreness. St. Francis of Assisi exemplified this dichotomy in his prayer: "Who are you, O God of sweetness, and who am I, worm of the earth and your lowly servant?" Ecstatic prayer goes beyond the frame of ordinary prayer and becomes an experience in which words fail. Mystics speak in turn of unity (*e.g.*, the 3rd-century-AD Greek philosopher Plotinus), of great pleasure (Augustine), or of intoxication (Philo). It is found in the accounts of Hindu, Persian, Hellenistic, and Christian mystics. "You are me, supreme divinity, I am you," says Nimbāditya. The Ṣūfī (mystic) of Islām Jalāl ad-Dīn ar-Rūmī sighs in the same words as a Christian mystic, Angelo de Foligno: "I am you and you are me." Mechthild von Magdeburg develops the same kind of reciprocity: "I am in you and you are me. We cannot be closer. We are two united, poured into a single form by an

eternal fusion." Such reciprocity that is so complete that it becomes identity is the supreme expression of ecstatic prayer. It is found in all of the mystic writings, from the Orient to the West.

FORMS OF PRAYER IN THE RELIGIONS OF THE WORLD

The forms that prayer takes in the religions of the world, though varied, generally follow certain fixed patterns. These include: benedictions (blessings), litanies (alternate statements, titles of the deity or deities, or petitions and responses), ceremonial and ritualistic prayers, free prayers (in intent following no fixed form), repetition or formula prayers (*e.g.*, the repetition of the name of Jesus in Eastern Christian Hesychasm, a quietistic monastic movement, or the repetition of the name of Amitābha Buddha in Japanese Buddhism), hymns, doxologies (statements of praise or glory), and other forms.

Primitive religions. Prayer is one of the most ancient expressions of religion. Practically the only evidence of early forms left, however, is that to be noted among the most primitive peoples of today. Together with his dependency in relation to his tribe, the primitive man is aware of his dependency in relation to the Supreme Being. He often addresses his prayers, however, to various numina (spiritual powers): the dead, the divinities of nature, protective gods or actor gods, the Supreme Being localized somewhere in heaven, or a feminine divinity linked to the earth (*i.e.*, the great mother). It is impossible to determine the historical precedence of one over the others, and it is difficult to describe the most primitive prayer because certain forms escape modern scholars, so much so that it has been assumed by some that prayer was absent in earliest religion. The first form may have been a cry, then brief formulas repeated as incantations, such as "Come . . . hear me . . . have pity." (*e.g.*, Algonkin Indians of North America).

Internalized prayer is found among the primitive Eskimos of North America, the Algonkin tribes, the Semangs (of the Andaman Islands in the Indian Ocean), and the Aboriginals of Australia. Prayer in gestures is found among the Semangs and other primitive peoples. Another form is spontaneous prayer, without any precise formulation, which is found, for example, among the Negritos of the Philippines and the Alacaluf (Halakwulups) of Tierra del Fuego. More developed liturgies and prayer vigils are found among the Negritos and the Pygmies of Gabon.

The concerns of prayers of primitive peoples

The prayers of peoples of a primitive culture generally are concerned with the self (egoistic) and concerned with well-being (eudaemonic) at the same time; they are clearly pragmatic, concerned above all with food, protection, and posterity. But the higher forms of adoration and recognition of obligations, of confidence, and self-abandonment are to be noted. Among the Australian Aboriginals are prayers on tombs for the dead, so they may be received in heaven, and prayers are also addressed to the spirits of ancestors. Request and pardon accompany sacrifices in the propitiatory rites of the Semangs. Of special interest is the fact that the Wiradjuri-Kamilaroi of Australia practice public prayer on only two occasions: the burial of a man and the consecration of puberty. They believe that excessive prayer serves no purpose.

Ancient civilizations. From the 3rd millennium BC to the beginning of the Christian Era, forms of prayer changed little among the Assyrians and Babylonians and their descendants. The oldest forms are composed of hymns and litanies to the moon goddess Sin and to the god Tammuz. Though some songs of joy have been found, most are adjurations. Some hymns of thanksgiving tell of gratitude to the divinity for victory over an enemy. One such hymn, addressed to Marduk (the Babylonian sun god), apparently goes back to the 12th century BC. A number of hymns of later date celebrate the king, but their intent is to request divine protection first for him and his country. Preserved in the library of Ashurbanipal (7th-century-BC Assyrian king) at Nineveh is a rather long hymn to the goddess Nana (queen of the world and giver of life), the consort of the god Nabu, son of Marduk and a god of wisdom and science. There also is a long acrostic poem in praise of the god Marduk, creator of heaven and earth, and hymns that the Babylonians recited at the new year, at the beginning of spring, and at the celebration of Marduk.

Other hymns accompany sacrifices, such as in the offering of a young gazelle in place of humans. A most important form of prayer, however, is found in the conjurations and exorcisms of a priest or believer and in lamentations, which are particularly numerous and which often end in a refrain similar to a litany.

Ancient Egyptian piety is preserved in numerous precepts engraved on the backs of scarabs. These engravings sometimes include praises of the divinity ("All good fates are in the hand of God"), statements of confidence, or requests for protection for the one praying and for his whole family ("God is the protector of my life; the house of one favoured by God fears nothing"). Hymns of thanksgiving, such as that of the artist Nebre, who obtained from the god Amon the healing of his son who had been struck with illness because of Nebre's fault, are numerous in ancient Egyptian religion. Protective magic, widely practiced, also utilized formulas of incantation, recited or written, and amulets (charms). Some of the incantation formulas (anonymously written) come from the earliest times, and others, more recent but no less efficient, were composed by magicians. In order to increase their authority and efficacy, several, such as those composed by pharaoh Ramses III (12th century BC) and preserved in Cairo, were attributed in origin to the gods themselves.

Collections of formulas, such as the Egyptian Pyramid Texts and the Book of the Dead, were compilations of magical prayers that allowed the dead to forestall all the dangers and meet all the eventualities. In particular, they contain negative confessions in which the dead man justifies himself before the court of Osiris (god of the dead). The funeral liturgies of the ancient Egyptians have preserved lamentations that echo the family in mourning. Hymns written on papyrus that are compositions in honour of a divinity and that were recited during sacred ceremonies have also been preserved. Such are the hymns of the pharaoh Akhenaton (Amenophis IV, 14th century BC) to the god Aton and the hymns in honour of the god Amon-Re that boast of divine benefits and sometimes confess misery and sin.

Ceremonial prayers

In Greece, poetic prayer can be distinguished from ceremonial prayer. The first, like all of the liturgical prayers, contains three essential parts: the invocation of the god, a justification for fulfillment (*e.g.*, sacrifices offered, favours given and received), and a conclusion that formulates the request, such as in the prayer of Diomedes to the goddess Athena in the *Iliad* (written by the Greek poet Homer in the 8th century BC). Generally, the ceremonial prayer followed a ritual pattern: washing of the hands, the prayer proper, then sacrifice and libations. The prayer initiated the liturgical action; without it there could be no ceremony. Prayers often were transformed into hymns, a characteristic of Greek religion. One of the oldest known Greek hymns is that of women devotees of Dionysus, the god of wine and fertility. That such hymns were not always sublime in character is attested to by the comment of a 6th-century-BC Greek philosopher in regard to a Dionysiac festival.

> If they did not hold a procession and sing a hymn to the genitals, it would be an outrageous performance. Hades and Dionysus, in whose honour they rage and celebrate the Bacchus rites, are one and the same.

Another ancient hymn is a morning hymn to Asclepius, the god of healing. All the hymns begin with invocations of the names of the gods to whom they are addressed. The invocation was believed to have an almost magic value. Though there are many individual Greek hymns in existence, the only official collection remaining contains the Orphic Hymns (addressed to the ancient hero Orpheus); it dates from the Greco-Roman period (*c.* 3rd century BC–*c.* 4th century AD).

Roman prayers begin with an invocation to the divinity. Addressing the god is of capital importance and one must be careful not to address the wrong god. In order to avoid this error, there were litanies of 15 gods and goddesses.

The prayer itself generally takes two forms, depending on whether it implies a request or is simply limited to praise. The prayer of request has a juridical pattern in which the offering, as a contractual element, dominates. The offering is what jurists call bail bond, a guarantee. The prayer of request's effectiveness depends on a precise formulation, with parallelisms, solemn repetition, and accumulation of synonyms. The verb *precor* ("I pray") is reinforced by many synonyms. Prayers of praise developed out of meditation or experiences of religious elevation and utilized various patterns in both public and private ceremonies. An example of collections of prayers of praise is preserved in the *Verba pontificalia* ("Priestly Words").

Another form of prayer is the *votum* ("vow"), in which a person undertakes to offer to the divinity, in exchange for divine favour, a sacrifice, the building of a temple, or other such offerings. It is a kind of bargain in which is still felt the prudence of the peasant who has experienced failure. These *vota* ("vows") become more numerous than other prayers the farther one goes from the historical origins of Rome. The most solemn form of the vow is the *devotio* ("act of devotion"), by which a chief offers himself to the divinity in order to obtain victory.

Religions of the East. Although the religion of the Vedas contains private prayers, it gives importance and hieratic stature to liturgical prayer, which may or may not include sacrifice. There exists a whole series of hymns, such as the morning hymn addressed to Agni (the god of fire), who brings light, and to the two Aśvin (twin gods of light). There is also an evening prayer, the *sāvitū,* more precisely a prayer for dusk, which the disciple of the Brahmins (priestly teachers) says at nightfall until the stars appear, and a benediction formula. The gestures of adoration (*upasthāna*) in effect give more intensity to the prayer. The prayers that accompany sacrifices and the numerous hymns of the Ṛgveda (a collection of sacred ritualistic lyrics), which were composed by the members of the priestly caste according to a stereotyped and schematic form, are addressed to the greatness of the divinity in exaltation of his great deeds.

In Hinduism there is an elementary form of prayer—*i.e.*, an affirmation of homage and refuge with the divinity. More frequent is a more elaborate prayer in two forms: *dhyāna* ("meditation") and the *stotra* ("praise"). The *stotra* occurs in a variety of subforms and generally opens with an invocation. It is often characterized by a sort of litany of the titles given, for example, to Viṣṇu (the preserver god) or Śiva (the destroyer god). The *Śivasahasranaman* ("The Thousand Names of Śiva") lists 1,008 titles. In this hymn, each strophe ends with the same refrain. When recited with concentration and pure heart, these prayers are believed to achieve remission of sins.

Hindu mystical prayer

Hindu mysticism gives great importance to spoken prayer, which, by progressive absorption, leads to ecstasy. The scale of the prayer of Hindu mystics is exemplified in the five stages of *bhakti* ("devotion") as taught by the Hindu mystic Caitanya (15th–16th century AD), who uses the metaphor of love in social relationships: *śānta* (peaceful love), *dāsya* (servant of God love), *sakhya* (friendship with God), *vātsalya* (filial attitude toward God), and *mādhurya* (love of God as one's lover). "When I was no longer capable of recognizing, I said me and mine. I am you and you are mine" (*Nalayiram*).

In Chinese Buddhism and Taoism, in addition to prayer that accompanies sacrifice, there is the monastic prayer (mu-yu), which is practiced morning, noon, and night to the sound of a small bell. There is also a prayer for the dead, related to the transmigration of souls, which is recited at funerals, the 30th day, the anniversary of the death, and the celebration of the deceased's day of birth. Taoism gave increased importance to this latter form.

Private prayer prepares the way for liberation and illumination. The *tsai-fei* is a prayer—to accompany abstinence—that monks will recite for a believer on payment of alms. Other prayers accompany vows and pilgrimages. Both Buddhist monks and laymen use a string with 108 beads, which monks always carry in their hands.

Religions of the West. In Judaism is one of the best known collections of prayers, the 150 psalms in the Bible. In these psalms, which always presuppose a collective witness, though they may be used by an individual privately, praise is descriptive (God is . . .) or narrative (God does . . .) in nature. Also included are hymns, exhortations to praise God, and supplications. The psalms of request include lamentations and songs of confidence or gratitude. Whether individual or collective, the psalms have a rather similar structure: a cry to God, a confession of sins, a protestation of innocence, and imprecations against one's enemies.

To the prayers of the Bible, the rabbis (religious teachers and leaders) added the Shema ("Hear"), which is a confession composed of three quotes from the Bible (Deut. 6:4–9, 11:13–21, Num. 15:37–41) with attendant blessings and which the Israelite recites daily. At the time of Christ, there appears the prayer *par excellence*, the *tefilla* or *ʿamida* (standing prayer), also called *shemone ʿesre* ("18 Benedictions"), which every Israelite recites two or three times a day. To these must be added the benediction before eating that raises the meal to the level of the dignity of a religious act.

Relationship of Christian to Jewish prayers

Christianity preserves the doxologies and benedictions from its Jewish heritage. It adds to them the Lord's Prayer, psalms, hymns, and canticles, the first specimens of which are furnished by the New Testament (*e.g.*, the *Nunc dimittis*, "Now let your servant depart"). Christian prayer, like that of other religions, includes liturgical prayer and personal prayer. Liturgical prayer frames and explains more especially the sacraments of Baptism and the Eucharist (Lord's Supper).

The liturgical collection, for Sundays as well as other days, includes readings from the Bible, collects (brief prayers including an invocation, petition, and conclusion in which the name of Jesus is called upon), and a litany (general prayer) for the intentions of the universal church. During the Eucharist, there is a consecration of the bread and wine to be used in the sacred meal. This consecration prayer is called the Eucharistic (Thanksgiving) Prayer, a long prayer in which the element of thanksgiving is dominant. Addressed to the Father, through the mediation of the Son, and in the Holy Spirit, this prayer develops, like the Jewish liturgies, from praise, to thanksgiving, to the memorial (or anamnesis), and finally to an invocation of the Spirit (epiclesis). Originally improvised and spontaneous, this liturgical prayer became fixed in stereotyped forms, first in the West, then —though with more flexibility—in the East.

The first Christians retained the custom of praying three times a day, reciting the "Our Father" (Lord's Prayer). Special times for prayer are morning and evening. Christ's custom of praying at meals (as a devout Jew) is also maintained. This framework can and does favour the life and spirit of prayer that make a Christian existence, according to the words of Clement of Alexandria, a 2nd–3rd-century theologian, "an uninterrupted celebration." Bible readings, silent prayer (in the West especially), brief, fervent invocations, and the repetition of formulas like the Kyrie eleison ("Lord, have mercy") in the East have enriched spiritual life and have led monks and laymen to contemplative prayer, as is shown by the growth of mysticism in both the West and East.

From its beginning in the 7th century AD, the most important part of Islāmic liturgy has been the ritual prayer called the *ṣalāt* (daily prayer), in which both Christian and Jewish influences can be seen. This minutely detailed prayer is recited while the suppliant turns toward Mecca (in Saudi Arabia) five times a day. On Friday, the *ṣalāt al-jūmʿah* (Friday prayer) replaces the noon prayer. It is celebrated by the community in the principal mosque and includes preaching and a *ṣalāt* of two ritual bowings. Twice a year, at the end of Ramaḍān and the 10th month, a solemn *ṣalāt* is celebrated, similar to Friday's.

Islāmic prayer is an act of adoration of Allāh (God) and thus it would not be suitable to add a request. Before adoring God the believer must purify himself by means of ablutions in pure water or, failing this, in sand. The prayer is accompanied by a meticulous ceremonial with

prostration of the body (*rak'ah*). The sense of adoration and conversation with Allāh has led many spiritual Muslims to the heights of mysticism (Ṣūfism).

In Mazdaism, Avestan (scriptural) prayer, sacerdotal prayer, and the prayer common to priests and laymen alike can be distinguished. In the very first poem of the Avesta, Zoroaster (Zarathushtra) presents himself to Ahura Mazdā (the Good Lord) in a prayer that ends with these words: "I will sing for you again praises of great value." What is characteristic of these hymns is that man proceeds almost exclusively by questions and answers. Only priests can understand the ceremony of the *Yasna* (the sacrifice), during which they recite verses from the Avesta, adding to it the *Visp-rat* (shorter liturgy), with or without the *Vidēvdāt* ("Law against the Demons"), which is concerned with ritual purity. Songs (involving light symbolism) accompany the five fire ceremonies that are celebrated daily. There are also ceremonies in which both priests and laymen participate. The great Bāj, a ritual offering of consecrated bread, grain, and butter, begins with a long preface: "In the name of God, Lord Ormazd, may your power and glory increase." The Satum, in praise of the dead, is recited at the beginning of a meal prepared in their honour every month for the first year after a death and then on each anniversary. Other prayers accompany benedictions, especially those used at the consecration of fire, initiation, and marriage. To these must be added the prayers of great purification.

Conclusion. Though historians of religion, psychologists, and anthropologists debate various theories concerned with the origin of prayer, the act of prayer itself is of great significance to the believers of all religions, whatever their inspiration, revealed or otherwise. Ludwig Feuerbach, a 19th-century German philosopher, summed up the significance of prayer when he stated, "The most intimate essence of religion is revealed by the most simple religious act: prayer."

As a religious phenomenon, prayer—in terms of its evolution—appears to be neither universally progressive nor progressively regressive. Its great moments and the appearance of men of prayer at various times, whether simple men or men of genius, are found throughout its long history, which thus marks it as a significant and characteristic element of most, if not all, religions. Whether halting or mystical, ceremonial or personal, prayer expresses the experience of a mystery that envelopes and surpasses man. In the presence of that mystery, prayer seeks and establishes dialogue.

BIBLIOGRAPHY. The classical work is still that of F. HEILER, *Das Gebet*, 5th ed. (1923), which provides the bibliography of the subject up to 1923 and defends the theory of religious syncretism. R. BOCCASSINO (ed.), *La Preghiera*, 3 vol. (1967), is a historical and psychological study of the whole subject and includes an up-to-date bibliography. G. VAN DER LEEUW, *Phänomenologie der Religion* (1933; Eng. trans. *Religion in Essence and Manifestations*, 1938), is an excellent overview and general introduction of the psychology of prayer. Also of a psychological bent are WILLIAM JAMES, *The Varieties of Religious Experience* (1902); and H.U. VON BALTHASAR, *Das betrachtende Gebet* (1955; Eng. trans., *Prayer*, 1961). For prayer in the various religions, in addition to *La Preghiera*, one should refer to M.P. NILSSON, *Geschichte der griechischen Religion*, 2nd ed., 2 vol. (1955–61; Eng. trans., *A History of Greek Religion*, 2nd ed., 1949); A. FALKENSTEIN and W. VON SODEN, *Summerische und akkadische Hymnen und Gebete* (1953); G.C. LOUNSBERY, *La Méditation bouddhique* (1935; Eng. trans., *Buddhist Meditation in the Southern School*, 1950); E. CONZE, *Buddhist Meditation* (1956); R.C. ZAEHNER, *The Teachings of the Magi* (1956) and *The Dawn and Twilight of Zoroastrianism* (1961). For a recent bibliography on biblical prayer, see the article "Prière," in the *Dictionnaire de la Bible*, suppl. 8, pp. 604–606 (1968). I. ELBOGEN, *Der jüdische Gottesdienst in seiner geschichlichen Entwicklung*, 4th ed. (1962), is a classic on Jewish prayer, to which should be added A.Z. IDELSOHN, *Jewish Liturgy and Its Development* (1967). On the origins of Christian prayer, see A. HAMMAN, *La Prière*, 2 vol. (1959–63).

(A.G.Ha.)

Precambrian Time

Precambrian time covers the interval between the formation of the crust of the Earth about 4,600,000,000 years ago and the beginning of the Cambrian Period, which started about 570,000,000 years ago. The Cambrian marks the earliest stage in the history of the Earth when extensive and varied forms of life were preserved as fossil remains in sedimentary rocks.

It was supposed formerly that life originated early in Cambrian times and that there was a fundamental distinction in this respect between the Precambrian and all later geological periods. It is now known that primitive forms of life were in existence over 3,000,000,000 years ago and that living matter was present throughout most, if not all, of Precambrian time. The nomenclature originally designed to bring out this supposed distinction persists, however, although it is now recognized that the Precambrian Era covers the greater part of geological time and that the Cambrian and all later geological periods represent little more than a tenth of the time that has elapsed since the formation of the Earth's crust.

There is, as yet, no generally accepted scheme for the division of Precambrian time. The terms Archeozoic and Proterozoic are widely used to denote the older and younger Precambrian. The boundary between the two divisions is not yet settled but is placed by many authorities at 2,500,000,000 years. Local divisions have been established in each of the principal regions where Precambrian rocks are exposed.

General nature of the Precambrian record

The most extensive exposures of Precambrian are those that outcrop over roughly equidimensional areas many hundreds of kilometres across. Other Precambrian rocks are known to be concealed by younger deposits, as are those below the North American plain, the lowlands of Germany, and the region south and east of the Baltic. Many of the buried Precambrian rocks covered by flat-lying younger deposits have undergone little change since Precambrian times and can be readily identified by age determinations made on specimens obtained by deep drilling. A third type of occurrence is found in mountain chains formed since the Precambrian, where highly modified Precambrian rocks altered by high temperatures and pressures may be found within belts of metamorphic schists and gneisses. Examples occur in western Norway and in the Appalachians. Occurrences of the first type, in which Precambrian rocks form extensive outcrops at the Earth's surface, are known as continental shields.

The largest shields occur in Canada, Greenland, Scandinavia and adjoining parts of the U.S.S.R. (the Baltic Shield), Siberia, China, peninsular India, Guyana, Brazil, Antarctica, most of Africa south of the Atlas Mountains,

and in Western Australia (see Figure 1). The term platform can be applied to a mass of Precambrian rock overlain by a cover of flat-lying younger deposits. The Russian and North American platforms, which are in effect buried extensions of the Baltic and Canadian shields, are examples. It follows from the wide distribution of the three types of Precambrian occurrences, the shields, the platforms, and the belts of altered Precambrian rocks found in younger metamorphic chains, that much of the continental crust of the Earth dates from Precambrian times. In contrast, Precambrian rocks are absent from the floors of major oceans except on such islands as the Seychelles, which can be regarded as fragments of a continent broken up during continental drift (*q.v.*). The abundance of Precambrian rock is one feature that distinguishes the crust of the continents and continental shelves from the crust below the deep oceans.

It was formerly supposed that each continent had grown around a central nucleus of Precambrian rock, about which successively younger belts of continental crust had accreted. Although it is true that regions such as the Mississippi or Niger deltas represent geologically recent additions to older land masses and that mountain chains of Paleozoic and younger ages tend to be peripheral to shield areas, the hypothesis that continents grow by the addition of a succession of younger rocks is somewhat inconsistent with the known distribution of Precambrian formations. These do not get systematically younger toward the margins of continents but form an irregular network of rocks of varying age.

On a worldwide scale the distribution of Precambrian outcrops can be seen to follow certain rules. With few exceptions, the Precambrian rocks that outcrop near the shores of the Pacific and along the Alps and Himalayas form parts of mountain chains. Any Precambrian rock in these regions is likely to be highly altered. On continents flanking the comparatively youthful Indian or Atlantic oceans, which have opened since Mesozoic times, the principal Precambrian outcrops occur in shields close to these young oceans. Thus, the Brazilian, Guyanaian, Canadian, Baltic, and West Africa shields border the Atlantic, and the East African, Indian, West Australian, and Antarctic shields lie around the Indian Ocean. Platforms of Precambrian rock concealed below flat sediments usually lie between the shields and the younger Alpine or circum-Pacific mountain chains with their highly modified Precambrian remnants.

Geological significance

Taken as a whole, the Precambrian rocks available for study do not provide a continuous record of Precambrian time. They suffice to demonstrate that processes of erosion and sedimentation similar to those that operate at the present day were affecting the crust at least as far back in time as 3,200,000,000 years ago. At that time, primitive forms of life such as the blue-green algae and certain bacteria had already evolved. The nature of the Precambrian rocks also shows that from time to time parts of the Earth's crust were heated and deformed, so that crystalline metamorphic rocks were produced. These rocks resemble those found in the deeper parts of more recent chains, but it is not yet clear whether the Precambrian crystalline rocks were connected with mountain building or whether the deformation of the crust took other forms during the early history of the Earth.

This article treats Precambrian rocks, life, and environments and the dating and chronology of Precambrian events. For further information on the place of the Precambrian in Earth history, see EARTH, GEOLOGICAL HISTORY OF; for additional detail on Precambrian life and environments, see FOSSIL RECORD; ATMOSPHERE, DEVELOPMENT OF; OCEANS, DEVELOPMENT OF; and PALEOGEOGRAPHY; see also MOUNTAIN-BUILDING PROCESSES; IGNEOUS ROCKS; and METAMORPHIC ROCKS for discussions of Earth processes and rock formation that are of relevance to the Precambrian record.

ABSOLUTE AGE DETERMINATION OF PRECAMBRIAN EVENTS

Isotopes and minerals involved. The isotopes (species of an element with the same atomic number but different atomic weight) that have proved useful for dating Precambrian material are those with a long half-life; in other words, those in which the time required for half of the original radioisotope to decay may be as long as several thousand million years. The decay of uranium and thorium to give lead and helium, the decay of the potassium isotope potassium-40, and the decay of the rubidium isotope rubidium-87 provide suitable data. The methods require that the decay constant of the radioactive nuclide be accurately known and that a proper correction be made for

Radiometric age and the thermal history of rocks

any radiogenic nuclide incorporated in the rock or mineral when it was formed or subsequently added or lost through processes other than radioactive decay. Radiometric measurements do not necessarily establish the age of a rock or mineral, but they do determine the time that has passed since the material last cooled to the temperatures below which the products of radioactive decay remain trapped within the mineral lattice.

Many crystalline (igneous and metamorphic) rocks have been repeatedly heated through their geological history, and if for this reason the products of the decay of an unstable isotope have been dissipated, accurate age determinations of any but the latest period of heating may be impossible. By a suitable combination of methods, however, these difficulties can be overcome. Sedimentary rocks may be dated if they contain a mineral, formed at the time of deposition of the sediment, that includes within its lattice a suitable radioactive isotope. In general, however, sedimentary rocks are dated by indirect methods, as, for example, when the age of a lava flow within a succession of sediments gives the approximate age of adjacent strata (see DATING, RELATIVE AND ABSOLUTE).

The two most widely used dating methods are those utilizing the decay potassium-40 and rubidium-87. The first method depends on the decay of potassium-40 to argon-40. The decay of potassium-40 also gives rise to calcium-40. The rubidium–strontium method is based on the decay of rubidium-87 to strontium-87. The precise value of the half-life of this decay system—namely, the time required for half the parent to break down—is not readily measurable. Despite this uncertainty, the method is particularly useful for determining the early history of rocks and minerals that may have been subsequently reheated. Any potassium-bearing minerals, such as the feldspars, micas, or glauconite, can be used for potassium–argon age determinations. Micas and potassium feldspars are among the most suitable minerals for rubidium–strontium dating. Because feldspars and micas are widespread, these methods can be applied to most varieties of crystalline rock.

Uranium- and thorium-bearing minerals, though much rarer, provide several methods of determining geological age utilizing the various radioactive isotopes that may be present. Comparison of the amounts of lead isotopes present in lead-bearing minerals can also be used in certain situations to determine the passage of time.

Distribution and significance of absolute dates. The dating of Precambrian rocks has shown that certain types of geological structure characterize different stages in the Precambrian evolution of the Earth. Very few existing rocks and minerals date from the first thousand million years of the history of the Earth (between 4,600,000,000 and 3,500,000,000 years ago). It would appear that most rocks formed during that span of time subsequently were destroyed or so modified that the time of their original formation cannot be determined by radiometric measurement. Well-authenticated records of rocks dated at more than 3,600,000,000 years in age are exceedingly rare. The oldest recognizable sedimentary and volcanic rocks range from about 3,800,000 years onward. It is probable that still older rocks were present, but this cannot be verified by radiometric age determinations. Sedimentary and volcanic rocks formed on the Earth's surface between about 3,800,000 and 2,700,000,000 years ago are always deformed and metamorphosed. The oldest unmetamorphosed flat-lying successions of sedimentary and volcanic rocks are those found in the lower parts of the Witwatersrand Basin in South Africa (see Figure 2). The development of this sedimentary basin, initiated about 2,700,000,000 years ago, appears to have marked a new stage in the evolution of the Earth, for it demonstrates that a section of the crust had become sufficiently rigid and cool for sedimentary rocks to accumulate and survive with little alteration.

The Earth's oldest rocks and early crustal history

Increasing rigidity within the crust also is suggested by large numbers of diabase dikes (intrusive rocks that penetrate pre-existing rocks and structures), which filled fracture systems in the Earth's crust that extend for many

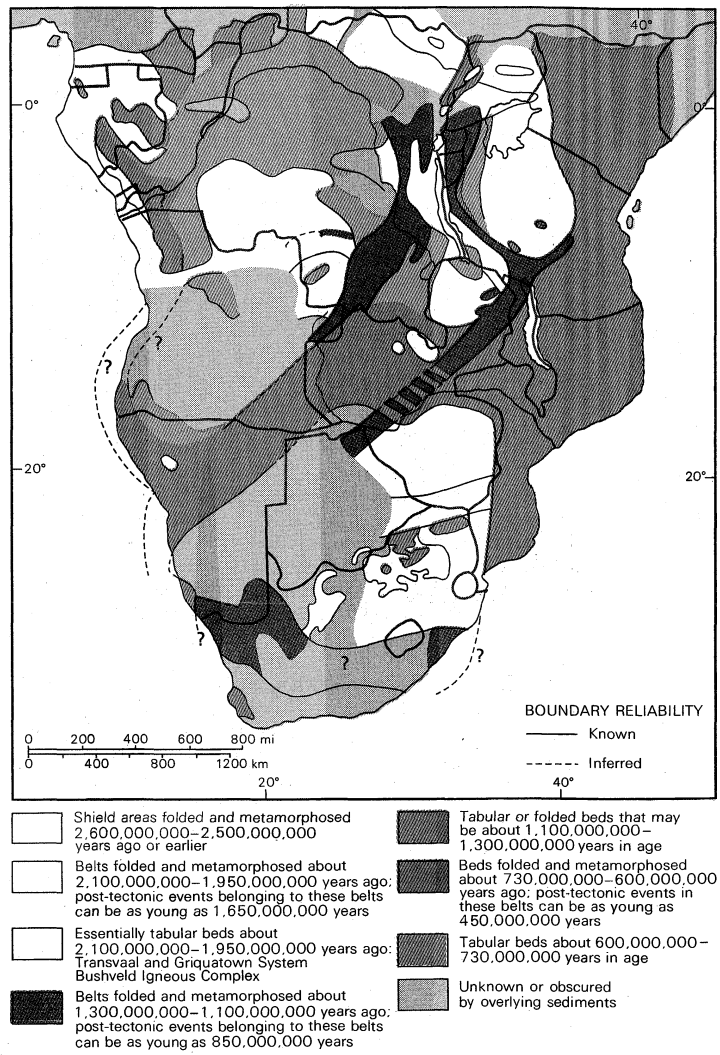

Figure 2: Distribution of Precambrian rocks in central and southern Africa.

Adapted from L. Cahen and N. Snelling, *The Geomorphology of Equatorial Africa* (1966); North-Holland Publishing Company, Amsterdam

hundreds of kilometres. Some of the earliest Precambrian dike systems date from between 2,400,000,000 and 2,500,000,000 years ago, as for example, those in the Transvaal of South Africa and in Western Australia. The Great Dyke of Rhodesia, which extends for several hundred kilometres, is 2,500,000,000 years old, as are somewhat similar structures in the western part of Australia. The development of these dikes and the survival of unaltered deposits in sedimentary basins show that by that time the Earth had attained a condition in which certain rigid areas were marked off from other regions of greater mobility. A mobile crust, in this connection, means a crust in which vertical and horizontal movements have occurred, in which melting or partial melting temperatures of rocks were reached, and in which all rocks show, to a greater or lesser degree, evidence of recrystallization or deformation.

It is not possible to distinguish individual mobile belts in the Early Precambrian because the entire crust was mobile, but once rigid areas had developed, the Earth's crust at any later point in geological time can be regarded as composed of stable rigid blocks set in a network of mobile belts.

Recognition of Archeozoic and Proterozoic events

The subdivision of Precambrian time into an older Archeozoic and younger Proterozoic Age was accomplished by recognition of the change from a wholly mobile crust to one composed of stable blocks bounded by mobile belts. The exact age of this change, which may not have occurred simultaneously in different parts of the crust, is not precisely known. It appears to have occurred about

2,500,000,000 years ago, which can be taken provisionally as marking the end of Archeozoic time and the start of the Proterozoic. In Late Precambrian times, about 1,000,000,000 years ago, another major change occurred in the structural behaviour of the Earth when a new system of mobile belts and rigid blocks superseded the system that had been established early in the Proterozoic. This Late Precambrian system has continued to influence the structural development of the Earth until the present time. Many Late Precambrian formations laid down since the system of structures was established are more closely linked with the younger Phanerozoic deposits that overlie them than with any older Precambrian rocks. These comparatively young Precambrian deposits, which lie for the most part outside the Precambrian shields, tend to foreshadow the arrangement of sedimentary basins and troughs that emerged in the Early Paleozoic.

PRECAMBRIAN ROCKS

As previously mentioned, Precambrian rocks outcrop over large areas to form continental shields, occur below flat-lying sediments, where they constitute continental platforms, and exist as more or less modified remnants within Phanerozoic (post-Precambrian) mountain chains.

Continental shields. Most of the knowledge of the older Precambrian comes from the study of the major shields, which are largely composed of rocks of Archeozoic and Early and Middle Proterozoic age. The shields are regions of the Earth's crust that have undergone little modification since Late Precambrian time. Many of the youngest Precambrian rocks, dating from the last 400,000,000 years of Precambrian time, occur outside the shields in close proximity to Phanerozoic rocks, into which they may pass without conspicuous unconformity. Many such rocks were later incorporated into Phanerozoic mountain belts, but some have survived as unaltered flat-lying formations such as the Scottish Torridonian. Good examples of folded Late Precambrian deposits are provided by the Adelaidian of southern Australia, the Sparagmites of Scandinavia, and the Late Precambrian rocks of the western Congo. The great majority of the Precambrian rocks, however, occur either within the shields or within their buried extensions on the continental platforms.

The Canadian Shield

The largest of the principal shields is the Canadian Shield, which extends for nearly 8,000,000 square kilometres (3,000,000 square miles) over eastern, central, and northwestern Canada from the Great Lakes to the Canadian Arctic and into Greenland. This constitutes the largest mass of exposed Precambrian rock in the world, and it is known to continue into the United States as basement, largely concealed by the more recent deposits of the North American plains.

It has been established that the Canadian Shield, like other shields, can be divided into several structural provinces, each of which evolved during a restricted period of Precambrian time. These provinces fall into three age groups. The oldest formed more than 2,500,000,000 years ago, the second between 1,800,000,000 and 1,400,000,000 years ago, and the youngest less than 1,200,000,000 years ago. Each province records a long history of sedimentation and erosion, volcanic activity, deformation, and recrystallization of igneous and metamorphic rocks.

The younger provinces contain relics of older rocks, and their presence demonstrates that the oldest structural provinces of the Canadian Shield were once more extensive and may have covered much of the region where younger Precambrian provinces have subsequently developed. Studies of the Canadian Shield have revealed a succession of changes in the behaviour of the Earth's crust during Precambrian time. The oldest provinces within the Canadian Shield result from the Kenoran mountain-building events, which ended about 2,500,000,000 years ago. The three principal Kenoran provinces are the Superior, or Keewatin, Province, which lies east, south, and southwest of Hudson Bay; the Slave Province in the northwest of the Canadian Shield; and the Atlantic Province. This last Kenoran Province extends from the Labrador coast eastward across Greenland to terminate on the continental shelves of the Atlantic, between Greenland and Scotland.

These three provinces contain belts of sedimentary and volcanic rocks many kilometres in thickness. They rest on a basement of older crystalline rocks, parts of which are at least 3,000,000,000 years in age. It is probable that this basement contains still older rock that may represent a highly modified portion of the Early Precambrian crust. The Kenoran volcanic and sedimentary rocks typically form irregular belts that may attain 400 kilometres (250 miles) in length. Although these rocks have been folded and metamorphosed to some extent, many original features are usually preserved. Long successions of pillow lavas as much as several kilometres in thickness, for example, may retain structures that formed when lava was rapidly chilled by eruption into water. Evidence of subaqueous volcanism is widespread, and it would appear that these belts represent regions of the crust that subsided as much as ten to 15 kilometres (six to nine miles) as volcanic rocks and sediments accumulated. The belts, which are often known as greenstone belts because of the appearance of the slightly altered volcanic rocks, have no exact equivalent among contemporary active volcanic regions, although they show some resemblances to present-day volcanic island arcs (*q.v.*).

Greenstone belts

In Canada, as in other parts of the world, gold mineralization is associated with the greenstone belts. The rocks around the greenstone belts are often predominantly granitic. It is probable that the tight folding that has been referred to is at least in part connected with the development of the roughly circular granite masses, which are typical of this association. Age determinations in other parts of the world have shown that the development of greenstone belts and granitic rocks characterizes many other areas of equally old crust (over 2,500,000,000 years in age). Comparable associations, for example, occur in Western Australia, southern India, and in central and southern Africa. They represent one aspect of the highly mobile crust that characterized Early Precambrian times.

The second group of provinces of the Canadian Shield contains structures developed between 1,800,000,000 and 1,400,000,000 years ago, in a complex of rocks composed partly of Kenoran rock more than 2,500,000,000 years in age and partly of younger successions, formed between about 2,300,000,000 and 1,800,000,000 years ago. Much of this Early Proterozoic, or Huronian, succession was involved in a series of metamorphic events that developed in a system of mobile belts. Within these belts both the old Archeozoic rocks and the Proterozoic cover were folded and metamorphosed so that distinctions between the two groups often are difficult to make. In contrast, regions outside these mobile belts were not so affected and in such regions unmetamorphosed Proterozoic rock can be identified resting unconformably upon Archeozoic basement.

The Proterozoic mobile belts contrast with greenstone belts of the older structural provinces in several ways. They are very much longer, extending for thousands of kilometres as a network of belts that still range across the Precambrian crust as it survives today. These networks probably were worldwide in extent when they originally formed. Another contrast is the fact that Proterozoic mobile belts were bounded by rigid areas of crust, whereas in Archeozoic times no such stable regions of crust appear to have been present.

Overview of rock types. There are few, if any, types of rock that are restricted to Precambrian formations. Despite this, certain kinds of rocks occur more abundantly in Precambrian terrains than in any younger groups. Furthermore, certain combinations of rocks are found only in the Precambrian. The uniqueness of some Precambrian terrains, therefore, lies in the extent to which certain associations of rock are present rather than in the existence of distinctive rock types.

Many Archeozoic provinces consist of strongly folded, steeply dipping volcanic successions compressed between granite bodies. These volcanic rocks characteristically occur in sequences that begin with ultramafic (rich in iron

and magnesium minerals) varieties and pass with time through mafic to felsic (granitic-type rock, relatively rich in potash and soda) rocks. Such sequences may be repeated several times within a single greenstone belt. They form a most distinctive feature of Early Archeozoic times.

Anorthosites, charnockites, and glaucophane schists

The igneous rock anorthosite, composed largely of plagioclase feldspar, is not confined to the Precambrian but was developed on a larger scale in the Precambrian than in any subsequent interval of geological time. Anorthosites older than 3,000,000,000 years of age have been found on the Moon (*q.v.*). Rocks of the Charnockite Series, which are distinguished by the presence of hypersthene and by the dark colour of the feldspars and quartz, were widely developed by crystallization from melts and by metamorphism of older rocks. Conversely, certain types of metamorphic rock that are common in the Phanerozoic, such as the glaucophane schists, have not yet been recorded from any region of Precambrian age. Because glaucophane schists are widespread in Mesozoic and Tertiary terrains, their absence from the Precambrian, taken in conjunction with the abundance of charnockitic rocks, suggests a change in the conditions under which regional metamorphism occurs within the crust. These facts are consistent with a higher heat flow during the Precambrian than at the present day. Most Precambrian shield terrains contain abundant gneisses and schists that do not differ significantly from their younger counterparts. These rocks have developed on an extensive scale, however—one which cannot be matched in more recent post-Cambrian metamorphic belts. This also may indicate a high flow of heat during the Early Precambrian (see EARTH, HEAT FLOW IN).

Precambrian sediments show several distinctive features. Chemical deposits such as carbonates, banded iron formations, and cherts are conspicuous. The earliest iron formations date from the Archeozoic, but there was a remarkable increase in the abundance of banded iron formations in Early Proterozoic times, about 2,000,000,000 years ago. These deposits provide important sources of iron ore in North America, around the Great Lakes and in Labrador; in the Hamersley region of Western Australia; and in Mauritania, in northwest Africa. Some of these iron deposits owe their origin to the action of bacteria or blue-green algae that promote precipitation of iron and silica. Hence, they can be regarded as biochemical deposits. Precambrian cherts were widely developed, usually as thin bands no more than a few centimetres in thickness, though locally, as in the Hamersley Basin, in much thicker sequences. Organic remains recently have been found in many such bands, the oldest of which were deposited more than 3,200,000,000 years ago and contain the oldest fossils yet discovered on Earth (Barberton area in South Africa).

Such Early Precambrian sediments are closely associated with volcanic rocks in the unstable belts that characterize much of the Archeozoic. In addition to the chemical and biochemical cherts, and carbonates and ironstones, thicker successions of graywackes and conglomerates derived by rapid erosion are present. Some were derived from the volcanic successions, whereas others represent the products of erosion of granites. The extensive ironstones of the Early Proterozoic lie within basins and troughs that are the earliest forerunners of the more recent geosynclines. In South Africa, a quartz-bearing conglomerate, or banket, of the Witwatersrand Basin is the host rock of the world's largest deposits of gold. The banket occurs in a sedimentary basin dating from Late Archeozoic and the Early Proterozoic.

Graywackes and conglomerates

In Late Precambrian time, from about 1,000,000,000 years onward, extensive troughs filled with clastic sediments (consisting of silt, sand, and larger particles) developed in many parts of the world. The deposits in these troughs mark the start of sedimentation that continued into the Phanerozoic. They provided much of the material to be subsequently folded and metamorphosed during periods of Paleozoic mountain building.

PRECAMBRIAN LIFE

During most of the 19th century, it was supposed that no life existed in Precambrian times and that the oldest fossils appeared at the base of the Cambrian (about 570,000,000 years ago). Fossil bacteria and blue-green algae are now known to occur in the oldest sedimentary rocks so far recognized, however. The age of these rocks exceeds 3,200,000,000 years. This occurrence raises two possibilities: either life evolved on Earth in some still older period of Precambrian time, in which case it is unlikely that sedimentary rocks old enough to record the first steps in this evolution have survived, or life came to Earth from some extraterrestrial source, and evidence as to the earliest forms of life will have to be sought outside the Earth.

Development of multicellular life forms. Over most of the Precambrian the predominant forms of life were microscopic unicellular organisms, and only in the late Precambrian, about 800,000,000 years ago, did a great variety of multicellular, or metazoan, forms appear. It is of considerable interest that Early Precambrian blue-green algae closely resemble forms living today, which demonstrates the extreme stability of these forms of life. The living organism *Kakabekia barghoorniana*, for example, isolated from soil at the base of Harlech Castle on the Welsh coast, is a form of an organism preserved in the Gunflint Chert of North America deposited about 2,000,000,000 years ago. This stability provides a possible clue to the contrasting fossil record of Precambrian and later times. The microfossils found in Precambrian rock more than 3,000,000,000 years old appear to be derived from procaryotic organisms, forms of life, principally represented by the bacteria and blue-green algae, that lack a distinct nucleus enveloped in a membrane and that are unable to reproduce by division and recombination of such a nucleus.

The Beok Spring Dolomite of eastern California, formed between 1,400,000,000 and 1,200,000,000 years ago, and the Bitter Springs Formation in Australia, deposited about 1,100,000,000 years ago, contain the oldest examples of the Eucaryota, more advanced organisms than the Procaryota, which contain a nucleus and can reproduce sexually. In these formations the Eucaryota are represented by green algae. The exact date of the evolution of the first Eucaryota is not known. The earliest multicellular, or metazoan, organisms are preserved in rocks about 800,000,000 years old.

Oldest eucaryotic organisms

After the appearance of the metazoans, there was a rapid burst of evolution, and by the end of the Precambrian a great variety of life forms had evolved; by the beginning of the Cambrian Period many of the existing invertebrate groups had come into being. Single-celled organisms without a nucleus evolved 3,200,000,000 years ago, and single-celled nucleate organisms capable of sexual reproduction appeared between 1,200,000,000 and 1,400,000,000 years ago. Multicellular animals were present about 800,000,000 years ago. All these dates should be regarded as minima likely to be extended farther back in Precambrian time by future research.

Fossiliferous deposits. Bacteria, blue-green algae, and other procaryotic organisms, as well as primitive fungi, are preserved in cherts, banded iron formations, shales, and limestones dating from the Archeozoic. The oldest examples, from the Barberton region in South Africa, exceed 3,200,000,000 years in age. Some of the best preserved fossils occur in cherts. The bacteria-like organisms are less than a micron in diameter, but the algae are larger. Geochemical investigations have shown an enrichment in the carbon-12 isotope, and this can be taken as an indication of organic activity. The presence of phytin and pristine indicates that photosynthesis took place. Mats of blue-green algae can trap carbonate sediments to build large structures known as stromatolites. Many Precambrian limestones and dolomites contain stromatolites, the oldest of which, in Rhodesia, are some 2,700,000,000 years in age.

The early Proterozoic deposits, about 2,000,000,000 years old, contain a number of fossiliferous cherts, of which the Gunflint Iron Formation of North America is probably the best known (Figure 3). This formation, including shales, limestones, and cherts, together with iron deposits, contains a variety of microfossils. Most are

Gunflint Chert and other Proterozoic deposits

closely similar to modern blue-green algae, though some of the filamentous forms resemble fungi. The Proterozoic Bitter Springs Formation of central Australia contains more advanced microfossils, derived from eucaryotid forms. These resemble present-day green algae, and it may be from these that the multicellular organisms of the Late Precambrian subsequently developed. Examples are preserved in South Australia, at several locations in the U.S.S.R., and as isolated forms such as the fossil *Charnia* in the Late Precambrian of Leicestershire.

PRECAMBRIAN ENVIRONMENTS

Paleogeography. The distribution of land and seas over much of Precambrian time is not known. During the Archeozoic the sediments and volcanic rocks of the greenstone belts were accumulating underwater. This is demonstrated by the nature of the abundant graywackes and by the widespread development of pillow lavas. At the present time they cannot be dated precisely, and all that is known is that a large number of such belts formed on the crust between about 3,400,000,000 and 2,500,000,000 years ago. In Canada, southern Africa, and Western Australia the remnants of such belts form roughly parallel systems in which each belt is separated from its neighbour by an irregular mass of granitic rock, perhaps derived partly from still older crust. This suggests that for unknown lengths of Archeozoic time, a number of belts of continental crust were probably submerged below the sea, and less probably below freshwater lakes.

Sedimentary basins

From about 2,700,000,000 years onward, individual sedimentary basins were formed. These basins have undergone little subsequent deformation and their original shape can therefore be discerned at the present time.

The Witwatersrand Basin of southern Africa is one of the oldest of these basins. The nature of the detritus suggests that sediments within this basin were derived from the erosion of older greenstone belts and granitic rocks. The gold in the conglomerates may well have been produced by the erosion of gold-bearing volcanics. The nature of the banded ironstone formations that occur in the upper part of the Witwatersrand Basin and in regions such as Western Australia indicates accumulation of chemical or biochemical deposits under conditions of extreme crustal stability. Other ironstone deposits, also dating from Early Proterozoic times, about 2,000,000,000 years ago, contain oolites and other structures that are indicative of shallow-water deposition. These deposits mark some of the oldest shorelines recognized in Earth history. Examples of such shorelines are present in Labrador and in Karelia, near the borders of Finland and the U.S.S.R. In these two regions shoreline deposits can be traced laterally into thicker sedimentary successions that appear to mark the sites of Early Proterozoic sedimentary troughs. Such troughs occur in eastern Canada along the coast of Labrador, in southern Greenland, and over much of Sweden and Finland. It is not yet possible to map these deposits on a worldwide scale. In Late Precambrian time, sequences of rocks up to ten or 15 kilometres (six or nine miles) in thickness accumulated in a network of troughs, many of which still are well preserved. In some areas it has been possible to identify the source areas from which these Late Precambrian deposits were derived. The Late Precambrian Torridonian rocks of Scotland, for example, formed between about 900,000,000 and 750,000,000 years ago and originated from the erosion of crystalline rocks to the west of the present coast of Scotland. The Late Precambrian is the earliest period for which some generalized distribution of sedimentary troughs and uplifted source areas can be established.

In general, it appears that a network of troughs extended over many thousands of kilometres but were no more than 100 or 200 kilometres (60 or 120 miles) in width. These troughs overlay subsiding continental crust and surrounded highland regions, possibly many hundreds of kilometres in diameter, from which detritus reached the sedimentary basins. Such basins occur in western Norway, northwestern Ireland and Scotland, Newfoundland, eastern Greenland, Spitsbergen, the Urals, eastern Australia, the western Congo, southwestern Africa, and in extensive regions in China.

Mountain building and deformation. Since the end of the Precambrian, a succession of mountain chains has formed. The oldest of these have been largely removed by erosion (Figure 4), but it is possible to identify their deep-

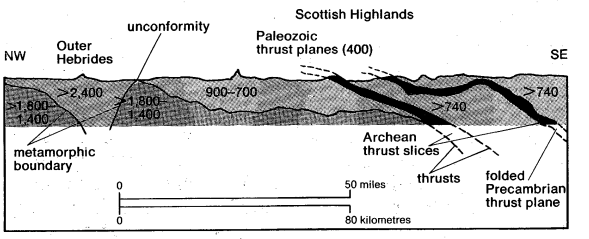

Figure 4: Geological section through Precambrian rocks of northwest Scotland, showing the remnants of an ancient mountain system. Numbers shown designate millions of years.

ly dissected roots, in which folded and metamorphosed rock were produced during mountain-building processes (*q.v.*). Somewhat similar metamorphosed and deformed rocks are widespread in Precambrian terrains, and this suggests that these also represent the roots of mountains, although no chains of Precambrian age survive as mountains at the present time. The possibility that Precambrian folded and metamorphic rocks developed in connection with processes other than mountain building cannot be eliminated, and perhaps the term orogenic should not be applied to the Precambrian belts of metamorphic and igneous rock until it can be demonstrated that these were in fact the roots of true mountain chains.

Geosynclinal deposition and deformation

The oldest belts of metamorphic and deformed rock are the greenstone belts, most of which date from between 3,400,000,000 and 2,500,000,000 years ago. The infilling of volcanic rock of many kilometres in thickness formed below sea level, and of shallow water sediments, indicates long-continued subsidence in such belts. The steep dips, thrusts, and folds show that intense deformation occurred. In some belts, such as those in Rhodesia (Figure 2), the presence of coarse detritus suggestive of rapid deposition indicates the possible occurrence of highlands subject to denudation. Generally, however, the surface relief of such Archeozoic structures is unknown.

Early in the Proterozoic, about 2,300,000,000 years ago, great sediment-filled troughs began to form. The

rocks of the Labrador trough of eastern Canada and the sediments of Sweden and Finland are examples of such deposits. In due course these sediments were folded and deformed, and it is possibly at this stage in the history of the Earth that a global system of mountain chains comparable to that of today was first developed. Certainly these Proterozoic structures were very much more extensive than the limited Archeozoic greenstone belts. To a large extent, regions where sediments accumulated in Early Proterozoic times continued as mobile belts, regions of unusual crustal movement, for many hundreds of millions of years. About 1,000,000,000 years ago a new system of mobile belts was developed; much of this system persisted into Paleozoic and more recent time to give the worldwide system of mountain chains that formed during the Caledonian and Hercynian orogenies.

Igneous activity

Extensive areas of igneous rocks were formed in each of these Precambrian periods of activity; that is, first, during and after the deformation of the Archeozoic greenstone belts; second, within the Early Proterozoic sedimentary troughs; and, finally, in the Late Precambrian troughs. It is uncertain whether this threefold structural division of the Precambrian based largely on data from North America and northern Europe can usefully be applied to other Precambrian shields.

Climatic conditions. Climatic conditions during most of Precambrian time are largely unknown. In Late Precambrian time, about 700,000,000 years ago, however, extensive glaciation is known to have occurred. Glacial deposits of Late Precambrian age are preserved in the Antarctic, in southern Australia, in southern and western Africa, in northwestern Europe, in Greenland and certain other Arctic islands, and in China. In some of these regions, glaciation was repeated. For this reason, the correlation of widely separated glacial deposits is not always clear. In general terms, however, it can be safely assumed that some time before the end of the Precambrian a widespread glaciation affected areas that now lie in both the Northern and Southern hemispheres. The suggestion has been made that this Late Precambrian Ice Age could be used to define the base of another geological period, which would extend from the time of these glaciations to the start of the Cambrian.

CORRELATION OF PRECAMBRIAN EVENTS

Problems of correlation. Despite the discovery of many fossiliferous formations, the rate of evolution throughout most of Precambrian time appears to have been so slow that it is unlikely that fossils can be used to establish the age of any but the youngest Precambrian. Similarly, the study of magnetic reversals during the Precambrian has not reached the stage where these can be employed to correlate rocks of this age. Widespread evidence of climatic change such as glaciation may be employed to correlate widely separated rocks, however. The existence of Late Precambrian glaciation is now well documented. It seems probable, though, that there was more than one Precambrian glaciation, and this promising method of subdividing the very latest Precambrian rocks may require further refinement before it can be adopted. In the near future the Late Precambrian glaciation and the Late Precambrian fossil assemblages, now known from more than a dozen localities, will provide a means of classifying the latest Precambrian rocks. It seems unlikely, however, that classical stratigraphic methods can be applied to rocks much older than 800,000,000 years in age. The problem of subdividing the main mass of Precambrian rocks will have to be dealt with on some other basis.

Radiometric data and correlation

Since 1960 the numbers of radiometric measurements on Precambrian rocks and minerals have been sufficient to establish local successions and to indicate the possible correlation of events on a worldwide basis. The data available at present, however, are insufficient to establish anything comparable to the detailed stratigraphical subdivisions that geologists have developed to mark the passage of Phanerozoic time. There are several reasons for this, but most important is the fact that sedimentary rocks seldom can be dated from the time of the formation of their contained sediments, and most age determinations on crystalline rocks indicate the time that has elapsed since the last time of cooling. It is often possible to correlate this cooling with some other geological event and thus determine the time when a region of metamorphic rock was deformed or was intruded by igneous rocks. In this way, a chronology of isolated geological events has been built up for many Precambrian regions, but from its very nature it is not a continuous record. It would appear that for a very long time to come, Precambrian time is likely to be measured by the dating of a number of distinct geological events and that no continuous stratigraphical record will generally be available. A number of sedimentary formations in the Precambrian can be placed within certain limits of time, although they cannot be precisely dated. It is often possible to show that a deposit must be younger than the youngest crystalline rock on which it rests and older than the oldest rock that intrudes it; but in many instances a very considerable uncertainty remains, and this may reflect several hundred million years. Intercontinental correlations from one sedimentary basin to another are hardly possible at present. On the other hand, intercontinental correlations of metamorphic and magmatic events can be made. It has been demonstrated, for example, that 2,000,000,000 years ago large numbers of diabase dikes (tabular igneous masses that intrude pre-existing rocks) were formed in many parts of North America, Greenland, and northwestern Europe. It can also be shown that certain widespread metamorphic events recorded in more than one continent came to an end over large regions at times that can be quite closely defined. The uncertainty may be of the order of 1 percent of the total time elapsed. It follows from this that the most extensive correlations are those concerned with the ending of igneous or metamorphic activity.

The potassium-bearing mineral glauconite has been used to date Late Precambrian deposits with some success, particularly in the Soviet Union. In any area where volcanism occurred within a sedimentary basin, it may be possible to date volcanic rocks and so decrease the range of uncertainty as to the age of adjoining sediments. The problems of intercontinental correlation of Precambrian structures have been greatly simplified by the recognition of the manner in which the continents fitted together before the last episode of continental drift. If concern is with earlier Precambrian time, however, the possibility that there may have been other periods in the Earth's history when the relative position of continents changed rapidly must be considered. Knowledge of Precambrian historical geology has not yet reached the stage where the effects of possible Precambrian continental drift can be assessed.

Summary of Precambrian events. The following general statement about the Precambrian chronology can be made (see Table). It is consistent with existing knowledge but will undoubtedly be modified as new information becomes available:

1. Formation of the Earth's crust about 4,600,000,000 years ago.
2. Modification of the original crust by the intrusion of igneous rocks, the extrusion of lavas, metamorphism, deformation, and erosion. At an unknown time between 4,600,000,000 and 3,500,000,000 years ago, the earliest sedimentary rocks were formed, almost certainly by the erosion of then-existing igneous material. During this period life either evolved on Earth or reached the Earth from some extraterrestrial source.
3. Between 3,500,000,000 and 2,500,000,000 years, the formation of a succession of greenstone belts occurred. Sediments and volcanic rocks accumulated in these zones and were subsequently deformed and metamorphosed. The belts lie on a crust of older rock that was itself invaded by many granites during the time when the greenstone belts were evolved. All greenstone belts did not form at the same time, but their chronology is not yet known in detail.
4. From 2,700,000,000 years onward the first stable areas to survive until the present day were developed on the continental crust. Flat-lying sedimentary deposits and un-

deformed diabase dikes survive within such regions; the Witwatersrand Basin of South Africa is an example. Important features dating from this period include the earliest stable sedimentary basins, formed about 2,700,000,000 years ago, and the earliest diabase swarms, intruded between 2,500,000,000 and 2,400,000,000 years ago. Extensive diabase swarms approximately 2,000,000,000 years old are known in northwestern Canada, eastern Canada, Greenland, and northwestern Europe.

5. The accumulation of Early Proterozoic sedimentary deposits marks the development of a new system of sedimentary troughs and basins. These date from approximately 2,000,000,000 years ago. Many banded ironstone formations, such as those in North America, South Africa, and Western Australia, date from this time.

6. From about 1,800,000,000 years onward, the Early Proterozoic sediments and the older Archeozoic rocks that underlie them were metamorphosed and deformed to produce new complexes of crystalline rock. Local names for such complexes include the Hudsonian of Canada, the Ketilidian of Greenland, the Laxfordian of Scotland, and the Svecofennid of Scandinavia.

7. Among the most important events toward the end of the Precambrian was the accumulation of the Late Precambrian deposits formed from about 1,000,000,000 years onward. These lie in a network of Precambrian troughs, many of which received further sediments during the Paleozoic and became involved in mountain building during periods of Paleozoic orogeny.

Precipitation

Atmospheric precipitation includes all forms of water particles, whether solid or liquid, that fall from clouds and reach the ground. It thus includes drizzle, rain, snow, snow pellets, ice crystals, and hail. All forms of precipitation are produced as the result of the condensation of atmospheric moisture to form clouds in which some of the particles, by growth and aggregation, attain sufficient size to fall out of the cloud and reach the ground.

Precipitation is one of the three main processes (evaporation, condensation, and precipitation) that constitute the hydrologic cycle, the continual exchange of water between the atmosphere and the surface of the Earth. Water is evaporated from ocean, land, and freshwater surfaces, is carried aloft as vapour by the air currents, condenses to form clouds, and ultimately is returned to the Earth's surface as precipitation. The average global stock of water vapour in the atmosphere is equivalent to a layer of water 2.5 centimetres (one inch) deep covering the whole Earth. Because the Earth's average annual rainfall is about 100 centimetres (40 inches), the average time that the water spends in the atmosphere, between its evaporation from the surface and its return as precipitation, is about 1/40 of a year or about nine days. Of all the water vapour that is carried at all heights across a given region by the winds, only a few percent is converted into precipitation and reaches the ground in that area. In deep and extensive cloud systems, the conversion is more efficient, but even in thunderclouds the quantities of rain and hail released amount to only some 10 percent of the total moisture entering the storm.

Measurement of amount and intensity

In the measurement of precipitation, it is necessary to distinguish between the amount—defined as the depth of precipitation (calculated as though it were all rain) that has fallen at a given point during a specified interval of time—and the rate or intensity—which specifies the depth of water that has fallen at a point during a particular interval of time. Persistent moderate rain, for example, might fall at an average rate of five millimetres (0.2 inch) per hour and thus produce 120 millimetres, or nearly five inches, of rain in 24 hours. A thunderstorm might produce this total quantity of rain in 20 minutes, but at its peak intensity the rate of rainfall might become much greater—perhaps 120 millimetres per hour, or two millimetres (0.08 inch) per minute, for a minute or two.

The amount of precipitation falling during a fixed period is measured regularly at many thousands of places on the Earth's surface by rather simple rain gauges. Measurement of precipitation intensity requires a recording rain gauge, in which water falling into a collector of known surface area is continuously recorded on a moving chart or a magnetic tape. Investigations are being carried out on the feasibility of obtaining continuous measurements of rainfall over large catchment areas by means of radar.

Apart from the trifling contributions made by dew, frost, and rime and by desalination plants, the sole source of freshwater for sustaining rivers, lakes, and all life on Earth is provided by precipitation from clouds. Precipitation is therefore indispensable and overwhelmingly beneficial to mankind, but very heavy rainfall can cause great harm: soil erosion, landslides, and flooding; and hailstorm damage to crops, buildings, and livestock occasion great economic loss each year.

This article treats the general causes of precipitation, its several different types, and its world distribution and effects. For detailed information on snow see the article SNOW AND SNOWFLAKES, and for related information on weather and climate see CLIMATE; CLOUDS; THUNDERSTORMS; and WINDS AND STORMS. See also WEATHER MODIFICATION for coverage of fog, storm, and hail suppression, as well as cloud seeding; HYDROLOGIC CYCLE and WATER RESOURCES for treatment of precipitation within the global water budget; and SEDIMENT YIELD OF DRAINAGE SYSTEMS and RIVERS AND RIVER SYSTEMS for further consideration of precipitation effects.

ORIGIN OF PRECIPITATION IN CLOUDS

Cloud formation. Clouds are formed by the lifting of damp air, which cools by expansion as it encounters the lower pressures existing at higher levels in the atmosphere. The relative humidity increases until the air becomes saturated with water vapour, then condensation occurs on any of the aerosol particles suspended in the air. A wide variety of these exist in concentrations ranging from only a few per cubic centimetre in clean maritime air to perhaps 1,000,000 per cubic centimetre (16,000,000 per cubic inch) in the highly polluted air of an industrial city (see URBAN CLIMATES). For continuous condensation leading to the formation of cloud droplets, the air must be slightly supersaturated. Among the highly efficient condensation nuclei are sea-salt particles and the particles produced by combustion (*e.g.*, natural forest fires and man-made fires). Many of the larger condensation nuclei over land consist of ammonium sulfate. These are produced by cloud and fog droplets absorbing sulfur dioxide and ammonia from the air. Condensation onto the nuclei continues as rapidly as water vapour is made available through cooling; droplets about 0.01 mil-

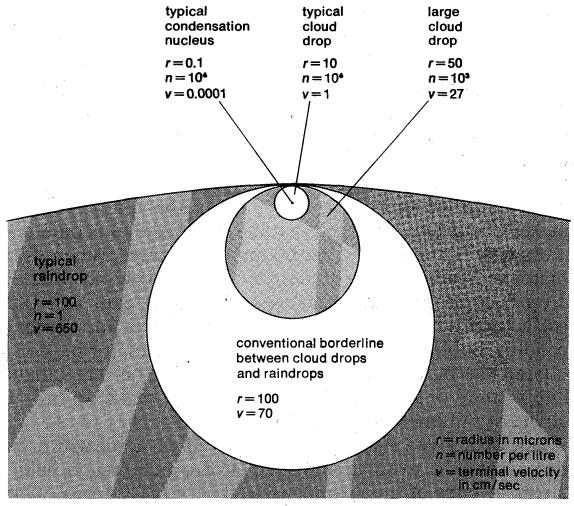

Figure 1: Comparative sizes, concentrations, and falling velocities of some particles involved in the condensation and precipitation process (see text).
Adapted from H.E. Landsberg and J. Van Mieghem, *Advances in Geophysics*, vol. 5 (1958); Academic Press Inc.

limetre, or ten microns (0.0004 inch), in diameter are produced in this manner. These droplets constitute a nonprecipitating cloud.

Mechanisms of precipitation release. Growing clouds are sustained by upward air currents, which may vary in strength from a few centimetres per second to several metres per second. Considerable growth of the cloud droplets (with falling speeds of only about one centimetre [0.4 inch] per second) is therefore necessary if they are to fall through the cloud, survive evaporation in the unsaturated air below, and reach the ground as drizzle or rain. The production of a few large particles from a large population of much smaller ones may be achieved in one of two ways. The first of these depends on the fact that cloud droplets are seldom of uniform size because droplets form on nuclei of various sizes and grow under slightly different conditions and for different lengths of time in different parts of the cloud. A droplet appreciably larger than average will fall faster than the smaller ones and so will collide and fuse (coalesce) with some of those which it overtakes. Calculations show that, in a deep cloud containing strong upward air currents and high concentrations of liquid water, such a droplet will have a sufficiently long journey among its smaller neighbours to grow to raindrop size. This coalescence mechanism is responsible for the showers that fall in tropical and subtropical regions from clouds whose tops do not reach the 0° C (32° F) level and therefore cannot contain ice crystals. Radar evidence also suggests that showers in temperate latitudes may sometimes be initiated by the coalescence of waterdrops, although the clouds may later reach to heights at which ice crystals may form in their upper parts.

The coalescence process

The second method of releasing precipitation can operate only if the cloud top reaches elevations at which temperatures are below 0° C and the droplets in the upper cloud regions become supercooled. At temperatures below −40° C (−40° F) the droplets freeze automatically or spontaneously; at higher temperatures they can freeze only if they are infected with special, minute particles called ice nuclei. The origin and nature of these nuclei are not known with certainty, but the most likely source is clay-silicate particles carried up from the ground by the wind. As the temperature falls below 0° C, more and more ice nuclei become active, and ice crystals appear in increasing numbers among the supercooled droplets. But such a mixture of supercooled droplets and ice crystals is unstable. The cloudy air is usually only slightly supersaturated with water vapour with respect to the droplets and is strongly oversaturated with respect to ice crystals; the latter therefore grow more rapidly than the droplets. After several minutes the growing crystals acquire falling speeds of tens of centimetres per second, and several of them may become joined together to form a snowflake. In falling into the warmer regions of the cloud, this flake may melt and hit ground as a raindrop.

The ice crystal process

The deep, extensive, multilayer cloud systems, from which precipitation of a widespread, persistent character falls, are generally formed in cyclonic depressions (lows) and near fronts. Such cloud systems are associated with feeble upcurrents of only a few centimetres per second that last for at least several hours. Although the structure of these great raincloud systems is being explored by aircraft and radar, it is not yet well understood. That such systems rarely produce rain, as distinct from drizzle, unless their tops are colder than about −12° C (10° F) suggests that ice crystals are mainly responsible. Such a view is supported by the fact that the radar signals from these clouds usually take a characteristic form that has been clearly identified with the melting of snowflakes.

Precipitation from layer cloud systems

Showers, thunderstorms, and hail. Precipitation from shower clouds and thunderstorms, whether in the form of raindrops, pellets of soft hail, or true hailstones, is generally of great intensity and shorter duration than that from layer clouds and is usually composed of larger particles. The clouds themselves are characterized by their large vertical depth, strong vertical air currents, and high concentrations of liquid water, all these factors favouring the rapid growth of precipitation elements by the accretion of cloud droplets.

In a cloud composed wholly of liquid water, raindrops may grow by coalescence with small droplets. For example, a droplet being carried up from the cloud base would grow as it ascended by sweeping up smaller droplets. When it became too heavy to be supported by the vertical upcurrents, the droplet would then fall, continuing to grow by the same process on its downward journey. Finally, if the cloud is sufficiently deep, the droplet will emerge from its base as a raindrop.

Adapted from J. McDonald, *Scientific American*, February, 1954, Scientific American, Inc.

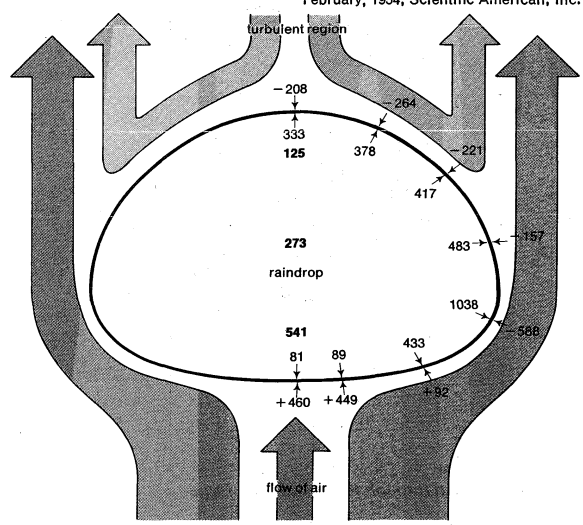

Figure 2: Pressure of air around a raindrop. Numbers outside the drop indicate the difference between the pressure around the drop and that of the atmosphere. Inside numbers denote the difference in surface pressure; boldface numbers indicate difference in internal pressure. Units are dynes per square centimetre.

In a dense, vigorous cloud several kilometres deep, the drop may attain its limiting stable diameter (about six millimetres [0.2 inch]) before reaching the cloud base and thus will break up into several large fragments. Each of these may continue to grow and attain breakup size. The number of raindrops may increase so rapidly in this manner that after a few minutes the accumulated mass of water can no longer be supported by the upcurrents and falls out as a heavy shower. The conditions that favour this rapid multiplication of raindrops occur more readily in tropical regions. In temperate regions, where the 0° C level is much lower in elevation, conditions are more favourable for the ice crystal mechanism.

Growth of hailstones

The hailstones that fall from deep, vigorous clouds in warm weather consist of a core surrounded by several alternate layers of clear and opaque ice. When the growing particle traverses a region of relatively high air temperature or high concentration of liquid water, or both, the transfer of heat from the hailstone to the air cannot occur sufficiently rapidly to allow all of the deposited water to freeze immediately. This results in the formation of a wet coating of slushy ice, which may later freeze to form a layer of compact, relatively transparent ice. If the hailstone then enters a region of lower temperature and lower water content, the impacting droplets may freeze individually to produce ice of relatively low density with air spaces between the droplets. The alternate layers are formed as the stone passes through regions in which the combination of air temperature, liquid-water content, and updraft speed allows alternately wet and dry growth.

It is held by some authorities that lightning is closely associated with the appearance of precipitation, especially in the form of soft hail, and that the charge and strong electric fields are produced by ice crystals or cloud droplets impacting on and bouncing off the undersurfaces of the hail pellets. For a detailed discussion of the cause and occurrence of electrical effects in clouds, see LIGHTNING.

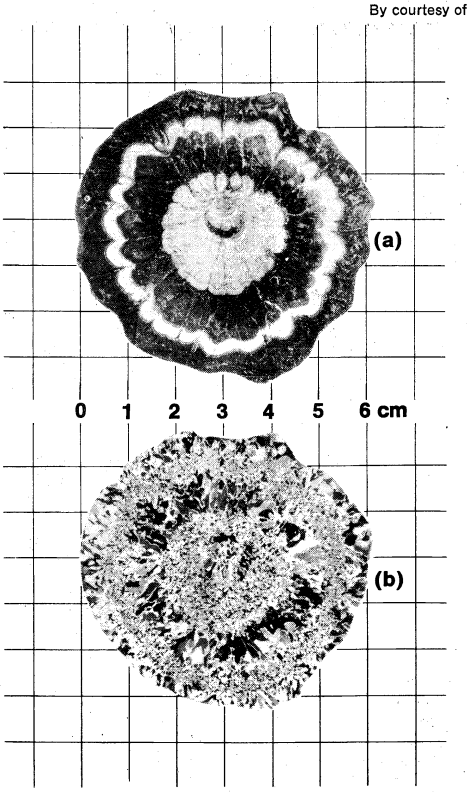

Figure 3: *Section through the centre of a large hailstone.*
(A) shows alternate layers of opaque (white) and transparent (black) ice seen in reflected light. (B) shows the individual crystals seen in polarized light. The opaque layers are composed of small crystals and the transparent layers of much larger crystals.

TYPES OF PRECIPITATION

Drizzle. Liquid precipitation in the form of very small drops, with diameters between 0.2 and 0.5 millimetre (0.008 and 0.02 inch) and terminal velocities between 70 and 200 centimetres (30 and 80 inches) per second, is defined as drizzle. It forms by the coalescence of even smaller droplets in low layer clouds containing weak updrafts of only a few centimetres per second. High relative humidity below the cloud base is required to prevent the drops from evaporating before reaching the ground; drizzle is classified as slight, moderate, or thick. Slight drizzle produces negligible runoff from the roofs of buildings, and thick drizzle accumulates at a rate in excess of one millimetre (0.04 inch) per hour.

Rain. Liquid waterdrops with diameters greater than those of drizzle constitute rain. Raindrops rarely exceed six millimetres (0.25 inch) in diameter because they become unstable when larger than this and break up during their fall. The terminal velocities of raindrops at ground level range from two metres (seven feet) per second for the smallest, to about ten metres (30 feet) per second for the largest. The smaller raindrops are kept nearly spherical by surface-tension forces, but, as the diameter surpasses about two millimetres (0.08 inch), they become increasingly flattened by aerodynamic forces. When the diameter reaches six millimetres, the undersurface of the drop becomes concave because of the airstream and the surface of the drop is sheared off to form a rapidly expanding bubble or bag attached to an annular ring containing the bulk of the water. Eventually the bag bursts into a spray of fine droplets and the ring breaks up into a circlet of millimetre-sized drops.

Rain of a given intensity is composed of a spectrum of drop sizes, the average and median drop diameters being larger in rains of greater intensity. The largest drops, with diameter greater than five millimetres (0.2 inch), appear only in the heavy rains of intense storms.

Freezing rain. When raindrops fall through a cold layer of air (colder than 0° C) and become supercooled, freezing rain occurs. The drops may freeze on impact with the ground to form a very slippery and dangerous "glazed" or "black" ice that is difficult to see because it is almost transparent.

Snow. Solid precipitation composed of small ice crystals at temperatures well below 0° C—but also of larger snowflakes at temperatures near 0° C—is termed snow. Sometimes the snow crystals become covered with small frozen cloud droplets that give them a rimed or jewelled appearance. Continued riming may lead to the formation of small flattened pellets of granular snow that rarely exceed one millimetre in diameter.

Snowfall is classed as slight, moderate, or heavy if the rate of accumulation (in the absence of drifting or melting) is less than 0.5 centimetre (0.2 inch) per hour, 0.5 to four centimetres (0.2 to 1.5 inches) per hour, or greater than four centimetres (1.5 inches) per hour, respectively. The water content of 30 centimetres (12 inches) of freshly fallen snow approximately equals that of 2.5 centimetres (one inch) of rainfall. For a description of snow crystals and snowflakes, see SNOW AND SNOWFLAKES.

Sleet. In British terminology, sleet is the term used to describe precipitation of snow and rain together or of snow melting as it falls. In America, it is used to denote partly frozen ice pellets.

Hail. Solid precipitation in the form of hard pellets of ice that fall from cumulonimbus clouds is hail. It is convenient to distinguish among three types of hail particles.

Types of hail

The first is soft hail, or snow pellets, which are white, opaque, rounded or conical pellets as large as six millimetres in diameter. They are composed of small cloud droplets frozen together, have a low density, and are readily crushed.

Second is small hail (ice grains or pellets), transparent or translucent pellets of ice, spherical, spheroidal, conical, or irregular in shape, with diameters as large as a few millimetres. They may consist of frozen raindrops, of largely melted and refrozen snowflakes, or of snow pellets encased in a thin layer of solid ice.

True hailstones, the third type, are hard pellets of ice, larger than five millimetres in diameter, that may be spherical, spheroidal, conical, discoidal, or irregular in shape and often have a structure of concentric layers of alternately clear and opaque ice (see Figure 3). A moderately severe storm may produce stones a few centimetres in diameter, whereas a very severe storm may release stones with maximum diameters of ten centimetres (four inches) or more. Large damaging hail falls most frequently in the continental areas of middle latitudes (*e.g.*, in the Nebraska–Wyoming–Colorado area of the United States, in South Africa, and in northern India) but is rare in equatorial regions. Hailstones of at least walnut size fall at least two days per year in the Denver area of

Colorado. The largest hailstones ever reported from the United States fell in Potter, Nebraska, on July 6, 1928, the largest being 13.8 centimetres (5.4 inches) in diameter and weighing 680 grams (1.5 pounds). Terminal velocities of hailstones range from about five metres (16 feet) per second for the smallest stones to perhaps 40 metres (130 feet) per second for stones five centimetres (two inches) in diameter.

WORLD DISTRIBUTION OF RAINFALL

Regional and latitudinal distribution. The yearly rainfall averaged over the whole Earth is about 80 centimetres (30 inches), but this is distributed very unevenly. The regions of highest rainfall are found in the equatorial zone and the monsoon area of Southeast Asia. Middle latitudes receive moderate amounts of precipitation, but little falls in the desert regions of the subtropics and around the poles.

If the Earth's surface were perfectly uniform, the long-term average rainfall would be distributed in distinct latitudinal bands, but the situation is complicated by the pattern of the global winds, the distribution of land and sea, and by the presence of mountains. Because rainfall results from the ascent and cooling of moist air, the areas of heavy rain indicate regions of rising air, whereas the deserts occur in regions in which the air is warmed and dried during descent. In the subtropics, the trade winds bring plentiful rain to the east coasts of the continents, but the west coasts tend to be dry. In high latitudes, on the other hand, the west coasts are generally wetter than the east coasts. Moreover, rain tends to be abundant on the windward slopes of mountain ranges but sparse on the lee sides.

Equatorial and desert regions

In the equatorial belt, the trade winds from both hemispheres converge and give rise to a general upward motion of air, which becomes intensified locally in tropical storms that produce very heavy rains in the Caribbean, the Indian and southwest Pacific oceans, and the China sea, and in thunderstorms that are especially frequent and active over the land areas. During the annual cycle, the doldrums move toward the summer hemisphere so that, outside a central region near the Equator, which has abundant rain at all seasons, there is a zone that receives much rain in summer but a good deal less in winter.

The dry areas of the subtropics, such as the desert regions of North Africa, the Arabian Peninsula, South Africa, Australia, and central South America, are due to the presence of semipermanent, subtropical anticyclones in which the air subsides and becomes warm and dry. These high-pressure belts tend to migrate with the seasons and cause summer dryness on the poleward side and winter dryness on the equatorward side of their mean positions. The easterly trade winds, having made a long passage over the warm oceans, bring plentiful rains to the east coasts of the subtropical landmasses, but the west coasts and the interiors of the continents, which are often sheltered by mountain ranges, are very dry.

Middle and high latitudes

In middle latitudes the weather and the rainfall are dominated by travelling depressions and fronts that give a good deal of rain in all seasons and in most places except the far interiors of the Asian and North American continents. Generally the rainfall is more abundant in summer, except on the western coasts of North America, Europe, and North Africa, where it is higher during the winter.

At high latitudes and especially in the polar regions, the low precipitation is caused partly by subsidence of air in the high-pressure belts and partly by the low temperatures. Snow or rain occur at times, but evaporation from the cold sea and land surfaces is slow, and the cold air has little capacity for moisture; for this reason precipitation amounts are small.

The influence of oceans and continents on rainfall is particularly striking in the case of the Indian monsoon. During the Northern Hemisphere winter, cool, dry air from the interior of the continent flows southward and produces little rain over the land areas. After the air has travelled some distance over the warm tropical ocean, however, it releases heavy shower rains over the East Indies. During the northern summer, when the monsoon blows from the southwest, rainfall is heavy over India and Southeast Asia. These rains are intensified where the air is forced to ascend over the windward slopes of the Western Ghāts and the Himalayas.

The combined effects of land, sea, mountains, and prevailing winds show up in South America. There the desert in southern Argentina is sheltered by the Andes from the westerly winds blowing from the Pacific Ocean, and the west-coast desert is not only situated under the South Pacific subtropical anticyclone but is also protected by the Andes against rain-bearing winds from the Atlantic.

Amounts and variability. The long-term average amounts of precipitation for a season, or a year, give little information on the regularity with which rain may be expected, particularly for regions where the average amounts are small. At Doorbaji, in the Thar Desert, for example, where the annual amount is about 13 centimetres (five inches), a rare storm produced 86 centimetres (34 inches) in two days. At Iquique, in northern Chile, four years once passed without rain, whereas the fifth year gave 1.5 centimetres (0.6 inch); the five-year average was therefore 0.30 centimetre (0.12 inch). Clearly such averages are of little practical value and the frequency distribution or the variability of precipitation also must be known.

Relation of variability and average amount

The variability of the annual rainfall is closely related to the average amounts. For example, over the British Isles, which have a very dependable rainfall, the annual amount varies by less than 10 percent above the long-term average value. A variability of less than 15 percent is typical of the middle-latitude cyclonic belts of the Pacific and Atlantic oceans and of much of the wet equatorial regions. But in the interiors of the desert areas of Africa, Arabia, and Central Asia, the rainfall in a particular year may deviate from the normal long-term average by more than 40 percent. The variability for individual seasons or months may differ considerably from that for the year as a whole, but again the variability tends to be higher where the average amounts are low.

The heaviest annual rainfall in the world was recorded at Cherrapunji, India, where 2,647 centimetres (1,042 inches) fell between August 1860 and July 1861. The heaviest rainfall in a period of 24 hours was 187 centimetres (73.62 inches) recorded at Cilaos, La Reunion, in the Indian Ocean on March 15–16, 1952. The lowest recorded rainfall in the world occurred at Arica, in northern Chile. The annual average, taken over a 43-year period, is only 0.05 centimetre (0.02 inch).

Although past records give some guide, it is not possible to estimate very precisely the maximum possible precipitation that may fall in a given locality during a specified interval of time. Much will depend on a favourable combination of several factors, including the properties of the storm and the effects of local topography. Thus it is possible only to make estimates based on analyses of past storms or on theoretical calculations that attempt to maximize statistically the various factors or the most effective combination that are known to control the duration and intensity of the precipitation. For many important planning and design problems, however, estimates of the greatest precipitation to be expected at a given location within a specified number of years are required.

In the design of a dam, the highest 24-hour rainfall to be expected once in 30 years over the whole catchment area might be relevant. For dealing with such problems, a great deal of work has been devoted to determining, from past records, the frequency with which rainfalls of given intensity and total amount may be expected to reoccur at particular locations and also to determining the statistics of rainfall for a specific area from measurements made at only a few points.

EFFECTS OF PRECIPITATION

Raindrop impact and soil erosion. Large raindrops, up to six millimetres (0.2 inch) in diameter, have terminal velocities of about ten metres (30 feet) per second and so may cause considerable compaction and erosion of the soil by their force of impact. The formation of a com-

pacted crust makes it more difficult for air and water to reach the roots of plants and encourages the water to run off the surface and carry away the topsoil with it. In hilly and mountainous areas, heavy rain may turn the soil into mud and slurry, which may produce enormous erosion by mudflow generation. Rainwater running off hard, impervious surfaces or waterlogged soil may cause local flooding.

Surface runoff. The rainwater that is not evaporated or stored in the soil eventually runs off the surface and finds its way into rivers, streams, and lakes or percolates through the rocks and becomes stored in natural underground reservoirs. A given catchment area must achieve an overall balance such that precipitation (P) less evaporation of moisture from the surface (E) will equal storage in the ground (S) and runoff (R). This may be expressed: $P - E = S + R$. The runoff may be determined by measuring the flow of water in the rivers with stream gauges, and the precipitation measured by a network of rain gauges, but storage and evaporation are more difficult to estimate.

Of all the water that falls on the Earth's surface, the relative amounts that run off, evaporate, or seep into the ground vary so much for different areas that no firm figures can be given for the Earth as a whole. It has been estimated, however, that in the United States 10 to 50 percent of the rainfall runs off at once, 10 to 30 percent evaporates, and 40 to 60 percent is absorbed by the soil. Of the entire rainfall, 15 to 30 percent is estimated to be used by plants, either to form plant tissue or in transpiration.

BIBLIOGRAPHY. There are three general works that treat the processes of condensation and precipitation from clouds from theoretical and experimental bases, and which provide peripheral information on such aspects as cloud seeding as well. These are: N.H. FLETCHER, *The Physics of Rainclouds* (1962); and B.J. MASON, *Clouds, Rain and Rainmaking* (1962), and *The Physics of Clouds,* 2nd ed. (1971). The last is quite comprehensive and each of these books is a source for additional references.

(B.J.M.)

Prefabrication and Shop Fabrication

Prefabrication as used here encompasses the assembly of buildings or their components at locations other than their final position in the completed structure. Prefabrication may take place at the building site itself or may be carried out at remote sites ranging up to several thousand miles away—occasionally even crossing international boundaries. Prefabrication methods may be used for items such as residential kitchen cabinets and appliances, wall panels, floor panels, roof trusses, window-wall elements, structural rigid frames, room-sized components, and even total buildings.

Basic types of preassembly

There are two basic types of preassembly associated with the construction industry: custom fabrication and general fabrication. The first method is used widely in commercial and institutional construction when the design calls for several identical components within a single structure or a complex of buildings. Hospitals, dormitories, apartment buildings, offices, and schools are examples of possible applications for custom prefabrication. On the other hand, the general prefabrication class of components is designed for broad usage and is marketed for application in a wide range of building types and designs. Some of the elements in this classification are roof trusses for residences and small commercial and industrial buildings; rigid frames for warehouses, bowling alleys, and small factories; and bathroom and kitchen "core" modules for residential use.

Although there is evidence to indicate that the enormous stone blocks of the Pyramids of Egypt were cut roughly to size in the quarries and hewn to exact shape on site prior to their final positioning, a process that would be called precutting in present-day terminology, the history of prefabrication starts in 1905 when a design was made for the construction of a factory to manufacture precast concrete box-shaped modules to be hauled by truck for consumer use in Chicago. From World War I on, prefabrication has made rapid, if irregular, strides in western Europe, the U.S.S.R., and the United States.

ECONOMICS OF PREFABRICATION

Time. The promise of reduced costs has been the prime, but not the only, motivation for the application of prefabrication techniques. The use of prefabricated modules in Russian apartment blocks, in the Palacio del Rio Hotel in San Antonio, Texas, and in Habitat '67 in Montreal, as well as in several other cases, was in response to a time requirement and not in anticipation of reduced costs.

Weight and durability of materials. The economics of buildings differs fundamentally from the economics of other manufactured items. Since buildings are not moved but must stand against the weather for 60 or more years, material selection for buildings follows far different criteria than for transportation equipment. Building materials can be heavy since they are transported to the building site only once and, after that, never relocated. Furthermore, building weight aids in resisting the corrosion that is associated with a long life of minimal maintenance.

Many manufactured items consist of a great number of small, intricate parts; buildings are made up of a relatively few large, simple parts. There is little need for malleability in the structural and architectural elements of buildings. Even in earthquake zones, buildings are subjected to only slight vibrations compared to those constantly experienced by most manufactured products. The need for highly efficient joining techniques is not as critical in buildings as it is in other products.

When the economic factors are well understood and properly dealt with in design, the prefabrication of major architectural elements up to and including whole buildings is feasible. A climate more favourable to prefabricated construction is currently developing. The use of low-cost plastics as binders of natural aggregates shows promise of providing materials of proper strength, workability, and cost to satisfy the specific needs of prefabrication and its associated transportation. In many countries, rising labour costs are increasing the demand for alternate methods of construction.

ADVANTAGES OF PREFABRICATION

Auxiliary equipment. The inherent advantages of prefabrication in construction are especially noteworthy in the area of auxiliary equipment. Complex duct systems for heating, ventilating, and air conditioning are prefabricated in the shops of subcontractors and delivered to the construction site for final erection. Networks of electrical raceways and heating- and cooling-system ducts are also shop fabricated. Concrete roof, floor, and decorative exterior wall panels are precast and frequently prestressed in large factories devoted specifically to those purposes. Open-web steel joists—featuring light metal framework and steel or even wood runners—rigid frames, and wooden roof trusses represent well-established general-purpose prefabricated items. All of these building elements are based on standard designs with dimensions varying for the specific project at hand.

Modular construction. Modularized prefabricated components are seen more in architectural, mechanical, electrical, and structural design uses than in readily visible applications. The term module has two meanings in building design: (1) It indicates a uniform linear dimensional guide for coordinated architectural and engineering design. For example, the architect may select a four-foot module for the floor plan of a particular building. The structural, mechanical, electrical, and other consulting engineers will design connections, joints, columns, etc. to fall on these four-foot grid lines. In this scheme wall panels may be four feet wide, columns may be spaced at 16 feet, and contraction joints of exterior concrete plazas may be on a 2-foot spacing. All of these dimensions are consistent with the four-foot module even though some elements are integral multiples of the basic module and some are integral divisions of it. (2) The

second common use of the term module refers to three-dimensional boxlike architectural–structural elements, generally with all utilities included. These building components also are designed on a modular basis as described under (1) above but are prefabricated in plants and delivered to the site as units to be "plugged" into the building. The usages of the term can be distinguished by the context. Modularized prefabricated components are represented by such items as kitchen cabinet and appliance units, electrical panels and switchgear, furnaces, water heaters, and bathroom elements. Habitat '67 in Montreal and the Palacio del Rio in San Antonio are examples of this concept in room-sized prefabricated components.

Economic considerations

Cost reduction through prefabrication is based principally on the use of lower cost labour and mass-production techniques in factories to supplant higher rate labour and slower manual methods at the construction site. Since the basic materials of construction are generally less expensive than those of any other industry, there is little hope of reduced material cost when using factory assembly methods. Indeed, it may be necessary to select materials more expensive than those presently used in on-site construction to take advantage of the available differences in labour cost. Development of materials tailored specifically for prefabricated construction use may be one of the keys to realizing the promise of factory-assembled building modules.

Interchangeable parts. Factory assembly cuts down the time needed for final erection of the building at the site. The influence of weather is markedly reduced. Realistic design of interchangeable subassemblies and components permits a wide variety of products to be made up from a few standard construction elements. Such an approach is conducive to manufacturing efficiency and at the same time makes it possible to avoid the bane of prefabrication: aesthetic monotony. In current projects to achieve the maximum use of standardized, interchangeable parts, the structure of the building merely provides a framework for the attachment of utility modules such as bathrooms, kitchens, sleeping elements, laundry and utility rooms, and entertainment alcoves. Space for living and working is divided by movable partition and closet units. Electric power, water, gas, and waste drainage are made available in a modular pattern so that utility units can be located in a wide variety of ways within a building. If a bathroom unit were to deteriorate or become obsolete, it could be removed and replaced in a few hours without major disruption of activities within the overall building.

Blankmeyer system

In its present state of development, this concept, called the Blankmeyer system after its inventor, Donald C. Blankmeyer of the United States, applies principally to residential construction. The principal value of the system is that it extends the function of existing appliance manufacturers into the construction of units containing their appliances but also incorporating small wall, floor, and roof elements. Manufacture of the modules would require standardization similar to that of the auto industry, but beyond that units could be competitively manufactured and distributed in the same ways that autos and appliances are now purveyed.

Prefabrication in construction is aimed primarily at the future, since the past is not full of successes and public acceptance. The system provides for production efficiency through mass manufacture of standard products, it allows for the proper selection of materials in direct response to needs, requires shipment of components small enough for easy handling without special escorts and truck sizes, reduces expensive on-site labour, allows the user to choose from among the offerings of many competitive manufacturers, and provides for orderly updating of components in direct response to normal deterioration and obsolescence.

Land and building considerations. Modular designs respond to the various desired lifetimes of the constituents of buildings and sites. For example, the land has an infinite life, except that its value may change in response to community needs for service. That is, a piece of land occupied by an apartment building may at some point in time be more valuable to the community if it supports a commercial building or factory. But compared to the life of a building, the life of its site can be considered as infinite. A properly designed and constructed foundation has an expected life of as much as 120 years. A structural framework is expected to be serviceable for 60 or more years and—with routine maintenance—the life of a roof is in the same range. But mechanical, electrical, and other utility systems have expected useful lives of only 5 to 15 years because of the greater susceptibility of these elements to deterioration and to obsolescence from the rapid advance of technology. Therefore, to retain the durability, safety, and variety required and at the same time to realize the economies inherent in the mass manufacture of components, any system must take into account the various lifetimes of the constituents of a building.

PRODUCTION PLANNING AND PROCEDURES

Specialized processes. The available market for prefabricated elements is nearly as broad as the facets of the construction industry itself. By such techniques as precasting and prestressing, and lift-slab construction, massive concrete components have been prefabricated and raised into place. Some lift-slab floors and roofs in a structure have approached one acre in total area and 2,000 tons in weight. Even domed roofs have been constructed through lift-slab operations.

Prestressing, precasting concrete

Prestressing and precasting is a technique wherein high-strength steel wires are run through concrete molds or formwork and tensioned. While the wires are in tension, concrete is poured into the mold and allowed to cure. After cure the wire tension is released; as the tension relaxes, the wires shorten, applying a compressive stress to the concrete (see also CONCRETE).

This technique is useful in concrete construction because concrete can tolerate only light tensile loads but can support extremely high loads in compression. Solid steel structural members can resist high tensile loads, but wires or rods alone can resist almost no compressive load because the small diameter of wire and rod introduces a tendency to buckle. By combining the best characteristics of the two materials, concrete and steel, prestressing provides efficient, lightweight, fire-resistant building units.

Lift-slab construction is used principally for the erection of floors and roofs. In this operation foundations are prepared in the usual fashion. Columns are erected to a height of as much as 40 to 50 feet (12 to 15 metres). After the base section of a column is set, the bottom floor slab is cast; this may be a basement floor or a grade-level slab. A special, liquid release compound, designed to prevent bonding of the concrete slabs, is applied to the top surface of the slab in preparation for other floors to be cast directly on it. Structural collars for each floor level are placed over the columns and lowered to the surface of the floor slab. These collars provide guidance for the next slab and establish clearance from the column so that the concrete will not adhere and restrain the upward movement of the slab during lifting. Lower slabs are used as the undermolds for the next-higher slabs; the casting process is continued at the ground level until all floors and the roof slab are cast. After the roof slab is suitably cured, the lifting process is initiated by placing one jack atop each column and attaching it to its collar by two long, threaded rods. These rods extend down from the jack on either side of the column and engage the collars by use of "lifting nuts" threaded onto the lower end of each rod. The jacks slowly pull the slabs up the columns by applying tension to the lifting rods. Power is provided by a central hydraulic unit and control is through a central electronic system. By alternately lifting in short increments and automatically taking up the lift by screwing down nuts engaged on the threaded rods, the slab is accurately raised either directly to its final position or first to an intermediate position for structural inspection before final lifting. As soon as any slab has reached its final position, it is welded permanently. The openings for engagement of the lifting rods in the collars also penetrate through all the slabs so that the rods extend through the upper slabs and attach to the next-lower slab.

Prehung doors

At the other end of the size and weight scale for prefabricated elements are prehung doors and windows, prefabricated electrical distribution centres, prefabricated plumbing assemblies, and prefabricated chimneys and vent stacks. The market scope is broad and the demand for construction is high, in response to expanding world population with its associated need for products and employment. In the case of these components, the speed offered by prefabrication is a factor in its further use even when there is no cost advantage.

Building codes, inspections. In general, governments have encouraged, or at least have not resisted, prefabrication provided that safe quality standards have been maintained, but inspection to assure adherence to local standards is made difficult by the fact that factories are frequently outside the cities of intended delivery. In prefabrication, on-site inspectors cannot observe hidden construction elements; in some countries this problem has created difficulties. The solution visualized is standardization of quality requirements and cooperative inspection at the factory and at the site.

Use of modern management techniques. Factory production enhances the value of systems engineering, and modern management techniques of planning and scheduling are fundamental to the achievement of the economic promise of prefabrication. Management methods developed for space exploration programs have demonstrated that it is possible to unify the planning and control of extremely broad, multifaceted projects. Computer analysis of progress and of plan changes provides the mechanism for quick response and sensitive control of complex operating systems. The development of resource allocation techniques and the understanding of construction logistics are contributing to improved efficiency. These management methods are the key to success of the prefabrication industry.

Logistics of prefabrication. Contemporary management techniques assist in decision making regarding proper compromises between hauling costs and labour saving through factory production. Large components such as room-sized modules require special design consideration to render them rigid enough for transportation. When rigidity is provided, the units become heavy and require special handling equipment for erection at the job site. When units are so massive that a truck can accommodate only one, economics dictates that the distance they must be hauled preferably be no farther than the round trip that the truck can make in one day, including allowance for unloading time. The economics of rail shipment or barging of very large units is often complicated because additional handling is required to get the units to the construction site.

Stockpiling

Another advantage of prefabrication lies in the possibility of having large volumes of materials delivered to a single storage point. Suitable warehouse space allows the purchase and stockpiling of materials at advantageous prices.

The scope of definition of component materials includes subassemblies and subsystems manufactured in plants owned either by the same producer or by others.

MATERIALS AND TECHNIQUES

Wood-framed units. *Precut lumber and prefabricated walls.* One of the earliest excursions into prefabrication was the adoption of precut framing lumber pieces for walls and partitions. The next evolutionary step involved prefabricating exterior wall and interior partition panel framing on the floor of the building, tipping the frames upright, and securing them. In recent years a few lumber suppliers have equipped themselves with fixtures and tooling to build these frames in their warehouses and have offered them for sale as prebuilt units. Many sophisticated and versatile systems were devised to facilitate the installation of insulation, exterior siding, interior finish, windows, and doors. One of these, the Queensbury system, employs a versatile fixture for quickly positioning studs, plates, and sills for wall framing. Framing for doors and windows at any location is accounted for within the scope of the system design.

In all of the evolutionary steps discussed thus far, the components are custom built for specific orders and no stockpiling of completed units is considered. This is also true in large fabrication organizations. The difference between the mode of operation of the large prefabrication company and the small lumber supplier lies mainly in the approach to design. The lumberman builds in response to a design brought to him by the building contractor, while the prefabrication company prepares designs intended specifically to facilitate factory production.

Truss designs. Prefabricated roof trusses are widely used in light construction. The early trusses used metal split-ring connectors, resembling short sections of pipe, which were driven into holes aligned within the lumber chords (horizontal units), and web (diagonal) members. To use these connectors, the lumber elements were offset, or overlapped, so that the members could pass alongside one another to accommodate the special characteristics of split rings. This made the trusses twice as thick as necessary and introduced undesirable secondary bending stresses. The next development placed the truss members in the same plane by abutting the ends and used small plywood gusset plates nailed or glued on either side of the joints to connect the members. This development was immediately followed by a multitude of metal gusset-plate designs and fabrication systems. Sophisticated fixtures and automatic saws were designed to automate the truss-making process. Presently, trusses are manufactured and stockpiled in standard sizes.

Plywood components

During the 1960s considerable research was done on the design and manufacture of prefabricated plywood structural components. In such components as stressed skin panels, box beams, folded plates—flat slabs, abutted and connected at their edges—and curved roof panels and arches, plywood and lumber are glue laminated to take best advantage of the structural characteristics of each material, a significant departure from merely prefabricating conventional framing in the shop.

Packaged structures. Another important new concept is that of the "folded plate." A typical folded plate structure consists of flat-plane (or plate) wall and roof members, interconnected and delivered to the construction site as a package (8 x 9 x 40 feet). With the assistance of a deck lift mounted on the delivery truck, the accordion-like package unfolds to form a building (40 feet wide by 72 feet long with a 14-foot ceiling height at the lowest point). All walls, doors, and windows are included. Such a building is not at present economically competitive in the commercial market but is of value in fulfilling certain special needs for quick erection and relocatability—*e.g.*, military. Yet the sophistication of the technique offers promise for the future.

Steel construction. Steel construction has always involved a degree of prefabrication in the sense that almost every steel structural member is cut to exact length and has connection holes punched in the shop. Complex framing systems are fabricated into subassemblies in sizes suitable for shipping, and before shipment these subassemblies are test connected to assure proper matching of connection holes. Steel columns and other compression members are cut to exact length and milled square in the shop. Steel reinforcing rods are cut to length and bent in the factory. Open-webbed steel joists are welded into complete structural units in fabrication plants. But in addition to these traditional fabrication processes, the approach presently used in the steel industry of the world goes much farther.

Steel rigid frames with spans up to 120 feet are listed in the catalogs of fabricators. Relocatable wall panels made of two layers of thin sheet steel separated by an insulating material are available for use in schools and office buildings. Porcelainized-steel exterior-curtain wall panels are in evidence in large volume. Commercial stairs are made of prefabricated steel with concrete (terrazzo) poured in metal pans to form the treads.

Metal deck panels for floors and roofs incorporate raceways and ducts for electrical work and the top surfaces provide forms for concrete or other finish material. Often floor tile or roofing is attached directly to the steel.

Whole systems of steel prefabrication have been designed in the U.S. for such purposes as school construction, in which a few well-designed modules can be fitted together in a variety of ways.

Civil-engineering works. Prefabrication, or "shop fabrication" as it is more generally known in this case, plays an increasingly important role in the construction of civil-engineering works, notably bridges. Instead of erecting roadway and stiffening trusses separately, in modern bridge construction whole units, weighing as much as 400 tons and comprising roadway skeleton sections and truss sections joined together, are fabricated "in the shop" and transported to the site. On the Verrazano-Narrows Bridge in New York, for example, the bridge is made up of 60 such sections.

Bridges

An even more striking innovation was tried in the late 1960s—prefabrication of suspension cables, increasingly used for suspending roofs as well as bridges.

Use of concrete. Precast concrete components range from sewer tile and septic tanks to the huge lift slabs discussed earlier. Although wooden components are used extensively in Scotland and the Scandinavian countries, concrete is the major material turned to for prefabrication in both hemispheres and on both sides of the Iron Curtain. Structural elements include slabs, beams, columns, panels, modular boxes, and stairways. Frequently, these elements are cast in combinations, as in tees and double tees designed as roof components up to 12 feet wide and over 100 feet clear span; *i.e.*, without support from columns or walls except at the ends. The structural components are termed tees because in section their profile resembles the letter T. Similar tees, standing upright, may form exterior walls. Several schemes for reducing the weight of concrete structural members are in evidence. Unnecessary material can be eliminated by casting closely spaced longitudinal cylindrical holes through slabs or by casting reinforced ribs or waffle patterns in the undersides of thin slabs. The performance characteristics of the basic material can be improved by prestressing as in the tees, double tees, and flanged beams, for buildings or highway bridge construction. Prestressed concrete can be made flexible enough for diving boards.

Flat concrete panels are used in England for large suburban apartment projects, for structures up to five stories in height. Walls and partitions are load bearing. Slabs are simple rectangles of uniform thickness. The Techcrete system developed by architect Carl Koch of the United States and the Balenci system of Italy are similar to the British system. Techcrete has been used in structures up to nine stories high. The Jespersen system of Denmark is also a wall-bearing panel and slab design. It differs from the other systems in that Jespersen incorporates stairs, beamed slabs, and many other special features.

Various national construction systems

Immediately following World War II, several precast factory buildings were constructed using rigid frames and slabs. A Danish box system also uses precast rigid frames, but the frames support box modules for residential occupancy. The Danish plant is subsidized by the government.

Several other nations experimented with similar systems but as of 1970 all had been abandoned. Russia developed two box systems: the lightweight and the massive. These units were both architectural and structural since the attractive faces of the box also were load bearing. The units used in the Palacio del Rio Hotel in San Antonio, Texas, and in Habitat '67, Montreal, were also load bearing boxes.

The most intricate precasting system appears in the Swedish Heart system of precast bathroom and kitchen elements. A wall is cast with piping and vents formed directly in the concrete. Sink, lavatories, bathtub, and water closets are all molded integrally with the wall and floor sections. The bathroom is on one side of the dividing wall and the kitchen on the opposite side in the usual back-to-back relationship. Various concrete finishes are made so that fixture material surface is different from wall and floor material. The fixtures are terrazzo-like while the walls and floors are of ordinary concrete. The workmanship is excellent but the rough surfaces may fall short of contemporary comfort standards.

Precast concrete is also widely used in shop fabrication for civil-engineering projects. A notable example in the 1970s was a double viaduct built in Switzerland to carry a European highway past Chillon Castle on Lake Geneva. An automated plant supplied concrete, preheated in winter, to the five casting beds in the prefabrication yard just south of the construction site. A total of 1,380 boxes were required to make up the two roadways, with many variations in form owing to the curve of the viaduct and the cantilevering from the piers, which meant deeper boxes directly over the piers and shallower ones farther out.

Other techniques and materials. *Utility cores.* A set of prefabricated elements not classified by basic material has had impact of various degrees upon prefabrication. The most important of these is the utility core in which kitchen, bath, and laundry are arranged along opposite sides of a common wall containing electric power, water, and drainage. The degree of fabrication varies among builders. Some fabricators assemble only the service elements attached directly to a wet wall. Others include the walls, floors, and ceilings of adjacent rooms. In the latter instance, a heat plenum or warm-air chamber is built into the ceiling; supply grilles are installed around the plenum to provide central heating for the entire dwelling unit. The principal manufacturers of these units are building material suppliers.

Plastics. The use of plastics in construction was rising in the early 1970s. Plastic drain waste and vent piping is well established in many areas of the world. Plastic water piping may prove to be successful. The ease of joining, coupled with more complex shapes possible with plastic piping, can reduce plumbing labour by 75 percent. Bonded vinyl exterior finishes not only replace paint in some instances but also provide the protection necessary for the use of metals as siding materials. The durable beauty of vinyl has been demonstrated through its use on autos. Inexpensive thermosetting plastic bonding agents under development, to be used like mortar, may fill a well-defined gap in the economic spectrum of building materials.

Site preparation. Modular design normally associated with prefabrication can help organize and standardize site work, but there will always be site preparation. A site-constructed structural system is necessary to compensate for the natural soil irregularities of the earth and the finished shapes of the building. Soil factor irregularities may include surface contours, load-bearing capability, or dimensional instability due to moisture-content changes and freezing.

Connections to water, sewer, gas, electricity, and telephone remain as projects at the building site. These items are no more expensive for prefabricated construction than for conventional buildings, but any unnecessary work at the site cuts down on the savings to be expected from factory assembly.

BIBLIOGRAPHY. There are no good English language texts published on this subject. Information may be found in periodical literature, such as the following: K.J. SEYMOUR-WALKER, "Czechoslovakia: Concrete Panel Production," *Interbuild,* 14:16–19 (1967), a description of sophisticated types of equipment for concrete panel wall production used in Czechoslovakia, where a large majority of dwellings are constructed by industrialized methods; "Building a City with King Kong Blocks," *Progressive Architecture,* 47:226–236 (1966), a detailed, illustrated description of Habitat '67, the housing project in Montreal, Canada, that was the first structure making practical use of precast concrete in house-size units; "System Building, Switzerland," *Interbuild,* 14: 24–27 (1967), a description of the "Norm-Module" precast concrete constructional system developed in Switzerland, primarily for industrial, scientific, and office building application; L.O. ANDERSON, "Development of an Improved System of Wood-Frame House Construction," *U.S. Forest Serv. Res. Pap. No. FPL47* (1965), reports on a new system of wood-frame residential construction using factory assembled, prefinished components for rapid assembly on site with minimum labour; H.B. DICKENS, "Housing Trends in Europe: A Seminar in Prague," *Nat. Res. Coun., Ottawa, Tech. Pap. No. 196* (1965), a discussion of system building activities and trends in industrialized housing in various European countries; H.L. SCOGGIN, "Prefabricated Building Systems in Europe," *Building Research,* 3:58–61 (1966), reports on a

survey of prefabricated building systems throughout the world, particularly in Europe, with emphasis on the degree of mechanization, range of application, and method of construction; R.M.E. DIAMANT, *Industrialised Building: 50 International Methods* (1964), selected articles from the *Architect and Building News* that describe systems representing the most advanced international thinking in the field of factory made buildings; R.T. LASKO, "Economics of Precast Concrete Construction," *Building Research*, 3:46–48 (1966), a discussion of the advantages and limitations of precast construction.

(E.B.F.)

Pregnancy

Pregnancy, as discussed in this article, is the physiologic process and the series of changes that normally take place in a woman's organs and tissues as a result of her having a developing offspring within her body. The terms "pregnancy" and "gestation" will be used synonymously. Most of the changes that take place during pregnancy serve to safeguard the mother and the fetus. Besides changes of this type, the present article will discuss some of the problems that can arise during the course of a pregnancy. (Gestation in animals is treated in the articles REPRODUCTION; REPRODUCTIVE SYSTEMS, ANIMAL.)

This article is outlined as follows:

I. The normal events of pregnancy
  Initiation of pregnancy
  Diagnosis of pregnancy
  Anatomic and physiologic changes that attend the progress of normal pregnancy
II. Abnormal changes in pregnancy
  Ectopic pregnancy
  Abortion
  Effects of systemic diseases on pregnancy and or pregnancy on systemic diseases
  Diseases of pregnancy

I. The normal events of pregnancy

INITIATION OF PREGNANCY

A new individual is created when the elements of a potent sperm merge with those of a fertile ovum, or egg. Before this union both the spermatozoon (sperm) and the ovum have migrated for considerable distances in order to achieve their union. A number of actively motile spermatozoa are deposited in the vagina, pass through the uterus, and invade the uterine (fallopian) tube, where they surround the ovum. The ovum has arrived there after extrusion from its follicle, or capsule, in the ovary. After it enters the tube, the ovum loses its outer layer of cells as a result of action by substances in the spermatozoa and from the lining of the tubal wall. Loss of the outer layer of the ovum allows a number of spermatozoa to penetrate the egg's surface. Only one spermatozoon, however, normally becomes the fertilizing organism. Once it has entered the substance of the ovum the nuclear head of this spermatozoon separates from its tail. The tail gradually disappears, but the head with its nucleus survives. As it travels toward the nucleus of the ovum (at this stage called the female pronucleus) the head enlarges and becomes the male pronucleus. The two pronuclei meet in the centre of the ovum, where their threadlike chromatin material organizes into chromosomes.

Union of the ovum and the sperm

Originally the female nucleus has 44 autosomes (chromosomes other than sex chromosomes) and two (X, X) sex chromosomes. Before fertilization a type of cell division called a reduction division brings the number of chromosomes in the female pronucleus down to 23, including one X-chromosome. The male gamete, or sex cell, also has 44 autosomes and two (X, Y) sex chromosomes. As a result of a reducing division occurring before fertilization, it, too, has 23 chromosomes, including either an X or a Y sex chromosome at the time that it merges with the female pronucleus.

After the chromosomes merge and divide in a process termed mitosis, the fertilized ovum, or zygote, as it is now called, divides into two equal-sized daughter cells. The mitotic division gives each daughter cell 44 autosomes, half of which are of maternal and half of paternal origin. Each daughter cell also has either two X-chromosomes, making the new individual a female, or an X- and a Y-chromosome, making it a male. The sex of the daughter cells is determined, therefore, by the sex chromosome from the male parent.

Fertilization occurs in the uterine tube. How long the zygote remains in the tube is unknown, but it probably reaches the uterine cavity about 72 hours after fertilization. It is nourished during its passage by the secretions from the mucous membrane lining the tube. By the time it reaches the uterus it has become a mulberry-like solid mass called a morula. A morula is composed of 60 or more cells. As the number of cells in a morula increases, the zygote forms a hollow bubble-like structure, the blastocyst. The blastocyst, nurtured by the uterine secretions, floats free in the uterine cavity for a short time and then is implanted in the uterine lining. Normally, the implantation of the blastocyst occurs in the upper portion of the uterine lining. (The mechanism of implantation is described below.)

The morula and the blastocyst

DIAGNOSIS OF PREGNANCY

Symptoms and signs; biological tests. There is usually little doubt about the diagnosis when a young woman has missed several menstrual periods, has morning nausea, fullness and tenderness of the breasts, and has been having a normal sexual life; but the positive and certain signs of gestation are the sounds of the fetal heartbeat, which are audible with a stethoscope between the 16th and the 20th week of pregnancy; X-ray views of the fetal skeleton, which can be observed by the 14th or the 16th week; and fetal movements, which usually occur by the 18th to the 20th week of pregnancy. X-ray examinations generally are avoided, however, because of their potential hazard to the fetus.

Persons who note their body temperature upon awakening, as many women do who wish to know when they are ovulating, may observe continued elevation of the temperature curve well beyond the time of the missed period; this is strongly suggestive of pregnancy. During the early months of pregnancy, women may notice that they urinate frequently, because of pressure of the enlarging uterus on the bladder; that they feel tired and drowsy; dislike foods that were previously palatable; have a sense of pelvic heaviness; are subject to vomiting (which can be severe) and to pulling pains in the sides of the abdomen, as the growing uterus stretches the round ligaments that help support it, singly or together. Most of these symptoms subside as pregnancy progresses. The signs and symptoms of pregnancy are so definite by the 12th week that the diagnosis is seldom a problem.

Biological tests for pregnancy depend upon the production by the placenta (the temporary organ that develops in the womb for the nourishing of the embryo and the elimination of its wastes) of chorionic gonadotropin, an ovary-stimulating hormone. In practice, the tests have an accuracy of about 95 percent, although false negative tests may run as high as 20 percent in a series of cases. False negative reports are frequently obtained during late pregnancy when the secretion of chorionic gonadotropin normally decreases. The possibility not only of false negative but also of false positive tests makes the tests, at best, probable rather than absolute evidence of the presence or absence of pregnancy. Chorionic gonadotropin in a woman's blood or urine indicates only that she is harbouring living placental tissue. It does not tell anything about the condition of the fetus. In fact, the greatest production of chorionic gonadotropin occurs in certain placental abnormalities and disorders that can develop in the absence of a fetus.

Biological tests for pregnancy

Tests using immature mice (the Aschheim-Zondek test) and immature rats have been found to be extremely accurate. Tests using rabbits (the Friedman test) have been largely replaced by the more rapid and less expensive frog and toad tests.

The use of the female South African claw-toed tree toad, *Xenopus laevis*, is based on the discovery that this animal will ovulate and extrude visible eggs within a few hours after it has received an injection of a few millilitres of urine from a pregnant woman. The male common

frog, *Rana pipiens,* will extrude spermatozoa when treated in the same way. Both of these tests are considered somewhat unsatisfactory because false positive reactions are not uncommon.

Several immunological reaction tests in common use are based upon the inhibition of hemagglutination (clotting of red cells). A positive test is obtained when human chorionic gonadotropin (HCG) in the woman's urine or blood is added to human chorionic gonadotropin antiserum (rabbit blood serum containing antibodies to HCG) in the presence of particles (or red blood cells) coated with human chorionic gonadotropin. The hormone from the woman will inhibit the combination of coated particles and antibody, and agglutination does not occur. If there is no chorionic gonadotropin in her urine, agglutination will occur and the test is negative.

Several "signs" noted by the physician during an examination will suggest that a patient may be in the early months of pregnancy. Darkening of the areola of the breast (the small, coloured ring around the nipple) and prominence of the sebaceous glands around the nipple (Montgomery's glands); purplish-red discoloration of the vulvar, vaginal, and cervical tissues; softening of the cervix and of the lower part of the uterus and, of course, enlargement and softening of the uterus itself are suggestive, but not necessarily proof of pregnancy.

Conditions that may be mistaken for pregnancy. Other conditions may confuse the diagnosis of pregnancy. Absence of menstruation can be caused by chronic illness, by emotional or endocrine disturbances, by fear of pregnancy or by a desire to be pregnant. Nausea and vomiting may be of gastrointestinal or psychic origin. Tenderness of the breasts can be due to a hormonal disturbance.

Absence of menstruation; false positive tests

Any condition that causes pelvic congestion, such as pelvic tumour, may cause duskiness of the genital tissues. At times a soft tumour of the uterus may simulate a pregnancy. The question of pregnancy may be raised if the woman does not menstruate regularly; the absence of other symptoms and signs of gestation indicates that she is not pregnant. There are rare ovarian and uterine tumours that produce false positive pregnancy tests. It may be difficult for the physician to exclude pregnancy on the basis of his examination if the uterus is tipped back and difficult to feel, or if it is enlarged by a tumour within it. He is helped by the fact that the other signs of pregnancy are absent and that the tests for pregnancy are usually negative.

Childless women who greatly desire a baby sometimes suffer from false or spurious pregnancy (pseudocyesis). They stop menstruating, have morning nausea, "feel life," and have abdominal enlargement caused by fat and intestinal gas. At "term" they may have "labour pains." Signs of pregnancy are absent. Treatment is by psychotherapy.

Menopausal women often fear pregnancy when their periods stop; information that they show no signs of pregnancy usually reassures them. Retained uterine secretions of bloody or watery fluid, caught above a blocked mouth of the uterus (cervix), prevent menstruation, cause softening and enlargement of the uterus, and may cause the patient to wonder whether she is pregnant. There are no other signs of pregnancy, and the hard cervix, closed by scar tissue, explains the problem.

Duration of pregnancy. There are, as a rule, 266–270 days between ovulation and childbirth, with extremes of 250 and 285 days. Physicians usually determine the date of the estimated time for delivery by adding seven days to the first day of the last menstrual period and counting forward nine calendar months; *i.e.*, if the last period began on January 10, the date of delivery is October 17. This is approximately 280 days or ten lunar months. Courts of law, in determining the legitimacy of a child, may accept much shorter or much longer periods of gestation as being within the periods of possible duration of a pregnancy. One court in the state of New York has accepted a pregnancy of 355 days as legitimate. British courts have recognized 331 and 346 days as legitimate with the approval of medical consultants. Fully developed infants have been born as early as 221 days after the first day of the mother's last menstrual period.

Since the exact date of ovulation is usually not known, it is seldom possible to make an accurate estimate of the date of delivery. There is a 5 percent chance that a baby will be born on the exact date estimated from the above rule. There is a 25 percent chance that it will be born within four days before or after the estimated date. There is a 50 percent chance that delivery will occur on the estimated date plus or minus seven days. There is a 95 percent chance that the baby will be born within plus or minus 14 days of the estimated date of delivery.

ANATOMIC AND PHYSIOLOGIC CHANGES THAT ATTEND THE PROGRESS OF NORMAL PREGNANCY

Changes in organs and tissues directly associated with childbearing. *Ovaries.* The ovaries of a nonpregnant young woman who is in good health go through cyclic changes each month. These changes centre about a follicle, or "egg sac." A new follicle develops after each menstrual period, casts off an egg (ovulation), and, after ovulation, forms a new structure (the corpus luteum).

Ovulation and formation of corpus luteum; progesterone and estrogen

If the egg is fertilized, it is sustained for a short time by the hormones produced by the corpus luteum. Progesterone and estrogen, secreted by the corpus luteum, are essential for the preservation of the pregnancy during its early months. If pregnancy does not occur, the egg disintegrates and the corpus luteum shrinks. As it shrinks, the stimulating effect of its hormones, progesterone and estrogen, is withdrawn from the endometrium (the lining of the uterus), and menstruation occurs. The cycle then begins again.

Pregnancy, if it occurs, maintains the corpus luteum by means of the hormones produced by the young placenta. The corpus luteum is not essential in human pregnancy after the first few weeks because of the takeover of its functions by the placenta. In fact, human pregnancies have gone on undisturbed when the corpus luteum has been removed as early as the 41st day after conception. Gradually the placenta, or afterbirth, begins to elaborate progesterone and estrogen itself. By the 70th day of pregnancy the placenta is unquestionably able to replace the corpus luteum without endangering the pregnancy during the transfer of function. At the end of pregnancy the corpus luteum has usually regressed until it is no longer a prominent feature of the ovary.

During the first few months of pregnancy the ovary that contains the functioning corpus luteum is considerably larger than the other ovary. During pregnancy, both ovaries usually are studded with fluid-filled egg sacs as a result of chorionic gonadotropin stimulation; by the end of pregnancy, most of these follicles have gradually regressed and disappeared.

The blood supply to both ovaries is increased during pregnancy. Both glands frequently show plaques of bright red fleshy material on their surfaces, which, if examined microscopically, show the typical cellular change of pregnancy, called a decidual reaction. In this reaction, cells develop that look like the cells in the lining of the pregnant uterus. They result from the high hormone levels of pregnancy and disappear after the pregnancy terminates.

The uterus and the development of the placenta. The uterus is a thick-walled, pear-shaped organ measuring seven centimetres (about 2.75 inches) in length and weighing 30 grams (about one ounce) before pregnancy. It has a buttonlike lower end, the cervix, that merges with the bulbous larger portion, called the corpus. The corpus comprises approximately three-fourths of the uterus. There is a flat, triangular-shaped cavity within the uterus. At term, the uterus is a large, thin-walled, hollow, elastic, fluid-filled cylinder measuring approximately 30 centimetres (about one foot) in length, weighing approximately 1,200 grams (2.6 pounds), and having a capacity of 4,000 to 5,000 millilitres (4.2–5.3 quarts).

The uterus before and during pregnancy

The greater size of the uterus as a result of pregnancy is due to a marked increase in the number of muscle fibres, blood vessels, nerves, and lymphatic vessels in the uterine wall. There is also a five- to tenfold increase in the size of the individual muscle fibre and marked enlargement in the diameters of the blood and lymph vessels.

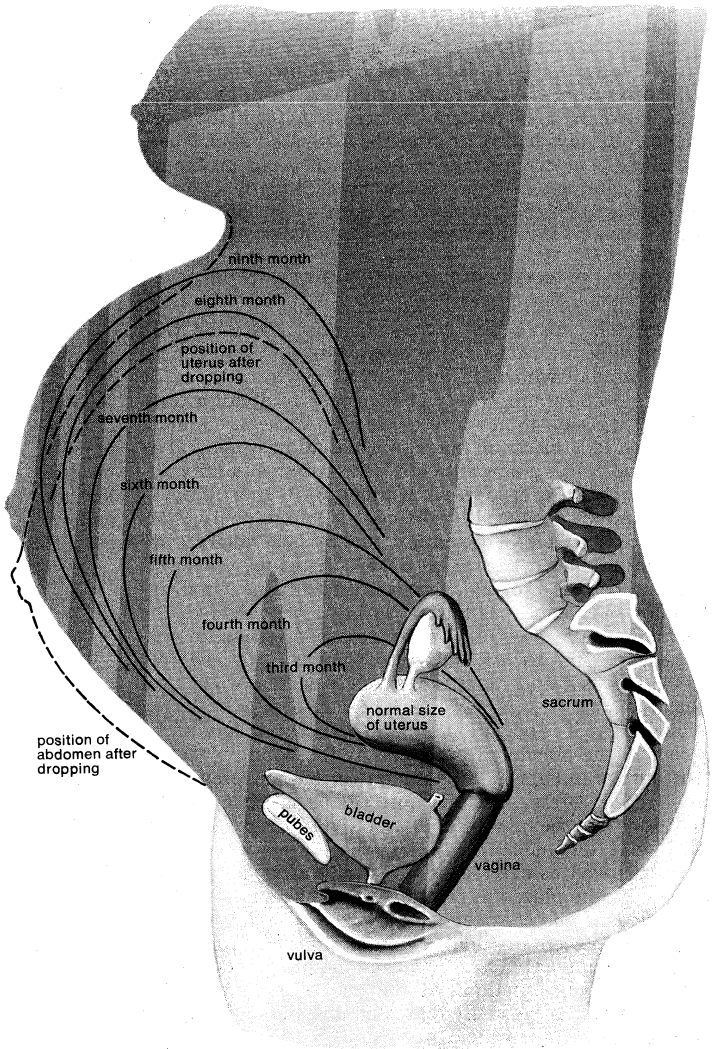

Figure 1: Levels of the uterus with advancing months of pregnancy.
From *Dorland's Illustrated Medical Dictionary*, 24th ed. (1965); W.B. Saunders Co., Philadelphia

During the first few weeks of pregnancy, the shape of the uterus is unchanged, but the organ becomes gradually softer. By the 14th week it forms a flattened or oblate spheroid. The fibrous cervix becomes remarkably softer and acquires a protective mucus plug within its cavity, but otherwise it changes little before labour. The lower part of the corpus, the isthmus, first becomes elongated and then, as the uterine contents demand more space, stretches and unfolds to form a bowl-shaped formation called the lower uterine segment. The fibrous nature of the cervix causes it to resist this unfolding action.

The uterine wall is stretched and thinned during pregnancy by the growing conceptus, as the whole product of conception is called, and by the fluid that surrounds it. By term, this process converts the uterus into an elastic, fluid-filled cylinder. It is only late in pregnancy that the cervix gradually thins out and softens; during labour it dilates for passage of the infant.

As pregnancy progresses, the uterus rises out of the pelvis and fills the abdominal cavity. It is top-heavy near term so that it falls forward and, because of the large bowel on the left side, rotates to the right. It presses on the diaphragm and pushes the other organs aside. The uterus may sink downward in the pelvis several weeks before term in a process that is known as lightening or dropping. This occurs as the fetal head descends into the pelvis. In some women, particularly those who have borne children, lightening does not occur until the onset of labour. Lightening may be impossible in women who have an abnormally small pelvis, an oversized fetus, or a fetus lying in an abnormal position.

For a short time after fertilization, the conceptus, a minute bubblelike structure called a blastocyst, lies unattached in the uterine cavity. The cells that will become the embryo (the embryonic disk) form a thickened layer on one side of the bubble. Elsewhere, the walls of the bubble consist of a single layer of cells; these cells are the trophoblast, which has a special ability to attach to and invade the uterine wall. The trophoblast plays an important role later in the development of the placenta or afterbirth. The conceptus makes contact with the uterine lining about the fifth or sixth day after conception. After contact the blastocyst collapses to form a rounded disk with the embryonic mass on the surface and the trophoblast against the endometrium (uterine lining). The part of the trophoblast that is in contact with the endometrium grows into and invades the maternal tissue. Concomitant disintegration of the endometrium allows the conceptus to sink into the uterine lining.

Implantation

Soon the entire blastocyst is buried in the endometrium. Proliferation of the trophoblast over the part of the collapsed bubble that is opposite the embryo is part of the implantation procedure that helps to cover the blastocyst. After a few days, a cavity forms that bears the same relation to the embryonic disk that the blastocyst cavity did before; this cavity will become the fluid-filled chorionic cavity containing the embryo. Ultimately it will contain the amniotic fluid that surrounds the fetus, the fetus itself, and the umbilical cord.

The chorionic cavity

The body stalk, which will become the umbilical cord, then begins to separate the embryo from the syncytiotrophoblast, the outer layer of the trophoblast lying against the endometrium; the inner lining of the trophoblast is called cytotrophoblast. As the syncytiotrophoblast advances into the endometrium, it surrounds minute branches of the uterine arteries that contain maternal blood. Erosion of the endometrium about these blood sinuses allows them to open into the small cavities in the trophoblast. The cytotrophoblast, which lines the cavity,

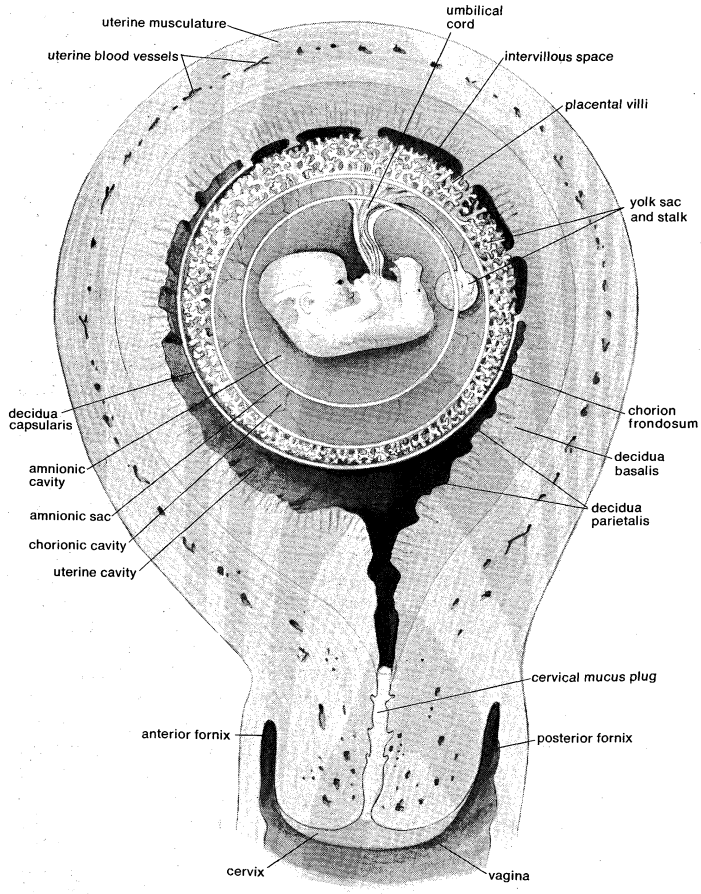

Figure 2: Sagittal section of the pregnant uterus at the seventh week of pregnancy showing the placenta and fetal membranes.

forms fingers of proliferating cells extending into the syncytiotrophoblast. After the placenta is developed, these fingers will be the cores of the rootlike placental villi, structures that will draw nutrients and oxygen from the maternal blood that bathes them. This is the first step in uteroplacental circulation, which supplies the fetus with all of the sustenance necessary for life and growth and removes waste products from it. During the third week of pregnancy, the syncytiotrophoblast forms a single layer of cells covering the growing villi and lining the syncytial lacunae or small cavities between the villi. The conceptus is buried in the endometrium, and its whole surface is covered at this time by developing villi. The greater part of the chorionic wall is now cytotrophoblast. Fingers of cytotrophoblast in the form of cell masses extend into the syncytial layer. Soon thereafter, a layer of connective tissue, or mesoderm, grows into the villi, which now form branches as they spread out into the blood-filled spaces in the endometrium adjacent to the conceptus.

By the end of the third week, the chorionic villi that form the outer surface of the chorionic sac are covered by a thick layer of cytotrophoblast and have a connective tissue core within which embryonic blood vessels are beginning to develop. The vessels, which arise from the yolk sac, connect with the primitive vascular system in the embryo. As growth progresses the layer of cytotrophoblast begins to regress. It disappears by the fifth month of pregnancy.

The layer of endometrium closest to the encroaching conceptus forms, with remnants of the invading syncytiotrophoblast, a thin plate of cells known as the decidua basalis, the maternal component of the mature placenta; it is cast off when the placenta is expelled. The fetal part of the placenta—the villi and their contained blood vessels—is separated from the decidua basalis by a lakelike body of fluid blood. This pool was created by coalescence of the intervillous spaces. The intervillous spaces in turn were formed from the syncytial lacunae in the young conceptus. Maternal blood enters this blood mass from the branches of the uterine arteries. The pool is drained by the uterine veins. It is so choked by intermingling villi and their branches that its continuity is lost on gross inspection.

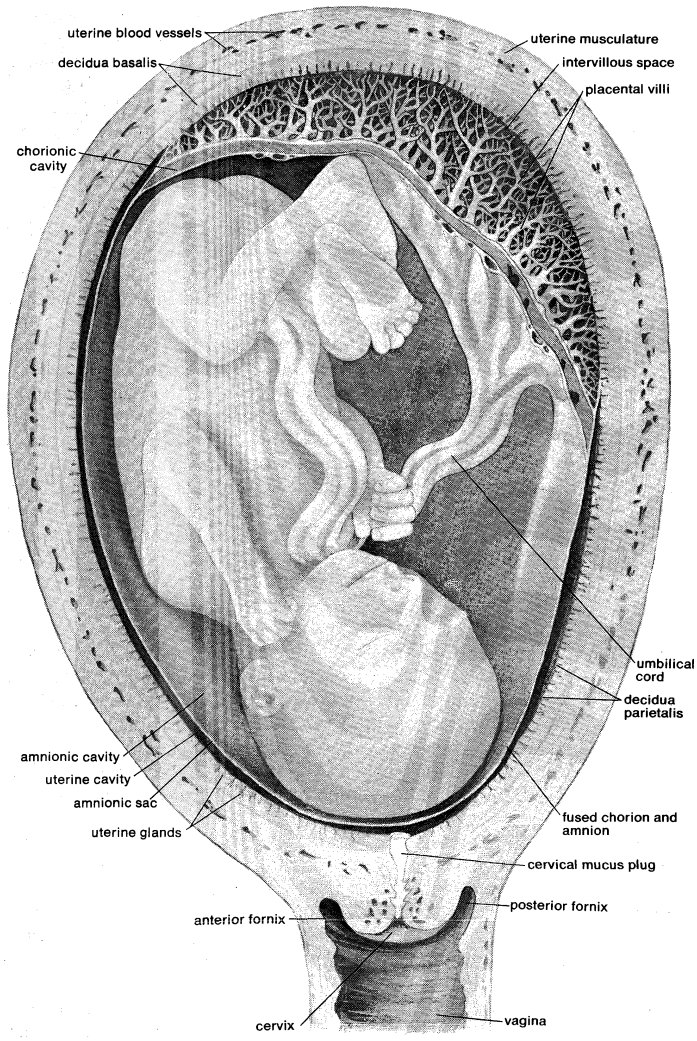

Figure 3: Sagittal section of the uterus at the fourth month of pregnancy.

The decidua capsularis, the chorion laeve, and the chorion frondosum

The chorionic cavity contains the fluid in which the embryo floats. As its shell or outer surface becomes larger, the decidua capsularis, which is that part of the endometrium that has grown over the side of the conceptus away from the embryo (*i.e.*, the abembryonic side) after implantation, becomes thinner. After 12 weeks or so, the villi on this side, which is the side directed toward the uterine cavity, disappear, leaving the smooth chorion, now called the chorion laeve. The chorion frondosum is that part of the conceptus that forms as the villi grow larger on the side of the chorionic shell next to the uterine wall. The discus-shaped placenta develops from the chorion frondosum and the decidua basalis.

At term, the normal placenta is a disk-shaped structure approximately 16 to 20 centimetres (about six to seven inches) in diameter, three or four centimetres (about 1.2–1.6 inches) in thickness at its thickest part, and weighing between 500 and 1,000 grams (1.1 and 2.2 pounds). It is thinner at its margins, where it is joined to the membrane-like chorion which spreads out over the whole inner surface of the uterus and contains the fetus and the amniotic fluid. The amnion, a thinner membrane, is adherent to and covers the inner surface of the chorion. The inner or fetal surface of the placenta is shiny, smooth, and traversed by a number of branching fetal blood vessels that come together at the point—usually the centre of the placenta—where the umbilical cord attaches. The maternal or uterine side of the placenta, covered by the thin, flaky decidua basalis, a cast-off part of the uterine lining, is rough and purplish-red, and has a raw appearance. When the placenta is cut across, its interior is seen to be made of a soft, crepelike or spongy matrix from which semisolid or clotted blood, caught when it is separated from the uterine wall to which it was attached, can be squeezed. Detailed examination shows that the villi and their branches form an arborescent (treelike) mass within the huge blood lake of the intervillous space. Anchoring villi extend outward from the fetal side and fuse with the decidua basalis to hold the organ's shape. Others, algae-like, float freely in the blood lake. Dividing partitions, formed from the trophoblast shell, project into the intervillous space from the decidual side. They divide the placenta into 15 or 20 compartments, which are called cotyledons.

Maternal blood flows from the uterine vessels into the trophoblast-lined intervillous blood lake. Within each villus is a blood vessel network that is part of the fetal circulatory system. Blood within the villous vessel is circulated by the fetal heart. The blood vessel wall, the connective tissue of the villous core, and the syncytiotrophoblast covering the villus lie between the fetal and the maternal bloodstreams. This is known as the placental barrier. As pregnancy progresses, the fetal blood vessels become larger, the connective tissue stretches over them, and the syncytiotrophoblastic layer becomes fragmentary. As a result, the placental barrier becomes much thinner. Normally, blood cells and bacteria do not pass through it, but nutrients, water, salt, viruses, hormones, and many other substances, including many drugs, can filter across it.

Uterine tube as site of fertilization

Uterine tubes. One of the two uterine tubes is the pathway down which the ripe ovum travels on its way to the uterus or womb. The spermatozoa from the male migrate up the tube, and it is there that they meet the ovum and fertilization occurs. During the first few days after fertilization the zygote, or fertilized egg, moves downward in the tube toward the uterus. While it is lying free in the tubal canal the young conceptus is nourished by secre-

tions from the tube. After the fertilized egg (or conceptus) passes into the uterus the tube ceases to play any part in the pregnancy; in fact, the only function the tube has is carried out during those few days before, during, and after conception. As pregnancy goes on the tube gradually enlarges, however, and contains more blood, as do all the pelvic organs; some of its cells may show a reaction, called a decidual reaction, to the hormones of pregnancy. As the uterus increases in size, the tubes stretch upward with it until they become two greatly enlarged elongated strands, one on each side of the uterus.

Vagina. The pinkish-tan colour of the lining of the vagina gradually takes on a bluish cast during the early months of pregnancy as a result of the dilation of the blood vessels in the vaginal wall; later the vaginal wall tends to become a purplish-red colour as the blood vessels become further engorged. The cells of the vaginal mucosa increase in size. Added numbers of these cells peel off the surface of the mucosa and mix with the increased vaginal fluid. This produces a profuse vaginal secretion. Thickening, softening, and relaxation of the loosely folded, succulent lining of the vagina and the sodden tissues beneath it greatly increase distensibility and capacity of the vaginal cavity; this is a process that partially prepares the birth canal for the passage through it of the large fetal mass.

External genital structures. Changes in the external genitalia are similar to those in the vagina. The tissues become first softened and more succulent and later extremely fragile, as an increasing amount of blood and fluid collects in them. They take on a purplish-red colour because of increased blood supply. Darkening of the vulvar skin, frequently seen during pregnancy, is particularly common among women of Mediterranean ethnic groups.

The blood vessels, muscles, and ligaments

Other pelvic tissues. The pelvic blood vessels and lymph channels become larger and longer. They develop new branches adequate to transport the greatly increased amounts of blood and tissue fluid that accumulate in the uterus and the other pelvic organs during pregnancy. Congestion and engorgement of blood in the pelvis, both within and without the uterus, are characteristic of pregnancy.

Changes in the muscles, ligaments, and other supporting tissues of the pelvis begin early in pregnancy and become progressively more pronounced as pregnancy continues. These changes are induced by the greatly increased hormonal levels in the mother's blood that characterize pregnancy. Before labour starts, the pelvic supporting tissues must have sufficient elasticity and strength to permit the uterus to grow out of the pelvis and yet support it. The muscles must be soft and elastic enough during delivery so that they can stretch apart and not obstruct the baby's birth. Softening and greater elasticity is brought about not only by the growth of new tissue but also by congestion and retained fluid within the tissues themselves.

The bones forming the mother's pelvis show relatively few changes during pregnancy. Loosening of the joint between the pubic bones in front and of the joints between the sacrum and the pelvis in back occurs as a response to the hormone called relaxin, which is produced by the ovary. Although relaxin, which causes marked separation of the pelvic joints in some animals, usually has too slight an effect in human beings to be noticed, softening of the attachments between the bones may be sufficient to cause a few women considerable distress. The strain on the joint between the sacrum and the spine becomes greater near term when the woman tilts her pelvis forward and bends the upper part of her body backward to compensate for the weight of the heavy uterus. When relaxation is excessive the woman suffers from backache and difficulty in walking. If it is extreme, she may have a waddling gait. Relaxation of the pelvic joints does not disappear quickly after delivery; it accounts for much of the backache complained of by women with new babies.

The mother's bones show no structural change if her calcium reserve and intake are normal. If her reserve and intake are not adequate, the fetus may draw so much calcium from her bones that the bones become soft and deformed. This condition is rarely seen, except in areas of the world where extreme poverty and serious calcium deficiency are major problems.

Changes in the breasts before and after delivery

Breasts. The earliest changes in the breasts in pregnancy are an exaggeration of the frequently experienced premenstrual discomfort and fullness. The sensation is so specific for pregnancy that many women who have been pregnant before are made aware of their condition by the feeling that they have in their breasts. As pregnancy progresses the breasts become larger, the lightly pigmented area (areola) around each nipple becomes first florid or dusky in colour and then appreciably darker; during the later months the areola takes on a hue that is deep bronze or brownish-black, depending on the woman's natural pigmentation. The veins beneath the skin over the breast become enlarged and more prominent. The small oily or sebaceous glands (glands of Montgomery) about the nipple become prominent.

These changes are due to the greatly increased levels of estrogen and progesterone in the woman's blood. These ovarian hormones also prepare the breast tissue for the action of the lactogenic (milk-causing) hormone, prolactin, produced by the pituitary gland. During the later part of pregnancy a milky fluid, colostrum, exudes from the ducts or can be expressed from them.

After delivery, the decrease in the estrogen and progesterone levels presumably permits the pituitary gland to release prolactin, which causes the breast to secrete milk. It is thought that the high hormonal levels inhibit the action or secretion of prolactin before delivery. Prolactin continues to be produced, and lactation usually continues, as long as the mother feeds her baby at the breast.

Anatomic and physiologic changes in other organs and tissues. *Cardiovascular and lymphatic systems.* During pregnancy the increasing needs of the growing fetus and of her own tissues throw an added burden on the mother's heart. The work that the heart does is measured by the amount of blood it expels per minute (the cardiac output). Rapid increase in the cardiac output occurs between the 9th and the 14th week of gestation. During the period from the 28th to the 30th week, when the load is heaviest, the heart of a pregnant woman is doing 25 to 30 percent more work than it was doing before pregnancy. As the time of delivery approaches, the heart's work load diminishes to some extent; when the baby is born the load is approximately equal to what it was when the mother was in the nonpregnant state. This decrease in cardiac output and cardiac work, which occurs in spite of the continued needs of the fetus and of the maternal tissues for blood-borne oxygen and nutriments, is explained by the more efficient way that the tissues draw on the mother's blood for oxygen and nourishment during the terminal weeks of pregnancy.

The position of the heart

The position of the heart is changed to a greater or lesser degree during pregnancy. As the uterus enlarges it elevates the diaphragm. This in turn pushes the heart upward, to the left, and somewhat forward, so that it is nearer the chest wall beneath the breast. Near the end of gestation the large uterus may raise the heart until the latter lies almost at a right angle to the long axis of the woman's body. These changes, which also bring some rotation of the heart, vary considerably in different individuals. When present to a marked degree, they may give an examining physician the erroneous impression that a normal heart is considerably enlarged. Actually, in spite of its greater work load, a healthy heart enlarges little or not at all even during the midportion of pregnancy, when the load is greatest.

Changes in the position of the heart, the greater work load, the increased volume of blood that the heart expels per beat, the decreased viscosity of the blood, and the larger amount of blood in the woman's blood vessels (discussed below), will, in many women, cause some distortion of the sounds that the physician hears when he listens to a patient's heart with his stethoscope. Such distorted sounds, called "functional" murmurs (as distinguished from "organic" murmurs, which may be present when the heart is diseased), do not indicate that anything is amiss, although they may be sufficiently atypical to

cause the obstetrician to refer the patient to a cardiologist for evaluation. Pregnancy sometimes produces minor changes in the electrocardiogram, but these changes are within normal limits.

Such is the ability of the heart to respond to an increased work load that even the pregnant woman with serious heart disease, given proper care and without an unexpected complication, will usually go through her pregnancy and delivery without a catastrophe. She is likely, however, to encounter disaster when she tries to cope with the stress of caring for her family after the baby is born.

Blood pressure and pulse rate

Normal pregnancy does not increase the mother's blood pressure. Indeed, a slight lowering of the blood pressure is commonly noted during the course of the pregnancy. Any notable rise in a pregnant woman's blood pressure is reason for alertness on the part of her physician, and if it continues to rise, for concern; it usually foretells the onset of toxemia (see below).

The pulse rate is a trifle more rapid during pregnancy, reflecting the more rapid heartbeat that is necessary in order to move the larger volume of blood present. The rate at which blood flows through the myriads of small blood vessels in the skin (the peripheral circulation) is accelerated during pregnancy, leading to the elevated skin temperature, the tendency to perspire, and, in part, to the redness of the palms and the tiny dilated blood vessels in some women as their pregnancies progress.

The most notable change in the circulatory system during pregnancy, other than those described in the heart, is a slowing of the blood flow in the lower extremities. With this decrease in the rate of flow there is an increase in the pressure within the veins and some stasis—stagnation—of the blood in the legs. These changes, which are believed to be caused primarily by the pressure of the uterus on the large blood vessels in the pelvis, are progressive during pregnancy and disappear after delivery. They also are thought to be caused in part by the marked increase in the amounts of the hormones estrogen and progesterone in the circulating blood. Increased venous pressure, slowing of the rate of venous flow, and partial stasis of the blood in the veins are major factors in causing the swelling of the legs and the varicose (abnormally dilated) veins of the lower legs that are commonly present near the end of pregnancy.

Edema in legs

The lymphatic vessels of the pregnant woman's pelvis become enlarged in response to the increased amount of tissue fluid in the engorged pelvic organs. As the uterus grows in size it presses on these channels, causing impairment of the lymphatic drainage from the woman's legs, with resultant swelling and distention of her feet and legs.

Although some fluid almost invariably collects in the feet, ankles, and legs near the time of delivery, sudden swelling of the feet and legs or a notable increase in swelling may be an early signal of impending toxemia, a serious disorder of pregnancy that is discussed below. Generalized swelling—*i.e.*, swelling of the hands, face, and other parts of the body—is a cause for serious concern.

Respiratory tract. One would expect that, as the uterus grows larger and pushes the diaphragm up, it would interfere with breathing, but the lungs actually work as efficiently as they do in the nonpregnant state. This is due to a change in the shape of the chest cavity during pregnancy; the chest diameter increases as its height decreases, so that there is actually a slight increase in the space that the lungs occupy.

The amount of air drawn in and expelled per minute by the lungs increases progressively during pregnancy. Immediately before delivery the number of breaths per minute is approximately twice what it is after the baby is born. This, like so many of the other changes in the mother's body, is an adaptation of one of her vital functions that is necessary to supply her tissues and those of the growing fetus with increasing amounts of oxygen.

Gastrointestinal tract. A number of alterations, often causing more or less distress, occur in the physical condition and functions of the gastrointestinal tract during pregnancy.

Taste and smell

Disturbances of the sensations of taste and smell, relatively common during early months of gestation, are often accompanied by a dislike of odours and a distaste of foods formerly found to be not disagreeable. The inflammation of the mouth and gums that some pregnant women complain of is more often caused by poor oral hygiene, by vitamin deficiencies, or by anemia than by the pregnancy itself.

Hydrochloric acid and pepsin, adequate amounts of which are necessary for satisfactory digestion, are produced by the stomach in decreased amounts during pregnancy. This decrease in the amount of acid in the stomach may explain some of the otherwise inexplicable anemias that occasionally occur during the course of an otherwise seemingly normal pregnancy.

During pregnancy the stomach muscles lose some of their tone and become more flabby, and the contractility of the stomach is reduced. As a result, the time it takes for the stomach to empty its contents into the intestinal tract is prolonged. As pregnancy progresses, the stomach is pushed upward; near term it lies like a flabby pouch across the top of the uterus instead of hanging downward, as it normally does, in a semivertical position. The loss of tone of the stomach muscles, the decrease in stomach acidity, and the change in position of the stomach are conducive to the flow of intestinal contents back into the stomach.

These disturbances in gastric function are responsible, in part at least, for the intolerance for fatty foods, the indigestion, the discomfort felt in the upper part of the abdomen, and the heartburn experienced by most pregnant women at some time during their pregnancies.

The musculature not only of the stomach but also of the entire intestinal tract loses much of its tonicity. As a result, peristalsis, the series of wave-like movements of the intestines, is slowed, the length of time it takes food to pass through the intestinal tract is prolonged, and there is more or less stagnation of the intestinal contents.

Intestinal problems

Constipation and hemorrhoids that cause rectal pain and bleeding are common complaints during pregnancy. The constipation is caused by lack of tone of the intestinal tract and stagnation of the bowel contents. Pregnant women may also lose the urge to defecate because of the pressure of the uterus on the lower bowel and inhibition of a reflex stimulus, known as the gastrocolic reflex, from the stomach to the rectum. The latter mechanism, which depends on normal stomach function, is responsible for the increased activity of the lower bowel that follows increased stomach activity, such as that induced by eating. It is this reflex that causes many persons to feel a desire to defecate within an hour or so after eating a full meal. Hemorrhoids—greatly enlarged or varicose veins in the lower rectum—that appear during pregnancy are due to constipation, to stasis of blood in the pelvic veins, and to pressure by the enlarging uterus on the blood vessels in the pelvis.

Liver. The liver, which plays an essential role in many of the vital processes—processes as diverse as participating in the metabolism of nutriments and vitamins and the elimination of the waste products of metabolism—changes anatomically and functionally during pregnancy to meet the added load placed on it by the maternal organism, the enlarging uterus, and, to a lesser extent, the growing fetus.

The liver's ability to synthesize proteins and to supply minerals and nutriments is augmented in response to the increased requirements of the mother's tissue and the fetus. The liver adjusts to the greatly augmented amounts of hormones circulating in the mother's blood during pregnancy. It helps to dispose of or detoxify the larger amounts of waste material produced by the metabolic processes in the growing fetus, the enlarging uterus, and the mother's tissues. Furthermore, the blood vessels in the liver enlarge to accommodate the larger amount of blood in the mother's blood vessels. At the same time, the liver must compensate for the larger number of circulating red blood cells.

In response to these demands the liver increases in size and weight, and its blood vessels become larger, but

otherwise its anatomical structure changes relatively little during pregnancy.

The hormones produced by the placenta and the metabolic changes in the maternal organism, rather than the fetus, are the factors responsible not only for the increased work the liver does but also for many of the physical and functional alterations that appear during gestation.

Changes in bladder function

Urinary tract. Changes that take place in the bladder and the urethra during pregnancy are attributable to relaxation of the muscles supporting these structures, to change in position, and to pressure.

The uterus lies over the bladder and presses upon it during early pregnancy. Later the uterus rises out of the pelvis. As the uterus grows larger and moves upward, the bladder is pushed forward and pulled upward. The urethra, the tube through which urine is discharged from the bladder, is stretched and distorted. As these distortions take place, the wall of the bladder becomes thickened, the blood vessels become enlarged, and fluid collects in the tissues forming the wall of the bladder. The results are swelling, stasis of blood in the blood vessels, and some mechanical inflammation of the bladder wall.

The woman is likely to urinate frequently during the early months of pregnancy when the heavy uterus presses on the bladder. Frequent urination is less common during midpregnancy, but it recurs after the baby descends into the pelvis near the time of delivery. As the bladder and urethra are pulled upward and distorted by the growing uterus, the stretched muscles that control urination are less efficient, and the woman may lose some urine involuntarily when she coughs, sneezes, or laughs; this is known as stress incontinence.

The swelling, mechanical inflammation, and stasis of blood in the blood vessels of the bladder near the end of pregnancy are conducive to bladder infection, a symptom of which is pain on urination. A microscopic examination of the urine is necessary to differentiate between the effect of pregnancy on bladder function and the symptoms caused by a bladder infection. An untreated bladder infection may lead to serious urinary tract troubles later.

Structure and functioning of ureters

Changes in the structure and function of the ureters, the two rubbery, spaghetti-like tubes that carry urine from the kidneys to the bladder, are present in 80 percent of all pregnancies. As pregnancy progresses each ureter becomes larger, so that it lies in multiple broad curves rather than forming an almost straight line downward from the kidney. In addition, both ureters, but particularly the right one, become greatly dilated, so that the urine flows very slowly or collects in them.

The funnel-like part of the kidney, called the kidney pelvis, also becomes dilated. With this dilation of the kidney pelvis and the ureters there is also a loss of tonicity or contractility in the pelvis of the kidney and the ureters. This loss of tonicity during pregnancy is similar to that mentioned in the description of the changes in the intestinal tract. Since it is the contractility of peristalsis within the ureter that propels urine downward from the kidney into the bladder, stasis of urine in the ureter is accentuated during the pregnancy. In the nonpregnant state the hydrostatic pressure in the kidney is greater than that in the bladder; during pregnancy the situation is reversed. This change of pressure further increases the stasis of urine in the ureter and kidney pelvis. As a result, bladder infections are more serious during pregnancy, because they are more likely to involve the kidney.

After delivery the ureters rapidly return to their normal condition.

Ordinary functioning of kidney; changes in pregnancy

The kidney of a healthy person selectively filters and secretes water, sodium, potassium, chlorides, protein, and other substances from the blood. It then reabsorbs water and essential elements in amounts that are needed to maintain the fluid, electrolytic, and other chemical balances in the body. It also filters waste products of metabolism from the blood and excretes them in the urine. During pregnancy the kidney continues to carry on these functions. The work load placed on it, however, is greater because of the increase in the amount of water and blood and in the rate of metabolism during gestation.

In early pregnancy, secretion of large amounts of dilute urine of decreased acidity, together with pressure of the uterus on the bladder, causes frequency of urination and nocturnal voiding. Less urine is excreted toward the end of pregnancy. The storage of large amounts of nitrogen, as part of the metabolism of proteins, causes a decrease in the urinary excretion of urea and of total nitrogen during gestation.

Although many healthy pregnant women occasionally show a trace of protein (albumin) in their urine, the detection of even small amounts of protein in the urine is a cause for alertness on the part of a physician, because anything more than an extremely small amount may be the first signal of impending toxemia or kidney disease, both of which are serious complications.

The kidney's ability to reabsorb sugar (glucose) is lower during pregnancy, and for this reason many pregnant women have transient periods during which their urine contains small amounts of glucose; such women have unimpaired ability to metabolize carbohydrates and have normal sugar levels in the blood. Glucose in the urine also may be the first sign that a person has diabetes mellitus, however; consequently, a pregnant woman whose urine contains traces of glucose is tested to make sure that she can metabolize sugar normally.

The preceding discussion of kidney function illustrates the need for a pregnant woman to be under a physician's care, an essential part of which is periodic examination of her urine for protein, sugar, pus, bacteria, and other abnormal constituents.

Increase in blood volume

Blood. The total amount of blood in a pregnant woman's body has increased by approximately 25 percent by the time of delivery. The increase is accounted for by the augmented volume of blood plasma (the liquid part of the blood), which is caused by fluid retention, plus an increase in the total number of red blood cells. Additional blood is needed to fill the large vessels of the uterus. Also, more blood is required to carry the oxygen and nutriments needed by the fetus and the maternal tissues and to carry away waste products. Furthermore, it is a protective reserve in case of hemorrhage during delivery.

During pregnancy the blood-forming organs, such as the bone marrow, make more erythrocytes, or red blood cells, which carry iron and oxygen. Despite this, there is usually a decrease in a pregnant woman's blood cell count—the number of red cells per cubic millimetre of blood—because the amount of blood plasma increases approximately 30 percent, while the total number of red blood cells increases by only about 20 percent. This results in apparent anemia. With these changes, the viscosity of the blood decreases and the hematocrit, which measures the relative amounts of liquid and solid constituents in the blood, is lower. Usually there is a moderate increase in the number of white blood cells per cubic millimetre during early pregnancy; this increase disappears during the latter part of pregnancy.

If a pregnant woman is otherwise healthy and receives adequate available iron for the production of hemoglobin, her red blood cell count does not ordinarily fall below 3,750,000 cells per cubic millimetre, her hemoglobin below 13.5 grams per 100 cubic millimetres of blood, and her hematocrit below 35. (Normal values for nonpregnant women are 4,200,000–5,400,000 cells, 13.8–14.2 grams hemoglobin, and 37–47 hematocrit.) Physicians usually make blood counts for their pregnant patients every two months because of the need for repeated evaluation.

Endocrine system. Most of the endocrine glands become larger, and some display alterations in function, during pregnancy; they all revert to a normal state after delivery.

Pituitary, thyroid, pancreas, and adrenals

The anterior lobe of the pituitary gland increases in size during pregnancy, but the production of pituitary gonadotropins, the gonad-stimulating hormones, ceases soon after the placenta begins to produce chorionic gonadotropins. The pituitary continues to secrete the hormones that stimulate the other endocrine glands. Near term, as the mother's estrogen level drops, a milk-stimulating hormone, prolactin, is produced by the pituitary. The poste-

rior lobe of the pituitary gland does not change in size or weight during pregnancy.

The thyroid gland enlarges moderately, but there is no true increase in thyroid function during gestation. The parathyroid glands also increase in size during pregnancy but presumably are not otherwise affected by it.

The part of the pancreas that secretes insulin, the islets of Langerhans, becomes larger. Whatever increase in function is displayed may be assumed to be a balanced response to the body's demand for the products of carbohydrate metabolism. The level of plasma insulin or of insulin-like substances in the plasma is higher during pregnancy, and the destruction of insulin is also more rapid.

The blood and urinary levels of 17-hydroxycorticosteroids, hormones that affect protein, fat, and carbohydrate metabolism and that are produced by the adrenal glands, rise during pregnancy; but there is no increased effect from the hormones, because their higher level is more than offset by the increased levels of transcortin, a protein that inactivates them.

As gestation progresses, there is an elevation in the secretion of aldosterone, an adrenal hormone that plays a role in the retention of salt and water in the body. It has been suggested that this is a protective mechanism to counterbalance the tendency for progesterone to cause the excretion of sodium ions in the urine.

Changes in sweat glands and skin colour

Skin. Pregnancy usually causes an increase in the secretion of the oil and sweat glands in the skin. Body odours may become more pronounced. Many women notice that their hair becomes thinner and drier and their nails more brittle. Others may develop an increased amount of facial and body hair. The "mask of pregnancy" seen particularly in brunettes is a deposit of brownish pigment in the skin of the forehead, the cheeks, and the nose. Puffiness and thickening of her skin may cause the pregnant woman's face to appear coarse and almost masculine. Increased pigmentation, particularly of the smooth skin about the nipples (the areolas of the breasts) and the vulva, is almost universal.

Bright red discoloration of the palms of the hands and tiny spiderweb-like red blood vessels in the skin of the arms or face are not unusual during pregnancy. Many of these changes are thought to be associated with the greatly increased levels of estrogen in the mother's bloodstream. Most of the changes disappear after delivery.

"Stretch marks," which appear on the breasts and abdomen during pregnancy, are due to the tearing of the elastic tissues in the skin that accompanies enlargement of the breasts, distention of the abdomen, and the deposition of subcutaneous fat. They are pink or purplish-red lines during pregnancy. The lines become permanent grayish-white scarlike marks after delivery. Some women never develop stretch marks despite bearing several children; others lose most of the tone in their skin after one pregnancy. Stretch marks cannot be considered evidence that a woman has borne a child, however, because they sometimes are seen in women who have not been pregnant.

Metabolic changes. Metabolic changes during pregnancy are among the many adjustments that the mother's organs make to meet the requirements created by the increase in her own breast and genital tissues and the growth of the conceptus (the fetus and afterbirth). In addition, reserves must be established to meet the demands that will be put on her body during pregnancy, delivery, and the lying-in period.

The basal metabolic rate. The amount of oxygen consumed is an index of the pregnant woman's metabolism when she is at rest—her basal metabolism. The rate begins to rise during the third month of pregnancy and may double the normal rate (+10 percent) by the time of delivery. The rate rises in specific proportion to the size of the fetus and represents the effects of the mother's activities plus those of the fetus and the uterine structures. An elevation of the basal metabolic rate (BMR) to 20 or 25 percent during pregnancy is not an indication of an overly active thyroid gland.

Weight. The early part of pregnancy usually is accompanied by moderate weight loss caused by the woman's lack of appetite and her nausea and vomiting. Between the third and the ninth month of pregnancy most women gain about 20 pounds or more. Ideally, during pregnancy body weight is gained at the rate of about one pound per week for a total of not more than 20 to 25 pounds. In an average pregnancy the infant, the afterbirth, and the fluid in the uterus weigh about ten pounds. The uterus and the breasts together weigh approximately five pounds. The remaining five pounds consist of stored fluids and fat. Weight gain exceeding 25 pounds usually represents fat and fluids that are in excess of the reserve requirements for a normal pregnancy. A woman loses approximately 15 pounds at delivery, and another five pounds of stored fluid are eliminated as the uterus shrinks. She does not lose many additional pounds during the weeks following the delivery of the baby unless she limits her caloric intake. Fat stored during pregnancy is lost more slowly than stored fluids, proteins, and carbohydrates.

Excessive weight gain during pregnancy is a matter of concern for both the patient and the doctor. Although it may be only the result of overeating, it may be caused by a disturbance in metabolism and by an abnormal retention of fluids and salts. In the latter instance it may be the first sign of toxemia.

Changes in protein, carbohydrate, and fat metabolism

Protein. During pregnancy, nitrogen, derived from the metabolism of ingested protein, is needed for growth of the fetus, the placenta, the uterus, and the mother's breasts and other tissues. A considerable amount of nitrogen also is required for the increase in the mother's red cell volume and blood plasma. The fetus's demand for nitrogen is slight at first, but during the last month of pregnancy it acquires almost half of its total protein. In the process of accumulating this store and of building a reserve for the period after delivery, the woman who is on an adequate diet retains between two and three grams of nitrogen daily during her pregnancy; by term she and the fetus will have acquired approximately 500 grams (about 1.1 pounds) of nitrogen.

Carbohydrates. During pregnancy greater quantities of blood are being processed through the kidneys, but the kidneys are incapable of reabsorbing increased amounts of sugar. Consequently, a lower level of sugar in the blood is tolerated, and slight amounts of sugar are excreted in the urine. During pregnancy the level of sugar in the blood after fasting is slightly lower, probably because there is less utilizable insulin in the blood to regulate the sugar metabolism. Oral glucose tolerance tests show a prolonged elevation of blood sugar after ingestion of glucose; this may be an indication that carbohydrate utilization is less rapid or that the absorption of glucose from the gastrointestinal tract is slower. Glucose tolerance tests that depend on injection of the sugar solution into the veins show no difference between nonpregnant and pregnant nondiabetic women. A few women who are potential or mild diabetics demonstrate diabetes for the first time when they are pregnant. This is because pregnancy taxes insulin productivity in women with a marginal pancreatic islet reserve, so that diabetes may first become evident during gestation.

Fat. The total blood lipids average 600 to 700 milligrams per hundred millilitres of blood in the nonpregnant woman. They increase to approximately 900 to 1,000 milligrams per hundred millilitres of blood during the latter part of pregnancy. This increase, which involves all the lipid fractions, has not been explained, but it is worthy of notice that the gain in fat reaches its acme during the period that the fetus acquires most of its adipose (fatty) tissue.

Increases in body fluids

Water. Pregnancy is characterized by increases in the amount of body water and in the total volume of body fluid. During pregnancy between 3,500 and 4,000 millilitres of fluid (about 3.2 to 3.6 quarts) will be added to that already present in the tissues of a healthy woman. The uterus, the placenta, the amniotic fluid, and the fetus each account for approximately equal amounts. In addition to the water that makes the increased blood volume, there is also added fluid in the mother's muscles, her pelvic soft tissues, her breasts, and her other tissues.

Toward the end of pregnancy a considerable amount of

(E) In the isthmic part of the tube. (F) In the ampulla of the tube. (G) In the infundibulum of the tube. (H) In the ovary. (I) On the peritoneum with development of an abdominal pregnancy. (J) In the cornu of a double or rudimentary horn of a uterus.

retained fluid accumulates in the woman's lower extremities. It is this fluid that produces the pitting and swelling of the legs that many normally pregnant women display during the month or two before delivery.

Retention of large amounts of electrolytes, particularly sodium, accompanies the increase in the amount of body fluids. Approximately 12 grams of sodium are retained monthly. In addition to a positive sodium balance, there is a positive chloride and potassium balance during pregnancy. As a result, additional water is required to maintain the balance of the solution of sodium, chloride, and potassium in the blood, in the fluid of the spaces between the tissue cells, and within the cells themselves. Not all of the sodium, however, goes into fluid. Some of it is stored, and some replaces potassium in the cells.

A number of factors contribute to a positive sodium balance, which in turn leads to retention of fluid; these include alterations in the kidneys' excretion of sodium and water; increased retention of water in the pregnant woman's legs; the large amounts of hormones, particularly estrogen, that the placenta secretes; and the secretion of adrenal hormones, especially aldosterone. The latter, in particular, reduces the kidneys' secretion of sodium. Since sodium and water interact with each other, whatever contributes to the retention of one leads to the retention of the other. Generalized swelling appears when the accumulation of sodium and water becomes too great. If the excess continues the pregnant woman eventually develops toxemia.

Minerals. The pregnant woman's reserves and intake of iron and calcium must be enough not only for her own needs but also for those of the fetus. An increase in serum copper levels occurs during pregnancy. The mother has some phosphorus reserve but must acquire enough from her diet to supply her own tissues and those of the fetus. The utilization of phosphorus and that of calcium are interdependent, so that the utilization of phosphorus depends on the calcium intake.

II. Abnormal changes in pregnancy

ECTOPIC PREGNANCY

An ectopic pregnancy is one in which the conceptus (the products of conception; *i.e.*, the placenta, the membranes, and the embryo) implants or attaches itself in a place other than the normal location in the lining of the upper uterine cavity. The site of implantation may be either at an abnormal location within the uterus itself or in an area outside the uterus. Ectopic pregnancies outside the uterine cavity occur about once in every 300 pregnancies. They are one of the major causes of maternal deaths.

Normally an ovum or egg passes from the ovary into the tube, is fertilized in the tube, and moves downward into the uterus. It buries itself in the lining of the upper part of the uterine cavity. It may pass farther down and attach itself to the lining of the mouth of the uterus (the cervix), creating a cervical pregnancy. These are rare and cause severe vaginal bleeding; the conceptus is expelled or discovered within a few months after implantation.

Types of ectopic pregnancy

If a conceptus attaches itself to the lower part of the uterine cavity it is a low implantation. When a low implantation occurs the placenta grows over the cervical opening, in a formation called a placenta praevia. This causes the woman to bleed, often profusely, through the vagina, because the placenta tears as the cervix begins to open during the latter part of pregnancy.

When the fertilized egg implants in the narrow space or angle of the uterine cavity near the connection of the uterus with the fallopian tube, it is called an angular pregnancy; many angular pregnancies terminate in abortions; others go to term but are complicated because the placenta does not separate properly from the uterine wall after birth of the baby. An angular pregnancy differs from a cornual pregnancy, which develops in the side of a bilobed or bicornate uterus.

Implantation in the narrow part of the fallopian, or uterine, tube, which lies within the uterine wall, produces what is called an interstitial pregnancy. This occurs in approximately 4 percent of ectopic pregnancies. An interstitial pregnancy gradually stretches the wall of the uterus until, usually between the 16th and 20th week of gestation, the wall ruptures in an explosive manner and the woman bleeds profusely into her abdomen.

Most persons associate ectopic pregnancies with tubal pregnancies, because most ectopic pregnancies occur in the uterine tubes. The tube beyond the uterus has three parts: the isthmus, a narrow section near the uterus; the ampulla, which is wider and more dilatable; and the infundibulum, the flaring, trumpet-like portion of the tube nearest the ovary. A tubal ectopic pregnancy is designated by the area of the tube in which it is implanted. An isthmic pregnancy differs from one in the ampulla or infundibulum because the narrow tube cannot expand. Rupture of the affected tube with profuse intra-abdominal hemorrhage occurs early, usually within eight weeks after conception.

Ampullar pregnancies, which are by far the most common, usually terminate either in a tubal abortion, in which the embryo and the developing afterbirth are expelled through the open end of the tube into the abdomen; by a tubal rupture; or, less commonly, by absorption of the conceptus.

Sometimes the tube ruptures into the tissues attaching it to the wall of the pelvis, producing an intraligamentous pregnancy. Rarely, the embryo is expelled into the abdo-

men and the afterbirth remains attached to the tube; the embryo lives and grows. Such a condition is referred to as a secondary abdominal pregnancy. Primary abdominal pregnancies, in which the fertilized egg attaches to an abdominal organ, and ovarian pregnancies are rarer still.

Causes of tubal pregnancies

It is generally believed, but not proved, that most tubal pregnancies are caused by scars, pockets, kinks, or adhesions in the tubal lining resulting from tubal infections. The infection may have been gonorrhea; it may have occurred after an abortion, after the delivery of a baby, or after a pelvic surgical operation; or it may have been caused by appendicitis. Kinking, scarring, and partial adhesions of the outside of the tube may be the result of inflammation following a pelvic operation or of peritonitis or other abdominal inflammation. Tubes, defective from birth, may be too small for the passage of the conceptus or may be pocketed or doubled with one tubal half forming a blind pocket. There may be areas in the tubal lining that behave like the lining of the uterus (they show a decidual reaction that is conducive to implantation) so that they offer a favourable spot for the fertilized egg to implant. Pelvic tumours may distort the tube or press on it and obstruct it so that the conceptus cannot move downward. Theoretically, endocrine disturbances may delay tubal motility.

Whatever the cause, when a tubal implantation occurs it may be assumed that either migration of the fertilized egg within the tube was delayed by an extrinsic factor so that the egg grew to the point where it should implant or that the mechanism for implantation within the egg itself was prematurely activated in the tube. One or the other of these causative factors can sometimes be seen when a woman is operated upon for an ectopic pregnancy. There are a great number of cases, however, in which no abnormality of the tube can be found. There is no satisfactory explanation for most abnormal implantations in the uterus, although defective uterine structure has been noted in some cases.

Primary abdominal and ovarian pregnancies can best be explained by a mechanism in which the fertilized ovum is swept out of the tube by a reverse peristalsis of the tube, but it is quite possible that, in rare instances, the ovum and spermatozoa meet and fertilization and implantation take place within the abdomen.

Signs of ectopic pregnancy

Ectopic pregnancy is frequently mistaken for other disorders, and other disorders are frequently mistaken for it. Typically, but not invariably, the woman who has an ectopic pregnancy in the ampullar part of the tube will have missed one or two menstrual periods. She need not have other symptoms of pregnancy. She has felt enough discomfort in the lower part of her abdomen to lead her to consult a physician. She has had recurrent episodes of rather light, irregular bleeding from the vagina. She has felt weak or faint at times. The signs of pregnancy are not likely to be present, and results of a pregnancy test are more often negative than positive. The physician, on pelvic examination, feels a tender, soft mass in one side of the pelvis. At this stage he has to differentiate between an ectopic pregnancy and an intra-uterine pregnancy with abortion; acute appendicitis; intestinal colic; inflammation of a fallopian tube; and a twisted ovarian tumour. Unless the diagnosis can be made, the patient continues to complain for several more days and then has a sudden severe pain and collapses from brisk bleeding within the abdomen.

Only rarely are sudden acute abdominal pain and collapse due to severe hemorrhage the first signs that something is amiss. If this does happen it is usually because implantation has occurred in the isthmic portion of the tube and hemorrhage and tubal rupture occur simultaneously. More frequently a woman has missed one menstrual period, has a sensation of pelvic pressure, feels that she must urinate and collapses in the bathroom. She may be unconscious and pulseless from loss of blood when she arrives at the hospital.

Interstitial pregnancies are often mistaken for intra-uterine ones, but the patient has more pain than she would with a normal pregnancy and may have intermittent vaginal bleeding. After several months she has sudden severe pain, collapses from a massive intra-abdominal hemorrhage, and may die before surgical help can reach her. Most of the women who die from ectopic pregnancies do so from interstitial ones.

Combined pregnancies, in which there is an ectopic pregnancy and a normal one in the uterus, or a fetus in each tube, have occurred and have compounded the difficulty in making a diagnosis. In a number of instances the ectopic conceptus has been removed without complications, and the uterine fetus has progressed to term.

Not all ectopic pregnancies end with a catastrophic hemorrhage and collapse. In a few instances tubal, abdominal, and broad ligament pregnancies have gone on until a living baby was obtained at the time of operation. In other cases the fetus died and, if very young, was resorbed; in others, when the fetus was larger, death was followed by absorption of the fluid in the sac and the fetus was gradually converted into a more or less mummified mass. Some ectopic pregnancies of this type have caused no symptoms and have been carried by women for years. Undoubtedly many ectopic pregnancies that are in an early stage when they are expelled emerge through the open end of the uterine tube, are resorbed, and are never recognized.

Once diagnosed, the treatment of ectopic pregnancies outside the uterine cavity is almost always a matter of prompt surgical intervention with proper attention to replacement of blood and fluid.

ABORTION

What abortion is

Abortion is the termination of a pregnancy before the infant can survive outside the uterus. The age at which a fetus is considered viable has not been completely agreed upon. Many obstetricians use either 21 weeks or 400–500 grams (0.9–1.1 pounds) birth weight as the base line between abortion and premature delivery, because few infants have survived when they weighed less than 500 grams at birth or when the pregnancy was of less than 21 weeks' duration. Generally speaking, the fetus has almost no chance of living if it weighs less than 1,000 grams (2.2 pounds) and if the pregnancy is of less than 28 weeks' duration. In one effort to resolve the matter, the American College of Obstetricians and Gynecologists has defined abortion as the expulsion or extraction of all (complete) or any part (incomplete) of the placenta or membranes, with or without an abortus, before the 20th week (before 134 days) of gestation. Early abortion is an abortion that occurs before the 12th completed week of gestation (84 days); late abortion is an abortion that occurs after the 12th completed week but before the beginning of the 20th week of gestation (85–134 days).

In the past the word abortion has usually meant to nonmedical persons the criminal interruption of a pregnancy, whereas "miscarriage" indicated that there had been a spontaneous expulsion of the uterine contents. The term miscarriage is seldom used medically.

Spontaneous abortion is the expulsion of the products of conception before the 20th week of gestation without deliberate interference. As a general rule, natural causes are responsible for loss of the pregnancy. An induced abortion is the deliberate interruption of a pregnancy by any means before the 20th week of gestation. It may be therapeutic or nontherapeutic. A therapeutic abortion is the interruption of a pregnancy before the 20th week of gestation for legally acceptable, medically approved indications. This term may be used when a pregnancy is terminated because it endangers the mother's life or health or because the baby presumably would not be normal. A nontherapeutic abortion is the interruption of a pregnancy for nonmedical reasons by any means before the 20th week of gestation. The terms criminal abortion and illegal abortion are legal rather than medical terms.

Stages of spontaneous abortion

A spontaneous abortion usually passes through several progressive stages. The first stage is a threatened abortion in which a woman, known to be less than 20 weeks pregnant, notices a small amount of bloody discharge from her vagina and, perhaps, a few cramping pains in her uterus. By pelvic examination it is determined that her cervix has not started to open or dilate. Either the symp-

toms subside or the matter progresses to an inevitable abortion, in which there is increased bleeding, the uterine cramps become more severe, and the cervix, or mouth of the uterus, opens for the expulsion of the uterine contents. An inevitable abortion terminates either as a complete or an incomplete abortion, depending on whether or not all of the products of gestation are expelled. The process may start abruptly with pain and profuse bleeding and be over in a few hours, or it may go on for days with only a modest loss of blood. Spontaneous abortions early in pregnancy tend to be complete. When the pregnancy is further advanced it is more likely to be incomplete. Usually the physician removes the retained tissue in the uterus surgically when there is an incomplete abortion.

If the fetus dies and is retained in the uterus for eight weeks or longer the condition is referred to as a missed abortion. Women who lose three or more consecutive pregnancies of less than 20 weeks' duration are said to suffer from habitual abortion. An infected abortion is an abortion associated with infection of the genital organs.

Approximately 10 percent of all pregnancies terminate in spontaneous abortion. Some are lost so early that the woman and her physician are not sure whether she aborted or had a menstrual period that was slightly delayed, particularly heavy, and more painful than usual. The majority occur between the 6th and the 12th week after conception. The number of nontherapeutic abortions is unknown, but it probably equals the number of spontaneous ones. Modifications in the abortion laws in several countries, including the United States, have greatly increased the number of requested abortions; it is believed that in some areas the number of abortions exceeds that of babies delivered alive.

At least half of all early abortions are caused by defective development of the structures that grow from the fertilized egg; *i.e.*, the baby, the afterbirth, and the membranes that surround the baby and hold the water that it floats in. Some of these abortions are genetic accidents caused by abnormal characteristics carried in the egg or sperm or by the failure of normal development of the chromosomes after the egg and sperm unite. It has been shown in animals that disturbances in the transportation of the fertilized egg to the uterus may cause premature or delayed implantation of the conceptus; too young or too old fertilized eggs tend to abort. Inadequate secretion of the ovarian hormones estrogen and progesterone, needed for the development of the newly fertilized egg, may cause failure of the lining of the uterus and its secretions to sustain the young embryo. Later, failure of the placenta to take over the hormone-producing function of the ovary may adversely affect the growth of the uterus and its contractility. X-rays in large doses, radium, and certain drugs may cause abortion because they damage embryonic tissues. Abnormal development of the mother's uterus may make it impossible for it to retain the pregnancy. Late abortion is sometimes caused by the weakness of the mouth of the uterus or by fetal death following knotting of the umbilical cord. Uterine tumours may cause abortion because they increase uterine irritability or create an unfavourable environment for embryonic growth. In most instances in which psychic factors allegedly caused an abortion, examination of the baby and of the afterbirth have shown defects in one or both that had occurred before the mother had suffered her emotional disturbance. Physical injury to the mother is a causative factor in only one in a thousand abortions. Abortions thought to be caused by automobile accidents, falls, kicks, and so forth are often the result of deleterious changes in the fetus and sac that occurred before the injury. Systemic diseases may play a role in causing an abortion. This is particularly true of acute infectious diseases with high fever and bacteria in the bloodstream, or of diseases such as pneumonia, in which there is a marked reduction in the supply of oxygen to the fetus. Heart disease, kidney disease, diabetes, high blood pressure, and other chronic diseases may be associated with premature birth and fetal death after the 21st week but do not ordinarily cause abortions.

Causes of abortion

Perhaps 3 percent of threatened abortions are prevented by rest and hormonal therapy. Most abortions are inevitable because the fertilized egg is abnormal; these cannot be controlled medically. Many women who suffer from habitual abortion respond well to treatment; in some of these cases corrective surgery is necessary. An early spontaneous abortion without infection is rarely followed by ill health when the affected person is properly treated; but no abortion, regardless of where it is performed or by whom, is without hazard to the woman's health and life. Infected abortions, many the result of nontherapeutic interruptions of pregnancy, have caused sterility, prolonged suffering, and chronic pelvic distress; an appreciable loss of life has resulted from such infections.

Avoidance of abortion; effects of abortion

EFFECTS OF SYSTEMIC DISEASES ON PREGNANCY AND OF PREGNANCY ON SYSTEMIC DISEASES

Heart disease. Heart disease occurs in approximately 1 percent of pregnant women. It is first as a cause of maternal deaths among the disorders incidental to pregnancy and fourth, after hemorrhage, toxemia, and infection, as a cause of all maternal deaths. Rheumatic heart disease is the most prevalent type. Congenital heart disease accounts for approximately one-fourth of the cases.

A number of factors, including her response to physical activity, a history of heart failure, the type of heart disease that she has, and her age, are used in estimating how a particular woman will fare during pregnancy and labour. A person whose heart disease causes no limitation of normal physical activity will usually go through a normal pregnancy and delivery without notable difficulty, provided that she avoids undue physical activity, has sufficient rest, avoids infections, and is under the care of an obstetrician and a cardiologist who are on the alert for signs of early heart failure. Such a person will not face an appreciably increased risk, and her heart disease will not be affected by the pregnancy.

The woman whose physical activity is limited to some extent because it causes undue fatigue, shortness of breath, heart palpitation, or heart pain, but who has never experienced heart failure, will seldom suffer heart failure if she follows a strict regimen outlined by her physicians throughout the pregnancy, the labour, and the puerperium (the period immediately after childbirth) and if she does not experience a complication of pregnancy or of her heart disease. A diseased heart, although able to carry the load put on it by pregnancy, may not be able to stand up under an additional burden. This is particularly true if the pregnant woman gains an excessive amount of weight; if she develops toxemia, kidney disease, pulmonary disease, or an infection; or if she overworks physically, is subjected to sudden severe emotional stress, or becomes anemic. The possibility that a woman with serious heart disease will have heart failure is greater if she is over 35 years of age. A number of persons with heart disease who get along well during pregnancy with good care do suffer heart failure when they take on the added labours of caring for their family, home, and the new baby.

Over half of the women who have suffered from heart failure before they become pregnant do so again during pregnancy, usually between the fifth and the ninth month, when pregnancy throws the greatest work load on the heart. Because so many women with a history of previous heart failure have difficulties during pregnancy, many obstetricians and cardiologists restrict the physical activity of such women and try to keep them in the hospital and under close medical surveillance. Some women with serious heart disease are kept in bed in the hospital throughout the course of the pregnancy and thus avoid heart failure. Cardiac surgery during the first few months of pregnancy, although a hazardous procedure, has lessened the necessity for prolonged bed rest in some cases and materially improved the prognosis in others.

Management of pregnancy preceded by heart failure

Women with serious heart disease often deliver prematurely, and their labours are often short and their deliveries easy. There is an increase in fetal mortality because many pregnancies are interrupted and because many of the babies of women with heart disease are born prematurely. Babies who are not born prematurely are not notably different from those of normal mothers.

Endocrine diseases. *Diabetes.* Before insulin was available, most diabetic women were sterile, or, if they became pregnant, aborted. Half of the babies and one-fourth of the mothers died if they went to term. Today, if they are adequately supervised, less than 1 percent of pregnant diabetic women die of diabetes during pregnancy or the puerperium. Diabetic women do suffer from an increased incidence of toxemia, infections, and polyhydramnios (excessive amniotic fluid). Abnormalities of labour are increased because the babies tend to be unusually large, and congenital abnormalities of the fetus are more common, as is polyhydramnios; polyhydramnios is a problem in 25 percent or more of diabetic women.

Complications from diabetes

Untreated diabetes is associated with a high incidence of fetal defects, abortion, stillbirths, premature labour, and excessively large babies. Even with diet and insulin, over 50 percent of the babies delivered by diabetic women weigh over eight pounds at birth. Even though they appear healthy at birth, many of them are not as strong as smaller babies whose mothers are not diabetic. Fetal loss is greater if the mother became diabetic in childhood, if she has been diabetic for a long time, or if she has vascular or kidney disease. Toxemia, which occurs with approximately 30 percent of diabetic pregnancies, would be more common if it were not for the practice of terminating such pregnancies several weeks before term.

Pregnancy frequently has an adverse effect on diabetes, and diabetes may first become evident during pregnancy. There is a tendency for the carbohydrate metabolism of the diabetic patient to be upset. Most diabetics need more insulin during gestation; a few, for reasons not understood, need less. The changing condition from day to day makes some diabetics, who have no problem maintaining a balance when they are not pregnant, difficult to manage. Even so, adequate medical supervision can bring most diabetics and their babies safely through pregnancy.

Goitres; pituitary insufficiency; adrenal hypo- and hyperfunction

Thyroid disease. Simple goitres that are not associated with a change in the amount of thyroid hormone in the mother's blood do not affect pregnancy, nor does pregnancy affect the thyroid in such a case. An inactive or too active thyroid gland, if not adequately treated during pregnancy, may be associated with an increased incidence of abortion. In the few cases in which persons with untreated myxedema, a severe form of hypothyroidism (deficiency of thyroid hormone), have conceived and gone to term there has been an increased incidence of congenital anomalies of the fetus. Pregnancy and hyperthyroidism (overabundance of thyroid hormone) seem to have no adverse effects on each other.

Pituitary disorders. Most persons with pituitary hypofunction fail to ovulate because their pituitary glands do not produce the gonadotropic hormones necessary for stimulation of the ovaries. Most of these persons also suffer from a lack of hormones from their other endocrine glands because these, too, lack stimulation by the pituitary. A few persons with hypopituitarism have, nevertheless, become pregnant. Their condition is better when they are pregnant because their placentas produce many of the hormones that their endocrine glands, lacking pituitary stimulation, do not ordinarily secrete.

Adrenal glands. Women suffering from adrenal gland insufficiency are not likely to become pregnant. If they do so, they have more tendency to suffer from circulatory disturbances and carbohydrate, electrolyte, and fluid imbalance because of the important role the adrenal glands play in the metabolism of water, sodium, potassium, chlorides, and glucose. Such patients and their babies do well if they receive hormonal therapy during gestation.

The increased secretion of adrenal hormones that occurs with hyperplasia of the adrenal cortex (enlargement of the outer layer of the adrenal gland, also called Cushing's disease) usually inhibits ovulation. A number of women with this disorder, after treatment with cortisone, have conceived, gone to term, and delivered normal children. Cushing's disease complicated by pregnancy is rare; the few cases reported have been associated with a high incidence of severe high blood pressure.

The maternal death rate is approximately 50 percent and the death rate of the child immediately before or after birth is approximately 40 percent when pheochromocytoma (a type of adrenal tumour associated with, among other things, a high blood pressure) complicates pregnancy.

Kidney and bladder infections

Urinary tract diseases. Infections of the urinary tract are more frequent during pregnancy, and women who have acute infections of the bladder and kidneys while pregnant have a higher incidence of premature labour. This is in accord with the known fact that pregnant women with any type of acute infection tend to deliver prematurely. Many women with pyelonephritis (infection of the kidney) in one pregnancy will enter a second pregnancy with bacteria already in the urinary tract but causing no symptoms. These women have a greatly increased chance of developing acute urinary tract infections during their prepartum course and have some risk of eventually developing serious kidney disease. Glomerulonephritis, a kidney disease that affects the clusters of capillaries in the nephrons, the functioning kidney units, usually is preceded by infection with streptococcus organisms. The incidence of abortion and of premature delivery is increased among women in whom the condition develops during pregnancy. If the glomerulonephritis has become chronic the fetus may not survive and the mother's life may be in danger of kidney failure.

Healed tuberculosis of the kidney is not a contraindication to pregnancy if the disease has been quiescent for three years or longer and kidney function is normal. If tuberculosis of the kidneys is present but without symptoms, pregnancy may cause it to become active. If this happens, and if the infection is limited to one kidney, there is an increased danger that the opposite kidney will become infected in some way. The interference with the flow of urine that is characteristic of pregnancy is an important factor in the development of such infections. The accepted treatment when tuberculosis was present in one kidney during pregnancy formerly was therapeutic abortion followed by removal of the tuberculous kidney. This procedure is now avoided in some instances because of the effectiveness of the antituberculotic drugs that have been developed.

Pregnancy after removal of a kidney. It is sometimes necessary to remove a person's kidney because of an infection, a stone, a tumour, or tuberculosis. The remaining normal kidney has a reserve that is greatly in excess of the demands that will be made by gestation, provided that it does not become infected. Infections, impaired kidney function, congenital defects, and toxemia, however, are more serious for a woman with a solitary kidney than they are for the patient with a normal urinary tract.

Pulmonary disease. Pulmonary disorders have a bad effect on pregnancy if they seriously decrease the amount of oxygen supplied to the fetus, if they make the mother desperately sick, or if they create a blood infection that is transmitted to the placenta.

Respiratory infections

An infection of the upper respiratory tract—the nose and throat—does not ordinarily disturb the course of gestation. It may be serious when it occurs in late pregnancy because of the danger that the mother will transmit disease-causing bacteria to her own genitalia or will carry virulent bacteria from her own nose and throat into the labour room and develop a blood infection after the delivery.

Epidemic influenza is associated with an increased incidence of maternal deaths. Many women who suffer from it abort or deliver prematurely. The infection may pass through the placenta and cause infection in the fetus. Pregnant women who acquire epidemic influenza are more likely to develop pneumonia than are persons who are not pregnant.

Pregnancy may increase or decrease the severity of asthma or may fail to affect it. A severe attack of asthma may be followed by abortion, but otherwise asthma does not affect pregnancy.

Pneumonia occurring during pregnancy is associated with a high rate of maternal and fetal death unless the pulmonary infection is susceptible to antibiotics or chemotherapy. The mother's cardiovascular system, already carrying the load placed on it by pregnancy, cannot sustain the added stress produced by pneumonia. The fetus

often dies from oxygen starvation or from intrauterine infection.

Severe bronchitis and bronchiectasis—abnormal dilation of bronchi with some destruction of bronchial walls—may so interfere with the mother's respiration that the extra strain put on her cardiorespiratory system by pregnancy may put her life in jeopardy. If the disorders are severe enough to cause impaired pulmonary ventilation the fetus may suffer from a lack of oxygen and may be either stillborn or delivered prematurely. Pregnancy does not adversely affect the course of these pulmonary diseases.

Pulmonary tuberculosis is not, as a rule, affected by pregnancy. This is particularly true if the patient's infection has been quiescent for several years before she becomes pregnant. Even women with active tuberculosis, if given adequate care, usually go through pregnancy without any deterioration in their pulmonary condition. This is not universally true, however, because there is a small group with active disease whose disease becomes worse during pregnancy. For that reason individual evaluation of each person is necessary.

Although there have been a few cases of infection transmitted to the fetus prenatally, the great majority of babies born of tuberculous mothers are healthy at birth.

Thoracic surgery. Pregnant women who have had portions of their lungs removed for tuberculosis, tumours, or other reasons do well provided that, before becoming pregnant, they are not short of breath with ordinary exertion. The added load of an additional pulmonary infection may not leave such persons with enough pulmonary reserve for the added burden of pregnancy; they may therefore experience difficulties if they contract pneumonia, severe influenza, or acute bronchitis during pregnancy.

Peptic ulcer; colitis; appendicitis

Gastrointestinal diseases. Women may already suffer from a gastrointestinal disease such as gastric or peptic ulcer, gallbladder disease, or ulcerative colitis when they become pregnant; or they may develop some type of gastrointestinal disturbance during the course of the pregnancy. In either event, pregnancy complicates their problems because the gastrointestinal disturbances that often accompany pregnancy may confuse the diagnosis in an individual case.

Gastrointestinal diseases have little or no effect on pregnancy. Pregnancy, on the other hand, tends to aggravate gastrointestinal disorders; the exception is gastric ulcer, which often improves because the concentration of acid in the stomach is decreased with pregnancy. Women with chronic ulcerative colitis are generally advised to avoid pregnancy until their bowel disease has been quiescent for two years; actually, since the woman's psychological reaction to pregnancy is what affects the bowel, the colitis may be made either better or worse by gestation.

Acute appendicitis, occurring during pregnancy, is often confused with other gastrointestinal complaints, and many patients' lives have been jeopardized either because they ignored the symptoms or because the diagnosis was confused by pregnancy. A diagnosis of acute appendicitis calls for an immediate operation regardless of the duration of the pregnancy or the hazard to the fetus.

Nervous system disorders. Neurological disorders and pregnancy most often are coincidental and have no effect on each other, but there are a few neurological diseases that develop during pregnancy, have a deleterious effect on it, or are adversely affected by it.

Epilepsy; poliomyelitis; polyneuritis; neuralgia

Epilepsy of unknown cause does not affect the course of pregnancy but may occur for the first time during gestation. An epileptic person may find her condition improved, aggravated, or unchanged by pregnancy; the effect of gestation cannot be foretold. There is some evidence that excessive fluid and salt retention induces epileptic seizures.

Pregnant women are more susceptible to poliomyelitis (infantile paralysis), but pregnancy does not affect the severity or the course of the disease, nor does poliomyelitis affect the course of pregnancy. If the muscles of respiration are paralyzed the patient will have difficulty during the latter part of pregnancy, when the uterus presses upward on the diaphragm. There have been a few instances in which babies have acquired infections from the mother before birth.

Polyneuritis, a disorder of the nerves usually resulting from vitamin B deficiency, may complicate pregnancy; this is particularly likely if the patient has suffered from severe and prolonged vomiting. Polyneuritis does not affect the gestation.

Neuralgia (pain that radiates along the nerve) occurs frequently near term. It affects especially the sciatic nerve, which is compressed between the pelvic wall and the head of the fetus.

Brain injury; psychoses

Brain injury, including hemorrhage into the substance of the brain, sometimes occurs as part of the clinical picture of severe toxemia. Some types of brain tumours appear to be adversely affected by pregnancy, but, for the most part, brain tumours are not altered by pregnancy and do not disturb gestation.

Latent psychiatric disorders in unstable persons may be aggravated by pregnancy, but major psychiatric problems seldom appear for the first time during the period before delivery. There are a number of mild emotional disturbances, such as increased anxiety, emotional irritability, and fear of labour or for the normality of the fetus, that are likely to be most intense during the early months of gestation. Such disturbances seem to be most prevalent in women who did not anticipate becoming pregnant or who are unduly worried about the baby. Psychiatric disorders rarely influence pregnancy. Emotional disturbances have been said to be a factor in some spontaneous abortions, but satisfactory proof of the relationship is lacking. An intensely unwanted pregnancy may so seriously disturb an emotionally unstable woman that therapeutic abortion may be recommended after psychiatric evaluation.

DISEASES OF PREGNANCY

Acute toxemia. The toxemias are disorders occurring spontaneously only in human females and only during pregnancy or the puerperium. They are characterized by one or more of the following signs: high blood pressure; an accumulation of fluid in the tissues, often with marked swelling (edema); weight gain and proteinuria (albumin in the urine). If the toxemias are severe the affected women may suffer convulsions and loss of consciousness (coma). In addition there may be eye, brain, kidney, heart, pulmonary, or gastrointestinal disturbances. Severe toxemia may cause death. The factors producing toxemia are unknown, but it has been shown that there is a generalized spasm of the arterioles (minute arteries) with associated severe circulatory effects.

The term toxemia of pregnancy is a misnomer, although it has long been in common use; there is no evidence to link the patient's symptoms and behaviour with the effects of toxic substances. The terms pre-eclampsia and eclampsia, used of subtypes of toxemia, are not particularly descriptive, although they are acceptable. Generally speaking, pre-eclampsia refers to the less severe, nonconvulsive type of toxemia. The term eclampsia is reserved for those instances in which there are convulsions or coma.

Toxemias classified by severity

Toxemias of pregnancy are classified according to the severity of their symptoms. The following classification, now in general use in the United States, was adopted by the American Committee on Maternal Welfare:

1. Acute toxemia of pregnancy (onset after 24 weeks)
   - *a.* Pre-eclampsia
     - (1) Mild
     - (2) Severe
   - *b.* Eclampsia (convulsions or coma, usually both, when associated with high blood pressure, edema or proteinuria)
2. Chronic hypertensive (vascular) disease with pregnancy
   - *a.* Without superimposed acute toxemia (no exacerbation of hypertension, no proteinuria)
     - (1) Hypertension known to antedate pregnancy
     - (2) Hypertension appearing during or before the 24th week and persisting after pregnancy
   - *b.* With superimposed acute toxemia
3. Unclassified toxemias
4. Recurrent toxemias

A woman is said to have mild pre-eclampsia when she is 24 or more weeks pregnant and exhibits one or more of the following signs: a definite trace or more of protein in her urine on two successive days; persistent edema of her face or hands; a systolic blood pressure of 140 millimetres of mercury (mm Hg) or more; a diastolic blood pressure of 90 mm Hg or more; or an elevation of 30 mm Hg or more in the systolic or 15 mm Hg in the diastolic pressures. (The systolic is the highest blood pressure after the heart has contracted; the diastolic, the lowest after the heart has expanded.) Her blood pressure is elevated on two occasions six hours or more apart.

Severe pre-eclampsia is characterized by the presence, after the 24th week of pregnancy, of any of the following: a systolic blood pressure of 160 mm Hg or above, or a diastolic pressure of 110 mm Hg or above, on two or more occasions at least six hours apart, with the woman resting in bed; the excretion of five grams (0.165 ounce) or more of protein in the urine in 24 hours; the excretion of 400 millilitres (about four-fifths of a pint) or less of urine in 24 hours; cerebral or visual disturbances; pulmonary edema or cyanosis (bluish or purplish colour of the skin).

Cerebral and visual disturbances and pulmonary edema and cyanosis are indications of a rapidly deteriorating situation in which the toxemia is seriously affecting, in the first instance, the patient's central nervous system or, in the second instance, her cardiorespiratory apparatus. Cyanosis and pulmonary edema (fluid in the lungs) indicate that the heart is not able to carry out its task and that heart failure is in progress.

The division of pre-eclampsia into mild and severe types by these rigid standards is not truly satisfactory because the physician, when he is attending a patient with toxemia, must evaluate many different things: her age and general appearance, her blood pressure, the amount of swelling, the severity of the proteinuria, her urinary output, and the presence of neurological symptoms. Any condition that has so many facets requires individualization in diagnosis and treatment for each patient.

The woman who develops pre-eclampsia often goes through a characteristic course: she has an inexplicable sudden weight gain of several pounds in a few days, moderate elevation of her blood pressure, and a small amount of albumin in her urine. She is unaware of the latter two symptoms. She is in serious jeopardy by the time swelling of her face and hands, headaches, blurred vision or even blindness, and reduced urinary output occur.

Characteristics of eclampsia

Eclampsia is the presence of convulsions and coma superimposed on the symptoms of pre-eclampsia; *i.e.*, high blood pressure, protein in the urine, and fluid retention.

During pregnancy essential hypertension (chronic hypertensive vascular disease, which many people identify more commonly as "high blood pressure") may become extremely severe, with the symptoms identical to those of pre-eclampsia/eclampsia. Also, pre-eclampsia/eclampsia may be superimposed on chronic hypertensive vascular disease, leading rapidly to an extremely dangerous situation and often ending in eclampsia. Although the reason is not known, chronic hypertensive vascular disease appears to be more common in nonwhite than in white populations.

Some degree of toxemia occurs in from 5 to 10 percent of pregnant women. It is most common in women having their first baby and is common in women with twins, diabetes, or hydatidiform mole (an abnormality of the conceptus that is discussed below); it is one of the three major causes of maternal deaths, along with infection and hemorrhage. It is thought that at least 30,000 babies in the United States are lost annually through stillbirths or prematurity as a result of the toxemias. Eclampsia occurs in less than 1 in 1,000 pregnant women when they receive adequate antenatal care. It is interesting to note that the toxemias occur more frequently in young women or in those who are having their first babies, and in women who are diabetic or have excessive amounts of amniotic fluid.

Eclamptic convulsion

An eclamptic convulsion may seize a toxemic patient at any time. It usually occurs near the end of pregnancy. It may happen when the woman is asleep. Characteristically it begins with facial twitching, a fixed stare, and body rigidity. The eyes then protrude, the face becomes a deep purplish-red, and all the muscles of the body go through rapid, strong, and agitated contractions and relaxations so that the woman throws herself about violently. She usually bites her tongue, foams at the mouth, and falls to the floor. The seizure lasts approximately 60 seconds and is followed by a period of unconsciousness, in which the woman breathes again, her face assumes a normal colour, and her breathing gradually becomes more rapid and deeper. There may be only one attack or many. Death may occur during or after the first seizure or may not occur even though the patient is unconscious for many days. A woman may be in labour when a seizure occurs or may go into labour after one. As a rule, delivery is followed by cessation of the convulsions. Eclampsia after delivery is rare.

When eclampsia occurs, it is usually, but not necessarily, in a patient who has toxemia. The pathological changes characteristic of eclampsia have been discovered in women dying with pre-eclampsia without convulsions, and even in a few rare instances in which the pregnant woman did not have hypertension, edema, or proteinuria. Death may be due to clots or hemorrhages into the brain, liver, kidneys, or heart muscles. The changes noted are characteristically in the blood vessels and are essentially due to generalized spasm of small arteries in many of the vital organs.

The cause of toxemia of pregnancy is unknown. A toxemia-like state has been produced experimentally in primates by partially obstructing the blood supply to the uterus. It is generally agreed that there is no evidence that toxic substances are responsible for the toxemias. Whatever the cause, it would seem that it produces an increase in tonicity or contractility of the walls of the finest capillaries throughout the body; this explains the proteinuria and the rise in blood pressure that are part of the clinical picture of toxemia.

Treatment of eclampsia

The earliest possible recognition of mild pre-eclampsia and its energetic treatment from the first appearance of the symptoms that herald its onset are effective in warding off severe pre-eclampsia and eclampsia. The effect of such care was dramatically demonstrated in Sydney, Australia, in the 1950s; when prevention was based on the earliest possible discovery of excessive weight gain and increased blood pressure, there were only ten cases of eclampsia among 37,850 patients delivered between 1948 and 1957. In order to achieve such a record it was necessary at times for the medical authorities in Sydney to send the constabulary to inform women who did not keep their appointments for prenatal care.

The treatment of mild pre-eclampsia is directed toward avoiding severe pre-eclampsia and eclampsia. Preferably the affected woman is hospitalized; retained salt and water are eliminated; and an adequate protein diet, rest in bed, and close observation are essential.

The treatment of severe pre-eclampsia attempts to overcome central nervous system hyperexcitability, to reduce vasospasm, and to lower the blood pressure through the use of suitable drugs. As a result, cerebral and renal circulation are increased, urinary output is promoted, and retained sodium and water are excreted. A patient with severe pre-eclampsia belongs in the hospital. Usually, but not invariably, it is safest to perform a therapeutic abortion if a woman has severe pre-eclampsia.

The treatment of eclampsia is directed toward prevention of further convulsions; decreasing vasoconstriction; reducing blood pressure; increasing urinary output; and maintaining fluid balance.

Termination of pregnancy by inducing labour or by caesarean section is the only definitive treatment for toxemia. If waiting is safe for the mother, it is desirable not to deliver the fetus until it can survive. Delivery is accomplished, after eclampsia is controlled, by whatever means seem best, induction of labour being preferable to caesarean section.

Diseases of the placenta. *Placenta praevia.* Implantation takes place in the lower half of the uterus in ap-

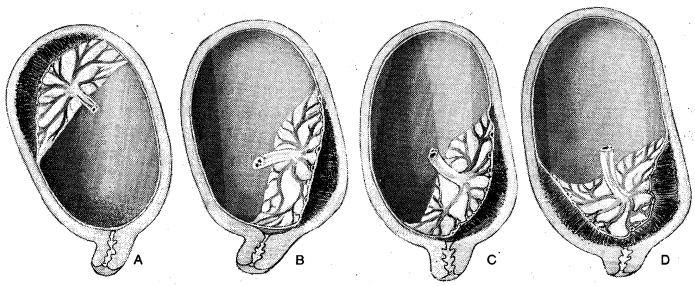

Figure 5: (A) Normal implantation of the placenta in the top or fundus of the uterus. (B) Low implantation. (C) Partial placenta praevia. (D) Complete placenta praevia.
From J. Huffmann, *Gynecology and Obstetrics* (1962); W.B. Saunders Co.

proximately 1 in 500 pregnant patients. The condition is known as placenta praevia when the placenta lies over all or a portion of the internal opening of the cervix. A total placenta praevia is present when the cervical opening is completely covered. When there is a low implantation of the placenta, the latter lies close to but not over any part of the cervical opening.

Recurrent painless bleeding from the vagina without other symptoms after the sixth month of pregnancy is the typical manifestation of placenta praevia. It is caused by disruption of the placenta as the cervix and lower uterine segment are pulled upward. Each bleeding episode tends to become heavier. Without proper treatment the baby is likely to die and the mother may do so. Unremitting watchfulness of the woman with placenta praevia until the fetus has a chance of survival, with preparation for immediate delivery if hemorrhage becomes brisk, a practice accepted in many clinics, has resulted in a decreased infant mortality without an increase in maternal deaths.

Characteristics, course, and outcome of abruptio placentae

Abruptio placentae. Abruptio placentae is separation, during the latter half of pregnancy, of the normally implanted placenta from its attachment to the uterus before birth of the baby. It also is correctly referred to as "premature separation of the normally implanted placenta" and is called "accidental hemorrhage" in Great Britain. It occurs in approximately 1 in 100 pregnancies. The cause is unknown. It is more common in women who have borne several children.

When a small portion of the placenta separates from the uterus, a condition called partial abruptio placentae, blood either collects in a pool between the uterus and the placenta (concealed hemorrhage) or seeps out of the uterus into the vagina (external hemorrhage). When the entire placenta separates from the uterus, there is massive hemorrhage into the uterine cavity and sometimes into the wall of the uterus. Massive hemorrhage is associated with uterine tenderness, abdominal pain, shock, and loss of fetal movement and fetal heart tones. The baby usually dies. If hemorrhage is severe the mother's life is in danger. Defective blood clotting occurs in at least 35 percent of patients with abruptio placentae. Kidney failure develops in approximately 1 percent of the cases; it is seen most often in those instances in which treatment has been delayed. Blood replacement, the treatment of shock, the administration of fibrinogen if the patient's clotting mechanism is defective, the administration of oxytocics, and early delivery are the basic essentials of the treatment of abruptio placentae. Delivery is usually by caesarean section.

Placental infarction. Infarction is degeneration and death of a tissue and its replacement with scar tissue. Small areas of infarction, caused by interference with the maternal circulation, occur normally in the placenta as pregnancy progresses. The fetus usually is not affected by infarction of the placenta unless the process is extensive.

Placenta accreta. Placenta accreta is an abnormal adherence of the placenta to the uterine wall. The chorionic villi attach themselves directly to the uterine muscle in areas where the decidua is poorly developed or absent. All or part of the placenta may be affected. As a result of this abnormality of implantation the placenta does not separate normally at the time of delivery. Attempts to remove it manually by the physician are frequently followed by severe hemorrhage. Removal of the uterus may be required to save the mother's life.

Placental cysts and tumours

Placental cysts and benign tumours. Placental cysts and benign tumours are relatively rare. Chorionic cysts of small size are disk-shaped, grayish-white structures filled with a yellowish fluid and located on the fetal side of the placenta. Decidual cysts are smoothly lined small cavities in the centre of the placenta; they are the result of decidual degeneration and are not true tumours. Angiomas, hemangiomas, fibromas, myxofibromas, and the like are benign growths arising from the placental blood vessels and connective tissue. Solid or semisolid tumours, usually creating small nodular elevations on the fetal side of the placenta, are rarely of clinical significance.

Inflammation of the placenta. Inflammation of the placenta is usually secondary to infection of the membranes. Most often such infections follow the introduction of pus-forming bacteria into the uterus by instrumentation through the vagina; they are the aftermath of prolonged labour or of prolonged rupture of the membranes. If labour is prolonged, bacteria penetrate the fetal side of the placenta, enter the fetal circulation, and often cause death of the infant after delivery.

The placenta may become infected from organisms in the maternal blood. Maternal syphilis, toxoplasmosis, tuberculosis, and malaria may affect the placenta. The viruses of chickenpox and smallpox may cause placental lesions. A number of pathogenic bacteria and viruses cross the placenta and sometimes kill the fetus without causing any specific changes that have been noted in the placenta.

Placental anomalies. Abnormalities in the structure of the placenta are relatively common. It may be partially divided into two or more lobes; there may be extra lobes; or the placenta may be divided into two or more separate structures. Abnormal placentas result from shallow and from deep implantation. The former type, called placenta circumvallata, is associated with several maternal and fetal complications; the latter type, called placenta membranacea, may cause problems at delivery; *e.g.*, bleeding, failure of the membrane to separate.

Anomalies of the umbilical cord. "False knots," which are simply enlarged blood vessels in the cord, are not significant. Actual knots in the cord may become tightened and kill the fetus by cutting off the blood to it. Twisting of the cord also may kill the fetus in the same manner. Spontaneous rupture of the cord interferes with the fetal blood supply and causes fetal death. Extreme shortness of the umbilical cord may interfere with delivery, cause premature separation of the placenta, or tear and cause fetal death from hemorrhage. Another abnormality, called velamentous insertion of the cord, in which multiple blood vessels spread out over the membranes and cervix rather than forming one single cord, is dangerous for the baby because the vessels may tear or be compressed during labour and delivery.

Excessive amniotic fluid

Abnormalities of the amniotic fluid. *Polyhydramnios.* Polyhydramnios is the presence of an excessive amount of amniotic fluid. Normally the uterus contains approximately 1,000 millilitres (slightly more than one quart) of amniotic fluid; anything over 2,000 millilitres is abnormal. Accumulations of more than 3,000 millilitres occur in approximately one pregnancy in a thousand. Lesser degress of polyhydramnios probably occur in about 1 in 150 deliveries. The appearance of large amounts of fluid within the space of a few days is rare; such a condition is met with in less than 1 in 4,000.

Polyhydramnios occurs most often in association with fetal abnormalities, particularly those of the nervous, digestive, and renal systems; when the fetus has erythroblastosis, a disease resulting from incompatibility between the infant's and the mother's blood; when there is more than one fetus; or when the mother has diabetes or one of the toxemias. Almost all pregnancies in which the fetus suffers from obstruction of the esophagus and half of those in which there are severe brain anomalies are accompanied by excessive amniotic fluid.

Acute polyhydramnios causes rapid overdistention and enlargement of the uterus. The woman experiences ab-

dominal pain, nausea and vomiting, and difficulty in breathing. Her heart and blood vessels are put under severe stress; she may show signs of heart failure. Swelling of the feet and legs develops. These manifestations are all caused by the pressure of the rapidly enlarging uterus upon the other viscera.

Chronic polyhydramnios usually causes enough pressure from the abnormally enlarged uterus to make the affected person uncomfortable.

The cause of polyhydramnios is unknown. The most tenable theory is that there is a reduction in the amount of fluid that passes from the fetus to the mother and an increase in the amount that passes from the fetus to the amniotic sac. This would explain the relationship between fetal anomalies and polyhydramnios.

The baby's prospects are poor when there is polyhydramnios. Many pregnancies complicated by an abnormal amount of amniotic fluid terminate prematurely. The fetus has a greatly increased chance of suffering from congenital anomalies. Roughly half of the babies in this group have been lost in the series of cases that have been reported. The greater the amount of fluid, the higher the fetal mortality. Women with polyhydramnios are also faced with a somewhat higher risk. Premature separation of the placenta and postpartum hemorrhage are the two most significant maternal complications associated with it.

Minor degrees of polyhydramnios require no treatment. Removal of the excess fluid is the only effective management if symptoms from uterine distention become too distressing. This may be done either by perforating the membranes through the cervix or, preferably, by inserting a needle through the abdominal wall and the wall of the uterus; care is taken to avoid injury to the woman's bowel or the placenta. Either procedure is likely to start labour.

Too little amniotic fluid

Oligohydramnios. True oligohydramnios, a deficiency in amniotic fluid, is a rare condition of unknown cause. If it occurs early in pregnancy there are usually firm adhesions between the membranes and the embryo, with distortion of the fetus. A decrease in the amount of fluid later in pregnancy allows the membranes and uterine wall to press on the baby. The baby's position is distorted, and as a result it may be born with a clubfoot or wryneck. Its skin is dry and thickened. Defective development of the kidneys is common with oligohydramnios. As a rule, the condition causes the mother no distress, but the infant has a greatly increased chance of being born with major anomalies.

Trophoblastic disease. *Hydatidiform mole.* A hydatidiform mole is an abnormality of the conceptus in which changes that began early in embryonic life convert the placental villi into a mass of thin-walled, grapelike, translucent vesicles, or blisters, filled with a gelatinous or watery fluid. In a typical case the uterus is distended by a spongy mass of these vesicles. The primary cause of molar changes is unknown; however, it has been correctly described as a "temporary missed abortion of a blighted ovum." The embryo is either absent or dead. The immediate condition that causes hydatidiform swelling is disappearance of the blood vessels in the villi, with continued growth and often overgrowth of the trophoblast. Distention of the villi by fluid is due to continued activity of the trophoblast in the absence of a functioning villous circulation.

In the ova there are many degrees of hydatidiform change; many of the changes, usually in younger specimens, are not marked enough to warrant being called hydatidiform moles. True moles—characterized by hyperplasia, or overgrowth, of the trophoblast, edema of the villous connective tissue framework, and defective growth of the villous blood vessels—occur perhaps once in 2,000 pregnancies. They are not tumours and are not the aftermath of a former pregnancy. They are themselves an abnormality of a current pregnancy. Occasionally in a twin pregnancy one fetus is normal and the other a mole. Eighty percent of the moles are expelled about the 20th week of pregnancy and bring the patient no more trouble. Approximately 16 percent of hydatidiform moles invade the uterine muscle, causing bleeding. This type of mole, referred to as an invasive mole or chorioadenoma destruens, may in rare instances perforate the uterus and cause death from hemorrhage. Rarely molar villi are carried to the lung or brain. When they are, the patient may suffer from hemorrhage into the lung or die from hemorrhage within the brain.

Signs of hydatidiform mole; complications

The woman who develops a hydatidiform mole has the symptoms of pregnancy; her uterus usually enlarges more rapidly than it should, she is more likely to suffer from toxemia, and she begins to bleed vaginally, usually by the 20th week of gestation. The molar pregnancy is expelled vaginally, or, if hemorrhage is severe, the obstetrician may remove it by surgery.

In approximately 2.5 percent of patients, hydatidiform moles change into choriocarcinoma, a highly malignant tumour of the trophoblast. For that reason, patients who have hydatidiform moles are observed carefully. Continued bleeding or a rising quantity of chorionic gonadotropin in her urine or blood after passage of a mole suggests that a patient has either an invasive mole or a choriocarcinoma. Chemotherapy has been effective treatment for many cases of this type. Removal of the uterus may be necessary. The complexities of diagnosis and the differences in situations require that therapy be keyed to the individual.

Choriocarcinoma. Choriocarcinoma is a rare, extremely malignant type of tumour arising from the trophoblast. The reasons that normal chorionic cells undergo cancerous change, with exaggeration of their natural and potent tendency to invade the uterine muscle and break down blood vessels, are unknown. Choriocarcinoma occurs approximately once in 160,000 normal pregnancies. In approximately 50 percent of the cases the tumour develops from a hydatidiform mole, in another 25 percent after an abortion, and in 25 percent after a normal pregnancy. Occasionally it appears after a tubal pregnancy. It has been known to coexist with pregnancy. It is, for some unknown reason, more common in the Orient. Choriocarcinoma developing as a teratoid tumour of the ovary (a tumour made up of a number of different tissues) is a rare entity not related to pregnancy and is not to be confused with the tumour being discussed here.

Signs of choriocarcinoma

As a rule, in the development of a choriocarcinoma there has been a normal pregnancy, an abortion, or the delivery of a mole, and the uterus has not returned to its normal size. The woman begins to bleed from the vagina. Blood loss may be modest or excessive in amount. Tissues obtained by a curettage (scraping) may be, but are not always, indicative of choriocarcinoma.

The tumour begins in the uterus, where it forms a spongy, bleeding mass of easily torn tissue or a shaggy ulcer. When examined microscopically, it is found to consist of both cytotrophoblast and syncytiotrophoblast. The cells spread rapidly by way of the bloodstream, producing secondary tumours in the lung, the brain, the liver, or elsewhere.

Choriocarcinoma formerly was almost invariably fatal. Today, an impressive (two out of three in some case series) number of patients have survived for many months after the administration of chemotherapeutic agents. Most workers in this field at this time are using methotrexate. The rapidly growing embryonic cells of the trophoblast need nucleic acids for growth and division; for the synthesis of nucleic acids, folinic acid is essential, and methotrexate, by preventing the conversion of folic acid to folinic acid, cuts off the supply of the latter. A number of other cytotoxic drugs (drugs destructive to cells) are also being used in the treatment of choriocarcinoma, and other chemotherapeutic agents are being tested for effect on this type of tumour. Removal of the uterus is frequently, but not always, a part of the treatment of choriocarcinoma.

Prehistoric Religion

Prehistoric religion comprises the religious beliefs and practices of early man. In the absence of any written records, statements about the nature of prehistoric religion are necessarily dependent on a complex body of theory, concepts, and data, and on inferences and reconstructions from archaeological remains.

BASIC PROBLEMS AND METHODS OF STUDY

Problems: nature and scope of prehistory. The term prehistory refers to the course of human events and to the study of these events, in so far as they were decisive in shaping contemporary and later conditions, before the invention of writing. As a subject of inquiry, prehistory comprises both the course of events in preliterate times and man as a cultural being in a state of illiteracy. Similarly, the study of prehistoric religion comprises two subjects: the history of early man's religion and the study of religion as a part of human culture or human nature or both.

Reconstruction of the past from material remains. As the British prehistorian G.E. Daniel has noted, "prehistory is written from many sources—the material remains of the past, deductions from language, physical anthropology, place names, and comparative ethnology. All these are sources that in historical times are auxiliary to the written sources. But in prehistory they are the main sources," and, he emphasizes, material remains are "by far the most important of them." The "reading" of such material remains requires, in the main, a functional interpretation; *i.e.*, discernment of their cultural and spiritual function in the life of prehistoric man. Above all, this functional interpetation makes use of comparisons with objects, circumstances, and processes that are directly known or that have been transmitted in written, pictorial, or oral form. Since the major part of prehistory leads back into the realm of so-called primitive cultures, comparative studies must take into account the conditions and behaviour patterns that research on contemporary "primitive" people has revealed. Such studies also serve to demonstrate the fragmentary character of archaeological finds. In addition, they show that for many archaeological objects, various functional interpretations are possible.

The significance of material remains

Problem of discerning cultural and religious phenomena. Religion is a mental or spiritual phenomenon in which the sacred or supernatural "word" plays an important part. Obviously, this essential expression of religion cannot be investigated archaeologically—the remains are wordless. Religious meanings can only be inferred indirectly and in exceptional circumstances from the material finds. The investigation of prehistoric religion faces the problem of determining which objects and finds are to be taken as signs of religious intention, experience, and activity. Not all unusual and puzzling finds necessarily reflect something religious; moreover, there are some remains that may have had a profane as well as a religious or magical function.

Conjectural nature of scholarly statements. In all probability, only a small number of the material remains of prehistoric religious practices have been preserved and still fewer of them discovered and adequately documented. This intensifies the necessarily fragmentary nature of all statements about prehistoric religion. Uncertainties about methodology further aggravate disputes among scholars as to the reliability or probability of their interpretations. As with historians in general, there is a positivistic position, the proponents of which desire little more than to classify, describe, and define their specific finds and findings. That stance is opposed by another position that, in addition, considers it important to relate these findings to common human experiences and to seek out analogies with situations in more recent times; that is, to attempt a reconstruction of prehistoric spiritual life.

Methods. *Material remains.* Although religion is largely a mental phenomenon, it involves numerous material accessories: artifacts and places of cultic and ceremonial significance, pictures and symbols, sacrifices, and votive offerings. In many cases religion makes use of art and, to some degree, certain inferences about religious conceptions can be drawn from burial sites. The interpretation of such sources from analogies with present-day religious practices means, in effect, that a more or less complete congruence or similarity is being inferred from a partial congruence that is observed. Not infrequently, particular findings can be explained in various ways. It is often unclear, for example, to which religious category a find belongs, since a sacrifice and a burial, cannibalism and human sacrifice, or animal sacrifice and an animal cult are frequently not distinguishable archaeologically. Thus, it is not enough to select some particular present-day "primitive" religious phenomenon and apply it automatically to archaeological material; rather, it is first necessary to carry out extensive comparative studies in order to ascertain connections of sufficient scope and to establish a basic congruence of meanings. Usually only general trends, rather than concrete particulars, can be comprehended in this fashion. Nevertheless, the find may be interpreted in various ways and, hence, it becomes necessary to select the most workable, or the most probable, interpretation.

Archaeological concepts. The first step in interpreting prehistoric finds consists in relating them only to those recent phenomena that are truly comparable, that is, that have basically similar or congruent structures. A historical religious phenomenon that is connected with the cultivation of domesticated plants, for example, cannot be employed, without further inquiry, to explain an object from a Paleolithic (Old Stone Age) hunting and gathering culture. Such an explanation, if it is to be valid, presupposes that the chronological sequence of the archaeological phenomena has been determined and that certain stages of the cultural development can be worked out. Today this task may be considered as solved in its main outlines, although the reconstruction as a whole still needs some refinement.

Archaeological finds and cultural stages

Less clear, and still disputed, is the reconstruction of corresponding stages on the basis of modern "primitive" phenomena, as well as the connection of the latter to the prehistoric stages; *i.e.*, the answer to the question of whether and how phenomena that still exist may be correlated with those of the past. Even where this can be done only tentatively, constructing comparable cultural stages or structures in the past is important for the interpretation of the phenomena. This is even more the case if the phenomena can be attributed to certain smaller units within the stages, such as "culture circles." The best way to establish such connections is a direct demonstration of continuity; *e.g.*, connecting the content of North African rock-pictures with recent religious conceptions within the "culture circle" of "Eurafrican hunter-collectors" of past and present times. Even where continuity or diffusion cannot be demonstrated, conformity or analogy in cultural structure or style furnishes valuable clues.

Methods of interpreting archaeological materials. Criticism of the use of historical-cultural analogies—particularly that of prehistoric phenomena to modern "primitive" religions—points especially to the large time span between prehistoric and contemporary "primitives," the numerous possibilities for changes in meaning, and the present proliferation of phenomena. At the same time, numerous examples show that a long elapsed time does not necessarily mean that fundamental changes have occurred, but rather that there are very strong tendencies toward stability. During all of prehistory, for example, the first truly epochal transformation, in terms of the

total culture (*i.e.*, the new form of developed hunter-collector cultures of the Upper Paleolithic Age), took place around 30,000 BC; thus, in comparison to the hundreds of thousands of years of early humanity, the time elapsed since then is rather insignificant. Consequently it is less unimaginable than one might think that primary elements of very early conditions have endured to the present time. In addition, in contrast to the present multitude and diversity of phenomena, it can be shown that the number of possibilities that can be realized under simple conditions is really rather limited. Further, a mental phenomenon, such as religion, does not develop entirely freely but is also governed by functional interdependencies and limitations, *e.g.*, even by economic or ecological conditions (see below). Temporal duration, the interaction of the tendencies of stability and change, the multiplicity of possibilities and limitations through general conditions, independent development, and functional interdependence are all to be weighed carefully one against the other. The different conceptions of the value of each of these criteria are to a large extent the basis for disputes among scholars over the meaning and persuasiveness of the inferences they draw from them.

Assumption of the psychic unity of mankind

A fundamental prerequisite for the use of historical-cultural analogies is the assumption of the psychic unity of human nature (*i.e.*, that human beings in all times and places are essentially the same mentally); hence, the basic question arises as to whether or not early prehistoric humans can be included in that unity. The particular answer one gives to this question corresponds to a great extent to his particular approach, whether from the point of view of biology or the humanities, of biological evolutionism or history. The biological sciences tend to view early man—even psychically—as half animal, while human studies emphasize more strongly the fundamental similarities that connect even the earliest humans and cause them to stand apart from the animals. Whatever the case, it can no longer be doubted that earliest man stands closer to present-day man from the evolutionary and biological aspect than to any of the animals known today (including the "highest" apes), and that the quality of early man's mental accomplishments separates him from other animals and binds him fundamentally to present-day humans. For that reason it is generally sound—at least as a guiding principle in empirical research—to view prehistoric man as essentially human, to understand him in terms of human nature, and to proceed from the assumption of the psychic unity of mankind without thereby excluding further evolution and development.

INFERRED PRACTICES AND BELIEFS

Burial customs and cults of the dead. The oldest known burials can be attributed to the Middle Paleolithic Period. The corpses, accompanied by stone tools and parts of animals, were laid in holes in the ground and sometimes the corpses were especially protected. In some cases, the findings give the impression that the dead were to be "held onto." Whether or not that meant that the dead were to be cared for lovingly or that their return was to be feared, it implies, in any case, a belief in life after death in some form. But it is not necessary to infer a belief in separate souls; rather, it could also indicate the concept of a "living corpse."

Implication of life after death

From the Upper Paleolithic Period on, the burials manifest richer grave goods; however, it is not possible to conclude from this that religious concepts had changed. The same holds for the adoption of other burial practices, as, for example, secondary burials, in which the bodies were first allowed to decompose fully and then the bones were buried, or in the burning of bodies (evident from the Neolithic Period). From these facts it is not possible to infer the existence of a definite belief in souls; it is also not possible to determine the advent of such concepts from archaeological evidence. Even the increase in the discoveries of grave goods, occasionally also including other human remains, is evidence not for a change of religious concepts but for increased needs of the dead in the beyond—*i.e.*, needs after death that are dependent on economic and social status in life. Analogies to recent (primitive) phenomena demonstrate that it is not possible to connect particular burial customs with particular notions of the beyond, or to any other religious conceptions. Other than the burial of the whole body, the disposition of the individual parts of the body, and especially the skull, is important. Ritual deposition of skulls is confirmed for the Middle Paleolithic Period. From even earlier periods, however, individual or multiple human skulls and long bones have been found within a single site (for example, with Peking man). It is not necessary to interpret these findings as remains of headhunting or developed skull cults; for even today some simple hunting and gathering societies have the custom of preserving such parts of corpses for long periods of time and even of carrying them around on their bodies. The same practice is observed also in the Upper Paleolithic and even later periods; but it is not possible to infer an elaborated ancestor cult directly from such prolonged connections of the living with the dead.

Burial of skulls and skull cults

The situation is different with findings from permanent settlements of agrarian people, in contrast to constantly shifting hunter-collectors. Evidences for ancestor cult practices dating to the 7th century BC were first discovered at Jericho in Palestine, where several skulls were deposited in a separate room, some of them covered with a plastic modelling of faces similar to that found on the ancestral skulls of present-day agrarian peoples of South Asia and Oceania. An elaborated skull cult is usually connected with the veneration of ancestors. An important theme of ancestral cults is the belief in a connection between the dead and the fertility of the land of their descendants.

Megalithic graves

An especially noteworthy kind of burial is that of the megalithic (huge stone) graves that appear in various areas from the Neolithic Period on. It is probable that in this practice there was also a vital believed link between the living and the dead, and that occasionally sacred areas and gathering places were connected with such graves. The practices of the megalith builders were probably rooted, to a considerable extent, in ideas about the dead and in ancestor cults to which their stones gave a particular durability and a monumental form. It is more difficult to explain the individual erect stones (menhirs), which, of course, could be the symbol or seat of ancestors, especially where they show indications of being sculpted in human form. It surely would be a mistake, however, to look for a uniform intepretation of all megalithic monuments or even to speak of a distinct megalithic religion. The megalithic monuments are rather to be understood as a complex of grandiose manifestations of ideas that could well have been diverse, but among which the cult of the dead, nevertheless, played an important role.

Cannibalism. In finds belonging to the Paleolithic Period, pieces of human bodies as well as the bones of other animals are found scattered throughout the archaeological layers and are sometimes broken or charred. This is often taken as evidence for cannibalism, but other interpretations are just as likely (*e.g.*, the action of carrion-eating animals [such as hyenas] turning up the bones to the surface and thus causing their burning by later fires at the same place). To be sure, the finds allow the interpretation of cannibalism; however, they do not necessarily or intrinsically require it but rather permit that explanation if one proceeds from the prior conviction that cannibalism already existed at that time. This obsolete conception, still held by some scholars today—*i.e.*, that cannibalism is an especially "primitive" phenomenon and therefore very ancient—must be abandoned. Ethnological studies show clearly that cannibalism appears almost exclusively in the practices of agrarian peoples, that is, in a later cultural stage, and evidently is essentially bound up with religious or magical conceptions in which cultivated plants play a large role. Even if a Paleolithic cannibalism existed on a large scale, it could not be explained by means of concepts that originated in a cultural stage so differently structured.

The situation in later periods, especially in the Neolithic, is different. Here, rather than isolated parts of human

skeletons scattered about a settlement, human remains occasionally are found in association with remains of foodstuffs in waste pits or in holes and tunnels that served as sacrificial sites. Especially where human skulls have been broken open and the hollow bones split, the interpretation of cannibalism is unavoidable. Since this inferred practice occurred in the realm of agrarian cultures, it is more feasible to make comparisons with present-day cannibalism, where the meaning is generally the acquisition of the powers and other qualities of the victim.

Sacrifices. Sacrifices (*i.e.*, the presentation of offerings to higher beings or to the dead) appear as early as the Middle Paleolithic Period. Pits with some animal bones have been found in the vicinity of burial sites; thus, it is a likely possibility that they represent offerings to the dead. There is a dispute over the interpretation of the arrangement of the skulls and long bones of bears, since they are deposited in such a manner that it is hardly possible to discern a profane explanation. It is assumed that they had a cultic or magical significance. Most likely, certain parts of the prey, such as the head and the meaty shanks, or at least the bones with brain and marrow, were sacrificed. Even if it cannot be definitely stated who the recipient of these sacrifices was, analogies with present-day "primitive" phenomena make it likely that a part of the prey was offered to a higher being who was believed to dispense nourishment. It could also, however, have been a matter of preserving parts of animals in order to resurrect the entire animal and preserve the species. Furthermore, finds of bones and drawings show that the preservation of skulls with still attached vertebrae, ribs, and front legs of oxen and reindeer played a certain religious or magical role. The sinking of whole reindeer into lakes is hard to explain other than as a sacrifice. This might be traced to the idea that what occupies the centre of attention is not the individual hunted animal but the whole herd; no longer only a part of an animal but a whole animal as part of a herd is sacrificed. The custom also existed in recent times among hunters and herders of central and north Asia. As such finds become more numerous, it seems evident that certain specific animals and parts of their bodies are selected for sacrifice.

Cultic and magical significance of sacrifices

It is difficult to differentiate between animal sacrifices and the immediate cultic veneration of an animal at the burial sites of animals. In the Neolithic Period, the sites become especially profuse and are usually found in connection with human burials; nevertheless, there are such burial sites of animals that are not related in this manner and that occur with pronounced frequency, characteristically in particular groups of cultures. In these cases, domestic animals almost exclusively are involved, and among them the dog and the ox predominate.

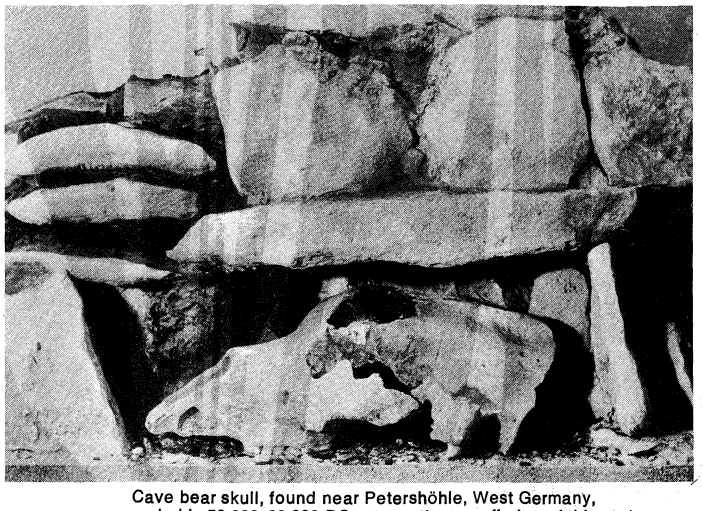
The question of human sacrifice is of special significance here. Human sacrifices often were related to cannibalism and to the sacrifice of animals. With conspicuous frequency victims discerned in ceremonial remains are females and children, sometimes along with young pigs. This practice is similar to fertility and agricultural rites that are known to have been practiced in the early Mediterranean civilizations. It is also similar to beliefs and practices observed among present-day "primitive" agrarian peoples (in which pigs are often substituted for humans), such as in ceremonies of secret societies, initiation rites, sacrifices, celebrations of feasts of the dead, and notions about fertility, especially in connection with the growing and ripening of cultivated plants.

In comparison, the inclusion of servants or women in the burial sites of highly placed persons can hardly be called sacrifice in a strict sense—that is, an offering to a higher power or deity. Such inclusions most likely reflect the social status of the deceased leader and his need for servants in the afterlife, rather than an offering. It is a sacrifice in the wider sense of respect and awe for the person and status—and all that this conveyed—of the deceased leader. This practice becomes more important only where correspondingly differentiated social conditions are found (such as in the royal graves at Ur in Mesopotamia and in those of the Shang dynasty in China). Sometimes it took on almost unbelievable forms, especially in terms of the numbers of persons and animals interred with the deceased leader.

The ritual preservation of objects also must be included in the realm of sacrifice (in a wider sense). This can be demonstrated for the first time in the Neolithic Period (for instance, the ritual depositing of axes); in later periods, it plays a large role. In finds from the Bronze Age on, weapons and jewelry frequently are found in wells and springs. In Iron Age finds, such objects are found in almost unbelievable quantities in a number of swamps and other bodies of water. It seems probable that they represent the sacrifice of war booty.

Ritual preservation of objects

Hunting rites and animal cults. In the oldest known examples of graphic art, the representations of animals play a large part; humans appear rarely and then frequently with animal attributes or as mixed human–animal figures. In the context of the whole situation, the view that these representations were merely ornamentations or served a purely artistic need may be dismissed; they are found without boundaries and background on rock walls and are not part of an interrelated scene. It is evident that animals played a predominant role in the mental world of the Upper Paleolithic Period insofar as this role is reflected in the art of the period. What is represented is, first of all, that which is essential to the animal, partly in its relation to the hunt, but also in relation to anthropomorphic figures showing the intermixing of human and animal forms. This indicates a special and intimate relationship between humans and animals that transcends and overcomes the boundaries between different realms of being that modern concepts and understanding require.



This phenomenon is similar to what is still known today as animalism (or nagualism or theriocentrism). It is characterized by close magical and religious ties of humans with animals, especially with wild animals. It is also characterized in terms of otherworldly and superworldly realms and practices, such as placating and begging for forgiveness of the game killed, performing oracles with animal bones, and performing mimic animal dances and fertility rites for animals. Animals were thought to be manlike, to have souls, or to be equipped with magical powers. Animalism thus expresses itself in various conceptions of how animals are regarded as guardian spirits and "alter egos," of the facile and frequent interchangeability between human and animal forms, and also of a theriomorphically (animal-formed) envisioned higher being—one who changes between human and animal forms and unifies them. Higher, often theriomorphic, beings are gods who rule over the animals, the hunters, and the hunting territory, or spirits in the bushland and with the animals. It is obviously not possible to identify special occurrences or forms of such higher beings during the Paleolithic Period, but their general features may be safely assumed.

Totemism

Animalism is, to a large extent, a basis for totemism, which involves various permanent relationships of individuals or groups to certain animals or other natural objects; hence animalism is occasionally called "protototemism." Individual and cultic totemism, as opposed to group totemism of an almost solely social function, are particularly close to animalism, whereas religious and cultic meanings in group or clan totemism are usually poorly developed. It is not possible to determine to what extent animalism had already assumed the character of true totemism in the Paleolithic Period; the early existence of clan totemism is improbable because it occurs primarily among peoples who are to some extent agrarian, and possibly a certain kind of sedentary life was prerequisite to its development.

Also, special sacrificial traditions were closely connected to game, particularly the custom of preserving the animal skeleton or a part of a skeleton in order to placate the ruler of the animals (see above) and to provide for continuation of the species.

A certain kind of bear ceremonialism is rooted in this conception and is to be recognized in several finds and pictures from the Upper Paleolithic Period on. A skin with attached head was evidently draped over the body of

Cave bear skull, found near Petershöhle, West Germany, probably 50,000–30,000 BC, suggesting an offering of this part of the prey.

By courtesy of the Naturhistorische Gesellschaft, Nurnberg, West Germany; photograph, Georg Pandura

a bear made out of clay; the skull and long bones of the bear were buried separately (a practice begun in the Middle Paleolithic Period); the bear was shot with arrows and killed by a shot or a thrust into the lungs; the animal or a bearlike figure was surrounded by dancers. Similar phenomena are documented for more recent periods, above all for the hunting cultures of Neolithic Siberia. These observations can be effortlessly fitted into the practice of bear ceremonialism that is still widely distributed in northern Eurasia and North America.

The question of whether animals were the immediate objects of a cult is extremely difficult to judge in each particular case. Nevertheless, with the beginning of the Neolithic Period, animal phenomena appear that probably go beyond functioning merely as a sacrifice and symbol. This applies especially to representations of oxen and bulls and to the symbolism of bull heads and bull horns.

Fertility statuettes

Female fertility deities. Small female figures, the so-called Venus statuettes, appear for the first time in the Upper Paleolithic Period. In some cases they are very schematically formed, and it is often difficult or impossible to recognize female attributes. In other cases, however, they are naturalistic representations of corpulent women whose secondary sexual characteristics (their breasts and buttocks) were given special prominence, though their faces, feet, and arms were almost completely neglected. Such strong emphasis on the anatomical zones that are related to the bearing of children and nourishing them easily conveys to one the idea of female fertility. Nevertheless, it is not necessarily true of all these small figures.

Dortes—B. Arthaud

Female holding a bison horn, stone bas-relief from Laussel, Dordogne, France. Gravettian period (25,000/20,000–18,000/15,000 BC). In the Musée d'Aquitaine, Bordeaux, France. Height of figure 37.72 cm.

Ethnological analogies with present-day primitive phenomena offer the equally plausible view that such figures were regarded as the representations of the abodes of spirits whose function was to help and protect, and especially during hunting. They also may have been conceived, among other things, as mothers or rulers of the animals, goddesses of the underworld, helpers during hunting and donators of game, and as sovereigns of the land and other regions and of natural forces, including that of fertility.

No known direct continuum connects these earlier Paleolithic figures to similar ones of the early Neolithic and later periods. In settlements and shrines of these later periods are found large numbers of female figurines of widely differing types. They may have been representations of deities and symbols or, perhaps, votive offerings, somehow connected with female fertility. This can be safely assumed for figurines that show an obvious indication of fertility or are connected with children, and even more for shrines containing figures with sculptured pairs of breasts, and figures on the walls of women in childbirth. Not all female figures can, however, be understood merely as fertility symbols; rather, in many cases they are assumed to be house gods or representations of ancestors, and, especially when appearing in graves, as substitutes for the bodies of maids, wives, and concubines. An appearance of a large number of smaller figures suggests a votive or magical usage.

Shamanism, sorcery, and magic. Shamanism is a rather variable and highly stratified complex of practices and conceptions; characteristic among these are the use of ecstasy, the belief in guardian spirits (who are often in animal form, with the function of helping and guiding the dead on their voyage to the beyond), and beliefs concerning metamorphosis (change of form) and travelling to the beyond (see also SHAMANISM). Pictures from the Upper Paleolithic Period indicate the existence at that time of ecstatic practices and of beliefs in protective and helping spirits, which assume the form of birds and other animals. On the other hand, it is doubtful whether shamanism existed in fully developed form at that time. Also, in the course of prehistory, objects appear that may well have belonged to the paraphernalia of shamanism. Noise-making objects (to drive away evil spirits) are often found in the material remains of the Iron Age and probably are connected with shamanism.

Belief in guardian spirits

Recent studies stress the religious character of shamanism, though in practice it is related to sorcery and magic. Shamanism is not to be identified with sorcery and magic if they are understood as attempts to manipulate the supernatural through certain human techniques, in contrast with religion, in which man approaches higher beings (gods) in an attitude of supplication. Magic or sorcery thus appears as the opponent of true religion and gains importance when religion declines or is overwhelmed. In fact, magic and sorcery may take over cultic forms and rob them of their religious meaning when this occurs. For these reasons, it is often difficult to decide whether prehistoric phenomena were of religious or magical character.

Magic also can be practiced to a large degree without the use of material objects, and it is, therefore, as hard to grasp archaeologically as true religion. In the interpretation of the art of the Upper Paleolithic, scholars have given great importance to magic because, for example, missiles (spears and arrows) were drawn on the pictures of animals. This has been interpreted to mean that an effort was made to insure and compel the success of hunters through magical action. But this interpretation is

highly speculative and it remains uncertain what these drawings mean. It is just as difficult to decide whether or not other pictures, sculptures, abstract symbols, amulets, and similar objects were used to make magic in this and later periods.

HISTORICAL DEVELOPMENT

Religious patterns and economic stages. Religion is always closely related to other realms of life, such as economic activities. These relations are partly direct and partly mediated by social forms. The latter are, on the one hand, at least partially dependent on economic conditions; on the other hand, social structures influence the formation of religious phenomena and often serve as models for their elaboration. In a negative sense, then, it is often possible to eliminate certain religious phenomena as inappropriate to a particular society. It is inconceivable, for example, that the religious conception of simple hunters and gatherers included an elaborately organized hierarchy of gods with detailed division of labour between the individual figures. Similarly, it is a mistake to attribute to hunters and gatherers conceptions that are bound up with agriculture and the fertility of fields. In a positive sense, however, certain economic and social conditions will encourage the development of certain corresponding religious conceptions. Animalistic notions will be especially effective in situations where animals play a large role as partners of humans. Nevertheless, the spiritual ties to animals will be considerably different among hunters or agrarian peoples who still find it necessary to rely heavily on hunting for their meat supply as compared with pastoral peoples. In fully agrarian cultures, on the other hand, ideas about the fertility of fields and cultivated plants play an important part; they are connected with other notions about fertility and influence other spheres of life.

Burial sites that indicate a belief in life after death

Religious patterns in the various periods. *Lower or Early and Middle Paleolithic.* The oldest burials that attest to a belief in life after death can be placed in the period between about 50,000 and 30,000 BC. The earliest evidence of human activity in any form, on the other hand, goes back more than 1,000,000 years. Yet, since religious conceptions are not always bound to material objects, and since there is evidence that truly human beings existed even during early Paleolithic times, it is inadmissible to infer that earliest man had no religion from the mere fact that no identifiable religious objects have been found.

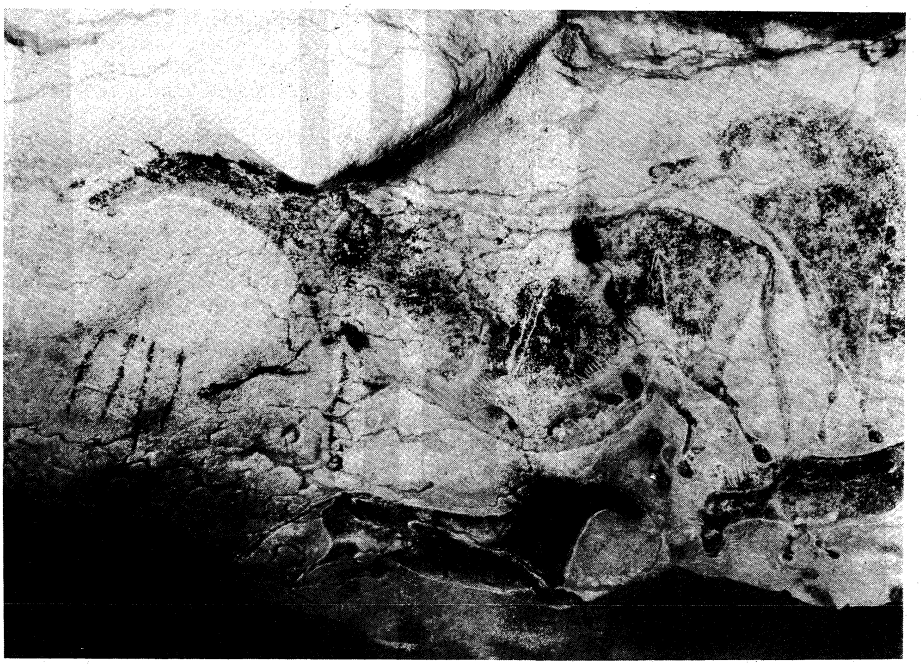
A study of very simple hunters and gatherers of recent times shows that several religious conceptions generally considered to be especially "primitive" (*e.g.*, fetishism) hardly play an important part, but rather that, among other things, the supposedly "advanced" conception of a personal creator and preserver of the world does play an important part. Such a belief could never be discovered by examining archaeological sources—the material remains—and hence cannot be ruled out for the Early Paleolithic Period. Whether or not the sacrifices in that era involved divine creators or preservers or other beings can only be a matter of conjecture. Features of animalism, magic, and various other views and practices may have played a role, but probably less so than in later epochs.

Upper Paleolithic and Mesolithic. The animalistic features encountered in the art of the Upper Paleolithic Period were most likely only a part of the religion that existed at that time. Among present-day "primitives" the animalistic realm often occupies only a lower sphere of what can be considered religious, and beyond and above that sphere are still other notions about gods. Practices concerning the resurrection of animals and the preservation of species evidently also played an important part and were closely tied to animalistic conceptions. The corresponding rituals clearly took on a special significance in relation to bears and became the basis for the bear ceremonies that were later widely diffused. Although shamanism may have been initiated somewhat earlier, it was now evident, at least in some of its aspects.

The realm of hunting was primarily a masculine sphere; nevertheless, it also includes in religious phenomena the feminine aspect, as symbols of female fertility (and probably also of female deities) demonstrate.

Proto-Neolithic and Neolithic. The characteristics of early religion were continued but transformed in the proto-Neolithic and Neolithic periods. Shamanism developed, especially among the pastoralists of central and north Asia. Animals, viewed as the hypostases (essences) of higher beings, especially the eagle or falcon and the raven, became highly significant in shamanism. Animalistic conceptions continued and often assumed the proportions of a true animal cult. Hoofed animals, especially sheep and oxen, played an important part as sacrifices and bulls particularly assumed a leading role; they seem to have been relegated to the masculine sphere. Horses appear as domesticated animals and as sacrifices only toward the end of the Neolithic Period. They may have been connected with a heavenly divinity, as later evidence suggests.

In the early period of agriculture, before the full development of the Neolithic Period, deposits of human skulls appear that suggest the presence of ancestor cults. A spiritual identification between humans and plants apparently played a predominant part in conceptions connected with headhunting and cannibalism. The death of a god was often considered a prerequisite to the appearance and prospering of the plants, and this mythical event was repeated through human sacrifice that was either accompanied by or replaced by animal sacrifice.



Dualism of masculine and feminine elements

At an early stage, in addition to an agricultural connection with the earlier feminine aspects, the masculine aspect appears in the form of portrayals of sexual union and, perhaps, of the "holy wedding," or sacred coupling, as well as in portrayals of couples and families. Among the material remains, however, the direct representation of the male element recedes sharply, yet perhaps the symbol of the axe and probably also that of the bull may indicate the male element. This dualism of the masculine and feminine aspects can possibly be interpreted in terms of father sky and mother earth, and in their union as a couple by which they become parents of the world. In the early civilizations, the conception of a supreme being or a heavenly god (which cannot clearly be recognized either in pictures or in other material objects) plays a minor role. That does not mean, however, that such a conception is necessarily of recent origin but rather that it probably existed at an early period in places where there was no literate tradition (predominantly among pastoral cultures).

Prehistoric religions and religions of the early civilizations. The decisive factors that brought about the early civilizations were the new kinds of economic and social organization, the large-scale exploitation of human energy, the formation of ruling classes, hierarchical organization, and the administrative division of labour. Under such conditions polytheism, which had undoubtedly been nascent before, could develop fully. The social order is mirrored in the conception of city and state gods and of a hierarchically organized "state of gods" with a division of labour. The concentration of power and people in one place, in contrast with the wandering of earlier nomadic cultures, enabled fixed central shrines to become influential. Yet the old traditions continued, and not least among them, that of animalism, in the form of conceptions about a ruler of the animals, animal cults, and similar phenomena. Female fertility figures remain generally prominent, such as the Great Mother and the Earth Mother.

PRESENT STATUS AND PROSPECTS FOR THE STUDY OF PREHISTORIC RELIGION

The material remains of prehistoric times naturally furnish more information about economics, technology, and society than about spiritual meanings. The poverty of the sources and the conjectural nature of what can be said point to the fact that the study of prehistoric religion remains predominantly at the periphery of scientific research. Its future expansion will depend not so much on an increase of source material and of research, but on whether or not it progresses methodologically—in its

Cave painting of a pregnant mare struck by arrows. Design at left is variously interpreted as a trap or a magical symbol meant to ensnare. Upper Paleolithic Period (20,000–10,000/8000 BC). Lascaux, Dordogne, France. Height 109.86 cm.
Jean Vertut—Ziolo

methods of inquiry and interpretation and in its basic theoretical concepts.

Knowledge of prehistoric religion will always remain fragmentary. Every attempt to sketch broad outlines of the area contains its own particular dangers. On the one side are the enthusiasts who try to make too much out of meagre sources; and on the other, the positivists, who set unnecessarily narrow limits to their interpretations. The use of preconceived evolutionary concepts is just as dangerous as undertaking a reconstruction that does not take into account the fact that the chronological sequence of material remains that reflect religious phenomena is not the same thing as a developmental sequence of great religious ideas. Some day perhaps the proper combination of factual, theoretical, and reconstructive capacities will provide a more satisfactory picture of prehistoric religion.

BIBLIOGRAPHY. Comprehensive presentations of prehistoric religion are rare and for the most part not written in English. A useful collection of materials on the Paleolithic, Mesolithic, and Neolithic-Chalcolithic periods is E.O. JAMES, *Prehistoric Religion: A Study in Prehistoric Archaeology* (1957). Even though it is antiquated and restricted to the Paleolithic Period, a classical work that is still very useful is T.H. MAINAGE, *Les Religions de la préhistoire: L'âge paléolithique* (1921). The method of historical-cultural comparison, which is used in this book, is consistently worked out after the "Vienna school" in J. MARINGER, *Vorgeschichtliche Religion* (1956; Eng. trans., *The Gods of Prehistoric Man*, 1960). The same basic concept, restricted to the most simple forms of culture, is shown by F. KERN, *Der Beginn der Weltgeschichte* (1953; Eng. trans., *The Wildbooters*, 1960). K.J. NARR, "Approaches to the Religion of Early Paleolithic Man," in *History of Religions*, 4:1–22 (1964), evaluates the problem in the perspective of the psychic status of early man. Further articles by the same author on specific problems of the religion of the Upper Paleolithic are: "Weibliche Symbolplastik der Älteren Steinzeit," in *Antaios*, 2:132–157 (1961) and "Bärenzeremoniell und Schamanismus in der Älteren Steinzeit Europas," in *Saeculum*, 10:233–272 (1959). No comprehensive presentation of the Neolithic Period has yet been written. The following book offers fundamental material for one of its important problems: G.E. DANIEL, *The Megalith Builders of Western Europe* (1958). The conception of a Megalithic mother goddess in the above book is criticized by A. FLEMING in "The Myth of the Mother Goddess," *World Archaeology*, 1:247–261 (1969). Also dealing with the mother goddess motif is E.O. JAMES, *The Cult of the Mother Goddess* (1959). Justified hesitations against a hasty or premature interpretation of female figurines portrayed as goddesses are brought forward by P.J. UCKO, *Anthropomorphic Figurines of Predynastic Egypt and Neolithic Crete* (1968). Another, probably exaggerated, interpretation of the Megalithic Period in its emphasis on the heavenly god is D.J. WOLFEL, "Die Religion des vorindogermanischen Europa," in F. KONIG (ed.), *Christus und die Religionen der Erde*, vol. 1, pp. 161–537 (1951).

(K.J.N.)

Preschool Education

Preschool education involves the earliest phases of childhood, beginning in infancy and ending upon entry into primary school at about five, six, or seven years of age (the age varying from country to country.) Although preschool education is ordinarily not compulsory, there exists in most countries some variety of preprimary schools, usually both public and private (most Socialist countries have only public facilities). Preschool education differs from the services of day-care and play centres in that the latter are usually merely custodial, providing care, safety, and health services for the children of working mothers or for children who cannot otherwise be cared for at home. The aim of preschool education is to foster the physical, emotional, social, and intellectual development of children—the relative emphasis depending on the prevailing philosophy and goals of the society.

Variety of preschool institutions

The institutional arrangements for preschool education vary widely around the world, as do the names applied to the institutions. The terms usually given to centres for the care of infants—those in the first phase of childhood (about three months to three years of age)—are infant school, nursery school, day nursery, and crèche—the term crèche being used not only in French-speaking countries but also in such places as Scandinavia, the United Kingdom, Czechoslovakia, Poland, the Soviet Union, and Israel. Nursery schools, or crèches, however, may admit older children as well; in Sweden, for instance, crèches welcome children from the age of three months on, until they enter kindergarten at four or five; in English-speaking countries, nursery schools include children of all ages under five or six, because education beginning in the fifth or sixth year is customarily considered a part of primary education.

For the second phase of early childhood, other institutional names and arrangements exist, the most common being the kindergarten and the "maternal school" (*école maternelle*). Typically, the maternal school (for ages

three to four or five) precedes kindergarten (for ages four or five to six), but in some countries—Italy, for instance—a child goes from the maternal directly to the primary school. In Germany, in addition to the *Kindergarten,* there is the *Schulkindergarten* (school kindergarten), which is for children of school age who are not considered sufficiently mature and which therefore serves as a kind of preparatory school for primary school. In the United States, kindergarten is considered a part of primary education.

Many countries have also instituted special schools: in the Soviet Union there are sanatorium kindergartens for children who are either physically handicapped or recuperating from illness; in the United States there are kindergartens for exceptional children, who are mentally retarded or otherwise physically or mentally handicapped.

BACKGROUND OF PRESCHOOL EDUCATION

The earliest institutions for the very young appear to have been philanthropic, established mainly as substitutes for home care rather than as educational supplements to the home. Most of these early institutions were for destitute or homeless children and were frequently in the hands of religious orders.

Early schools. The name usually associated with the initiation of early childhood education in modern times is Johann Friedrich Oberlin, an Alsatian Lutheran pastor in Waldersbach, who took it upon himself to educate his townspeople and, among other things, founded in 1767 the first *salle d'asile* (literally, "hall of refuge"), or infant school, for the care and instruction of very small children while their parents worked in the fields. Young women were employed to teach the young to play and the slightly older to spin, sew, and engage in handicrafts; all were engaged in nature study, with short field trips undertaken to gather flowers and other specimens. Local opposition to Oberlin's innovations were strong, but the French government eventually awarded him a money prize, and Germans as well as French began imitating his infant school—in Lippe-Detmold, Berlin, Kaiserswerth, Paris, and elsewhere. In France, the *salles d'asile* changed from private to state-supported institutions in 1833 when they were made part of the national educational system. Later, their name was officially changed to *écoles maternelles.*

Salles d'asile, or early maternal schools

Seemingly independently of the Continental infant-school movement, the Scottish reformer Robert Owen in 1816 founded in his model community New Lanark an "Institute for the Formation of Character." It served about 100 children of the workers in his cotton mills, mostly from 18 months to 10 years of age; and there were separate infant classes for two- to five-year-olds, who spent half their time in instruction and half in recreation. There they were "trained to associate in kind and friendly manner with their little companions; thus practically learning the pleasure to be derived from such conduct in opposition to envious bickerings or ill-natured disputes." No punishment was employed in the process of education. In bad weather, instruction was conducted indoors; in good weather, out-of-doors for the "benefit of sufficient exercise in the open air."

First infant school

The New Lanark school led to the establishment of England's first infant school in London in 1818. This school was set up by the man who had directed Owen's institute, James Buchanan, and it cared for children aged one to six years. According to contemporary accounts, Buchanan brought to London the methods that he had evolved at New Lanark:

> He began with simple gymnastic movements, arm exercises, clapping the hands, and counting the movements. *Viva voce* lessons followed, arithmetical tables, etc. . . . Watt's Divine and Moral Songs and similar hymns soon followed, and the children never tired of singing them to the accompaniment of his flute. He also gave the little people simple object lessons in which they did most of the talking, and learned to observe and describe.

Buchanan's school was imitated by others, notably by Samuel Wilderspin, who wrote some of the earliest and most widely disseminated monographs on infant education. It may be noted that the founders of the *salles d'asile* in Paris in the 1820s drew upon the work not only of Oberlin but of Buchanan and Wilderspin as well and seem even to have derived their chief inspiration from the English experience.

Meanwhile, in the late 1820s in Italy a Roman Catholic father, Ferrante Aporti, while working to establish elementary schools, became dissatisfied with the progress made by his pupils and was led to investigate the conditions under which their preschool years had been passed. Among other things, he read a translated work of Wilderspin's and, as a result, established Italy's first infant school in Cremona in 1829 and devised an educational plan that aimed at a harmonious combination of moral, intellectual, and physical education. Manual work, at all educational ages, was to give education a certain concreteness and rationality, making it a process of pupil involvement; the very young were to start off becoming accustomed to discipline, friendly cooperation, and piety.

The chief drawback of all these early efforts—at least the chief drawback as seen from a modern viewpoint—is that the schools for infants were largely miniature copies of schools for older children, or they became so as time passed and as public authorities assumed a larger role in the direction of infant schools or *écoles maternelles.* Young children were subjected to books and lessons and training in "good habits." Three-, four-, and five-year-olds were required to sit still in rows in large classrooms, recite lessons in which pictures took the place of living things or activities, and spend hours on reading, writing, and arithmetic.

Froebel and later reformers. With Friedrich Froebel, the German founder of the kindergarten, there arose the first systematic theory of early childhood pedagogy: instead of considering early schooling a form of babysitting or social philanthropy or considering it merely a period of preparation for adult roles, Froebel saw early childhood development as a special phase during which the child expresses himself through play. Child's play was a spontaneous expression of the "divine within him"; it was a "free manifestation of the inner world," a process of discovery and recognition that educated the child to the unity, as well as the diversity, of things in nature. These educational premises guided Froebel's pedagogical institute at Keilhau (founded in 1816), but it was not until 1837 at nearby Bad Blankenburg that he opened his first infant school, which he later called a *Kindergarten,* or "garden for children." He called his school a garden for children for the simple reason that he wished his children to grow and develop as do things in nature. He pointed out that "young animals and plants are given rest, and arbitrary interference with their growth is avoided, because it is known that the opposite practice would disturb their pure unfolding and sound development," but regrettably this has not been the practice with the "young human being," who has been "looked upon as a piece of wax, a lump of clay, which man can mold into what he pleases."

At his kindergarten Froebel sought to put his theories into practice. He devised a collection of geometric playthings (or "gifts," as he called them) that were somehow to symbolize, for the child, nature's concurrent unity and diversity—the sphere representing unity, the cube diversity, and the cylinder a blending of the two. Other figures—solids, planes, lines, and dots—were also included, and various exercises or occupations, such as folding, cutting, and weaving, were offered to make the symbolic forms real or dynamic for the child. Froebel believed that the young child learned best not through formal instruction but through play and imitation, "self-activity." He felt, "All true education in training and instruction should . . . at every moment, in every demand and regulation, be simultaneously double-sided—giving and taking, uniting and dividing, prescribing and following, active and passive, positive yet giving scope, firm and yielding." Since Froebel's day, educators have viewed the preschool years as a period of great educational possibilities. Indeed, his educational plan gained widespread acceptance. Within 25 years after Froebel's death in 1852, kindergartens were

founded in leading cities in Austria, Belgium, Canada, Germany, Great Britain, Hungary, Japan, The Netherlands, Switzerland, and the United States.

In 1892 in Italy, the Agazzi sisters, Rosa and Carolina, initiated a blending of Aporti's infant school and Froebel's kindergarten and produced a prototypical Italian maternal school (*scuola materna*). Rosa Agazzi agreed with Froebel's notion that within the child himself were motivations for self-improvement and discovery and "humanity." In the school the children were thus induced to become collaborators in the search for the instruments of their own education—seeking *realia* (objects from real life) as well as Froebelian symbolic objects to examine. The point of such education was to allow each young human being to find his own singular life-style through natural processes of socialization and acts of responsibility.

The Montessori method

Similarly concerned with nurturing or favourably exploiting the young child's natural impulses—in a safeguarded, constructive way—was one of the most famous figures in preschool education, Maria Montessori, a graduate in medicine and a researcher in experimental psychology and pedagogic anthropology. She began her studies of educational problems with culturally deprived and mentally deficient children in 1899, when she became director of the Orthophrenic School, in Rome. There she achieved remarkable results, for children under her tutelage passed the state examination in reading and writing for normal children. Because her methods worked with defective children, she felt that they might yield even better results with normal children. Thus, in 1907 she took under her care 60 children, aged three to six, from the slums of the San Lorenzo quarter of Rome and thus inaugurated her Casa dei Bambini ("Children's House"). This and later Case dei Bambini justified her hopes, and the schools became world famous.

Individual initiative and self-direction characterized the Montessori philosophy, and thus the teacher was to withdraw to the background and merely supervise the use of "didactic materials," which the children used individually unless helping or being helped by other children. The aim was to train children to be inquirers—so sensitive to the specific characteristics of things about them and so expert in classifying them that everything would possess interest and value for them. The didactic materials were a large complex of educational tools that Dr. Montessori herself developed—such as lacing frames, number rods to develop concepts of numbers, map puzzles, sandpaper letters that children were to trace with their fingers. Also, although usually each child worked alone, group or social activity was not ignored, for there were group gymnastics, games, and religious exercises; and social manners were taught in serving meals, waiting on tables, and the like. The children learned to read, write, and count and to express themselves artistically.

Montessori's method was based on the theory that children go through a series of "sensitive periods," during which they are most susceptible to learning certain skills, such as writing (starting in sand and then progressing to paper), basic arithmetic, and so on. When these periods are missed, or when the child is held back by the teacher, difficulties in learning reading or number concepts may result. Thus, they must be given a measure of freedom (though not license), each child working at his own pace without the tensions of competitiveness. Each child must achieve a sense of order, however; Montessori strongly believed that real freedom demanded both self-discipline and respect for authority. As one of her major achievements, Montessori put to practice the idea that early childhood represents a distinct phase of maturation.

Across Europe, in Belgium, meanwhile, another doctor of medicine, Ovide Decroly, was pioneering in the education of the very young, also proceeding from the psychological study of abnormal or exceptional children. In 1907 he opened his École de l'Ermitage ("School of the Hermitage"), near Brussels. Unlike Montessori's children, however, Decroly's worked in groups; and like the Agazzis' children, they worked with real things drawn from everyday life. His educational system was based upon three processes: observation, expression (oral, written, manual, artistic), and association of space and time. He stated that the young child started to explore his immediate environment and then proceeded to a broader one. He felt the universal needs of the child to be food, protection against danger, endurance for the frustrations of life, work, play, self-evaluation, and self-discipline.

Across the channel in Great Britain were two pioneers in the movement to improve the health and environment of the very young: Grace Owen and Margaret McMillan. Both saw the nursery school as a place fostering health and physical development (prerequisites to any other kind of development) and as a place that should be an extension of the home. Owen wanted every housing development to have a nursery school, where children of various ages would comprise a group resembling a large family and where play would facilitate socialization. McMillan wanted the nursery school to make up for any neglect that the child experienced at home (she worked chiefly with underprivileged children in the London slums) and to provide a kind of compensatory education and care; she had regular meetings with the mothers and required her staff of teachers to live in the neighborhood of the nursery school. She outlined a plan for a three-year course for training teachers for the nursery schools, maintaining that only trained personnel should work with children from three to six years of age. Training centres at Manchester (under Owen), at Deptford (under McMillan), and at London supplied nursery teachers for the entire British Commonwealth as well as for the early nursery schools in the United States. In short, the training of teacher-nurses was important in the theoretical systems of these women; moreover, McMillan felt that one of the main tasks of the teachers should be to help to develop imagination in the young children because "reason is a later growth, depending very much . . . on the previous upspringing of the creative power."

Nursery schools as supplements to the home

The first decade of the 20th century saw the start of what might be called "collective" upbringing. In what was then Palestine the new settlers established kibbutzim, in which were established separate homes for the children in order to free the mothers to work in the commune. As the system has now evolved, all children of a kibbutz from birth to one year remain in an "infant house," cared for by a *metapelet* (upbringer) in charge of four or five babies. During the nursing stage mothers feed their babies in the infant house. The "toddler house," containing about eight children one to three or four years old, emphasizes socialization. All children visit home daily for a few hours. In the next stage, kindergarten, the child three or four to seven years old is under the care of a teacher and her three assistants (*metapelet*). The aim of this period is readiness for the first grade.

Another variety of collective preschool education is found in the Soviet Union, where crèches and kindergartens (*detskiye sady* and *yasli*) were inaugurated about 1919, partly through the persuasions of N.K. Krupskaya (the wife of Lenin), who viewed preschool education as the first step in creating a new Soviet man. Today, children are placed in the crèches (voluntarily) from two months until three years of age; these crèches are under the jurisdiction of the Ministry of Health. The kindergarten, under the jurisdiction of the Ministry of Education, accepts children three to seven years old. All teaching materials used are didactic. The socialization process, respect for authority, and the subordination of individual needs to those of the collective are stressed. Self-discipline and self-reliance are key teaching objectives.

MODERN VIEWS OF PRESCHOOL EDUCATION

The proliferation of nursery schools and other institutions of preschool education in the 20th century can be traced to a number of developments: (1) a new scientific interest in early childhood, resulting from applications in the fields of psychology, medicine, psychiatry, and education; (2) recognition of the importance of child guidance and parent education; and (3) the efforts of individuals and agencies to improve the educational programs of day nurseries already established for the care of children of working mothers. Because the nursery school movement

has sprung from such a variety of social forces, no one type of school may be described as representative of the movement. Nevertheless, it is profitable to consider a few modern views of early childhood education.

Psychological theories. Psychoanalytic theory—with its concepts of unconscious motivation, early stages of libido development, the concept of id, ego, and superego as integral parts of the personality—has clear relevance to early childhood education; and indeed Anna Freud, together with her followers, applied many of her father's and her own concepts to her work with very young children. In the 1950s the American psychologist Erik Erikson enriched the traditional ideas of child development by viewing early childhood as a sequence of stages of development during which there took place important "crisis encounters"—inner conflicts such as trust versus mistrust, autonomy versus shame and doubt, initiative versus guilt. The successful resolution of these crisis encounters depended not only upon the child himself but also upon his milieu. From this can be deduced the importance of careful training for teachers of preschool children.

Theories of Piaget

A second major contribution has been the developmental psychology of Jean Piaget and his followers, who are convinced that children advance through rather regular stages of intellectual development. The first two periods—sensorimotor intelligence (from birth till two) as well as representative intelligence (from two to seven or eight)—relate to the field of early childhood. In the first stage (sensorimotor) the child learns to use his muscles and senses to deal with external objects and events while his language begins to form. He also begins to deal with and know that things exist even if they are beyond his sight and touch. He also starts to "symbolize" (represent things by word or gesture). In the second stage the child experiences the greatest language growth; words and other symbols become a way to represent both the outside world and inner feelings. At this time "magical explanations" make sense to him. He begins to gain a sense of symmetry. His adjustments depend on learning by trial and error, and he manages things by intuition. He begins to integrate symbolization and elementary types of relationships, such as logical and mathematical relationships (grouping, sizes, quantities, and qualities) and spatial and temporal relationships. Piaget's theory laid the groundwork for recognizing the importance of cognitive learning processes and concept formation in the young child. Piaget also stressed the importance of an environment conducive to learning the necessary skills.

New areas of concern. One of the major concerns of nursery schools and kindergartens has been language development. Most investigators agree that true speech starts when the child begins to develop meaningful associations with the words he uses (an infant who imitates the word "mama" without understanding its meaning is not engaging in true speech). For a child between two and six, oral speech is a major task, involving both expression and comprehension. By about the age of four he has mastered the fundamentals of the systematic grammar of his language. By the age of six the average child has increased his vocabulary to about 2,500 words or so—the degree of increase depending on the environment, its variety, and on the willingness of adults to relate to the child. Many studies show that the very young child in an impersonal institution, such as an orphanage, generally lags in language development behind children of the same age in a family setting or in a setting with a close relation between family and nursery school.

Language development of the child

One of the many tasks of early childhood education is to provide training in elementary language skills for all children, but especially for those who need compensatory work. To improve their comprehension and speech there are listening and language games. Educators who find educational games a successful teaching device claim that they stimulate the children's interest in learning.

In recent years a new factor, that of nutrition or malnutrition, has been discovered to have a significant bearing upon early child development. The currently available data from different countries regarding the effects of malnutrition (especially protein and iron deficiency) upon the physical and intellectual growth of children indicate that it can cause mental retardation, especially if it happens during the first year of life. Some studies indicate that permanent changes in the brain may result. Other studies suggest that psychological changes brought about by malnutrition at an early age may persist later in life. In any event, the malnourished child usually appears apathetic, without initiative or energy; previously this "laziness" was stereotyped as a characteristic of certain minority ethnic groups or lower social classes.

Compensatory early childhood education calls for a well-balanced diet for the young child. Furthermore, to assure a good start for the newborn, attention must also be paid to meeting the mother's nutritional needs during pregnancy. In this sense, it may be said that preschool education, as a preparatory measure, has come to be concerned with the child even before birth.

The main goal of early childhood education is usually defined in terms of the prevailing philosophical, political, and religious trends of the given society and from one historical period to another. Thus, the objectives and methods vary from society to society. Nevertheless, there is general agreement that the nursery school is the first very important step in the education of the child because it helps him in achieving later success in school and because it starts to mold him in the image of the society that he is to perpetuate. In societies based on the concept of the collective, the preschool child is already expected to be a participating member; hence great stress is placed upon his socialization. In societies in which individualism predominates, the child is expected to become an individual and to fend for himself at an early age.

BIBLIOGRAPHY. One of the most detailed surveys of the great pioneer figures of early childhood education is ROBERT R. RUSK, *A History of Infant Education*, 2nd ed. (1951; reprinted 1967). Some of the more important classic works are H. SILVER (ed.), *Robert Owen on Education* (1969), containing a collection of Owen's writings; MARIA MONTESSORI, *Il metodo della pedagogia scientifica* (1909; Eng. trans., *The Montessori Method*, 1912, reprinted 1964); MARGARET MCMILLAN, *The Nursery School*, rev. ed. (1930); HARRIET M. JOHNSON, *Children in the Nursery School* (1928, reprinted 1971); and JEAN PIAGET, *Le Langage et la pensée chez l'infant*, 4th ed. (1956; Eng. trans., *The Language and Thought of the Child*, 3rd ed. rev., 1959), and *La Formation du symbole chez l'infant*, 2nd ed. (1959; Eng. trans., *Play, Dreams, and Imitation in Childhood*, (1962). One of the most comprehensive books of readings is JOE L. FROST (ed.), *Early Childhood Education Rediscovered* (1968). The two classic works dealing with communal education in Israel are BRUNO BETTELHEIM, *The Children of the Dream* (1969); and MELFORD E. SPIRO, *Children of the Kibbutz*, new ed. (1965). The most important work on the education of the young in the U.S.S.R. is Н.К. КРУПСКАЯ, *Дошкольное воспитание* (1959), which is vol. 6 of the author's collected writings. An overview of Soviet pedagogy in English is contained in HELEN B. REDL (ed.), *Soviet Educators on Soviet Education* (1964). See also various publications of the UNITED NATIONS EDUCATIONAL, SCIENTIFIC, AND CULTURAL ORGANIZATION (such as the annual *International Yearbook of Education*) and the WORLD ORGANIZATION FOR EARLY CHILDHOOD EDUCATION (such as reports of conferences).

Prescott, William Hickling

A United States historian best known for his dramatic narratives of Spanish conquests of Mexico and Peru, Prescott has been called America's first scientific historian.

William Prescott was born in Salem, Massachusetts, on May 4, 1796, of a prosperous, old New England family. He received three years of rigorous instruction in a preparatory school headed by the Jesuit John Gardiner, who infused in him a love of classical learning. In 1811 he entered Harvard, where his academic record was good but undistinguished; he had serious difficulties with mathematics, and in later life the prospect of appraising the mathematical achievements of the aboriginal Mexicans almost prevented him from completing his work. Near the end of his junior year, a crust of bread thrown during a melee in the student commons caused virtual blindness in his left eye; the weakness of his other eye, caused by

His impaired vision

infection, sometimes prevented him from carrying on any kind of literary work. Throughout his life, Prescott's vision seems to have fluctuated from good to total blindness; and he often resorted to the use of a noctograph, a writing grid with parallel wires that guided a stylus over a chemically treated surface. Substantial portions of all his books and correspondence were composed on this device.

Prescott, daguerreotype portrait, *c.* 1845.

Following his graduation from Harvard in 1814, Prescott's health deteriorated after attacks from what appears to have been an acute type of rheumatism, with swellings in his larger joints and lower legs. He convalesced at his grandfather's home in the Azores and then, encouraged by an apparent recovery, toured Europe. After his return to Boston, he embarked upon serious historical studies, shunning a career in business or law because both occupations demanded more stamina than his delicate health and eyesight could allow. At least the youthful Prescott used this argument as late as 1820, when he married Susan Amory. With no obvious occupation, he was known as "the gentleman" by his Boston friends. His wife, as well as other readers, provided the eyes that helped Prescott at this time to embark on a literary career.

His first publication was a number of reviews and essays in the *North American Review* in 1821. Some of these were reprinted in *Biographical and Critical Miscellanies* (1845). His "Life of Charles Brockden Brown" (1834) in Jared Sparks's *Library of American Biography* served notice of Prescott's high abilities as a writer. Largely on the advice of his friend the teacher and writer George Ticknor and the later encouragement from the miscellaneous writer Washington Irving, Prescott turned to Spanish themes for his life-work. The appearance in 1838 of a three-volume *History of the Reign of Ferdinand and Isabella the Catholic,* the product of some ten years of work, was an agreeable surprise to Boston's literary world. This work launched Prescott's career as a historian of 16th-century Spain and its colonies. In his first and only such work, *A History of the Reign of Philip the Second, King of Spain* (3 vol., 1855–58), Prescott produced graceful, authoritative narratives of Spanish military, diplomatic, and political history that had no equal in their time. His modern popularity rests with his epic *History of the Conquest of Mexico* (3 vol., 1843) and his *History of the Conquest of Peru* (2 vol., 1847).

Working with a superb personal library of perhaps 5,000 volumes and with the help of such overseas associates as Pascual de Gayangos, the Spanish aide who discovered manuscripts and rare books for him, Prescott made rigorous use of original sources. His critical use of historical evidence was such that he might well be called the first U.S. scientific historian. The fact that Prescott's histories continue to be popular with scholars as well as lay readers after more than a century of criticism attests to their vitality and readability. Though further research has revised his view of 16th-century Spanish monarchy, Prescott's basic work is still judged to be generally fair and accurate. It was in narrating the Spanish conquests at that time that Prescott's republicanism penetrates his histories so as to colour his picture of the Spanish state and the aboriginal governments of the Aztecs and the Incas. Moreover, his New England Unitarianism made it difficult for him to appreciate the acceptance of the miraculous or supernatural among peoples of another age or to understand the peculiarities of the conquistadors.

Criticisms of his approach

Perhaps the most severe unfavourable criticisms of the *Conquest of Mexico* and the *Conquest of Peru* are based upon his romantic version of native civilizations, which later findings in archaeology and anthropology have found to be distorted. Prescott's failure to visit the historical settings of his narratives and to examine actual remains of the native cultures he described was partly responsible for this defect in his books. Yet the contributions to understanding of pre-Columbian civilizations were made by scientists after Prescott's time, and modern scholars have concluded that Prescott's historical narrative, based upon Spanish chronicles, is essentially sound. What Prescott hoped to do with his histories was to instruct and to entertain. His history was narrative and descriptive rather than philosophical or analytical. His colourful prose dealt with conquests, war, diplomacy, and politics—not with cultural, social, or economic themes. In his Spanish histories his concern was almost exclusively with the Spanish courtiers and other aristocrats.

Despite such criticisms, Prescott's achievements as a historian and as a literary artist were remarkable. For example, the persistent demand for the *Conquest of Mexico* has resulted in its publication in ten languages at least 200 times and that of the *Conquest of Peru* in 11 languages at least 160 times. He was the first English-speaking historian to reach a wide audience outside the Hispanic world with a history expressing the Spanish point of view. Spaniards, in Prescott's histories, were often forerunners of progress. Thus the Moors in Spain and the aboriginal peoples of Mexico and Peru make way for the achievements of Spanish characters. Throughout the conquistador histories, Prescott exposes the reader to vivid landscapes, battles, and processionals as the march of Spanish civilization overwhelms the savage world. Prescott's literary artistry convincingly shows the conquistador Cortés caught up in a series of crises that, on the eve of final victory, tend to become more and more complex. In the end, however, "pusillanimity" of the Aztec emperor Montezuma is the advantage that the forthright Cortés has in determining the outcome of events.

Prescott weaves a dramatic fabric that completely envelopes his narrative. Indeed, much of the same story is repeated in both the *Conquest of Mexico* and the *Conquest of Peru* in respect to descriptions of battles, characterizations, use of metaphor, dramatic encounters, and crises, suggesting that Prescott perhaps manipulated his narratives for literary effect. Yet critics generally agree that he accurately follows his sources. His empathy with the Spanish point of view still makes him the greatest Anglo-U.S. historian of the Hispanic world.

Prescott won for himself and for the United States the distinction of making a significant contribution to historical literature that was recognized throughout the world. Even in his lifetime his achievement was recognized, for, as his biographer George Ticknor maintained, Prescott's visit to England in 1850 was the most distinctive visit ever made to England by an American who was not a government official. By the time of his death on January 28, 1859, Prescott had proved that epic history could be written as literature. In this sense he prepared generations of readers for the polished writings of Boston's other literary historians, such as John Lathrop Motley, George Bancroft, and Francis Parkman. Tall, handsome in appearance, Prescott's personal charm was such that he was popular with the society of his day despite his delicate health and difficulties with sight. His interest in Boston's Perkins School for the Blind, as well as his histories, have served to remind later generations that his triumph over physical obstacles was in itself a heroic achievement.

BIBLIOGRAPHY. C. HARVEY GARDINER, *William Hickling Prescott: A Biography* (1969), is a critical biographical study of Prescott as a writer and as a historian based upon exhaustive research. Gardiner and all other writers on Prescott are indebted to GEORGE M. TICKNOR, Prescott's lifelong friend and associate, for *Life of William Hickling Prescott* (1864). Prescott's talents and faults as a writer are examined in DAVID LEVIN, *History As Romantic Art: Bancroft, Prescott, Motley, and Parkman* (1959); an appraisal of Prescott's scholarship and his significance is made in WILLIAM CHARVAT and MICHAEL KRAUS, *William Hickling Prescott* (1943). Additional sources on Prescott's life and work are C. HARVEY GARDINER (ed.), *The Papers of William Hickling Prescott* (1964) and *The Literary Memoranda of William Hickling Prescott*, 2 vol. (1961); and W.H. MONROE (ed.), *The Works of W.H. Prescott*, 22 vol. (1904).

(W.R.J.)

Pressure and Temperature, Biological Effects of

All biological activities depend upon the chemical reactions that constitute the metabolism of living things. These reactions are influenced by both temperature and pressure, and living things vary greatly in their ability to withstand exposure to pressures and temperatures beyond normal ranges of activity. Most animals are active between about 10°–40° C, although two species of blue-green algae are known to live in thermal springs at temperatures exceeding 85° C and the marine clam, *Yoldia arctica*, is found in waters colder than 0° C.

Physiological ranges of pressure and temperature

Terrestrial organisms at sea level are subjected to one atmosphere of pressure (14.7 pounds per square inch). As altitude increases, atmospheric pressure decreases, until, at the top of Mt. Everest, the highest point on earth at 8,824 metres (29,028 feet) above sea level, atmospheric pressure is less than five pounds per square inch. With the exception of some micro-organisms and insects, there are no living things at this altitude. Since water is 773 times more dense than air, aquatic organisms experience higher pressures than do terrestrial ones. Even though water pressure increases one atmosphere for each 10 metres (33 feet) of depth, a remarkable variety of life exists in the deepest marine trenches (11,000 metres, or 36,000 feet), where pressures exceed 16,000 pounds per square inch.

With regard to temperature, the earth provides a relatively moderate environment compared with outer space, where the temperature approaches absolute zero (0° K, or −273° C), and the surface of the sun, which is 6,000° K. The lowest temperature on earth (−68° C) occurs in Alaska and Siberia; the highest, in hot springs of New Zealand, may exceed the boiling point of water (100° C). Although most of the life on earth is found in regions of less extreme temperatures, some organisms are able to survive the natural temperature extremes cited above.

BIOLOGICAL EFFECTS OF PRESSURE

Effects of pressure on cells. In the 19th century, dredging expeditions disclosed that animals live at depths of 11,000 metres in the sea. Samples of the ocean floor have been brought to the surface under pressure, so that the single-celled organisms that normally live there under great pressures may be studied.

Many species of bacteria are able to grow at pressures of 200–300 atmospheres (atm); higher pressures, however, usually inhibit growth, which is measured as rate of reproduction. For reasons not yet known with certainty, bacteria isolated from ocean depths grow better at low pressures than at high ones, and attempts to grow them at the pressures from which they are obtained (more than 1,000 atm) have not yet been successful. The failure of most bacteria to grow at high pressures stimulated studies of their structure and biochemistry under conditions of high pressure. One of the most frequently observed effects of high pressures (exceeding 300–400 atm) on cell structure is the formation of long filaments, often accompanied by a thickening of cell walls. Several bacterial species develop swollen or bizarre shapes near the threshold of pressure tolerance. Biochemical studies have revealed that the amount of hereditary material, deoxyribonucleic acid (DNA), in the bacterium *Escherichia coli* is considerably less at high pressures than at normal ones; the decreased amount of DNA may be related to inhibition of cell division at high pressures.

The ability of micro-organisms to survive high pressures is influenced not only by the amount of pressure but also by its duration and the temperature at which it occurs; generally, the longer that cells are exposed to high pressure, the more it affects their structure and survival. The harmful effects on cells of high pressure over a long period of exposure, however, often are offset either by lowering or raising the temperature, relative to the temperature for optimum growth at one atmosphere; in a similar manner, high pressure appears to retard cell death at high temperatures. Certain bacteria that reduce sulfate to hydrogen sulfide during metabolism have been found to be able to survive the combination of highest temperature and pressure; sulfate-reducing bacteria have been maintained for several days at a pressure of 1,000 atm and a temperature of 104° C.

High pressures may produce a number of effects on both external and internal chemical environments of cells, which, in turn, may influence the rates of important chemical reactions. High pressure also may influence the structure of cellular proteins, including enzymes (organic catalysts) essential to the chemical reactions that occur in cells. The most complete analysis of the effects of pressure on chemical reactions has been derived from the Arrhenius theory, discussed below.

Arrhenius theory

About 1889, the Swedish chemist S.A. Arrhenius offered a theory to explain the increase in rate of chemical reactions with increases in temperature. The theory proposes that molecules require a certain amount of energy, called the activation energy, before they are able to enter into a reaction; the higher the activation energy of a molecule, the higher must be the temperature before a measurable reaction rate occurs. The theory, when applied to molecular volume changes that accompany chemical reactions, results in a determination of the volume change of activation—*i.e.*, the volume change that chemical reactants undergo in reaching a state of activation sufficient to produce a chemical reaction. The volume changes that occur during chemical reactions at ordinary pressures are small and of little importance; at high pressures, however, volume changes are important in interpreting the effects of pressure on biochemical reactions.

The rates of biochemical reactions may be either retarded or accelerated by increases in pressure, depending on volume changes that occur; a reaction involving increases in the volumes of the reactants, for example, is inhibited by increases in pressure, whereas a reaction involving decreases in the volumes of the reactants is accelerated by increases in pressure. Since most chemical reactions involve volume increases, they are inhibited by high pressure, so that many of the harmful effects of high pressure on cells may be the result of inhibition of essential biochemical reactions.

Despite the explanation provided by the Arrhenius theory, the problem of the ways in which micro-organisms are adapted to live on the ocean floor remains unsolved. The existence of life at such high pressures would appear to involve some mechanism for counteracting the inhibitory effects of pressure on cellular processes.

Effects of pressure on plankton. A number of factors influence the distribution of small organisms in the sea. In addition to high pressure, life in ocean depths is limited by low temperatures, lack of light, and shortages of food. As a result, much oceanic life is found within 50–100 metres (160–330 feet) of the surface; even near the surface, however, pressure, a major indicator of depth, is important. Most plankton remain in a relatively shallow zone. Some species, whose weight equals that of the water they displace, float within this narrow zone; active movements, however, are necessary for most species to stay within the limits at which they are able to live. Although light provides some information about depth near the surface, it varies in intensity, both with distance from the ocean surface and on a daily basis; changes in pressure, therefore, provide organisms with more accurate information on depth. Many species of invertebrate plankton,

which are sensitive to minute changes in water pressure, probably respond to these changes by using information received from specialized receptors that detect small changes in pressure associated with changes in depth.

Effects of pressure on plants. Marine plants must remain near the surface of the ocean since light is necessary for photosynthesis. Most plants, however, are unable to move actively and remain near the surface by increasing their buoyancy (ability to float), usually by secreting low density gases into specialized structures, such as vacuoles or pneumatocysts.

Although pressure influences marine plants, some interesting examples also are encountered in pressure effects in terrestrial plants—*e.g.*, the lifting of sap from lower than ground level to the tops of trees that may attain heights of 100 metres (about 330 feet). A suction pressure of at least −20 atm at the top of a tree is required to raise a column of sap 100 metres, to maintain this pressure, and to overcome the friction in the plant tissue (xylem) in which the sap is carried. Pressures are even more pronounced in other plants—*e.g.*, saltwater mangroves use suction pressures up to −60 atm to pull freshwater into the sap against the pressure of seawater, and, in parasitic plants such as mistletoe, suction pressures 10 to 20 atm greater than those of the host are maintained. Columns of water are maintained under large negative pressures in the small tubelike structures found in the xylem of trees because cohesion, or holding together, is a property of water confined to small spaces.

Effects of pressure on animals. Some animals living in the sea are able to float by depositing low-density substances (for example, fat) in their tissues. Most fishes and some invertebrate animals, however, float by using gases. Gases, because they contract as pressure increases and expand as pressure decreases, require special adaptations. In order to control buoyancy, these animals must maintain a constant volume of gas as the water pressure changes, and some aquatic animals have evolved unique structures for maintaining buoyancy under pressure.

The invertebrate cuttlefish, an agile and rapid swimmer, has a unique structure, called a cuttlebone, along its upper surface. The cuttlebone, composed of layers of many small chambers encased in a rigid network of calcium carbonate, has a bonelike appearance; part of the cuttlebone contains gas (primarily nitrogen), part liquid. A cuttlefish increases its floating ability, or buoyancy, by moving water out of the cuttlebone, thus increasing its proportion of gas-filled space; expansion of gas as pressure decreases is prevented by the rigid matrix surrounding the chambers. Buoyancy decreases when water enters the cuttlebone, reducing the proportion of gas-filled space. Further decreases in buoyancy occur as the cuttlefish sinks because the higher water pressure forces water back into the cuttlebone.

Swim bladder in fishes

In most fishes, buoyancy is maintained by the secretion of gases into a structure called a swim bladder. The swim bladder, normally about 5 percent of the weight of a fish, keeps the fish from sinking and is flexible. If a fish rises toward the water surface (with a decrease in pressure), the swim bladder expands, and gas must be removed if the fish is to regain its buoyancy. In some fish (the Physostomi) the swim bladder is connected to the esophagus, so that gas can pass out through the mouth. In many deep-sea fish (the Physoclisti), however, the swim bladder has no external opening, and gas is removed by the oval chamber (see Figure 1), which has a rich blood supply and is normally separated from the rest of the swim bladder by a ring of muscle. When the muscle relaxes, gases in the swim bladder pass into the blood, thus reducing the volume of gas in the swim bladder.

Fishes that swim into deep waters regain their buoyancy only if the volume of the swim bladder is increased by adding gas, a function that is performed by a special structure known as the gas gland, which transfers dissolved gases from the blood to the swim bladder (see Figure 1). Most fish transfer oxygen into the swim bladder against enormous pressures—*i.e.*, the pressure of oxygen dissolved in seawater and blood is about one-fifth of an atmosphere, but at 4,500 metres (about 15,000 feet),

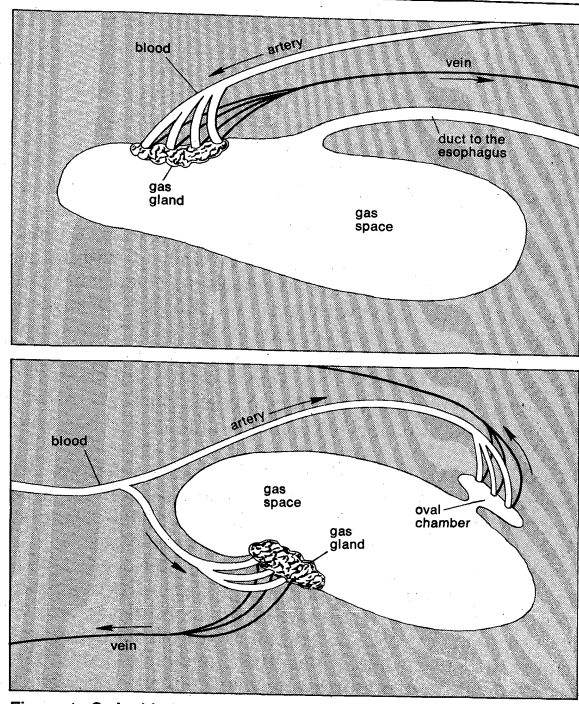

Figure 1: Swim bladders of a physostomid fish (top) and a physoclistid fish (bottom).
From E.J. Denton, *Progress in Biophysical and Biophysiological Chemistry* (copyright 1961); reprinted with permission of Pergamon Press Ltd.

the depth at which fishes with swim bladders live, the gas in the swim bladder is under a pressure of 450 atmospheres. In addition to the oxygen in the swim bladder, there are other gases, such as argon, that are present in measurable quantities. Since no known biochemical reactions involve this element, its transfer by the gland is probably a physical process.

Fishes obtain oxygen from air dissolved in water, and increases in pressure have no effect on this process. Air-breathing animals that enter or live in the ocean, however, face special problems. Air is taken into the lungs at the water surface, and the pressure increases that occur when the animals dive decrease the volume of the lungs, forcing gases into the blood; two things may happen as a result of the high concentration (80 percent) of nitrogen in air. First, large quantities of nitrogen under pressure readily dissolve in tissues, a condition that is toxic to a man diving in deep water, producing an anesthetic effect called raptures of the deep, or nitrogen narcosis. Second, if a diver rises rapidly to the surface, pressure decreases rapidly, the nitrogen in tissues comes out of solution, forms bubbles, and the result is the painful, and often fatal condition, known as bends, or caisson disease.

Although the above-mentioned problems affect man when he descends to considerable depths, many air-breathing animals live in the sea and dive to great depths; the sperm whale, for example, attains depths of 1,000–2,000 metres (3,300–6,600 feet) and returns quickly to the surface unharmed after being submerged for 1–1½ hours. Diving animals have a unique reflex for diving to great depths and staying submerged for extended periods of time without ill effects—before diving, they exhale, thereby reducing the volume of air in the lungs and helping to prevent nitrogen from entering the body; as this occurs, the rate of the heartbeat decreases, and blood flow to most parts of the body, except to the brain and heart, is reduced, allowing the diving animal to conserve the oxygen in the blood for vital tissues.

BIOLOGICAL EFFECTS OF TEMPERATURE

Effects of temperature on cells. As stated previously, Arrhenius proposed a theory to explain the effects of temperature on chemical reaction rates; his concept that molecules require a certain amount of energy (activation energy) before they are able to react was based on the observation that the rate of chemical reactions increases

with increases in temperature. Since higher temperatures provide more energy for reaction, the rate of cell functions increases at high temperatures and decreases at lower ones, within the physiological range. A descriptive expression for activation energy is temperature coefficient, or Q_{10}, which is defined as the change in the rate of a reaction when the temperature changes by 10° C; thus the rate of a reaction with a Q_{10} of two is doubled with an increase in temperature of 10° C and is reduced by one-half with a 10° C decrease in temperature. The normal temperature range of most cells is 10°–40° C; within this temperature range, the Q_{10} (temperature coefficient) for many processes is between one and three. For diverse phenomena, such as certain enzymatic reactions, rate of movement by insects, chirping of crickets, and flashing of fireflies, the Q_{10} is about two. Temperature coefficients for reactions involving physical processes, such as photochemical and diffusion phenomena, are usually less than 1.5.

Temperature coefficient

Determination of temperature coefficients allows descriptions of the effects of temperature on cellular processes within normal physiological limits. If the temperature increases above 45° C or decreases below 5° C, many types of cells die. Heat death, or cell death above 45° C, may be related to the effects of heat on proteins or, more specifically, on the enzymes that control most cellular functions; exposure of proteins to high temperatures causes structural alterations that inactivate many enzymes. High temperatures also may influence the structure of cell membranes. Since high pressure reverses many of the effects of high temperature (see above, *Effects of pressure on cells*), it may retard heat death. Cold death, or cell death below 5° C, may result from a general reduction of metabolic rate as the temperature decreases; if a reaction has a temperature coefficient (Q_{10}) of two, for example, a temperature decrease from 40° C to 0° C results in a 16-fold reduction in metabolic rate. In addition, either the internal structure of cells may be injured by ice crystal formation at the freezing point or the cells may become excessively dehydrated as water in them freezes.

Although most cells live within a temperature range of 10°–40° C, some live at higher or lower temperatures; bacteria and blue-green algae thrive in hot springs at temperatures above 60° C, and some molds and bacteria survive in ice cream at −10° C. Cells that live at high temperatures contain enzymes that are able to resist breakdown by temperature better than enzymes of cells that live within the normal range. The membranes of heat-resistant cells also are more stable at high temperatures than are those of cells within the normal range. The ability of cells to survive low temperatures, however, may be influenced by the rate at which they are cooled—*i.e.*, rapid freezing may result in ice formation, very slow freezing may result in supercooling, which is a decrease in temperature below the freezing point without ice formation. In nature, temperatures usually decrease slowly, often with the result that cells are supercooled; the temperatures of several species of fish that live in deep Arctic fjords, for example, are below the freezing point, but their cells are not damaged by ice formation. Some cells reduce the danger of cold death with an antifreezelike compound, which lowers the freezing point of the internal contents.

Although some cells are able to survive extreme temperatures of heat and cold, many temporarily suspend life activities (*i.e.*, become dormant) if conditions become unfavourable; bacteria form spores, protozoans and some invertebrate animals form cysts. These dormant forms are much more resistant to temperature extremes than are active forms; thus, temperatures up to 170° C for one-half hour may be required to kill spores and cysts, and some spores are capable of germinating even after exposure to temperatures as low as −272° C (see also DORMANCY).

Effects of temperature on plants. Unlike many animals, plants are not capable of generating heat in order to maintain temperatures independent of their surroundings; plant cells, therefore, are subjected to injury from either low or high temperatures, and their ability to function depends on the temperature coefficients (Q_{10}) of their cellular processes. Structural and functional adaptations also enable some plant species to survive harsh environments, although temperature changes may have pronounced effects on plant development.

Daily fluctuations in temperature, called thermoperiods, have dramatic effects on the growth of most plants. Temperature changes at night are particularly important, since most plants grow best when night temperatures are lower than day temperatures. The thermoperiod that produces optimum growth varies among different plants. For a given species, however, slight changes in night temperature can produce extreme changes in growth; if night temperature is not within a few degrees of 17° C, for example, fruit production of tomato plants is severely inhibited. The significance of the decrease in night temperature is not yet completely understood, although lower temperatures may act as triggers, promoting plant growth at the most favourable time of year.

Thermoperiods

Annual temperature changes are also important for plant development. In many species of trees, seasonal exposure to low temperatures is necessary for leaf formation the following spring. Artificial exposure of plants to low temperatures before transplanting, called vernalization, is practiced commercially to enhance fruit and seed production in many important crops.

Although the importance of exposure of plants to cold is known, the mechanisms by which some plants survive freezing temperatures in winter have not yet been established. Cell damage from ice formation and freezing of columns of sap in woody plants may occur. When water freezes to form ice, gases come out of solution, and small bubbles should form in plant tissue called xylem. When ice melts, the movement of sap under negative pressure should be hampered by pockets of gas in the xylem; seasonal changes apparently occur, however, in some plants, enabling them to withstand such freezing. Experimentally induced freezing of trees during summer months may cause damage that does not occur in winter. During the fall months, therefore, trees must become accustomed to, or acclimate to, cold; acclimatization in trees is not yet completely understood, although for some plant species it may involve water loss from cells (see also ACCLIMATIZATION).

Plants are exposed to high temperatures, sometimes up to 50° C, in deserts, which also lack water—a component essential for life and one that evaporates readily at high temperatures. A shortage of water may be a more important factor than high temperatures in limiting the number of successful desert-plant species. Nondesert plants grow at high temperatures as long as sufficient water is provided to compensate for high losses from evaporation; without adequate water, however, plants wilt as evaporation causes excessive water loss. Most desert plants adapt to their environments by storing available water, and they have thick, waxy surfaces that help to prevent excessive water loss at high temperatures. In addition, some plants lose their leaves during periods of drought when the temperature is high, thereby reducing water loss, since water evaporates during respiration through leaf openings (stomata); when water again becomes available, new leaves grow, and photosynthesis resumes. Drought in the hot desert has an effect on plants similar to that of cold in that both result in loss of leaves and temporary suspension of photosynthesis.

High-temperature adaptations of plants

Seeds provide a means by which many plant species are able to survive extreme cold, heat, or drought. Seeds resemble spores and cysts since all are able to remain dormant. The seed coat is a primary defense against the environment; it protects the plant embryo inside from excessive water loss, mechanical injury, and temperature extremes.

Seeds as protective devices

Effects of temperature on animals. Based on their ability to maintain an internal temperature, animals may be divided into two types—cold-blooded, or poikilothermic, animals, including all invertebrate animals, fishes, amphibians, and reptiles, that usually have about the same temperature as their environment; and warm-blooded, or homoiothermic, animals—mammals and birds—that maintain a relatively constant body temperature (about 37° C

for mammals, 40° C for birds) regardless of the environmental temperature.

Poikilothermic animals, greatly influenced by environmental temperatures, are limited, with only a few exceptions, to areas with a temperature range of 10°–40° C; some poikilotherms, however, compensate for extremes in temperature by taking advantage of the fact that most complex environments contain microclimates in which temperatures suitable for life may be found. Many desert reptiles, for example, seek the sun during cool mornings, retreating to cooler, shady burrows when the temperature increases. Some terrestrial poikilotherms maintain remarkably constant body temperatures by seeking out microclimates. Interestingly, the microclimates are usually close to 37° C, the approximate body temperature of homoiothermic animals.

Since homoiotherms maintain constant body temperatures, they are able to remain active in situations in which poikilotherms cannot. Body temperatures of homoiotherms are kept at a constant value by regulatory mechanisms that counteract the effects of the external environment. In cold environments, therefore, regulatory mechanisms maintain body temperature by increasing heat production and decreasing heat loss; in hot environments, regulatory mechanisms maintain body temperatures by increasing heat loss. Within a neutral range (27°–31° C for man) neither heat gain nor heat loss is necessary to maintain body temperature (see also HOMEOSTASIS).

The metabolic rate of homoiotherms exposed to temperatures below the neutral range increases (in contrast to the decrease that takes place in poikilotherms), and the heat thus produced counteracts the increased heat loss due to the low temperatures, so that body temperature remains constant. In order to control the rate of metabolism, homoiotherms have receptors that detect changes in body temperature; some are located in a specific area of the brain called the hypothalamus. When this area of the brain detects a temperature decrease it activates nerves that cause reactions in muscles (*i.e.*, shivering), which increase metabolism and heat production.

Although the increase in metabolism resulting from responses to decreases in temperature enables homoiotherms temporarily to increase heat production, animals in permanently cold areas would have to expend excessively large quantities of energy to maintain a high metabolic rate. Arctic homoiotherms, instead, have evolved two mechanisms to prevent the loss of heat from the body. One is increased insulation; Arctic mammals have thicker fur, Arctic birds thicker feather coats, and whales in Arctic seas thicker layers of blubber than do similar animals from temperate regions. The entire body is not covered with insulation, however; *e.g.*, the feet of most birds have no feathers, the nose of a wolf has no fur. The second mechanism for decreasing heat loss occurs in the extremities and is based on opposite direction of blood flow in arteries and veins. When it is warm, most of the blood returning to the body from extremities is carried in veins close to the skin (Figure 2). When it is cold, however, the blood returning to the body flows in veins that are close to the arteries, and veins close to the skin constrict (Figure 2). Some of the heat from the arteries, which carry warm blood to the body extremities, passes to (and therefore warms) the cooler venous blood coming from the extremities. This mechanism, which is called countercurrent heat exchange, is one of the important ways for Arctic animals to prevent body heat loss.

From K. Schmidt-Nielsen, *Animal Physiology* (1964)

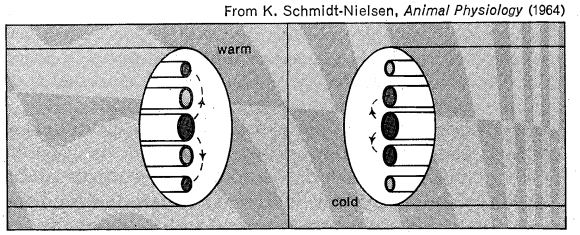

Figure 2: Change in venous blood flow in extremities from near the skin in warm environments to near the arteries in cold environments.

Even though homoiotherms have mechanisms for generating and conserving heat, the energy provided by food, which may be scarce during the winter months, is necessary to maintain a constant body temperature. Some birds migrate to avoid exposure to cold. Some mammals hibernate. A characteristic of hibernation is a decrease in body temperature, which, in turn, means that less energy is required to maintain normal body temperature. By saving energy in this way, however, hibernating animals sacrifice their ability to remain active, since their lower body temperature forces them into a state of lethargy or torpor.

Homoiothermic regulation in a hot environment

When environmental temperatures are above the neutral range (27°–31° C for man), homoiotherms increase heat loss from the body to maintain a constant temperature by one or more of the following methods: conduction, radiation, or convection of heat or evaporation of water. The amount of heat lost by conduction, radiation, or convection is related to the difference between the temperature of the animal and the temperature of the environment. As the environmental temperature increases, this temperature difference decreases, and the amount of heat lost by these methods also decreases; most homoiotherms, therefore, evaporate water to cool themselves when environmental temperatures are high.

Heat is lost when water evaporates because energy, called the heat of vaporization, is needed to change water from a liquid to a gas. About 580 calories of heat are lost whenever one gram of water evaporates from a body. Because terrestrial animals normally contain more water than the environment, water normally evaporates from them by diffusion. Loss of water by diffusion alone, however, is not rapid enough in a hot environment to maintain a constant body temperature. Three mechanisms evolved by homoiotherms to increase the rate of evaporation of water include sweating, panting, and grooming with saliva; all involve an increase in the secretion of watery fluid by specialized glands.

Sweating is used for temperature regulation in some primates (including man), in camels, horses, antelope, sheep, and cattle. Small sweat glands, distributed in large numbers over the body surface, are capable of secreting considerable quantities of fluid. Man sweats profusely in the heat; a 200-pound man in the desert, for example, may lose more than two pounds of water per hour, mostly as a result of sweating.

Panting, which involves an abrupt increase in respiratory rate, is used for temperature regulation by all birds, many carnivores (*e.g.*, dogs, cats), and some antelope and cattle, which also sweat. Inspired air (air breathed into the lungs) is saturated with water before it reaches the lungs, but this water is lost during expiration (removal of air from the lungs). An increase in the rate of respiration, therefore, increases evaporation of water, most of which is from secretory glands and cells in the lining of the respiratory tract. Many animals pant through their noses, thus aiding evaporation of water, since nasal passages, smaller than the mouth, cause more air to come in contact with the moist nasal tissues. In the dog, which pants with its mouth open, air is inspired primarily through the nose and expired through the mouth.

Mammals that cannot pant or sweat groom themselves with saliva to regulate their body temperatures in a hot environment; among this group are most small mammals, such as rodents and bats, and many marsupials. An elephant, which neither sweats nor pants, may spray its body with saliva from its mouth. The use of saliva for cooling has been studied in the laboratory rat, which has three pairs of salivary glands called submaxillary, sublingual, and parotid glands. When the body temperature of the rat increases from 37° to 38.5° C, saliva from the submaxillary glands, secreted rapidly into the mouth, is removed by the rat and placed on the body surface where it evaporates and cools the animal. Saliva is secreted from the parotid glands only if the body temperature of the rat increases to 40° C; secretions from the sublingual glands apparently do not increase with increasing temperatures.

Cooling by saliva

Temperature receptors in the hypothalamus of the rat brain may control the secretion of saliva from different glands as the temperature increases.

The use of water for regulating body temperature in a hot environment is not an efficient mechanism for desert animals because of the scarcity of water. Man, for example, can live in the desert only if he provides himself with large quantities of water to compensate for dehydration, which results from sweating. Some small mammals (for example, the kangaroo rat), however, live in the desert and never drink water. They obtain water from food and have efficient kidneys and other mechanisms adapted for reducing water loss. In addition, they save water by avoiding heat—*i.e.*, their burrows beneath the ground remain cool, and many stay in them during the hot day, coming out only in the cool of the evening. In habit, these small mammals are similar to some poikilotherms, which select favourable microclimates to regulate their body temperatures.

Large desert animals, such as the camel, cannot use burrows to escape from the scorching heat and, contrary to popular myth, do not store water in their bodies. Camels are able to withstand severe dehydration, but their greatest asset in the desert probably is a body of large size, which requires a large amount of heat to cause an increase in temperature. During the hot day, camels store heat by allowing their body temperatures to rise a few degrees; at night, when the environment is cooler, the stored heat is lost, and body temperature falls. Both heat storage and loss occur without the evaporation of large quantities of water.

Prices, Statistics of

Information about prices is required for a wide variety of purposes in a modern market economy. Perhaps the most important of these is as a tool in the formulation of economic policy at the governmental level. Price statistics are required to measure economic growth; to measure changes in the relative position of particular groups (such as wage earners or recipients of old-age pensions) in the economy; and to determine the degree to which the government will pursue policies that stimulate or dampen economic activity.

Price statistics are important in the business world, too. Sometimes contracts are concluded at a stated price (or wage rate) that is subject to upward revision ("escalation") if prices change. A more widespread and important use of price statistics in business is in connection with planning. In making investment plans for the future, a firm must compare the estimated costs of each investment project with the estimated receipts; this requires information on the prices of materials and wages. Some large firms maintain systematic price records so that cost estimates can be quickly prepared when desired.

HOW PRICES ARE MEASURED

Prices for specific commodities, services, or securities are not hard to gather or to understand. Wholesale price quotations for primary products (coffee, wheat, etc.) and for basic manufactures (iron, steel, aluminum, etc.) are published in trade journals or by government agencies in many countries. Well over 100 such quotations for different products and different countries can be found each month in the United Nations' *Monthly Bulletin of Statistics*. Retail prices for commodities are most usually available on a regular (monthly) basis in government publications. In the United States, for example, the Bureau of Labor Statistics publishes the average urban prices of food and fuels each month. In some countries, including West Germany and Japan, prices are available for a much larger number of nonfood items than in the United States. The Japanese data are particularly detailed and include prices for many commodities in many different parts of the country.

Summary measures of price movements

Indexes. For many purposes the prices of separate commodities are not enough. The reason is that prices for individual commodities (or types of services, or securities) tend to change in different degrees and sometimes even in different directions. What is required is a summary measure of the average amount of the price change for all commodities. This is provided by a price index—that is, a series of numbers arranged so that a comparison between the values for any pair of dates will show the average change in prices from one date to another. Usually a particular date is selected as the base; the index is set equal to 100 at that date, and the values for other dates then indicate at a glance the difference in price level from the base date. The series can easily be shifted to a new base by dividing all numbers in the series by the value for the desired base date and multiplying by 100.

There are a number of practical and theoretical difficulties involved in the making of price indexes. Price indexes are usually based only in part upon quotations that are actually published. The consumers' price index and the wholesale price index typically published in each country by the official price statistics agency usually require the collection of additional price quotations that are used for index number computation but are not made public. The U.S. wholesale price index, for example, is based on unpublished prices for many types of equipment and machinery. One reason, in the case of some machinery items, is that the price information is obtained on a confidential basis. More often, the statistical organization preparing the indexes considers that its sample of price quotations is adequate only for the measurement of changes in the general level of prices.

Data. The central problem of price-data collection is to gather a sample of prices representative of the various price quotations for each of the commodities under study. Sampling is almost always necessary. The larger and the more complex the universe of prices to be covered by the index, the more complex the sampling pattern will have to be. An index of prices paid by consumers in a large and geographically varied country, for example, ideally should be based on a sample representative of price changes in different cities and localities, in different types of outlets (supermarkets, department stores, neighbourhood shops, etc.), and for different commodities. The number of prices chosen to represent each type of city (or metropolitan area), type of outlet, and category of

commodity would ideally be proportionate to its relative importance in the expenditures of the nation. Most price indexes are based on some approximation to such a sampling design.

Once the commodity sample has been chosen, the collection of prices must be planned so that differences between the prices of any two dates will reflect changes in price and price alone. Ideally one would collect the prices of exactly the same items at each date. To this end, commodity prices are sometimes collected in accordance with detailed specifications such as "wheat, no. 2 red winter, bulk, carlots, f.o.b. Chicago, spot market price, average of high and low, per bushel." If all commodities were as standardized as wheat, the making of price indexes would be much simpler than it is. In fact, except for a limited range of goods consisting mainly of primary products, it is very difficult to describe a product completely enough so that different pricing agents can go into stores and price an identical item on the basis of description alone. In view of this difficulty, price collection agencies sometimes rely upon each respondent, usually a business firm, to report prices in successive periods for the same variant of a product (say, men's shoes); the variant chosen by each respondent may be different, but valid data will be obtained as long as each provides prices for the same variant he originally chose. Because a product may vary in quality from one observation to another, even though it retains the same general specification, the usual procedure is to avoid the computation of average observed prices for each commodity for each date. Instead, each price received from each source is converted to a percentage of the corresponding price reported for the previous period from the same source. These percentages are called "price relatives."

Weighting. The next step is to combine the price relatives in such a way that the movement of the whole group of prices from one period to another is accurately described. Usually, one begins by averaging the price relatives for the same specification (*e.g.*, men's high work shoes, elk upper, Goodyear welt, size range 6 to 11) from different reporters. Sometimes separate averages for each commodity are calculated for each city, and the city averages are combined.

A more difficult problem arises in combining the price relatives for different commodities. They must be given different weights, of course, because not all the commodities for which the prices or price relatives have been obtained are of equal importance. The price of wheat, for example, should be given more weight in an index of wholesale prices than the price of pepper. The difficulty is that the relative importance of commodities changes over time. Some commodities even drop out of use, while new ones appear, and often an item changes so much in composition and design that it is doubtful whether it can properly be considered the same commodity. Under these conditions, the pattern of weights selected can be accurate in only one of the periods for which the index numbers have been calculated. The greater the lapse of time between that period and other periods in the index, the less meaningful the price comparisons become. Price indexes thus can give relatively accurate measures of price change only for periods close together in time.

Sources of bias

Another problem of price index number construction that cannot be completely resolved is the problem of quality change. In a dynamic world, the qualities of goods are continually changing (permanent-press clothing, colour televisions, banded tires, self-cleaning ovens, and so forth) to such a degree that it is doubtful whether anyone living in an industrialized economy buys many products that are identical in physical and technical characteristics to those purchased by his grandfather. There is no fully satisfactory way to handle quality changes. One way would be to make price comparisons between two periods solely in terms of goods that are identical in both periods. If one systematically deletes goods that change in quality, the price index will tend to be biased upward if quality is improving on the average and downward if it is deteriorating on the average. A better approach is to attempt to measure the extent to which an observed change in the quoted price represents a change in quality. It is possible, for example, to obtain from manufacturers estimates of the increase or decrease in cost of production entailed in the main changes in automobiles from one model year to the next. The amount added or subtracted from the cost by the changes can then be regarded as a measure of the quality change; any change in the quoted price not accounted for in this way is taken as solely a change in price. The disadvantage of this method is that it cannot take account of improvements that are not associated with an increase in costs.

Whether or not a failure to make sufficient allowance for improvements in the quality of goods causes most price indexes to be biased upward is a matter of dispute. An expert committee appointed to review the price statistics of the U.S. government (the Stigler Committee) declared in 1961 that most economists felt that there were systematic upward biases in the U.S. price indexes on this account. Since the U.S. indexes are usually thought to be relatively good, this view would seem to apply by extension to those of most other countries. The official position of the U.S. Bureau of Labor Statistics has been that errors owing to quality changes have probably tended to offset each other, at least in its index of consumer prices.

Another possible source of error in price indexes is that they may be based on list prices rather than actual transactions prices. List prices probably are changed less frequently than the actual prices at which goods are sold; they may represent only an initial base of negotiation, a sellers' asking prices rather than an actual price. When prices are collected largely by mail, as is generally the case with indexes of wholesale prices, the respondents may give only their list prices, with the result that the indexes will show greater short-run stability than is warranted. One study has shown that actual prices paid by the purchasing departments of government agencies were lower and were characterized by more frequent and wider fluctuations than were the prices for the same products reported for the price index.

CONSUMER PRICE INDEXES

Although consumer price indexes are familiar to everyone, they date only from the final decades of the 19th century. Efforts have been made to reconstruct the movement of consumer prices in earlier periods, but such work has often had to be based on the assumption that changes in the retail price of a given commodity could be inferred from changes in its wholesale price. (Mention may be made, however, of a quite exceptional series on London bread prices dating back to 1545, by B.R. Mitchell and P. Deane.)

What the indexes measure

The indexes that began to be produced in the last decades of the 19th and the first decades of the 20th century were called "cost of living" indexes, reflecting their origin in a concern about the welfare of workers and a consequent interest in the purchasing power of wages. Early indexes tended to concentrate on foods and other necessities. World War I brought a further stimulus to the establishment of official cost of living indexes because of the need for measures of consumer price changes in connection with wartime wage controls. Later, the term consumer price index was generally adopted in order to make it clearer that the indexes were attempting to measure the cost of living at a given standard. The term consumer prices is usually preferred to retail prices since the former more clearly covers whatever it is that the consumer spends his money on, including rents, medical services, taxes, and so forth, whereas the latter has the more limited connotation of measuring only prices paid at retail shops. It may also happen, as in Germany, that consumers purchase significant amounts of some types of goods at wholesale or factory outlets rather than at retail shops. The United Kingdom and a number of other countries nevertheless describe their indexes as "retail price" indexes, and even the term cost of living is still used in a few countries.

Current consumer or retail price indexes are, then, usually defined as being designed to show the changes over time in the prices of the commodities and services pur-

chased by a specified group of consumers. Such indexes are available for more than 100 countries (see the United Nations' *Monthly Bulletin of Statistics*) and are usually prepared by the country's ministry of labour or central statistical office. The indexes of the various countries differ widely in coverage and methods, but there are some general characteristics that can be described.

Limitations in coverage

The population group covered almost always includes families of wage and salary earners, but the indexes vary in the extent to which they include single individuals and other occupational groups such as the self-employed or professionals. The United States index, for example, includes only wage and salary earners, whether living alone or with families, whereas the United Kingdom index covers all households except those headed by a person with income in excess of a stated amount (£40 in 1965) and those with at least three-quarters of their total income derived from pensions. Sometimes special indexes are prepared for particular groups in the population, such as the indexes for pensioners in the U.K.

It is quite common for the indexes to refer only to urban areas, and some are restricted to a limited number of cities (*e.g.*, six state capitals in Australia) or even to the capital city alone (*e.g.*, Mexico City). Some indexes are, of course, broader in coverage; the Japanese index, for example, includes all households, urban or rural, except one-person households and those headed by farmers or fishermen. These limitations in the coverage of the indexes are often overlooked. For broad analytical uses such as measuring changes in the national welfare, a comprehensive index is needed that covers the whole population, including persons living in rural areas, single persons, and high-income families in urban areas.

In most countries, the consumer price indexes, usually published monthly, include indexes for major categories of expenditures such as food, clothing, rent, and so forth. Sometimes they include more detailed categories (such as dairy products) and even individual items (such as milk). This depends partly on the number of products for which prices are gathered. In countries that can afford more extensive price collection and that need it because of the diversity of products purchased by their consumers, the number of items covered is usually between 250 and 450; but in smaller countries or poorer ones, the number is often between 100 and 150, and in a few countries even less than 50.

The formula. The most common formula used in calculating consumer price indexes is a weighted arithmetic mean of price relatives. The price relatives described earlier are weighted according to the amounts consumers spend on each product; the resulting figures are summed for all commodities and divided by the sum of the base year expenditures for the same collection of commodities.

The expenditure weights reflect the relative importance of each item in the expenditures of the population group covered by the index. This information is usually obtained from a survey of a sample of the covered families, in which data are gathered about the expenditures upon each commodity and service. The weights need to be revised from time to time as new products appear and as spending habits change. In the U.S., the Stigler Committee recommended a comprehensive revision of the weights at least once a decade and revisions for the more volatile categories at least every five years. The main obstacle to frequent weight revision is the cost of the family expenditure surveys, although modern sampling methods have made it possible to obtain reliable results with smaller numbers of observations than were used in the early days of consumer price indexes. In some countries, however, family expenditure surveys are conducted continuously, as they are in the annual surveys in the U.K. or the monthly surveys based on overlapping panels of households in Japan.

Conceptual difficulties. A fundamental difficulty in existing consumer or retail price indexes is that they are defined in terms that are not really appropriate for the uses to which they are put. The official compiling agencies describe them as measures of the change in price of a fixed basket of goods and services. This seems clear enough, but difficulties arise as soon as the index is put to use. One may wish, for example, to ascertain whether an urban family with an income of $10,000 in 1969 was better off than a similar family with an income of $8,000 in 1959. One may find that the consumer price index rose by 27 percent in the ten-year period. This more than offset the 25 percent increase in money income, and the family is therefore slightly worse off. Although this is a fair illustration of the way the indexes are generally employed, the underlying reasoning is defective. In the first place, the implicit assumption is that the family bought exactly the same goods in 1969 as in 1959. Even if all goods in the market were identical at the two dates (no new products and no quality change), the family would not necessarily purchase the same items; it could logically be expected to substitute goods that had smaller-than-average price increases for goods that had larger-than-average price increases. As a result of these shifts, the family might actually prefer the new bundle of goods at the new prices to the old bundle at the old prices. Thus, the cost of acquiring a bundle of goods that yielded the same satisfactions would have risen not by 27 percent but by some smaller percentage. An index that takes into account the subjective preferences of consumers is called a constant-utility index, since it measures not the change in price of a constant bundle of goods but the change over time in the costs of purchasing bundles of goods that yield a constant level of utility or satisfaction. Even this formulation is not completely rigorous because the utilities or satisfaction obtained by a given individual from a given bundle of goods will vary over time as his tastes change. All that an index can do in strict theory is to measure differences in the money incomes required at different price structures to make a given individual with given preferences indifferent as to the price structures.

Conceptually, there is little doubt that the constant-utility index is superior for virtually all of the analytical purposes for which indexes are used, but there are great difficulties in constructing one that would command wide support and confidence. Some authorities believe that the present indexes could be improved if the physical units were selected so as to represent the characteristics or utilities really sought by buyers. They hold, for example, that it would be more appropriate to compare the costs of an appendectomy or of an obstetrical delivery than the costs of an office visit to a doctor or eight hours of nursing care. The Stigler Committee felt that some improvement could be made if new commodities were introduced into the indexes when they first begin to be purchased by the population; the indexes would then reflect the gains to consumers that come with reductions in prices after a product achieves wide acceptance.

The Stigler Committee was concerned lest the important economic interests that make use of the consumer price index institutionalize it and hamper improvement of it. The Committee feared, for example, that neither labour nor management would welcome changes in the methods of preparing an index, the movements of which automatically result in wage adjustments for millions of employees under labour–management agreements.

WHOLESALE PRICE INDEXES

Indexes for commodities

Wholesale price indexes measure the changes in commodity prices at a selected stage or stages before goods reach the retail level; the prices may be those charged by manufacturers to wholesalers or by wholesalers to retailers or by some combination of these and other distributors. In the U.S., the index measures the price movements of all commodities flowing into primary markets of the U.S.—whether domestically produced or imported. Primary markets are those in which a good in a given stage of fabrication is first sold in substantial quantities. Since primary markets include goods of all degrees of fabrication, the same commodity is often priced at several stages of processing. Cotton, for example, is priced in the form of raw cotton, cotton yarn, cotton gray goods, cotton piece goods, and cotton clothing.

One of the earliest wholesale price indexes was produced for Great Britain in 1886, covering the period after 1846.

The official wholesale price index in the United Kingdom, produced by the Board of Trade, goes back to 1871. In the United States, the first major effort to summarize wholesale price changes through index numbers was published in a report of the U.S. Senate in 1893. The present wholesale price index of the United States, maintained by the Bureau of Labor Statistics, has been computed for the period since 1890. In both the U.K. and the U.S., economic historians have attempted to reconstruct wholesale price indexes for the 19th century that are superior to the early efforts.

The number and character of the commodities included in wholesale price indexes vary widely from country to country. In large industrial countries like the U.K., the U.S., and Germany, the number of commodities included numbers in the thousands; but for most countries it is much smaller, often only 100 or 200. The smaller numbers of products will serve well enough if only a general all-commodities index (or a few subindexes at most) is wanted. Greater numbers are required when many subindexes are desired. The U.S., for example, publishes indexes for commodities classified according to stage of processing (crude materials, intermediate materials, and finished goods), according to the durability or nondurability of the products, and according to the economic sector for which goods are intended (consumers, producers, etc.). The commodities are also grouped into 15 categories and nearly 100 subgroups (fresh fruits, grains, etc.) and a large number of product classes (apples, bananas, barley, corn, etc.), for each of which monthly price indexes are published. In addition, there are a number of indexes for special commodity groups such as various categories of pharmaceutical preparations. The number of commodities included in the U.S. index has expanded from 250 when the index was started in 1902 to about 2,400 in 1970. The new commodities have tended to be more highly fabricated and to have more stable prices, and they have therefore dampened the fluctuations in the index. One reason for the inclusion of more commodities was a gradual shift in the conception of the function of the index. Originally it was regarded as a measure of movements in the general price level, but as other indexes became available, such as the consumer price index and the implicit national income deflators (see below), less reliance was placed on the wholesale price index for this purpose. At the same time, there was a growing demand for subindexes pertaining to particular classes of products for various business and analytical purposes.

Countries in which industrial production is not highly variegated usually have smaller numbers of product classifications; these serve to distinguish between price movements of domestic goods and price movements of imports and between those of food or agricultural products and those of industrial products. Raw materials and standardized products in early processing stages that are easy to price tend to be well represented in the wholesale price indexes of all countries; whereas more complex types of producers' goods, such as heavy electrical equipment, tend to be underrepresented or omitted even in the indexes of the advanced industrial countries. This is a source of upward bias in the general wholesale indexes since there is reason to believe that technological change has been particularly important in bringing about improvements in complex goods.

Many of the technical problems of wholesale price indexes are similar to those discussed in connection with consumer price indexes, although it is probably fair to say that the wholesale indexes have been subject to much less criticism and have been produced with fewer resources than consumer price indexes. Prices are usually gathered from business firms by mail, less frequently from trade journals and trade associations, and also from government purchasing agents. Weights are generally based on relative sales volume. Data from censuses of production (manufacturing, mining, agriculture, etc.) are used for weights when they are available. The formula used for computing the indexes is most frequently the base-weighted arithmetic average of price relatives already explained in connection with consumer price indexes.

IMPLICIT PRICE DEFLATORS

Comprehensive price indexes

Measures of price change that are more comprehensive than either the consumer or the wholesale price index have evolved as a result of the recent development of national income statistics. After statisticians had compiled estimates of gross national product in terms of current prices (*i.e.*, the prices prevailing in each year), they turned their attention to estimating them in terms of constant prices (*i.e.*, estimating the gross national product, for example, for a whole succession of years in terms of the prices of a single year). This was necessary if the figures were to distinguish between real changes in physical output and changes in prices. This is done by expressing each component of gross national product in terms of the prices of the selected base year, using whatever available price series seems most suitable for that component. Most of the price series are apt to be elements of the official wholesale (*e.g.*, agricultural machinery) and retail price indexes (*e.g.*, food), but a wide range of other price information is also employed. When these "deflated" components of gross national product are added up, the result is an estimate of gross national product in terms of base period prices. In most countries, national income and product statistics are published both in current prices and in constant (*i.e.*, base-period) prices. There is, of course, a comprehensive price index implicit in the comparison of the current and constant-value series. For example, from the fact that the 1966 Japanese gross national product was 35,092,000,000,000 yen in current (1966) prices and 26,822,000,000,000 yen in 1960 prices, an implicit price index of 130.8 can be computed (35,092 divided by 26,822 and multiplied by 100) for 1966 on a 1960 base. Implicit deflators are usually available for various components of the gross national product both in terms of the output of particular industries and in terms of the final products purchased by consumers, investors, and government. Implicit price indexes for many countries are published in the United Nations' *Yearbook of National Account Statistics.*

Implicit price deflators are generally superior as a measure of the overall behaviour of prices because, in addition to being more comprehensive than the major indexes previously discussed, they refer to a universe that can be more readily defined than that of the wholesale price index. They are usually available, however, only on a quarterly or annual basis, and therefore the other indexes are still used as month-to-month indicators of price behaviour.

The implicit deflators obviously contain within themselves whatever defects characterize the underlying consumer, wholesale, and other price series upon which they are based. If, as suggested above, there has been an improvement in the quality of many goods that escapes measurement so that the price indexes have tended to overestimate the extent of price increases, then the use of implicit deflators leads to a corresponding underestimation of the increase in real national product and real national income.

INDEXES FOR SPECIAL PURPOSES

Export and import price indexes

There are various ways of measuring price changes in international trade. A few countries of the world, including Germany and Japan, have export and import price indexes. The U.S. and most other countries have unit-value indexes for their exports and imports. A unit-value index differs from a price index in that it measures the changes in the average value per physical unit regardless of whether the change is due to a change in price or to a change in size, quality, or other circumstance.

Unit-value indexes are computed from foreign trade data on values and quantities. The unit value for each component series is derived by dividing quantities into values; the changes in the individual unit-value series are then collected into an overall index through the use of export or import values as weights. Unit-value indexes are usually constructed according to Fisher's ideal index number formula: that is, each index represents the square root of the product of base-year weighted and given-year weighted indexes. This formula is used rather than the

one discussed above because the composition of exports and imports, and therefore the appropriate weights, changes much more rapidly than does the market basket of goods in the consumer or wholesale price indexes. The Fisher formula averages the results of using current-year weights and base-year weights. Usually the previous year is taken as the base year, and the percentage changes calculated in this way are linked to form a continuous series.

Unit-value series are not reliable approximations of price changes because even for relatively simple types of products, like steel pipe, changes in the mix of export or import products (as from narrow to wide pipe, thick to thin, etc.) can change the unit value even though no single export or import price has changed. Another handicap is that quantity data are simply not collected and published for many types of manufactures because the number of units would be meaningless when the size, quality, design, and other characteristics of the product vary widely from one unit to another.

Despite these objections, unit-value indexes continue to be produced. They are relatively easy to compute; true price indexes require much more money and personnel. Unit-value indexes are often used for analytical purposes as if they were price indexes, although wholesale price data, reweighted to take account of the relative importance of different products, may be better indicators of price changes in international trade. Wholesale prices are not fully satisfactory either because domestic prices (which are what the wholesale price indexes mainly measure) do not always move parallel to export prices.

The indexes discussed in the preceding sections are the most important and most widely used. There are, however, a wide variety of others. Most industrial countries have indexes of hourly earnings and wage rates; the most common types are indexes of average hourly, weekly, or annual earnings in manufacturing.

Construction-cost indexes are found in many countries. Virtually all construction-cost indexes are put together by pricing the inputs of labour and materials or a combination of labour and materials and units of construction work (excavation, brickwork, concrete pouring, etc.). The disadvantage of this approach is that it does not take account of changes in the efficiency with which the inputs are combined to accomplish the construction task.

Indexes of security prices are available wherever there are active securities markets such as in New York, London, Paris, Tokyo, Brussels, Frankfurt, and Zürich.

The general user of price indexes can usually find what he needs in most countries by looking in the monthly bulletins of the central statistical office; the ministry of labour, commerce, or economics; or the central bank. Daily newspapers and trade journals in each country also contain price quotations for many commodities, services, and securities. The United Nations and its specialized agencies, particularly the Food and Agricultural Organization and the International Labour Organization, include compilations of prices from many countries in monthly bulletins and in yearbooks of statistics.

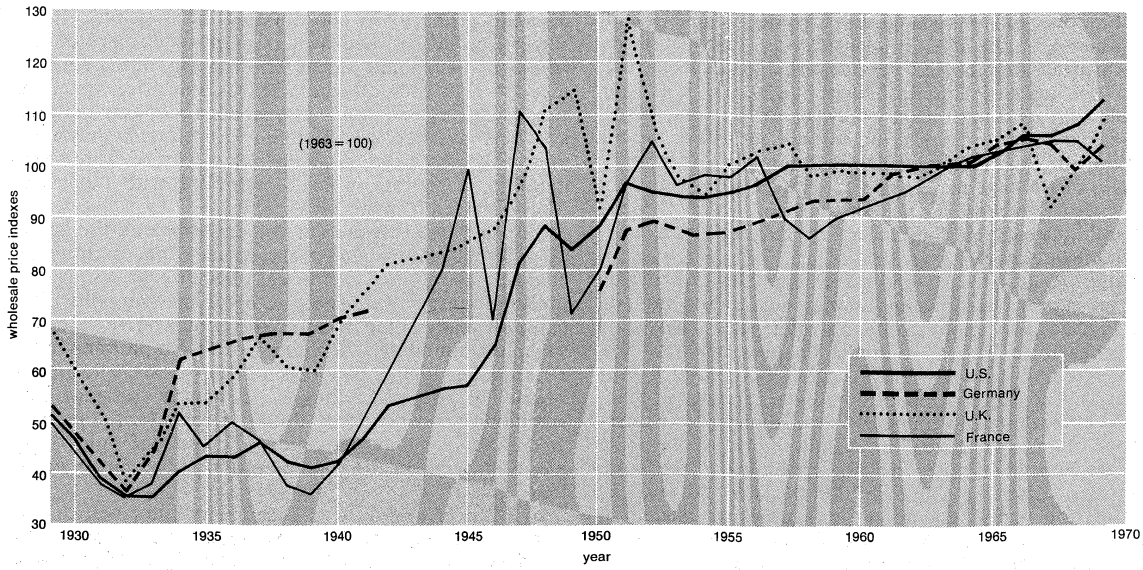
PLACE-TO-PLACE PRICE INDEXES

City-to-city and country-to-country comparisons

Comparisons of the levels of prices in different places may sometimes be required. One of the complaints of the New York City postal workers in their 1970 strike, for example, was that the practice of paying uniform nationwide salaries was unfair to them because a given number of dollars purchased substantially fewer goods in New York City than in certain other parts of the United States. The problems and techniques of preparing place-to-place price indexes are similar to those of time-to-time indexes. The price universe has to be defined, a sample chosen, careful pricing made of equivalent qualities of goods in different places, and weights selected to collect the (place-to-place) price relatives for different goods into an overall index. In the actual operation, however, place-to-place indexes are more difficult to prepare because it is harder to assure that identical goods are being priced in every locality.

The U.S. Bureau of Labor Statistics compared the 1966 costs of a city worker's family budget at a moderate standard of living in 39 metropolitan areas. The standard budget was prepared for a family consisting of an employed husband, age 38, a wife not employed outside the home, a girl, age 8, and a boy, 13. (A standard budget was also prepared for a retired couple.) The budget quantities were derived from scientific or technical judgments about the requirements for physical health and well-being (*e.g.*, for food and housing) and from analytical studies of choices actually made by consumers (clothing and recreation)—all adjusted to climatic and regional differences. With the U.S. urban average marked as 100, the indexes ranged from 94 in Dayton to 110 in Honolulu, San Francisco, and Los Angeles.

International comparisons. Price comparisons between countries are needed because the exchange rates between currencies do not necessarily reflect their relative purchasing powers. Efforts to calculate "purchasing-power parities" between currencies have a long history, but because of the extensive work required to compare prices item by item (and to be certain that prices for equivalent items are being compared), this area remains a major gap in the world statistical system.



Several of the purchasing-power comparisons were made in order to compare the standard of living of workers in different countries. The early cost of living study carried out by the U.K. Board of Trade in 1908 compared wages, food prices, and rents in the U.K. with those in Belgium, France, Germany, and the U.S. In 1954 the European Coal and Steel Community compared wages received and prices paid by steelworkers and coal miners in its six member countries.

Other comparisons have arisen out of the need of employers such as the United Nations, foreign ministries, and international firms to pay the same real salaries to their employees of comparable grades regardless of country of assignment. This requires price comparisons so that money salaries can be adjusted to compensate for differences in the purchasing power of different currencies. A readily available comparison designed to serve this purpose is published each June and December in the United Nations' *Monthly Bulletin of Statistics*. The indexes compare the cost of purchasing a basket of goods and services bought by a typical international civil servant in about 100 foreign cities with the cost in New York City, where the UN headquarters is. The indexes are based on prices for 150–200 items; housing is excluded from some of the published figures because the rents paid by international civil servants are sometimes subsidized. Weights for the indexes are derived from the expenditure patterns of the covered personnel.

Comparisons of GNP. Price indexes may also be used to compare the gross national products (GNP) of different countries. The UN and other sources currently publish such comparisons, derived mainly or entirely from the use of exchange rates. These are known to be inaccurate because of the differences between exchange rates and purchasing-power parities already alluded to. The Statistical Office of the UN has set out to develop actual purchasing-power comparisons of GNP and its major components (consumption, capital formation, and government expenditure) among different countries.

Difficulties in making international comparisons of GNP

The kind of work that is involved in such comparisons may be seen in a study carried out in the early 1950s at the Organization for European Economic Cooperation. Purchasing power equivalents and comparisons of real product per capita were prepared for four European countries (France, Germany, Italy, and the United Kingdom) in relation to the U.S. It was found that, for the bundle of goods included in the U.S. GNP, the purchasing powers of the European currencies in 1950 were from 8 to 24 percent higher than the exchange rates would indicate; for the bundle of goods in the European GNP, they were from 57 to 91 percent higher. The purchasing power of the British pound, for example, was not 2.8 times that of a dollar, as the 1950 exchange rate of $2.80 = £1 would have suggested, but 3.47 times for the U.S. bundle of goods (24 percent higher than 2.8) and 4.59 times for the European bundle of goods (64 percent higher than 2.8).

Fluctuation of wholesale price indexes in France, Germany, the United Kingdom, and the United States during a 40-year time period.

These differences between the purchasing-power parities and the exchange rates meant that to translate the European GNP's into dollar terms by using exchange rates underestimated them relative to the U.S. GNP. The per capita GNP of the U.K., for example, when converted to dollars at the official exchange rate, was 37 percent of the U.S. per capita GNP, but the percentage rose to 53 when both U.K. and U.S. products were valued at European prices and to 63 when valued at U.S. prices. Differences of this magnitude can be important when member countries in international organizations have to agree upon sharing financial burdens, as they do in aid programs for poor countries or in military alliances such as NATO.

Without purchasing-power comparisons, no one can be sure what the real differences are in the levels of income (or GNP) attained by various countries. The same difficulty applies to important subaggregates of GNP. One of the major variables affecting economic growth, for example, is the amount of fixed capital formation (*i.e.*, investment in new construction and equipment). In order to know how much real investment there has been in each country, purchasing-power comparisons are necessary. Not only will the conversion of capital expenditures into dollars or some other common currency by means of exchange rates be misleading but even the ratio of capital expenditures to gross national product, in terms of each country's own currency, may not be comparable from one country to another; the comparability of the ratios requires that the relative purchasing powers of each pair of currencies be the same for capital goods as for all other goods. In fact, capital goods are relatively expensive in some countries and relatively cheap in others. In 1960, for example, it took about 165 Argentine pesos to buy one U.S. dollar's worth of capital goods (the currency rate was 82.7 pesos per dollar). In terms of pesos, Argentina devoted about 22 percent of its gross product to investment; but when all outputs were revalued to reflect the average of U.S. and Latin American prices, Argentine investment was equivalent to about 11 percent of its gross output. Thus, by international standards Argentina's real new capital formation relative to other components of real product was much more modest than the Argentine figures taken alone would suggest.

THE MOVEMENT OF PRICES OVER TIME

Price movements in different countries are linked through international trade, and, if due allowance is made for movements in exchange rates, the broad changes in prices will be found to be very similar for countries maintaining relatively open economic relations with the rest of the world. This can be seen in the Figure, which shows the behaviour of prices in some leading countries over a period of nearly half a century.

Long-term changes. The course of prices in the 19th century was characterized by relatively moderate changes except for the rather violent fluctuations associated with war and postwar periods. Prices rose during wartime, when governments made large purchases of war materials, and fell afterward. The end of World War II, however, was not followed by a period of declining prices. This may be due in part to the fact that it was as much a period of continued war as one of peace; the Korean War in the early 1950s and the Vietnam War in the late 1960s were clearly associated with rising prices, and the Cold War served to buoy up prices in between these periods of actual fighting.

The historical record of prices has been cited as evidence for the existence of long swings in economic activity. The first of the upswings, 1789–1814, has been associated with the effects of the Napoleonic wars and the Industrial Revolution; the second, 1849–65, with the discovery of gold, the building of railroads, and the American Civil War; the third, 1896–1920, with "electrification and motorization" and World War I; and the fourth, from 1932 on, with World War II, its unpeaceful aftermath, and the greatly expanded sphere of governmental activity in the economy. Downswings have generally been explained in terms of the eventual loss of impetus in the technological innovations that had played the major role in the preceding upswings.

Cyclical changes. Another pattern of price change is that seen in the familiar business cycle. The fluctuations observed in the business cycle are, of course, changes in aggregate values produced, traded, or consumed; these changes in values are the result of changes in both prices and quantities. Thus, even as a symptom of what is happening in the business cycle, price changes must be considered in connection with changes in quantity. Studies have indicated that prices and quantities fluctuated about equally over the course of a cycle. There has, however, been a significant difference in timing: on the upswing, prices rose only 80 percent as much as quantities did; but on the downswing, they have declined more than quantities. Also, quantities have tended to rise in the final stage of contraction, while prices have still been falling. Not all prices have followed this pattern, nor has every cycle corresponded to the generalized picture. For farm products, foods, consumer goods, and nondurable goods, prices varied more than quantities during the course of the cycle, but the combined variation of both price and quantity (*i.e.*, value) was characteristically low. On the other hand, for durable goods, capital equipment, and nonfarm products, prices were relatively stable, and cyclical influences were reflected in relatively large changes in quantities.

Some notion of the nature of the changes in price rela-

Changes in relative prices

tionships over time may be gleaned from a comparison of components of the U.S. wholesale price index at three cyclical peaks roughly 20 years apart. Farm prices rose relative to industrial prices between 1929 and 1948 and declined in absolute terms between 1948 and 1969, whereas the rate of price increase in industrial prices accelerated. Among industrial prices, lumber rose sharply in price in the first period and continued with a greater than average increase in the second period. Rubber prices lagged in the early period, and rose relatively to the average in the later period.

Changes such as these—and the even greater diversity of changes in price relationships among individual commodities—reflect two major groups of influences. One set of influences is to be found in the changes affecting the supplies of and demands for the various goods and groups of goods. The other is represented by differences in market structure that cause some goods to respond more readily than others to a general movement of prices. The great increase in lumber prices may be attributed to the large quantities of lumber demanded for the war and postwar construction booms and to the difficulties in expanding the quantity supplied. The prices of tires and tubes and of other rubber products did not rise very much in the two decades following 1929 because these years saw important cost-reducing technological changes in rubber manufacturing, particularly the development of synthetic rubber.

The growth of productivity with the consequent rise in consumer incomes is also likely to have an impact on relative prices. Higher incomes, including higher wages, mean relatively greater price increases for things that utilize labour intensively relative to things that require larger amounts of materials and equipment for their production. Prices of services, for example, have increased considerably more than commodity prices in recent decades.

Changes in price relationships are attributable also to the varying responsiveness of different prices to a general shift in the price level. In the case of farm products, government policy has a great deal to do with price movements. Changes in industrial prices, on the other hand, may reflect the structure of particular industries. Certain economists have held that, in industries with a small number of firms, businessmen have the power to set their own prices. These "administered" prices are not changed very often; responses to changes in demand take the form of output adjustments. The existence of administered prices has been widely accepted by economists, although there are some who argue that their rigidity has been exaggerated.

BIBLIOGRAPHY. A classic study in index number construction is W.C. MITCHELL, "The Making and Using of Index Numbers," *Bull. U.S. Bur. Labor Statist. 284*, pt. 1 (1921; reprinted as *Bull. 656*, 1938). A more recent review of the problems of price statistics, particularly with reference to the U.S., may be found in PRICE STATISTICS REVIEW COMMITTEE, NATIONAL BUREAU OF ECONOMIC RESEARCH, *The Price Statistics of the Federal Government* (1961). Analytical studies of price behaviour include: F.C. MILLS, *The Behaviour of Prices* (1927), and *Price-Quality Interactions in Business Cycles* (1946); A.L. BOWLEY, *Wages and Income in the United Kingdom since 1860* (1937); A.C. NEAL, *Industrial Concentration and Price Inflexibility* (1942); and G.J. STIGLER and J.K. KINDAHL, *The Behaviour of Industrial Prices* (1970). Historical price series may be found in U.S. DEPARTMENT OF COMMERCE, CENSUS BUREAU, *Historical Statistics of the United States, Colonial Times to 1957* (1960); and B.R. MITCHELL and P. DEANE, *Abstract of British Historical Statistics* (1962). Current sources of price statistics include the U.S. DEPARTMENT OF LABOR, *Monthly Labor Review*; the U.S. DEPARTMENT OF COMMERCE, *Survey of Current Business* (monthly); and the UNITED NATIONS, STATISTICAL OFFICE, *Monthly Bulletin*. For international price comparisons, see M. GILBERT and I.B. KRAVIS, *An International Comparison of National Products and the Purchasing Power of Currencies* (1954); and I.B. KRAVIS and R.E. LIPSEY, *Price Competitiveness in World Trade* (1971).

(I.B.K.)

Price System

The price system, as its exists in western Europe and the Americas, is a means of organizing economic activity. It does this primarily by coordinating the decisions of consumers, producers, and owners of productive resources. Millions of economic agents who have no direct communication with each other are led by the price system to supply each other's wants. In a modern economy the price system enables a consumer to buy a product he has never previously purchased, produced by a firm of whose existence he is unaware, which is operating with funds partially obtained from his own savings.

Prices are an expression of the consensus on the values of different things, and every society that permits exchanges among men has prices. Because prices are expressed in terms of a widely acceptable commodity, they permit a ready comparison of the comparative values of various commodities—if shoes are $15 per pair and bread 30 cents per loaf, a pair of shoes is worth 50 loaves of bread. The price of anything is its value in exchange for a commodity of wide acceptability (a money): the price of an automobile may be some 50 ounces of gold or 25 pieces of paper bearing the picture of an eminent statesman.

A system of prices exists because individual prices are related to each other. If, for example, copper rods cost 40 cents a pound and the process of drawing a rod into wire costs 25 cents a pound, then, if the price of wire exceeds 65 cents, it will be profitable to produce wire; and if the price of wire falls below 65 cents, it will be ruinous to produce wire. Competition, therefore, will hold the price of wire about 25 cents per pound above that of rods. A variety of such economic forces ties the entire structure of prices together.

The system of prices can be arranged to reward or penalize any kind of activity. Society discourages the production of electric shoe-string-tying machines by the simple expedient of making such a machine's attainable selling price less than the prices of the resources necessary to produce it. Society stimulates men of large athletic promise to learn golf (rather than polo or cricket) by the immense prizes (= prices) that are given to tournament winners. The air in many cities is dirty because no one is charged a price for dirtying it and no one can pay a price for having it cleaned.

THE BASIC ECONOMIC TASKS

Three functions of a price system

Every economic system has three functions. In a decentralized (usually private enterprise) economic system, the price mechanism is the instrument by which these functions are performed.

One function is to determine what is to be produced and in what quantity. Even a primitive economy must choose between food and shelter, weapons and tools, priests and hunters. In a modern economy the potential variety of goods and services that may be produced is immense. Consider simply the 10,000 new book titles published each year or the hundreds of colours of paint or the thousands of styles of clothing—each of these actual collections being much smaller than modern technology permits.

A price system weighs the desires of consumers in terms of the prices they are willing to pay for various quantities of each commodity or service. The payment of $1,000 for the services of a skilled surgeon (a price much influenced by the number of surgeons) reflects the great importance of his services to the buyer-patient, whereas the offer of 75 cents for a month's use of an additional telephone outlet reflects the minor convenience it provides. Of course the offers of consumers are influenced by their wealth as well as their desires, but for any one consumer relative desires are proportional to price offers.

Universal laws are most uncommon in social life. Economists nonetheless place immense confidence in the proposition that the consumer will buy less of any commodity when its price rises. This *law of demand* is by no means a necessary fact of life; rather it is an empirical rule to which there are no known, reliable exceptions. Bread, caviar, education, narcotics—a man will buy more of each when its price falls. These demand prices are the guides to producers that in effect tell them which commodities to produce and in what quantities.

The second function an economy must perform is to decide how the desired goods are to be produced. There is more than one way not only to skin a cat but also to grow wheat, train lawyers, refine petroleum, and transport baggage. The efficient production of goods requires that certain obvious rules be followed: no resource should be used in producing one thing when it could be producing something more valuable elsewhere; and each product should be made with the smallest possible amount of resources.

A functioning price system steers resources into their most important use by appealing to the desires of their owners for large incomes. The man capable of being a surgeon is drawn to this occupation from, say, that of a high school teacher by the promise of annual earnings (= price of labour) much more than those of the high school teacher. Capital is drawn from a faltering trade to a booming new industry in which it receives a higher return.

This same price system seeks to achieve production efficiency through the sanction of competition. If one firm can produce shoes with fewer resources than its rivals, it will make larger profits; so it is stirred to discover more efficient combinations of inputs and location of plant, to devise wage systems to stimulate workers, to use computers to reduce inventories, and so forth without end.

The third function of an economy is to determine who gets the product. Family A gets $5,000 worth of goods this year, family B five times as much—how is the division to be decided? The incomes of individuals are determined by the quantities of resources (labour skills, capital in all its forms) they own and the prices they receive for the use of these resources. Workers are incited by the price system to acquire new skills and to exercise them diligently, and families are encouraged to savings (capital accumulation) by the payment of interest or dividends. The inheritance of both personal ability and wealth also enter into the distribution of income.

If the price system is working reasonably well (some of the common failures will be noted later), it performs all of these economic functions with remarkable subtlety and precision. Society desires not only the correct amount of wheat but also that it be consumed more or less evenly over the crop year, with a surplus to carry over in case of a partial failure of the next year's crop. The price system provides a seasonal price pattern that encourages the holding of inventories rather than early splurging and richly rewards speculators who correctly anticipate a crop failure and hold grain that will alleviate it. In the same way, the desires of every sizable group of consumers (or resource owners) are registered through the price system; entrepreneurs are incited by price offers to provide opera and musical comedy, kosher food, and Persian delicacies. One might almost say that the price system is devoted to minority rule, since the only pressure toward uniformity is in the possibility of lowering costs of production by standardizing goods.

High prices in a properly functioning price system thus serve as incentives to produce more and consume less, and lower prices serve as corresponding deterrents. In addition the price system is a method of communicating information. Herbert Spencer once stated, rather ponderously, that only by constant iteration can alien truths be impressed upon reluctant minds: the price system, with its capacity for infinite repetition, is well suited to this sometimes unpleasant task. A higher price of steel scrap, for example, tells thousands of owners and collectors of scrap that more scrap is wanted and that more exhaustive search for abandoned rails, boilers, radiators, and machines is worth undertaking. A higher price of gasoline tells thousands of automobile drivers that gasoline should be used more sparingly, and the message is repeated each time each driver purchases more gasoline.

HOW THE PRICE SYSTEM WORKS

The complexity and variety of tasks performed by the price system will be illuminated by an examination of three specific economic problems.

The choice of occupation. Individuals must be distributed among occupations in such a way as to serve two basic purposes. First, the labourer must be placed where he is most productive—making certain that Enrico Fermi becomes a physicist rather than a chef and that there are not too many plumbers and too few electricians. Second, the individual worker should be given an occupation that is congenial to him: since he will spend a large part of his life at work, it will be a better life if he can choose the type he prefers.

The price of labour

The price of labour is the instrument by which workers are distributed among occupations: wages in rapidly growing occupations and rapidly growing parts of the nation are higher than in corresponding employment in declining occupations and areas. The choice of occupation involves, however, much more than simply a comparison of wage rates. The following are a few of the complications: (1) The wages of an occupation must as a rule be sufficient to compensate the costs of training. (2) The wages of an occupation must be sufficient to compensate special disadvantages (such as a large chance of unemployment). (3) Wages must be higher in large cities than in small because living costs are higher in large cities. (4) Wages must compensate men for their additional skill as they acquire experience (they usually reach a peak of earnings between ages 40 and 55) and thereafter decline as the worker's efficiency declines. (5) Wages will reflect differences in taxation, fringe benefits (pensions, vacations), etc. Accordingly the wage structure even for a single occupation in a single city is elaborate. When a single wage (price) is imposed upon an occupation, labourers are no longer properly distributed by wages; for example, a city school system that pays all teachers of given experience the same wage finds it difficult to staff its less attractive schools.

The preferences of the individual worker cannot be given full play, or each man would become president of the corporation at a sumptuous salary. Yet the labourer may choose to live in California rather than Maine; then the price system will incite employers to move their operations to California, where they can hire this labourer more cheaply. The labourer may prefer to work long hours or short hours, and employers are induced by wage offers to cater to these diverse preferences. In fact it is equally appropriate to speak of the worker buying conditions of work and of the employer buying the services of the worker.

The conservation of resources. A society has some resources that can be replaced by investment: timber is now largely grown as a commercial crop. Farmland is a more ancient example: the fertility of soil can be increased by prudent cultivation. Other resources are not replaceable, such as coal and petroleum. How does the price system conserve these exhaustible resources?

Pricing and conservation

The method of using a resource is independent of the pattern over time of income and expenditures that the owner of the resource desires. Suppose that a farm will have a value of $100,000 if it is maintained at a constant level of fertility and yields a yearly income of $10,000 forever but that it can be cultivated ("mined") intensively to yield $12,000 a year for five years at the cost of a much reduced yield thereafter, with a value of $90,000. Even if the farmer is in urgent need of immediate funds and does not expect to live more than five years, he will still cultivate the farm at the uniform rate. Only then is it worth its maximum value to him, and only then (by sale or mortgage) can he obtain the largest possible funds even in the near future. In short, one need not adapt his expenditure pattern to his income pattern so long as he can borrow or lend.

If the growth of consumption or the decline of reserves threaten the exhaustion of supplies of a resource, then the price of that resource will rise and promise to rise more in the future, and this rise will serve to reduce current consumption and to reward the owner of the resource for holding back much of the supply for the future. This rise in price will therefore also stimulate buyers to find more economical ways of using the commodity (for example, burning the fuel more efficiently) and stimulate producers to find new supplies or substitute products. The price system will, therefore, ensure that the supply of the re-

source will be stretched out so that the resource will be available in both the present and the future.

The special case of the automobile. The number and severity of automobile accidents would seem to lie outside the system of prices, but it can be shown that they are much influenced by prices. The driver may buy protection by owning a new and heavy automobile rather than an old and small one; for the heavier the car and the better its tires and brakes, the lower the rate of serious accidents. Every driver, in effect, accepts some rate of accident: his driving habits and the highway conditions will on the average lead to some rate of accident per thousand miles of driving. The frequency of these accidents could, of course, be reduced but only at the cost of slower travel, fewer trips, and other costs that are higher than the cost of accidents. The fines imposed upon speeders are, in effect, a price charged for fast driving.

If the price system for drivers were not supplemented by extensive regulation and licensing, each driver would adjust his manner of driving so as to take those risks of accident that on balance "paid": the expected benefit from the driving would equal the expected cost of accidents. He might wish to insure himself against these risks, just as he insures his house against fire; but then his insurance premiums would reflect the level of accidents to which his driving led.

Pricing and accidents

Here it is necessary to take account of a previously neglected factor: the use of a price system involves substantial costs. When an accident occurs, under the price system the fault of each party must be determined, and this can give rise to lengthy and expensive litigation. Some recent proposals in the U.S. to settle small claims by a state fund, without determination of fault, are designed precisely to eliminate these costs of a price system. Of course the alternative system of compulsory insurance will have its own costs, one of which is the reduction in the incentive to drivers to be careful.

Minor accidents may be viewed as a form of waste, and it is never economically feasible to eliminate all waste. To pursue efficiency to its very limit is of course inefficient; the economist J.M. Clark commented on the "irrational passion for dispassionate rationality." A penny saved is indeed a penny earned, but this may be a low wage.

LIMITATIONS AND FAILURES OF THE PRICE SYSTEM

The price system is an extraordinarily powerful instrument in organizing an economic system, but it is subject to three broad classes of limitations.

Private and public price control. Sometimes prices are not permitted to do their work. Monopolies are able to exert control over prices; and they use it, sensibly enough, to raise their profits above the level allowed by competition. The monopolist (or group of colluding enterprises) sets prices at a level such that prices are above costs or, to use words of identical significance, such that resources earn more in the monopolized industry than they can earn elsewhere. The basis of the monopoly is its ability to prevent outsiders from entering the industry to share in the unusual profits and, by the act of producing, actually serve to eliminate them.

The cost of monopoly

The fixing of prices by monopolists reduces the income of society. This is, in fact, the only well-established criticism (on grounds of efficiency) to be levied against monopolies: there is no reason to assume that they will make products less suited to consumer tastes or innovate more slowly or pay lower wages or otherwise misallocate resources. But the basic inefficiency led, first in the United States in 1890 and then increasingly in European nations, to governmental policies to maintain or restore competition.

Public price control has two aspects. A large part of public regulation is intended to correct monopolistic pricing (or other failures of the price system); this includes most public-utility regulation in the United States (transportation, electricity, and gas, etc.). Whatever the success of these endeavours—and on the whole there has been a substantial decline in confidence in the regulatory bodies—they are usually instructed to achieve the goals of an efficient price system.

Other public price controls are designed to serve ends outside the reach of the price system. Prices of farm products are regulated (raised) in most nations with the intention of improving farmers' incomes, and the fixing of interest rates paid by banks is undertaken to improve bank earnings. Such policies are invariably defended on various economic and ethical grounds but reflect primarily the political strength of large and well organized producer groups.

Externalities and the price system. A second class of limitations consists of things that should be done but are not performable by a price system. Even when prices are freely established by competition, there is a class of economic relationships called "externalities" not efficiently controlled by prices. These may be illustrated by the air pollution caused by automobiles. Since no single automobile makes a significant contribution to air pollution, the owner has no incentive to bear the cost of installing antipollution devices even though all drivers would be better off if each did so. Yet if there are many automobiles in a region, it would be prohibitively expensive for drivers to contract with one another to have each install devices in his automobile to reduce pollution. The external effects of any one automobile's exhaust fumes are so diffuse and affect any one person so triflingly that they cannot be regulated by the price system.

The class of "externalities" is as broad as the class of actions that have effects upon people who are not parties to the contracts governing the actions. An attractive garden pleases passers-by, but they cannot be charged a portion of its cost. A new piece of scientific knowledge will prove useful to unknown persons. These two examples indicate that some externalities are economically trivial and some are highly important.

When the price system cannot deal with diffused effects, other social controls often take its place. The state invokes a whole arsenal of policies to deal with externalities, of which the following are only examples: (1) The state may subsidize activities that do not end in a product that can be sold. Thus basic scientific research that does not lead to patentable processes is subsidized. (2) Individuals may be compelled to act uniformly in areas where contracts would be too expensive; traffic laws, zoning laws, and compulsory vaccination are examples. (3) The state may itself undertake an activity that cannot be financed by sale of services, the most obvious example being national defense.

Traffic congestion and prices

An interesting type of externality is the problem of highway congestion. Any one person's presence on a highway at a time and place of peak density has only a negligible effect upon others, so that, except on toll roads, private contracts have not been feasible. The state itself has not been able to deal effectively with highway congestion. More highways can be built until no highway is ever crowded, but this would be intolerably expensive. The state has lacked a method of inducing drivers to shift to less crowded hours and routes by charging fees to those drivers who impose high congestion costs by driving at peak times. Recent developments in technology may make it feasible to use the price system to reduce congestion. For example, cameras at appropriate points could photograph automobile licenses and a computer could accumulate the charges based on route and time for each automobile. Then only a person for whom travel at peak times was worth, for example, 25 cents per mile would impose (and pay for) the congestion he created.

Imperfect knowledge and tastes. A third class of limitations to which the price system is subject has to do with the control of knowledge and tastes. To the extent that an economic actor, whether a consumer, a labourer, or an investor, is poorly informed, he is likely to make decisions whose consequences are much different from those he desired and expected. What follows relates only to consumer decisions, but parallel issues arise in labour markets, securities markets, etc.

A consumer can satisfy his desires only if he makes intelligent purchases—that is, only if the goods he buys are what he believes them to be. How can the consumer know whether the meat is free of disease or whether the

washing machine will function well and long or whether the fabric of the garment is one synthetic fibre or another? To ascertain these facts personally, the consumer would have to be a versatile scientist equipped with a superb laboratory—and then he would need to spend so much time testing goods that he would have little time to enjoy them.

In some measure the consumer does experiment in his buying: whenever he buys a thing repeatedly, experience tells him much concerning its properties. Direct experience is a sufficient guide in buying celery or hiring domestic servants, but usually the purchase of information takes a less direct form. The city's premier department store can sell at prices somewhat higher than less well-known retailers; and the difference represents the payment of a price for reliability, responsibility, and the guarantee of quality. In parallel fashion the consumer buys the washing machine of a company that made his excellent refrigerator. Occasionally, information is bought directly: the advice of a lawyer, the knowledge of an appraiser, the taste of an interior decorator.

The need for information

The most important and controversial method of informing consumers is by advertising. Many critics are outraged by the self-serving statements of sellers, some of whom indubitably provide irrelevance and deception rather than information. Yet the informational content of advertising may not be as deficient as its critics believe: advertising itself meets two market tests. In the first place, the direct sale of information by consumer advisory services has never become important, although there are no obstacles to entering this business. In the second place, there has been a general, sustained improvement in the quality of consumer goods over time: the automobile tire goes many more miles than formerly; the airplane flies more safely.

Nevertheless, recent public policy has paid great attention to increasing the safety of products and to raising the accuracy of advertising claims.

Knowledge is sometimes difficult to distinguish from taste: does the consumer who persists in smoking cigarettes have inadequate knowledge or simply different comparative values for the pleasures and risks of smoking? Censorship, in any event, is fairly common in every economic system: no society allows young children or incompetents full freedom of action or allows the unlimited sale of narcotics. Since the price system never forbids an effective demand (a demand backed by a willingness to pay the supply price), some form of restriction of prices is, therefore, necessary if certain tastes are to be forbidden or restricted. Compulsory school attendance can be viewed as, in effect, a form of censorship; and so are the controls on sale of firearms and the taxes on tobacco and liquor.

OTHER PRICE SYSTEMS

The foregoing discussion has been confined to the price system as it exists in capitalist economies. The Communist countries have prices, but not autonomous price systems; in those countries the direction of economic activity is largely in the hands of the central authorities, and prices are used mainly as a marketing device. None of the three allocative functions of an economy—determination of what will be produced, of how it will be produced, and of who will get the product—is performed by the price mechanism in the Soviet-type economies.

The relative scarcities that money prices measure exist, of course, in all countries and would exist in a world where no money or exchanges were allowed. Robinson Crusoe had a problem of allocating his time between sleep, garnering food, building shelter, etc.; and he confronted implicit costs of extending any one activity, for more food meant less of other things. The economist calls these implicit exchange ratios "shadow prices," and they appear in one form or another in all areas of life in which men make deliberate choices.

Price systems are therefore the result of scarcity. The basic proposition of economics, that scarcities are essentially ubiquitous, is often phrased as "there is no such thing as a free lunch"; and it reminds one that the price of the lunch may be future patronage, a reciprocal lunch, or a boring monologue. The task of economic organization is the task of devising price systems that allow a society to achieve its basic goals.

Priesthood

Throughout the history of religion, the official institution that mediates and maintains a state of equilibrium between the sacred and the profane aspects of human society, and that exercises a stabilizing influence on the social structures and cultic organizations, is the priesthood. The term priesthood is derived etymologically from the Greek word *presbyteros* ("elder"), of which it is a contraction, and is equated with the Latin word *sacerdos* (the Roman officiant at the sacrifices and sacred rites).

NATURE AND SIGNIFICANCE

The role of the priest

The primary role of the priest is that of the ritual expert, the one who has a special and sometimes secret knowledge of the techniques of worship, including incantations, prayers, sacrificial acts, songs, and other acts that are believed to bridge the separation between the divine or sacred and the profane realms. The priest gains such knowledge through the institution known as the priesthood, which may be composed of various groups or guilds devoted to all or only a few aspects of the priestly craft. Because the priest gains his special knowledge from a school for priests, he is differentiated from other religious and cultic leaders, such as the magician, shaman (healer and visionary), diviner, or prophet, who obtain their positions by means of individual efforts (*e.g.*, learning from a master magician or diviner; individual ecstatic experiences that are publicly recognized). As a member of the institution that regulates the relationship between the divine or sacred and the profane realms through ritual, the priest is the accepted religious and spiritual leader in his society.

At various times in the history of a culture or society the priestly institution may be attacked by other institutions or groups that vie for the religious leadership (and thus sometimes the social, political, and economic leadership) of a people. Such anticlericalism is a phenomenon not only of modern society (as noted in the Russian Revolution of 1917, the Mexican Civil War that began in 1857, and other less dramatic movements) but also in the ancient world, such as in Egypt in the 14th century BC, when the priesthood of the god Amon and the priesthood of the god Aton changed positions. Anticlericalism may be fostered by battles for religious leadership between two or more opposing priestly groups, or by prophets and others who are concerned with religious experiences in their personal rather than in their institutional forms. Among Protestants, the doctrine of the priesthood of all believers (*i.e.* all believers have direct access to God) militates generally against strong anticlerical tendencies within their own ranks. In Islām, there is, technically, no priesthood, though there are local spiritual and community leaders, such as the *imām*, the *mullah*, the *muftī*, the *qāḍī*, and others.

THE PRIEST AND HIS OFFICE

The function of the priest as the mediator and maintainer of the equilibrium between the sacred and the profane in human society, and as the stabilizer of the social structures and the cultic organizations, determines the various criteria for holding the priestly office. In preliterate society the functions are accomplished by ritual experts who are trained in the special knowledge and techniques of magico-religious disciplines in which sacred power is believed to be inherent. They also are trained in disciplines that enable them to gain a supernormal psychic knowledge and in the techniques of mystical experience. As agents of the sacred power, they are believed to have the ability to control and manipulate through ritual natural processes and events, and to engage in a sacramental relationship between man and the sacred order on which the community and its members depend for their sustenance, survival, and well-being.

Functions and criteria

Because religious institutions and beliefs are intimately connected with other social institutions, those who are set apart to establish efficacious relations with the transcendental powers that are believed to control the universe, as well as human affairs and destinies, occupy a key position at the dynamic centre in the social structure. Thus, in certain types of societies the office and functions of the priest may be limited to those having a particular ancestry, those belonging to certain tribes (such as the Levites in Judaism), families (such as the Eumolpids of the Eleusinian mystery religion of Greece), or castes (such as the Brahmins in Hinduism), and those initiated into certain professional orders (such as the cure doctors among the Maya).

Besides such sociocultural criteria, there are also certain personal requirements in various cultures for those who would become members of a priesthood. Celibacy (as in Roman Catholicism and the Arcakas of the Digambara sect in Jainism), asceticism (as in various Buddhist groups), and religious experiences (as among some holiness Protestant sects) are among the personal requirements for those who aspire to or are chosen to assume the priestly office.

The religious functions of priests are quite varied. In his specific role as the officiant of the rites that unite the sacred and the profane realms, the priest as a *pontifex* (from the Latin word that means maker of a bridge) celebrates or administers at the rituals of initiation into the cult or church, presides over ritual re-enactments of creative, redemptive, or salvatory (salvation-working) events, and offers sacrifices to the gods or to one God. He also functions as a perpetuator of the sacred traditions, practices, and beliefs and as a teacher, healer, counsellor, and diviner.

In all their respective offices, functions, and capacities, those who have exercised and manipulated sacred power have attained a uniquely prestigious position as the spiritual and social leaders *par excellence*. When perplexing and emotional situations that appear to be beyond human control, knowledge, skill, or techniques have arisen in a community, the people have a recourse in the priest, who has the special knowledge of the relationship between the divine or sacred and the profane realms. The priest is often called upon at critical junctures in the lives of individuals (such as birth, puberty, marriage, and death) and in the life of a community (such as seasonal changes or at times of flood, drought, and famine).

PRIESTHOOD IN THE RELIGIONS OF THE WORLD

Primitive cultures. The office of priesthood in primitive society ranges from the medicine man, who magically manipulates the sacred power as a quasi-impersonal force, to the shaman, who, as an agent of divine or spiritual beings, may be at once a medicine man, a visionary, occult diviner, and a genuine sacerdotal cult leader. Not infrequently, chiefs or headmen of a clan or village may become sacred men or ritual experts displaying supernatural insight and knowledge as the agents of spiritual beings. As such, they may eventually become prophets or sacral kings occupying a unique status in the community. This status may be acquired by accepted claims of descent from a mythical divine ancestor or god on whom the fertility of the crops and the welfare of the community in general are thought to depend. Occult power and insight may be derived from spirits with whom the prophet or diviner is related in a trance or ecstasy, or else in dreams, visions, or in auguries and oracles (divination techniques) that make known the divine will and predictions. To occupy such a position, a strenuous course of training is frequently required involving some knowledge of therapeutics (healing), leechcraft (use of leeches in healing), trephining (operating on the skull), herbs, poisons, and perhaps sleight of hand and similar techniques, together with the development of psychical and occult qualities. While charlatanry (pretentions to medical knowledge) is often practiced, the office also demands an understanding of the technical equipment calculated to bring about the results that are sought, and the proper type of temperament, conditions of mind, and state of emotion.

Medicine men and cult leaders

Unlike the shaman and the medicine man, both of whom exercise their respective functions while relying largely on their own initiative and psychic and occult powers of divination, healing, and direct access to the spirit world at their command, the priest supplicates and conciliates supernatural forces superior to himself, guards the sacred tradition in his care, and acts as the master of sacrifice. The shaman or magician officiates in his own name and by his own methods and techniques; the priest serves the altar, in the temple or shrine, as the representative of the community in his relations with the gods and the sacred order by virtue of the status and its functions that have been conferred upon him at his ordination, bestowing its sacredness and attendant taboos.

The ancient Near East. In the Nile Valley the occupant of the throne (the pharaoh) was regarded as a god incarnate, the sacred king. Because he was believed to be the epitome of all that was divine, he alone was the intermediary between mankind and the gods whom he summed up in his complex personality. Before the rule of Upper and Lower Egypt was centralized by the founder of the 1st dynasty (*c.* 3100–*c.* 2890 BC), Menes, the high priest and king "Scorpion" was traditionally considered to be the incarnation of Horus (the sky god). Under the powerful influence of the priesthood of Heliopolis, the sacred kingship was given a solar significance; the pharaohs were represented as the sons of the sun god Re, who was identified with the god Atum. When Memphis became the imperial city, Re-Atum was brought into relation with its god Ptah (the creator) and subsequently with Osiris, a fertility god who also was regarded as a god of the dead. Osiris was equated with the life-giving waters of the Nile and believed to be the first civilizing king, reigning in the person of the pharaoh as his posthumous son Horus. Therefore in Egypt the divine origin and status of the monarchy was so firmly established that it became the stabilizing force of the civilization in the Nile Valley.

Sacred kingship and the priesthood in Egypt

In theory, the king of Egypt was the high priest of every god, and in all important ceremonies he alone was depicted in the temple scenes as the officiant. For practical purposes, however, he delegated his functions to the particular professional local priesthoods. In due course the priests, courtiers, and officials shared in his divine powers and privileges. Even though they only acted on behalf of the divine ruler, they shared in some measure his personality and potency. As the priest *par excellence*, the pharaoh remained unique, and it was from him that the priesthood and nobility exercised their sacerdotal functions when the solar theology of Heliopolis was established in the 5th dynasty (*c.* 2494–*c.* 2345 BC). After the 5th dynasty he was accredited exclusively with having built all the temples, and on their walls he was portrayed officiating as the mediator between mankind and the gods in all important rites. In fact, nevertheless, his place was taken by one of the retinue of priests attached to the royal household or to the local temples. Only very occasionally did he perform his sacerdotal duties in person. Every temple had its high priest who, in addition to his sacred offices, might also be a high judicial official, thereby combining sacred and profane roles, varying with the actions performed.

From the number of titles assigned to priestly officials in the Old Kingdom (*c.* 2686–*c.* 2160 BC), it appears that one priest must have served simultaneously a multiplicity of cults in the shrine to which he was attached and received a share of the offerings and emoluments. In wealthy great temples in the New Kingdom (*c.* 1567–*c.* 1085 BC) there was an elaborate organization, and a large staff engaged in administrative, civil, and educational duties, as well as in their sacerdotal and mortuary functions. There were also a number of priestesses associated with the mother goddess Hathor (wife of the sun god Re), who were mainly concerned with playing the sacred sistra and other musical instruments. From the 18th to the 21st dynasties (1567–1085 BC), however, under the Theban priesthood of Amon-Re, the priestly hierarchy was able to create an absolute "state within a state."

Priestly classes and functions in Mesopotamia

In Mesopotamia, where kingship occupied a less prominent position than it did in the Nile Valley, powerful priesthoods and highly organized temples were firmly established in and after the 4th millennium BC. The temples were centres of sacred learning of the content and methods of incantation, prognostication, exorcism, and of political and economic administration, and their attendent priests were divided into classes with special sacerdotal and secular functions. The valleys of the Tigris and Euphrates rivers contained a series of city-states loosely bound together under the rule of a governor (*patesi* or *ensi*) and of a high priest (*sangu mah*). Their main functions were to integrate the temple communities of the city, their revenues and boundaries, and the *unigallu*, or head of the priesthood, was responsible for the performance of the seasonal rites, with the assistance of those who sang the liturgies and directed the temple music and those who uttered the lamentations, invoked the oracles, and interpreted the astrological signs and omens. The duties of other members of the priesthood included making incantations and pronouncing spells and exorcisms. The seers, or *baru*, foretold the future by means of soothsaying, interpreting dreams and visions, and revealing revelations.

An important function of the priesthood in the ancient Near East was that of exorcism. All down the ages good and evil have been viewed as two contending forces in perpetual conflict, and in the dual task of the riddance of evil and the induction of good the exorcist, the shaman, and the seer have exercised complementary functions hardly distinguishable in the higher cultural levels in Babylonia and Assyria. When the function of the driving out of demons from human beings and building by incantations and ritual expulsions was separated from the interpretation of omens and astrological portents, the office of the exorcists was in ever increasing demand. According to cuneiform texts from around the 3rd millennium BC, exorcists held a position of supreme importance, assisting at the consecration of temples, at funerals, and at seasonal ceremonies. In the temple schools, exorcists, diviners, and astrologers, together with physicians, scribes, and judges, fostered the study of astronomy, medicine, and jurisprudence. In their sacerdotal functions and capacities they were regarded as the agents and exponents of the gods, having a monopoly on sacred knowledge, controlling for good or evil the destinies of the community and its members. Therefore, their power was enormous, and they maintained the relation between religion and culture by their all-embracing hierarchy that determined the present welfare and future destinies of both human beings and the social order.

Canaanite priesthood

Similar beliefs and practices occurred in northern Syria in the middle of the 2nd millennium BC, before the Israelite settlement in Canaan. Here, again, the priesthood was responsible for the dramatic rituals on which the social structure and the well-being of mankind were believed to depend, especially in the climax of the autumnal festival that culminated in the enthronement of the year god. The priestly movement was centred in the temple of Ugarit, and the religious texts discovered there (Ras Shamra) were essentially liturgical documents devised to make the sacred drama enacted efficacious. Baal, the weather god, was regarded as "the lord of the furrows of the field," responsible for the rain and the production of the fruits of the earth. A series of temples was erected in his honour in Syria and Palestine. The temple at Ras Shamra was a considerable structure with a lattice, the opening of which was supposed to produce the autumnal rains, and its liturgical ritual was celebrated by the priests and priestesses in their official capacities as those who personified the gods and goddesses responsible for providential bounty and beneficence.

With the advent of Persian sovereignty in Mesopotamia, a new approach to cosmology and mythology was introduced. In the religion founded by Zoroaster (*c.* 7th century BC), the ultimate ground of the universe was reduced to a single supreme deity, Ahura Mazdā, the All-wise Lord. Astrology became widely practiced by the Iranian Magi (priests of the Zoroastrian religion) who were highly skilled in the knowledge of astral lore and the signs of the zodiac. In the three centuries after the Persian occupation of Mesopotamia (6th century BC), the Babylonian priests under Iranian influence made remarkable strides in astronomical learning that ultimately dethroned astrology from its exalted position in sacred tradition. Beyond the Euphrates Valley, however, it survived until after the Muslim rule, when the astrologer and the astronomer became indistinguishable.

Greece and Rome. The ancient Greeks were devoid of hierarchic institutions composed of men and women through whom the gods were approached, though priests and priestesses could be found in many places engaging in specific sacerdotal functions and ritual acts. Some of them attained considerable social and civic prestige and importance and were attached to particular temples or shrines such as the oracle at Delphi, which was consulted on private and state matters. Their duties, however, were generally those of members of a household engaged in everyday affairs, rather than of a caste or sacerdotal order set apart and consecrated for the performance of sacrificial and other rites, functions, and practices. Though not regarded as mediators between the gods and men, they did act in such ritualistic capacities in certain civic and administratve areas. There was no specific distinction, however, between them and lay members of society. On the contrary, such officials as magistrates might be priests and vice versa. Some exercised considerable influence if they were regarded as outstandingly efficient, wise, or distinguished in their respective civic or religious capacities.

Civic importance of the priesthood in ancient Greece and Rome

Similarly, in ancient Rome when the agricultural religion of Numa (the legendary second king) was transformed into an institutional state cult in the republic, it was organized as a hierarchy with the *rex sacrorum* ("king of the sacred things") inheriting the office and attributes of the former priest-king. He had to be a patrician and was chosen for life, subordinate only to the *pontifex maximus*, who was the head of the college of *pontifices* ("advisors on the sacred law") and *flamines* ("priests devoted to a particular god"), three of whom were assigned to the gods Jupiter, Mars, and Quirinus, the remaining 12 to other deities. The flamen Dialis, dedicated to the supreme sky god, Jupiter, occupied a unique position socially, politically, and sacerdotally and was subject to strict taboos and regulations because of his sacred office. The *flaminica*, the wife of the flamen Dialis, participated in his sacredness and official status, and so vital was her association with him and his office that if she died he ceased to perform his functions.

Attached to the temple of the goddess Vesta on the Forum in Rome were the six Vestal Virgins dedicated from childhood to the service of the sacred fire in the *atrium Vestae* (hearth temple), and to the care of the store house (*penus*). Originally they were selected from patrician families by the *pontifex maximus*, but later plebians were eligible for election. During their 30 years of service to the goddess, beginning in childhood, chastity had to be strictly observed on pain of death by starvation, but after the completion of the period of service the virgins were free to marry. The duties assigned to them at very ancient festivals, such as the Lupercalia (a fertility festival) on February 15, and at other occasions, indicate their unique position and significance in the state cult going back, in all

probability, to their origins in the family tradition, associated with the *pontifices* as the officiating priests. Augurs (divinatory personages) had a powerful influence on state religious beliefs and practices, especially in divination to ascertain the will of the gods and the blessing of the crops. They also interpreted signs in the sky as good or bad for the guidance of the magistrates. At the end of the republic (in the 1st century BC) this practice led to abuses that were ridiculed by the politician and orator Cicero. Among other groups of Roman priests were the Salii on the Palatine Hill (the 12 Leapers of the god Mars), and the Luperci, whose sacerdotal functions were confined to the Lupercalia. The *fetiales* were Roman officials employed in making treatises or declarations of war, whose work gradually fell into disuse at the beginning of the empire (late 1st century BC) when the state cult was in decline and losing its vitality.

Ancient Judaism. When Christianity became the legal religion of the Roman Empire after AD 313, it had already inherited from its Jewish background a concept of an organized priesthood. The Jewish priesthood had been centralized in the Temple at Jerusalem (destroyed by the Romans in AD 70) since the 10th century BC. The Hebrew designations for those who exercised oracular, divinatory, and ecstatic functions in ancient sanctuaries that were prominent cultic centres prior to the building of the temple, such as Mamre, Hebron, Bethel, Shechem, and Gilgal, were *cohen, levi, navi'*, and *ro'e*, corresponding to priest, Levite, prophet, and seer, respectively. *Cohen* is the equivalent of the Arabic word *kāhin*, diviner, and in Hebrew it has the meaning of "priest," denoting the occupant of the office concerned with obtaining oracles by the aid of the ephod ("pouch") containing the Urim and Thummim (sacred lots) and by inspiration, as well as with officiating at a sanctuary. After the 7th century BC, when worship was concentrated in Jerusalem, the capital, the priesthood was restricted to the Levitical house of Aaron (brother of Moses, the 13th-century-BC lawgiver) after having been previously drawn from other lines of descent, such as those of David, Nathan, Micah, and Abinadab (royal, prophetic, and priestly families).

Priests, Levites, prophets, and seers

Whether in fact the Levites ever were members of a sacerdotal tribe is open to debate, but in any case they represented a special fraternity set apart to be guardians of the sanctuary and to engage in oracular and prophetic function, over against the rival priestly *cohenim* in their respective independent confraternities. It was not until after the Exile of the Jews to Babylon in 586 BC, when the Priestly Code was drawn up, that the distinction between priests and Levites became absolute. The priesthood was confined exclusively to those claiming succession from Aaron, in spite of the Zadokites claiming priestly descent from Eleazar as an "everlasting covenant" (Num. 18:2–7, 25:13; I Chron. 24:37). The Zadokites may have constituted the survival of an ancient Jebusite (Canaanite) royal priesthood, giving them special duties and privileges in the Temple worship above those of the Levites. Later, when the priesthood became reserved for the descendants of the family of Aaron alone, the title was restricted to members of the non-Aaronic families of the tribe acting as the servants of the Temple.

The oracle given by the priests as the inspired word of the Law, called the Torah, which was referred back to Moses in postexilic Judaism, acquired a new significance, involving a rigid observance of its ritual and legal commands that permeated every aspect of life, worship, and conduct. The cessation of the daily sacrifice and other Levitical priestly ministrations in the Temple after the fall of Jerusalem (AD 70) gave a new emphasis to and interpretation of the Torah in the synagogue and in domestic rituals. The prerogatives of the high priest, and those of the priesthood in general, with its exclusive lineage, were maintained after the revolt of the Jews under the leadership of the Maccabees against the Hellenistic Syrians in the 2nd century BC, and the priestly blessing (*dukhan*) in the synagogue remained the exclusive right of the *cohenim* claiming descent from Aaron. They also have had the right to be the first called upon to read the Torah in the synagogue, followed by a Levite. Their privileges, however, have been questioned by some rabbinical (nonpriestly Torah scholars and religious leaders) authorities. The Sadducees (deriving their name from the Zadokites) were the high priests in Jerusalem during and after the time of the Hasmoneans, the descendants of the Maccabees (135–104 BC). They exercised considerable influence in the Jewish Sanhedrin (supreme rabbinic court) as the conservative class of the religious aristocracy, favoured accommodations to Greek culture, and maintained the importance of the letter of the Written Law over against the oral tradition of the rival Pharisees. The high priesthood, however, was declining in status under the increasing control of the Roman authorities.

Emphasis on interpretation of the Torah

Christianity. At this critical juncture in Judaism, Christianity, with its own particular conception of priesthood and sacrificial redemption, began in Palestine and rapidly spread throughout the surrounding regions in the Greco-Roman world. In the New Testament, the imminent destruction of the Temple in Jerusalem and its worship is predicted, and the culmination of its high priesthood in the person of Christ, after the order of Melchizedek (the priest-king of Jerusalem revered by Abraham in the Old Testament), is proclaimed. The Jewish Aaronic priesthood and its ritual are represented in the Letter to the Hebrews as imperfect shadows, in a Platonic sense, of the archetypal order of the eternal sacrifice of Christ. Only Christ, who was described as "beyond the veil" (referring to the veil that separated the "Holy of Holies" section from the other areas of the Temple), was believed to be able to save those who came to God through him, since he had removed the barrier of sin that separated man and God for those in a state of grace. In Christ's reconciling offering as both priest and victim on the cross, the writer of the Letter to the Hebrews stated that he accomplished the removal of the barrier in the heavenly tabernacle. This was interpreted in terms of the Hebrew Day of Atonement, a ceremony in which the Jewish high priest made expiation annually for himself, the priesthood, and the whole congregation of Israel. The view of Christ as king, high priest, mediator, and victim influenced the establishment and gradual development of the Christian priesthood in the church, which shares in and makes accessible to its baptized members the all-sufficient priesthood of Christ.

The relationship between presbyter and bishop

Originally the term *presbyter* ("elder") and *episkopos* ("overseer"), current in the New Testament and the early church, were probably identical. From the 2nd century on, however, the sacerdotal hierarchy developed along the lines of the Hebrew priesthood, the title *episcopus*, or bishop, becoming reserved for those who presided over the presbyterate, then called *sacerdotes* because they shared in the episcopal *sacerdotium* ("priesthood"), which included the offering of the eucharistic sacrifice of bread and wine. But the conferring of holy orders (ordination of presbyters) and administering the sacrament of confirmation were confined to the episcopate, together with administration of the diocese (jurisdictional area). In due course the threefold ministry of bishops, priests, and deacons (administrative and liturgical assistants in a parish) became organized on a diocesan basis. This remained the norm in the Western Church until the Reformation in the 16th century, when it was repudiated by the continental Reformers (*e.g.*, Luther, Calvin, and Zwingli). In Roman Catholicism, Anglicanism, Swedish Lutheranism, and Eastern Orthodoxy, apostolic succession and jurisdiction has been maintained, especially in the Roman Catholic papacy and in Eastern Orthodox patriarchates.

In European Christianity in the Middle Ages (*c.* 6th to 14th centuries), the deeply laid tradition inherited from the theocracies and priesthoods in the ancient Near East of a common social, judicial, political, and religious structure was sustained and gave expression to medieval civilization, especially in the Latin West. Church and state became so closely associated that they were virtually identical, as in the cases of the sacred and secular in preliterate societies. As Dante (1265–1321) contended in *De Monarchia* ("Concerning the Monarchy"), the pope, as the head of the spiritual aspects of society, and the emperor, as the ruler of the temporal areas of concern, were equal-

ly ordained by God to exercise their functions in their respective spheres of power and influence for the welfare of mankind. If this duality of control did not endure, because the church gradually usurped more and more of the civil jurisdiction and dominated emperors, kings, and other ecclesiastical rulers, the unification of the body politic was rendered more complete as an integrated whole, and the life and character of medieval civilization was determined through the papacy and its priesthood.

Hinduism. In Vedic India, the early period of Hinduism, when the priestly caste (Brahmin, or Brāhmaṇa) was vested in a particular tribe or special class, it occupied the primary place of importance in the segmentation of Hindu society. The king was subordinate in some respects to the Brahmins, though at one time both sometimes were chosen from the Kṣatriya, or warrior caste. Nevertheless, because the existence of the universe and all cosmic processes were made to depend upon sacrificial offerings, the king delegated such functions to the priests before the end of the 7th century BC, the priests having usurped that position previously held by the kings. The priesthood then exercised supreme control over the fortunes of the gods and men, of heaven and earth, and of the state, though not infrequently priests worked in the service of princes. The Brahmins, however, were so firmly established in the caste system as the twice-born masters of sacrifice and of the sacred knowledge that they alone possessed that they were viewed as holding the universe in their grasp. As "lords of creation" by divine right they were divided into ten tribes, above all other castes. They were required to pass through four *āśramas* (the celibate religious student, married householder, forest hermit, and wandering ascetic), or conditions of life, prior to and after marriage, to become anchorites (or hermits), and to attain the plenitude of their status, vocation, and authority, thus renewing the creative process by the due performance of the sacrificial offering.

The role of the Brahmin caste

Against this Brahmanic sacerdotalism and its caste organization, the reaction noted in the *Upaniṣads* (writings representing the end of the Vedic period) about 600 BC introduced a mystical conception of the priesthood in Hinduism, and subsequently in Buddhism. Living as hermits in the forest, groups of mystics, reacting to Brahmanic ritualism, gathered around them disciples to learn and propagate a philosophical doctrine based upon the quest to discover a new function for the priesthood, in which the identification of the inner eternal self of man (*Ātman*) with the divine ground of the universe (Brahman) was achieved by asceticism, renunciation of the world, and mystical experience and realization, rather than by the sacrificial offering. This quest was eventually associated with the meditative techniques of *yoga* (mental and physical exercises) and opened the way for the rejection of the exclusive claims of the Brahmins in favour of the mystical insights and esoteric knowledge accessible to all who adopted the Upaniṣadic teaching and way of life.

With the establishment of the four *āśramas*, sacrifice and Brahmanic study of the Vedas were rehabilitated and brought into relationship with the Upaniṣadic tradition. The Brahmin was thus regarded as occupying the highest state of life; he was

Revival of sacrifice and Vedic study

> one who has sensed the deepest self and acts out of that consciousness, [communicating it to others], . . . gives moral guidance, . . . lays down the science of values, draws out the blueprints for social reconstruction, and persuades the world to accept the high ends of life. (From S. Rādhākrishnan, *Eastern Religions and Western Thought.*)

This view has lacked, however, a conception of the godhead with whom personal relations are possible, thereby making the priesthood an aspect of an impersonal divine power (Brahman), of a pantheistic principle executing its functions with automatic precision by virtue of its sacerdotal equipment, of an alternating mystical and ascetic priestly sublimation.

Jainism and Buddhism. In Jainism and Buddhism, arising within Brahmanism as nontheistic sectarian movements, the Brahmin priesthood was sublimated and the Vedic caste and sacrifice eliminated. In their place a monastic system was evolved, with monks and nuns devoted primarily to rigorous asceticism in the quest of perfection, including the prohibition of taking life in any state or form, and in the pursuit of chastity and truthfulness. Complete detachment from all phenomenal possessions and connections in Jainism (founded by Mahāvīra in the 6th century BC) made paramount the mendicant life of meditation and spiritual exercises dependent upon the fulfillment of vows of poverty. The functions of the priesthood were sublimated in a process of self-salvation, centred around the purpose of the deliverance of a suffering humanity from the cycles of rebirth. Since in Buddhism *taṇhā* ("desire") was regarded as the fundamental cause of *dukkha* ("the burden of existence"), priestly intervention and the sacrificial offerings were considered to be of no avail in the pursuit of the Eightfold Path leading to the passionless peace of Nirvāṇa (the state of bliss).

In the absence of any conception of a deity in Buddhism, the question of sacerdotal mediation could be ignored, though, in the Mahāyāna ("Greater Vehicle") school, and in the Tantric (esoteric, magical) school, some elements of the priestly tradition survived. The earliest converts to Buddhism were Brahmins for the most part, and a religious organization in monasteries developed, with various prescribed roles for their inhabitants, with daily routines, certain periods devoted to alms and quests, and periods for sacred learning and the translation of literary and theological works. To these activities were added other functions, such as recitations of the sacred texts at births, marriages, and in sicknesses to keep evil influences at bay. In the temples, shrines were erected to the honour of the eternal Buddha, and the image of the Blessed One on a lotus bedecked with flowers has become the central object of worship in certain Buddhist groups. The recitation of the ancient Pāli *sūtras* (divine revelations) is believed to transmit the merit inherent in the texts, as is the endless repetition of the sacred formula *Namu O-mi-to* (*Amida-butsu*), "Homage be to the Buddha of infinite light." This, however, is not a sacerdotal devotion performed by, or requiring the presence of, a priest. Buddhism, in fact, has never been able to produce a strong and lasting ecclesiastical organization or a hierarchical segmentation (as in Hinduism), because it has interpreted unity in terms of Becoming, instead of in terms of Being.

Priestly traditions in Tantric and Mahāyāna Buddhism

Buddhism, Taoism, and Shintō in China and Japan. In the Mahāyāna Buddhist sects, the monks, and those who are popularly known as bonzes, can hardly be said to exercise definitely sacerdotal functions in the temples, monasteries, and shrines. For the most part, these functions have been confined to recitations and invocations, which all of the believers share. In China, the Taoist "priesthood" emerged as an organized institution at the beginning of the Christian Era. Some were celibates and others were married, living ordinary domestic lives. A number were mendicants and some engaged in alchemy and astrology; others were illiterate. There were also those who assisted in ceremonies and collecting the revenues. In the 6th century AD, in imitation of Buddhism, the Taoist celibates lived in monasteries with a patriarch as the head and interchanged facilities with their Buddhist counterparts. In the Zen contemplative sect in Japan, an attempt was made to attain a state of enlightenment (*satori*) by a strict discipline and training in quasi-*yoga* intuitive methods, without priestly intervention or divine grace. The Zen temples and halls of meditation have become centres of learning, art, and education as well as of vigorous austerity and contemplative mysticism, which has not been without attractions to various persons of the West in recent times.

When Buddhism reached China, Japan, and Tibet in the opening centuries of the Christian Era, it came under the influence of the indigenous faiths, cults, and social structures, and, reciprocally, it became a most important influence, adapting its beliefs and customs to those already established in these regions. In the second half of the 6th century AD, after Buddhism had acquired official recognition, pagodas, temples, and monasteries were erected with ornamentations of Buddhist origin. Buddhism adapted itself to Shintō, the native religion of Japan, and to its

shrines, festivals, and rites. The functions of the four priestly classes (*e.g.*, as ritual experts, diviners, musicians, female dancers, and "abstainers" to ward off pollution) that emerged from the family or tribal cults of Shintō were absorbed by Buddhism.

When Shintō was restored as the national religion of Japan in the 19th century, after a period of decline, the Shintō and Buddhist priests were assigned their respective duties and offices by the State Department of Religion without discrimination, for the maintenance of reverence for the gods and love of country (the Truth of Heaven and the Way of Humanity) and proper respect for the sacral emperor (the mikado). This dual sacerdotal combination lasted only until 1875, because Buddhism and Shintō were basically incompatible. This resulted in Shrine Shintō becoming the national faith under the Imperial family, maintaining its divine status, cultic practices, and priesthood, but leaving Buddhism free to propagate its *dharma* (or law) in its own way. New rituals and ceremonies were composed by the government for use at the Shintō shrines, and the duties and grades of the priests were fixed.

THE PRESENT SITUATION

In recent years, in Christianity especially, notwithstanding the doctrinal divergencies and modes of expression in the nature and function of the priesthood, new approaches have been made by both Catholic and Protestant theologians, liturgical scholars, and laymen. This is particularly apparent in the ecumenical and liturgical movements in Western Christendom, in the administration of the sacraments, and in the participation of the laity in the liturgy and in the other offices. In Roman Catholicism, especially under the influence of the second Vatican Council (1962–65), and in the contemporary Anglican Convocations, the "priesthood of the laity" has been more widely recognized and practiced, though this has been a cardinal doctrine of Protestantism since the Reformation. Lay persons trained in liturgical functions have assumed functions, such as reading of the Scriptures and administering the eucharistic elements of bread and wine, in various Protestant churches and, in some instances, in Roman Catholic celebrations that in the past have been the prerogatives of priests. In the Eastern Orthodox churches, such movements and influences have been less effective and operative, largely because of the heavy pressure they have endured from governments that have been hostile in the Communist countries where Orthodox membership is concentrated. They have always, however, preserved a living unity of faith, worship, and organization. Priesthood is inherent in these institutions; it has proved to be the unifying, stabilizing force in Eastern Orthodoxy, the second largest Christian body (after Roman Catholicism), beset as it has been by so many hazards and hostilities in its long and checkered history.

Participation of the laity in liturgical and other functions

BIBLIOGRAPHY. The nature, characteristics, and significance of priesthood in primitive cultures ancient and modern are discussed by GRAHAME CLARK in *Archaeology and Society*, 3rd rev. ed. (1957); EMILE DURKHEIM, *Les Formes élémentaires de la vie religieuse* (1912; Eng. trans., *Elementary Forms of the Religious Life*, 1915, reprinted 1964); and the cultural and scientific development by JACQUETTA HAWKES and LEONARD WOOLLEY, *History of Mankind*, vol. 1, *Prehistory and the Beginnings of Civilization* (1963). The prominent features of priests and kings in the rise of civilization are considered by H.J.E. PEAKE and H.J. FLEURE in the 4th volume of their "Corridors of Time" series (1927). G. LANDTMAN, *The Origin of Priesthood* (1905); and E.O. JAMES, *The Nature and Function of Priesthood* (1956), are comparative and anthropological studies of the subject in its wider aspects with full bibliographies. In ancient Egypt and the Near East the organized priesthoods are treated by J.H. BREASTED (ed.), *Ancient Records of Egypt*, 5 vol. (1906–07), and in *Development of Religion and Thought in Ancient Egypt* (1912, paperback edition 1959); by HENRI FRANKFORT in *Ancient Egyptian Religion* (1948), and in his important exposition of the *Kingship and the Gods* in Egypt and Mesopotamia (1948). The available Sumerian evidence is produced by S.N. KRAMER in his *Sumerian Mythology* (1944). The priestly aspects of the Annual Festival are surveyed by S.H. HOOKE in the *Origins of Early Semitic Ritual* (1938), and in *Myth, Ritual and Kingship* (1958). The Canaanite counterparts are recorded in G.H. GORDON, *Ugaritic Literature* (1949); and in G.R. DRIVER, *Canaanite Myths and Legends* (1956). For the Hellenic conceptions of priesthood, a full bibliography is appended to the article on "The Religion and Mythology of the Greeks" by W.K.C. GUTHRIE in *The Cambridge Ancient History*, rev. ed., vol. 2, ch. 40 (1961). The origin and status of the Levites and the Levitical code in the Hebrew priesthood are investigated by T.J. MEEK in *Hebrew Origins*, rev. ed. (1950). For the origin of the Christian priesthood, see K.E. KIRK (ed.), *The Apostolic Ministry* (1946). In India the Vedic, Brahmanic and Upaniṣadic conceptions of priesthood, and the predominance of the Brahmin caste in Hinduism are discussed in A.B. KEITH, *Religion and Philosophy of the Veda and Upanishads*, 2 vol. (1926); J.H. HUTTON, *Caste in India*, 2nd ed. (1951); S. RADHAKRISHNAN, *Eastern Religions and Western Thought*, 2nd ed. (1940), and *The Hindu Way of Life* (1963); and R.C. ZAEHNER, *Hinduism* (1962), with a full bibliography. For the sublimation of priesthood in Buddhism in India, China, and Japan, see EDWARD CONZE, *Buddhism: Its Essence and Development* (1951); and P. DAHLKE, *Buddhism* (1927). D.H. SMITH, *Chinese Religions* (1968), is an introduction to religious thought and sacerdotal practice in China. *Religious Studies in Japan* (1959), is a very informative composite volume by a group of Japanese scholars in English. Concerning the Zen sect, see D.T. SUZUKI, *The Manual of Zen Buddhism* (1950); A.W. WATTS, *The Way of Zen* (1957); and reference to it in R.C. ZAEHNER, *Mysticism, Sacred and Profane* (1957). The priesthood in Shintō is discussed by D.C. HOLTOM in *The National Faith of Japan* (1938). For studies on the present situation of the priesthood in Christianity, the following works should be consulted: J.D. BENOIT, *Liturgical Renewal* (1958); J.H. SRAWLEY, *The Liturgical Movement* (1954); E.B. KOENKER, *The Liturgical Renaissance in the Roman Catholic Church* (1954); B. LEEMING, *The Vatican Council and Christian Unity* (1966); B.C. BUTLER, *The Theology of Vatican II* (1967); and B.C. PAWLEY (ed.), *The Second Vatican Council* (1967).

(E.O.J.)

Priestley, Joseph

A clergyman, political theorist, educator, and scientist, Joseph Priestley represented the spirit of English dissent that, in the 18th century, produced major advances in liberal thought and experimental science. A prolific writer on many subjects, he exercised a wide influence on politics, religion, and science in Europe and North America. His textbooks, teaching, and classroom demonstrations in science were major innovations in education. Modern Unitarianism owes much to the theological ideas he developed, which stressed man's spiritual autonomy. Known also as one of the discoverers of oxygen, he performed many original experiments with gases, which provided much of the empirical data that contributed to the theoretical foundations of modern chemistry. A man of buoyant optimism, he believed that human progress would be the natural result of political and religious freedom and of the applications of science.

Priestley was born at Birstall Fieldhead, near Leeds, Yorkshire, on March 13, 1733, the oldest of six children. His father, a cloth dresser by trade, employed a few workmen in his home in the finishing treatment of a cloth known as homespun. For several years during his childhood Joseph was often sickly; but, perhaps as compensation, he became an avid learner on his own. Although his parents were Calvinists, they were open to other religious views and wanted him to enter the ministry of the Dissenting church, the diverse congregations of which, such as Presbyterian or Independent, did not conform to the Church of England. To prepare himself, he studied "Hebrew, Chaldee, Syriac, and a little Arabic" with a local Dissenting minister.

With improving health, in 1752 he entered a new Dissenting Academy at Daventry, Northamptonshire, one of the educational institutions that, in the 18th century, was established independently by Nonconformists. These academies offered high-quality education and attracted the best teachers and students. As a theological student, his unorthodox opinions developed even more as he added to the required curriculum his own intensive study of history, philosophy, and science, and a daily translation of 10 folio pages of Greek. In 1755 he left Daventry Academy to become assistant minister to the independent

Early liberal views

Presbyterian congregation in Needham Market, Suffolk; but having become a "furious freethinker," his unorthodox and even heretical opinions gradually lost him the confidence of his orthodox congregation. "After much pain and thought," he renounced the doctrine of the Atonement; moreover, his examination of St. Paul's epistles in the New Testament satisfied him that the Apostle's reasoning "was in many places far from being conclusive." Priestley's intellectual development passed from the Calvinism of his family, through Arianism, with its denial of Christ's divinity, to a rational Unitarianism, with its complete denial of the Trinity. At no stage of this development, however, did he ever waver in the sincerity of his religious convictions or in the genuine piety of his life.

In 1758 Priestley transferred to a more sympathetic congregation in Nantwich, Cheshire, where he opened a day school with 36 students. Becoming interested in science at this time, he provided them with "philosophical instruments," such as an air pump and a static generator for electrical demonstrations. His teaching success led to his appointment in 1761 as a tutor in language and literature at Warrington Academy in Lancashire. Because the universities and learned professions were barred to Dissenters, Priestley developed new courses that were suitable for students preparing for careers in industry and commerce. Textbooks were not available, and these he set himself to write. In 1761 he published the *Rudiments of English Grammar*, a work that was radical in its description of English usage as opposed to prescription on the basis of dead classical languages; it remained in use for 50 years. Ordained a Dissenting minister in 1762 at Warrington, in the same year he married Mary Wilkinson, aged 18, the only daughter of an ironmaster at Bersham in Wales. They had a daughter and three sons.

Contributions to education

Priestley enriched the curriculum with his *Theory of Language and Universal Grammar* (1762), *Chart of Biography* (1765), *Essay on a Course of Liberal Education for Civil and Active Life* (1765), and *Lectures on History and General Policy* (1765, 1788). By emphasizing history, science, and the arts rather than the classics of university curricula, he sought to prepare students for a practical life. His educational activities made Warrington Academy the most distinguished school of its kind in England. The degree of LL.D. was conferred on him by Edinburgh University in 1765.

Priestley became even more interested in science while attending lectures and demonstrations on practical chemistry given in 1763–65 by the surgeon Matthew Turner. Beginning in 1765, Priestley spent a month of every year in London, where he met the leading men of science, including the American statesman and inventor Benjamin Franklin. On the basis of his electrical experiments, Priestley in 1766 was elected to membership in the Royal Society of London. The next year, with Franklin's encouragement and generous loan of the requisite books, he published *The History and Present State of Electricity*, an original work in which he summarized the knowledge of electricity to his time and described his own experiments. He anticipated the inverse square law in electrical attraction with his observation that when he electrified a hollow sphere there was no charge inside. He also discovered that charcoal conducts electricity and noted the relationship between electricity and chemical change, whereby one could cause the other. This work "drew him into a large field of original experiments" that were not in electricity. As he became more interested in chemistry, he reflected on the similarity between the processes of burning and respiration.

Contributions to electricity

In 1767 Priestley was appointed minister of Mill Hill Chapel, in Leeds, Yorkshire, where he had more leisure for writing and experimenting. Although not primarily theoretical in his approach to science, he was able to perceive what research would be most fruitful. He studied gases, or "airs," as they were then called, a subject that led him to perform many significant experiments. The facts he discovered became central in the theoretical development of chemistry. His work on gases began while he was living next to a brewery in Leeds, where he observed "fixed-air" (carbon dioxide) as it effervesced from vats of fermenting liquor. Before his work, only three gases were known: air, carbon dioxide, and hydrogen. With zeal and enthusiasm he discovered 10 new "airs," four in 1767–73 while at Leeds: nitric oxide (nitrous air), nitrogen dioxide (red nitrous vapour), nitrous oxide (diminished nitrous air, later called "laughing gas"), and hydrogen chloride (marine acid air). His success resulted in large part from his ability to design ingenious laboratory apparatus, particularly an improved pneumatic trough, and his skill in its manipulation. Moreover, by collecting gases above mercury in the trough, instead of in water, he was able to isolate, by trial and error, those that were water-soluble.

First gas experiments

Concurrently with these experiments, Priestley developed rapidly as a political theorist. Representative of 18th-century liberal thought was his *Essay on the First Principles of Government, and on the Nature of Political, Civil, and Religious Liberty* (1769), in which he emphasized individualism; he believed that people should have a voice in their government and power over their own actions. The English economist Jeremy Bentham acknowledged that this influential book inspired his phrase "the greatest happiness of the greatest number." Throughout his life Priestley was an ardent believer in human progress and perfectibility.

Political theory

In his gas experiments, Priestley showed that the volume of air decreases by one-fifth during respiration, putrefaction, and combustion. In 1771 he observed that plants restored air used by a live mouse or a burning candle. The next year he discovered that mixing colourless nitric oxide and ordinary air resulted in a diminution in total volume, which he measured in a eudiometer, and a reddish colour (nitrogen dioxide). This was an important new technique; it substituted nitrous oxide for mice as a measure of the "goodness of air" and made possible quantitative tests of chemical changes that involve gases. His summary of this work in the *Philosophical Transactions*, "On Different Kinds of Air" (1772), promptly drew the attention of the French chemist Antoine-Laurent Lavoisier, who proceeded to give a theoretical interpretation of Priestley's observations.

In 1772 Priestley's *History and Present State of Discoveries Relating to Vision, Light, and Colours* was an original contribution to optics. It brought an invitation to join Capt. James Cook's second voyage of exploration (1773–75) as an astronomer, but he was obliged to decline when opposition mounted to his Unitarian views. His technique for "impregnating water with fixed-air" (using sulfuric acid and chalk), however, was suggested for use on the voyage to make drinking water palatable —and also later made possible the soda-water industry.

In December 1772, William Fitzmaurice-Petty, 2nd earl of Shelburne, later 1st marquis of Lansdowne, appointed Priestley as librarian, literary companion, and tutor to his two young sons, on generous terms, with the freedom to preach and write as he wished. He settled at the Shelburne estate at Calne, Wiltshire, in July 1773. The following November he was awarded the Copley Medal by the Royal Society for his experiments on gases, on which he continued to report in a series of volumes entitled *Experiments and Observations on Different Kinds of Air* (6 vol., 1774–86).

Priestley's most famous discovery occurred on August 1, 1774, when he obtained a colourless gas by heating red mercuric oxide (he called it *mercurius calcinatus per se*). Finding that a candle would burn in it "with a remarkably vigorous flame," he called it "dephlogisticated air" because he believed, accepting prevailing theory, that ordinary air became saturated with phlogiston when it could no longer support combustion or life. (Phlogiston was thought to be a material that was transferred during burning and respiration; a unifying idea in 18th-century chemistry, it avoided quantitative considerations but was the reverse of the oxidative interpretation of combustion and respiration established by Lavoisier in 1789.) Priestley was not yet sure, however, that he had discovered a "new species of air." (Oxygen was also discovered by the Swedish chemist and apothecary Carl Wilhelm Scheele,

The discovery of oxygen

probably by 1773.) The following October Priestley accompanied Shelburne on a journey through Belgium, Holland, Germany, and France, where in Paris he informed Lavoisier how he obtained his new "air." The meeting of the two scientists was highly significant for the future of chemistry: Lavoisier required no more than the barest intimation of the success of Priestley's experiments to appreciate their significance. He immediately repeated them and in 1775-80 conducted intensive investigations from which he correctly deduced the elementary nature of oxygen, recognized it as the active "principle" of the atmosphere, interpreted its role in combustion and respiration, and gave it its name (1789). Priestley, however, did not accept all of Lavoisier's views and continued in particular to uphold the phlogiston theory until, in his old age, he became its last champion.

Continuing his studies of the atmosphere, Priestley discovered ammonia (alkaline air), sulfur dioxide (vitriolic acid air), silicon tetrafluoride (fluor acid air), nitrogen (also discovered by Daniel Rutherford in 1772), and a gas later identified as carbon monoxide. Of striking significance was his observation that light was important for plant growth and that green plants gave off "dephlogisticated air" (really oxygen). These observations became fundamental to the systematic work on photosynthesis by the Dutch physician Jan Ingenhousz (begun in 1779) and by the Swiss clergyman-naturalist Jean Senebier during the next two decades. Drawing then on his earlier knowledge of electricity, Priestley decomposed ammonia by sparking with electric sparks and noticed the formation of dew when mixtures of hydrogen and oxygen are exploded.

In 1779, for reasons not entirely clear, Priestley left Shelburne's employ and settled in the industrial town of Birmingham as minister of the New Meeting congregation. He received a small annuity from Shelburne, and friends raised a subscription to defray the expenses of his experiments. The years at Birmingham were the happiest and busiest of his life. He wrote books on religion and theology and published sermons, tracts, and catechisms. In his *History of the Corruptions of Christianity* (1782), he rejected most of the fundamental doctrines of Christianity, including the Trinity, predestination, and the divine verbal inspiration of the Bible and traced them to their historical sources of error. This work aroused another storm of protest. By the time of the French Revolution he had acquired a reputation as the antagonist of all establishments, both political and religious.

Priestley regularly took part in meetings of Birmingham's Lunar Society, which met monthly at the full moon. Flourishing independently of the Royal Society of London, this organization in 1766–91 actively promoted science and its applications to industry and crafts. There, Priestley was the honoured colleague of the naturalist Erasmus Darwin, the pottery manufacturer Josiah Wedgwood, and the inventor of the steam engine, James Watt. Concluding his scientific work, he observed that "calces" (oxides) are changed to the metallic state (reduced) when heated in hydrogen; but he did not notice that water is also produced, and he gave a phlogistic interpretation.

During these years, Priestley was widely known as the defender of the principles of the French Revolution and an ardent advocate of civil and religious liberty. He angered the anti-revolutionary populace by publicly disagreeing with the *Reflections on the Revolution in France* (1790), written by the British statesman Edmund Burke, who opposed the Revolution. On July 14, 1791, on the second anniversary of the fall of the Bastille prison in Paris, an outbreak of mob violence occurred in Birmingham, in the course of which Priestley's house, library, and laboratory were destroyed. He was driven from Birmingham, never to return.

For the next two years Priestley resided at Hackney, near London, where he taught at the New College (Hackney College); but the progress of the French Revolution, the execution of Louis XVI in 1793, and the declaration of war against France the same year excited further rancour against him. His three sons had emigrated to the United States in August 1793; Priestley and his wife followed in April 1794, taking up residence in Northumberland, Pennsylvania. He was welcomed by various learned societies, including the American Philosophical Society, and offered the chair of chemistry at the University of Pennsylvania; but he refused to accept any public office. Move to America

During his years in America, Priestley continued his literary and religious activities, but he was hampered in his scientific work by the limitations of communicating with his friends in England. He published in the United States a four-volume *History of the Christian Church to the Present Times.* He was a friend and correspondent of two leaders of the American Revolution, John Adams and Thomas Jefferson, both of whom held views on religion similar to his own. His *Doctrines of Heathen Philosophy compared with those of Revelation* appeared after his death. It had been written at the suggestion of Jefferson, who felt, however, that "it did not do justice to the undertaking," adding that Priestley "felt himself pressed by the hand of death." He died at Northumberland on February 6, 1804.

BIBLIOGRAPHY. The best book-length biography, which does justice to all aspects of Priestley's work, is F.W. GIBBS, *Joseph Priestley: Adventurer in Science and Champion of Truth* (1965). A complete bibliography of Priestley's published writings is R.E. CROOK, *A Bibliography of Joseph Priestley, 1733–1804* (1966). By far the best account of Priestley's discoveries in chemistry, with an extensive list of references to the Priestley literature, is contained in J.R. PARTINGTON, *A History of Chemistry*, vol. 3, pp. 237–301 (1962). A more popular description is K.S. DAVIS, "Priestley the Experimenter," in *The Cautionary Scientists* (1966). A sympathetic biography, which stresses the significance of the socio-economic background of Priestley's England is found in J.G. CROWTHER, *Scientists of the Industrial Revolution* (1962), The relation of Priestley's religious philosophy to the literary and philosophical background is described in BASIL WILLEY, *The Eighteenth Century Background* (1940). For an admirable brief account of Priestley's theology and writings on religious subjects, see CAROLINE ROBBINS, "Honest Heretic: Joseph Priestley in America," *Proc. Am. Phil. Soc.*, 106:60–76 (1962). Older but still useful essays are PHILIP HARTOG, "The Newer Views of Priestley and Lavoisier," *Ann. Sci.*, 5:1–56 (1941); and R.E. SCHOFIELD, "The Scientific Background of Joseph Priestley," *ibid.*, 13:148–163 (1957).

(S.R.)

Primates

The mammalian order Primates, which includes the prosimians, monkeys, apes, and man, has long excited human interest, because it contains man's closest relatives. The obvious similarity of monkeys and apes to man was noted long before any genetic relationship was postulated. Recognizing that monkeys possess intelligence substantially exceeding that of other familiar mammals, man has valued these animals as companions and pets for centuries. In recent decades, in addition to becoming increasingly popular as pets, nonhuman primates have served as substitutes for man in situations, such as experimental medicine and space science, which require near-human biological reactions.

The two main groups of the order Primates are the prosimians (lemurs, lorises, and tarsiers) and the anthropoids (monkeys, apes, and man). As classified at present, the suborder Prosimii consists of six families; the Tupaiidae (tree shrews, though these are considered by some authorities to belong in the order Insectivora, a view elaborated in INSECTIVORA), Lemuridae (lemurs), Daubentoniidae (aye-aye), Lorisidae (galagos and lorises), Tarsiidae (tarsiers). Collectively, the prosimian suborder is frequently referred to as lower primates.

The suborder Anthropoidea, sometimes called "higher" primates, also comprises six families: Callitrichidae (marmosets and tamarins), Cebidae (South American monkeys other than marmosets), Cercopithecidae (African and Asian monkeys), Hylobatidae (lesser apes: siamangs and gibbons), Pongidae (great apes: orangutan [orangutan], gorilla, and chimpanzee), and Hominidae (men, living and extinct). The two geographically separated stocks, the Old World and the New World monkeys, are often referred to as catarrhines and

platyrrhines, respectively, terms which derive from the shape of the nose (see below, *Form and function*).

I. General considerations

HISTORICAL BACKGROUND OF PRIMATE STUDIES

The inclusion of man in the order provides the rationale for the vigour with which this group has been studied by scientists since the time of Galen of Pergamum. Aristotle and Hippocrates, in the 3rd and 4th centuries BC, recognized the similarity of man and apes, but it was Galen who demonstrated the truth of this kinship by dissection. He wrote, "the ape is likest to man in viscera, muscles, arteries, veins, nerves and in the form of bones." It should be noted that Galen was in fact referring to monkeys, not the true apes, which were unknown to western man until the 15th century. None of these early scientists saw any evolutionary significance in the similarity of man and "apes," a correspondence that they regarded as purely coincidental. An inkling of the truth of man's relationship with primates must have penetrated the mind of Albertus, a leading naturalist of the Middle Ages, who produced a classification of animal life in his book *De Animalibus*. Albertus' classification, which placed man between "apes" (monkeys) on the one hand and "animals" on the other, provides the first whiff of the "missing-link" concept, which later was to befog the issue of man's place in nature.

The Dark Ages were aptly named as far as knowledge of primates is concerned. The first evidence of a renaissance of interest was in the time of Vesalius, the great Belgian anatomist of the 16th century, who published a comparative anatomy of man and "apes" in order to confound the precepts of Galen. He did not succeed in disproving Galen's assertion that "apes were likest to man" but, unwittingly, he succeeded in stirring up an interest in the biology of primates that has never since flagged. The first true ape studied as a scientific specimen was a chimpanzee dissected by Edward Tyson, an English anatomist, in 1699. Tyson's specimen, which he called the "Orang-Outang, sive Homo Sylvestris," is to this day housed in the British Museum (Natural History), mounted in a standing position that reflects Tyson's belief that he had discovered the pygmy, a race of humans known since the time of the ancient Greeks. Tyson wrote of his "pygmie" that it was "no man, nor yet a common ape but a sort of animal between both." It never occurred to Tyson or his contemporaries, who believed that all animals had been created independently in their current image, that man, apes, and monkeys were connected by common evolutionary descent. In 1758, Linnaeus—the father of animal and plant classification—added the lemurs and bats to the monkeys, apes, and man and called the whole assemblage the Primates. It is to be noted, however, that Linnaeus was sufficiently perceptive to see that man was a primate. His conclusion was regarded as a grave blow to human dignity, and it was followed by new classifications such as that of Blumenbach in 1776, placing man in a separate order. Man was not again considered part of the primate order until a century later when the English anatomist St. George Mivart in the climate of post-Darwinian thought published his classification of primates.

Discovery of the first true ape

The first evolutionist was a French scholar of the late 18th century, the Chevalier de Lamarck, who saw animal life as an uninterrupted continuity in which old species were transformed into new species in a sequence of increasing complexity and perfection. In 1821 Baron Georges Cuvier, a rabid anti-evolutionist, had the historic distinction of describing *Adapis*, the first fossil primate genus ever recognized. Fossils such as *Adapis*, Cuvier believed, were the remains of animals destroyed by past catastrophes (floods, earthquakes, etc.) and living animals were new stocks divinely created to fill the vacuum, a view consistent with the widely held notion that species were immutable. During the early 19th century a number of geologists and biologists questioned the doctrine of immutability, but it was not until 1859, with the publication of Charles Darwin's "On the Origin of Species by Means of Natural Selection," that positive evidence was provided, along with a sound alternative theory. The Darwinian contention that not only had man evolved, but he had evolved from a simian ancestor resulted in acrimonious debate among scientists, theologians, philosophers, and laymen. As influential zoologists and anatomists rose to support Darwin, the truth of man's primate consanguinity began to be accepted, if not actually relished.

Figure 1: Representative prosimians.
Drawing by R. Keane

Today, few scientists deny that man and the lower primate belong in the same order; in fact, much current research is directed toward closing the apparent gap between the highest of the nonhuman primates, the chimpanzee and gorilla, and man.

In times past, the public image of primates was largely dictated by prevailing religious beliefs. In Asian countries, where primates abound, monkeys have for a long

Religious views toward primates

time been regarded with various degrees of deference that, among Hindus in India, for instance, amounts to worship. In Europe and North America, where monkeys and apes are totally absent, no religious sect has attached divine significance to them and, in fact, the reverse has been the case, monkeys at various times having been regarded as the personification of evil and depravity, familiars of the devil. This image, however, is fading as a result of enlightened instruction in schools and the advances in naturalistic presentation of primates in zoos. The nonhuman primate is becoming generally accepted by laymen as an animal of peculiar interest to man with many amusing and endearing qualities.

The qualities of primates, however, are less endearing to farmers and agriculturists in certain parts of the world. In South Africa, the chacma baboon (*Papio ursinus*) competes with domestic sheep for grazing lands and is an occasional predator of lambs; in West and Central Africa native crops are subject to daily assaults by forest-living monkeys; and, in India, macaques, which have been accorded a semi-sacred status, live alongside man in towns and villages and are parasitic upon him for their food and shelter.

Scientific interest in nonhuman primates, their structure at all levels and their way of life, is currently in the ascendancy. Their value as research animals increases year by year, so that at present over a quarter of a million wild monkeys are consumed annually by laboratories in the study of human diseases, in the production of vaccines, in the experiments of organ transplantation, in the testing of drugs and, even, for the clinical trials of new cosmetics. Clearly their scientific usefulness raises important problems of conservation of primate stocks in the wild. Other disciplines whose researches depend upon observations and upon experimentation with nonhuman primates include those of endocrinology, neurology, psychology, and sociology. Much is being learned as a result of such studies that is of great significance for man and his future betterment.

SIZE RANGE AND ADAPTIVE DIVERSITY

Size and weight

Members of the order Primates show a remarkable range of size and adaptive diversity. The smallest primate (in linear dimensions) is probably the dwarf or mouse lemur (*Microcebus murinus*) of Madagascar, which measures approximately 13 centimetres (about five inches) in head and body length; the most massive is certainly the gorilla (*Gorilla gorilla*), whose head and torso length may reach 100 centimetres (39 inches; the comparable dimension in man may exceed this figure, but the gorilla is considerably more robust). In terms of body weight, the range is even more striking. The pen-tailed tree shrew (*Ptilocercus lowii*) weighs on average 46 grams (about 1½ ounces); the gorilla's weight may be more than 3,000 times as great, varying from 140 to 180 kilograms (about 300–400 pounds).

In terms of habitat, primates are tropical animals and occupy two major vegetational zones: the tropical forest and woodland–grassland vegetational complexes. Each of these zones has produced in its resident primates the appropriate adaptations, which are not remarkable for their diversity. There is perhaps more diversity of bodily form to be seen amongst forest-living species than among savanna inhabitants. One of the explanations of this difference is that it is the precise pattern of locomotion rather than the simple matter of habitat that governs overt bodily adaptations. Within the forest there are a number of ways of moving about. An animal can live on the forest floor or in the canopy, for instance, and within the canopy it can move in three particular ways: (a) by leaping—a function principally dictated by the hindlimbs; (b) by arm swinging (brachiation)—a function particularly of the forelimbs; (c) by quadrupedalism—a function equally divided between the forelimbs and the hindlimbs. On the savanna, or in the woodland-savanna biome, which substantially demands adaptations for ground-living locomotion rather than those of tree-living, the possibilities are limited. If bipedal man is discounted, there is a single pattern of ground-living locomotion, which is called quadrupedalism. Within this category there are at least two variations on the theme: (a) knuckle-walking quadrupedalism, and (b) digitigrade quadrupedalism. The former gait is characteristic of the African apes (chimpanzee and gorilla), and the latter of baboons and macaques, who walk on the flats of their fingers. After man, the Cercopithecinae are the most successful colonizers of nonarboreal habitats.

The structural adaptations of primates resulting from locomotor differences are considered below in more detail, but they do not prove to be very extensive. Primates are a homogeneous group in terms of morphology, and it is only in the realm of behaviour that differences between primate taxa are clearly discriminant. It can be said that the most successful primates (judged in terms of the usual criteria of population numbers and territorial spread) are those that have departed least from the ancestral pattern of structure, but furthest from the ancestral pattern of behaviour. "Manners makyth man" is true in the widest sense of the word; in the same sense, manners delineate primate species.

DISTRIBUTION AND ABUNDANCE

The nonhuman primates have a wide distribution throughout the tropical latitudes of Africa, India, Southeast Asia, and South America. Within this tropical belt, which lies between latitudes 25° N and 30° S, they have a considerable altitudinal range. In Ethiopia the gelada baboon (*Theropithecus*) is found living at altitudes up to 5,000 metres (16,000 feet). Mountain gorillas of the Virunga Volcanoes are known to travel across mountain passes at altitudes of more than 4,200 metres (13,800 feet) when travelling from one high valley to another. The howler monkeys of Venezuela (*Alouatta seniculus*) live at 2,500 metres (8,000 feet) in the Cordillera da Merida and in northern Colombia the dourocouli (*Aotus*) is found in the tropical montane forests of the Cordillera Central.

Temperate zone species

A few primate species occur naturally in temperate latitudes. The rhesus monkey (*Macaca mulatta*), for example, is found near Peking, and Japanese macaques (*Macaca fuscata*) are to be found on the Shimokita Peninsula, a hatchet-shaped promontory of the Japanese island of Honshu on latitude 41° N, where snow covers the ground for four or five months of the year. Macaques are particularly hardy animals and can withstand cold climates in the wild and captivity extremely well. The limiting factor to the occupation of temperate zones by monkeys is the winter food supply, combined with the short daylight hours available for foraging.

Primates in general are still plentiful in the wild; for the majority of common species there are few serious conservation problems at present. A number of species, particularly the orang-utan, the gorilla, some of the Madagascan lemurs, and some South American species, such as the golden marmoset, however, are in serious danger of extinction unless their habitats can be preserved in perpetuity and predatory habits of man kept under control.

II. Natural history

REPRODUCTION AND LIFE CYCLE

The stages of the life cycle of primates vary considerably in duration. Among the most primitive members of the group, these stages are broadly comparable to those of other mammals of similar size. Higher in the phylogenetic scale they are substantially extended. The life span of a lemur is about 15 years, of a monkey 25–30 years, of a chimpanzee 40 years, and of man 70–75 years. The greatest differential between man and prosimians, indeed between the prosiminans and apes and between apes and man, is in the duration of the infant and juvenile stages combined. The least differences occur in gestation period which, despite the general belief, can not be consistently correlated with adult body size. Gibbons, which weigh considerably less than macaques, have a 20 percent longer gestation period.

The clear trend toward prolongation of the period of juvenile and adolescent life is probably to be associated with the corresponding trend towards a progressive elabo-

ration of the brain. The extended period of adolescence means that the young remain under adult (primarily maternal) surveillance for a long period, during which time the juvenile acquires, by example from its mother and peers, the knowledge that will allow it to become properly integrated as a fully adult member of a complicated social system. One might expect, therefore, a close correlation between the period of adolescence, the brain size, and the complexity of the social system; and, insofar as the latter factor can be assessed, this appears to be the case.

Breeding periods. The reproductive events in the primate calendar are copulation, gestation, birth, and lactation. Owing to the long duration of the gestation period, these phases occupy the female primate (among higher primates anyway) for a full year or more; then the cycle starts again. The female does not usually come into estrus (physiologically receptive period) until the infant of the previous pregnancy is weaned.

The reproductive patterns of prosimians differ from those of anthropoids. Prosimians show one or more discrete breeding seasons during the year, during which time they may undergo more than one reproductive estrous cycle. The breeding seasons are separated by periods of anestrus, which in galagos are accompanied by changes in the skin of the vulva (the external organ of the genitalia), which closes over, completely sealing the vagina. In the Sudan estrus occurs only twice yearly in the African bush baby (*Galago senegalensis*), during December and August; but in captivity, breeding seasons may occur at any period in the year. In the wild, birth seasons are closely correlated with the prevailing climate, but in captivity under uniformly equable laboratory conditions, this consideration does not apply. In its native Madagascar the ring-tailed lemur (*Lemur catta*) has only a single breeding season during the year; conception occurring in autumn (April) and births taking place in late winter (August and September); but in zoos in the Northern Hemisphere a seasonal inversion of the birth period occurs in which it shifts to late spring and early summer. These examples suffice to indicate the influence of environmental factors on the timing of the birth seasons.

Reproductive cycles in the Anthropoidea continue uninterrupted throughout the year, though seasonality in births is characteristic of primate species living either outside the equatorial belt (5° north and south of the Equator) or at high altitudes in equatorial regions, where dry seasons and seasonal food shortages occur. Seasonality of births in macaques (*Macaca* species) has been documented in Japan, on Cayo Santiago in the Caribbean (where an introduced population thrives under semi-natural conditions), and in India. Observations on langurs in India and Ceylon, on geladas in Ethiopia, and on patas monkeys in Uganda have also demonstrated seasonality in areas with well-marked wet and dry seasons. Anthropoids within the equatorial belt display birth peaks rather than birth seasons. A birth peak is a period of the year in which a high proportion of births, but not by any means all, are concentrated. Equatorial primates such as guenons, colobus monkeys, howlers, gibbons, chimpanzees, and gorillas might be expected to show a pattern of births uniformly distributed throughout the year, but population samples are as yet too small to make this assumption. In captivity, under both laboratory and zoo conditions, anthropoids breed throughout the year with little evidence of seasonality. Even in man there is evidence of high birth peaks. In Europe, the highest birth rates are reached in the first half of the year, and in countries in the Southern Hemisphere in the second half. This may, however, be a cultural rather than an ecological phenomenon, for marriages in certain western countries reach a peak in the closing weeks of the fiscal year, a fact which undoubtedly has some repercussions on the birth period.

Distribution of births through the year

Gestation period and parturition. The period during which the growing fetus is protected in the uterus is characterized by a considerable range of variation among primate species, but shows a general trend towards prolongation as one ascends the evolutionary scale. The range of prosimians overlaps that of the anthropoids, which is never shorter than 140 days. Tree shrews, for example, have a gestation period of 41–50 days, lemurs 132–134 days, macaque monkeys 146–186 days, gibbons 210 days, chimpanzees and gorillas 250–290 days, and man (on the average) 267 days. Even small primates like bushbabies have a gestation period considerably longer than those of nonprimate mammals of equivalent size, reflecting the increased complexity and differentiation of primate structure compared with that of nonprimates. Although in primates there is a general trend towards evolutionary increase in body size, there is no absolute correlation between body size and the duration of the gestation period. Marmosets, for example, are considerably smaller than spider monkeys and howler monkeys but have a slightly longer pregnancy (howler monkeys 139 days; marmosets 140–150 days).

An extraordinary and somewhat inexplicable difference exists between the dimensions of the pelvic cavity and the dimensions of the head of the infant at birth in monkeys and man on the one hand, apes on the other. The head of the infant ape is considerably smaller than the pelvic cavity, so that birth occurs easily and without prolonged labor. When the head of the infant monkey engages in the pelvis the fit is exact, and labour may be a prolonged and difficult affair as it is in man, in whom similar conditions prevail. Human parturition, however, is generally a much more extended process than that of monkeys. Like the human infant, the monkey is born head first. Twin births are as rare in Old World monkeys and apes as they are in man, but certain New World monkeys (*e.g.*, marmosets) habitually produce twins.

Condition of the newborn primate

The degrees of maturation and mother dependency at birth are obviously closely related phenomena. Newborn primate infants are neither as helpless as kittens, puppies, or rats, nor as precocial as the newborn gazelles, horses, and other savanna-living animals. With a few exceptions, primate young are born with their eyes open and are fully furred. Exceptions are the lowly tree shrews and mouse lemurs, which carry their young in their mouths in the manner of many mammals which bear altricial infants. Primate life being peripatetic, it is axiomatic that the infants must be able to cling to the mother's fur. The young of most higher primates have fully prehensile hands and feet at birth and are thus able to grasp the maternal fur without assistance; only man, chimpanzee, and gorilla need to support their newborn infants. In man this stage persists throughout the nursing period (six months or more), but in gorillas it lasts only four weeks and in chimpanzees for an even shorter period.

It seems likely that the difference between the African apes and man in respect of postnatal grasping ability is related to the acquisition in man of bipedal walking. One of the anatomical correlates of the human gait is the loss of the grasping function of the big toe, which is aligned in parallel with the remaining digits. Such an arrangement precludes the use of the foot as a grasping extremity. The human infant and, to a lesser degree, the gorilla infant must depend largely on its grasping hands to support itself unaided. The fact that man is habitually bipedal and that, consequently his hands are freed from locomotor chores, may also be a contributory factor; the human mother can move about and at the same time continue to support her infant. Selection for postnatal grasping, therefore, has not had the high survival value that it has in nonhuman primates in which the survival of the infant depends on its ability to hold on tightly. It is a well-known fact, of course, that newborn human infants can support their own weight, for short periods, by means of their grasping hands. Clearly adaptations for survival are not wholly lacking in the human species. Perhaps there are involved cultural factors which have the effect of suppressing natural selection for early infant grasping ability. The first may be that the social evolution of a division of labour between the sexes and a fixed home base has allowed the mother to park her infant with other members of the family as baby-sitters; the second that in more peripatetic communities, the in-

vention of infant-carrying devices, such as the papoose technique of North American Indians, has made it unnecessary for the infant to support itself. Whatever the biological or cultural reasons, the human infant is less precocial, than the young of any other primates.

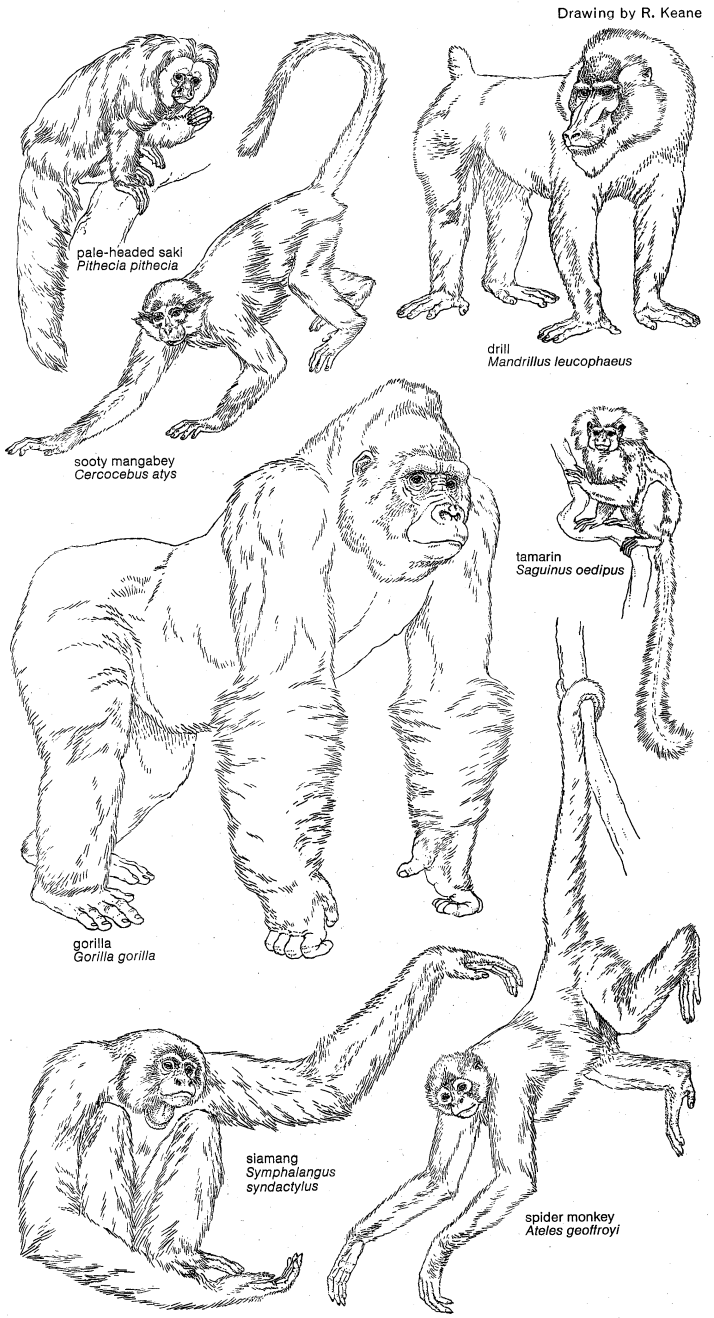

Figure 2: Body plans of representative anthropoids.

Once the primate infant learns to support itself by standing on its own two (or four) feet, the physical phase of dependency is over; the next phase of psychological dependency lasts much longer. Man, metaphorically, is tied to his mother's apron strings for much longer periods than are the nonhuman primates. The reasons for this are discussed below. According to Adolph Schultz, the anthropologist whose comparative anatomical studies have illuminated knowledge of nonhuman primates during the last 40 years, the juvenile period of psychological maternal dependency is 2½ years in lemurs, 6 years in monkeys, 7–8 years in apes, and 14 years in man.

GROWTH AND LONGEVITY

The characteristic pattern of weight-growth curves of man is also shared by higher nonhuman primates such as chimpanzees (*Pan troglodytes*) and rhesus monkeys (*Macaca mulatta*). There seems little reason to doubt that similar curves will be found to exist in other higher primates not yet studied. It has been suggested that the growth curves of primates are closely akin to the basic curves of mammals in general.

The trend toward the prolongation of postnatal life as a characteristic of primates affects all postnatal life periods including infantile, juvenile, adult, and the period of senescence. The period which shows the least change in apes and man is that of gestation. The relative stability of the gestation period is a clear indication that, developmentally speaking, in the degree of structural complexity and cellular differentiation, there is little difference between apes and man. The differences that undoubtedly exist can probably be attributed to cultural factors. There is no reason to suppose that apes are not built to last equally as long as man; it is simply that the natural hazards of gorilla or chimpanzee life are not buffered by the blessings of civilization, except under conditions of captivity, in which case life spans of 40 years and more are known. The potential life span of the chimpanzee has been estimated at 60 years.

Average and potential life span

The characteristic growth spurts of human infants in weight and height also occur in nonhuman primates but start earlier in the postnatal period and are of shorter duration. Primates differ from most nonprimate mammals by virtue of a delayed puberty in both sexes until growth is nearly complete; in male macaque monkeys, as in man, the growth spurt precedes the onset of puberty. To postpone this latter event is of selective advantage because it ensures that the juvenile males in a primate society are not sexually competitive with adult males until they are large enough and strong enough to contribute fully to the responsibilities of the society in which they live by taking part, for instance, in defense against predators.

LOCOMOTION

Primate locomotion, being an aspect of behaviour which arises out of anatomical structure, shows much of the conservativeness and the opportunism that characterizes the primates. Primates with remarkably few changes in their skeletons and musculature have adopted a bewildering variety of locomotor patterns. The "natural" habitat of primates—in the historical sense—is the canopy of the forest. Although many primates have adopted the ground as their principal foraging area during the day, given the opportunity, they return to the trees to sleep at night. Trees provide cover from the climate and protection from predators; they are of course also a source of food. Only the gelada (*Theropithecus gelada*), the hamadryas baboon (*Papio hamadryas*) of the mountainous regions of Ethiopia, and the chacma baboon (*P. ursinus*), which lives on the rocky coast of the Cape of Good Hope, South Africa, are ground sleepers; even these animals seek the protection of the cliffs and rocky precipices of their habitats at night. No primate sleeps totally unprotected; as a consequence of their relative immunity from predation, primates are heavy sleepers.

The essential arboreality of primates has guaranteed the relative uniformity of the locomotor apparatus. Even man, who has long since abandoned the trees as his principal lodging place, has only partially lost the physical adaptations for tree climbing; his hands remain in the arboreal mold. Only his feet have lost their primitive prehensility in adapting to bipedal walking. Primate locomotion can be classified on behavioral grounds into four major types (see Table). Within these major categories there are a number of subtypes, and within these subtypes there are an infinite number of variations between species and, by virtue of individual variability, within species. The differences between the four major categories lie principally in the degree to which the forelimbs and hindlimbs are used to climb, swing, jump, and run.

Locomotor types

Vertical clinging and leaping, for instance, is primarily a function of the hindlimbs, as is bipedalism, whereas brachiation is performed exclusively with the forelimbs. Quadrupedalism involves both forelimbs and hindlimbs,

Locomotor Classification

category	subtype	activity	primate genera
Vertical clinging and leaping		leaping in trees and hopping on the ground	*Avahi, Galago, Hapalemur, Lepilemur, Propithecus, Indri, Tarsius*
Quadrupedalism	slow climbing type	cautious climbing—no leaping or branch running	*Arctocebus, Loris, Nycticebus, Perodicticus*
	branch running and walking type	climbing, springing, branch running and jumping	*Aotus, Cacajao, Callicebus, Callimico, Callithrix, Cebuella, Cebus, Cercopithecus, Cheirogaleus, Chiropotes, Lemur, Leontideus, Phaner, Pithecia, Saguinus, Saimiri, Tupaia*
	ground running and walking type	climbing, ground running	*Macaca, Mandrillus, Papio, Theropithecus, Erythrocebus*
	New World semi-brachiation type	arm swinging with use of prehensile tail; little leaping	*Alouatta, Ateles, Brachyteles, Lagothrix*
	Old World semi-brachiation type	arm swinging and leaping	*Colobus, Nasalis, Presbytis, Pygathrix, Rhinopithecus, Simias*
Brachiation	true brachiation	gibbon type of brachiation	*Hylobates, Symphalangus*
	modified brachiation	chimpanzee and orangutan type of brachiation	*Gorilla, Pan, Pongo*
Bipedalism		striding	*Homo*

Source: From J.R. and P.H. Napier, *A Handbook of Living Primates.*

of course, although not to an equal extent. Some quadrupeds are hindlimb dominated; in others, the forelimb and the hindlimb are equally important. The hindlimb-dominated primates, such as the langurs and colobus monkeys, employ a large element of leaping in their movements, a less notable feature of the more generalized quadrupeds such as the species of the genus *Cercopithecus*. The quadrupedal category is inevitably somewhat of a grab bag, and the gaits included in it have not yet been studied critically. One subtype, here designated as slow climbing, differs profoundly from the other subtypes of the category, being somewhat ponderous and devoid of elements of leaping or jumping. The species in this category are all arboreal nocturnal prosimians.

As many authorities who have studied locomotion in free-ranging primate species have pointed out, the classifications of locomotion into categories is a somewhat artificial procedure. A chimpanzee shows a variety of different gaits according to the circumstances of the environment, and brachiation may form only a minor part of its repertoire; this holds true also for the langurs and colobus monkeys, which are placed in the subtype Old World semibrachiation. Although the categories are phrased in behavioral terms, their implications are strictly anatomical. Brachiation is the mode of locomotion for which the animal is specifically adapted; the anatomical correlates of brachiation are quite unmistakable and can be determined equally as well in fossil bones as in living animals. A purely behavioral classification, based on observations in the living, can have little value in paleontological diagnosis. It is quite arguable that although pure arm swinging is rare in Old World semibrachiators, it is nevertheless one of the principal survival mechanisms of the group, an adaptive advantage that in critical circumstances provides these species with an "edge" over their competitors. In some instances it may well be the case that the particular category is of evolutionary significance only. The gorillas, for instance, whose anatomy is that of a brachiator, in fact, seldom brachiate; adult males probably never do. Gorillas are large animals and bulk-food eaters, forced by their dietary demands to obtain their food on the ground; living gorillas have adapted to a terrestrial life by adopting a compromise gait in which they walk quadrupedally bearing their weight on the backs of their knuckles. This is a form of quadrupedalism (inasmuch as all four limbs are employed) but, once again, the anatomy of their bodies indicates that in past time gorillas (or their evolutionary forebears) were smaller animals which lived and moved in trees. The modern gorilla differs widely from its historical counterpart in behaviour but, structurally, its kinship with its arboreal ancestor is overtly apparent.

Changes in climate and geography during the evolutionary history of primates may also have led to structural atavisms in the anatomy of living primates. Many chimpanzees now living in woodland-savanna conditions in Africa, where the trees are widely spaced and generally unsuitable for the classic arm swinging progress of a brachiator, have adopted a largely ground-living life. Like the gorilla, the chimpanzees are also knuckle walkers, but given an environment like that of a zoo with a cage specially designed with a plentitude of overhead bars and ropes, they brachiate freely and frequently. Habitat changes in the past undoubtedly account for many apparent anomalies in the locomotor classification of present-day primates.

The relation of locomotion to habitat changes

When the subject of primate arboreal locomotion is studied in evolutionary terms, through the medium of fossils, it becomes clear that locomotor categories are not discrete, but that they constitute a continuum of change from a hindlimb-dominated gait to a forelimb-dominated one. The best single indicator of gait, one that has the added advantage of being strictly quantitative, is the intermembral index. Briefly, the index is a ratio expressed as percentage of arm length to leg length; an index over 100 indicates relatively long arms. The intermembral index provides a model by means of which the locomotion of an early primate can be inferred by determination of the intermembral index of the fossil skeleton. Animals do not necessarily fall discretely into categories. Species with indices lying between those of clearly recognizable locomotor types represent transitional types, whose style of locomotion manifests features of both of the bracketing categories. Some lemurs have indices that fall between 65–75, but their gait is a combination of vertical clinging and quadrupedalism. The ring-tailed lemur in fact shows an intermediate form of behaviour; it is generally quadrupedal but, given the right environmental milieu, can be observed in vertical clinging and leaping. The South American spider monkeys (*Ateles*), whose index lies between 100–108 show a type of locomotion that contains the elements of both quadrupedalism and brachiation.

The intermembral index

Applying the intermembral index to fossil primates, it has become apparent that the earliest primates living in the Eocene Epoch, from about 54,000,000 to 38,000,000 years ago, moved about in the manner of modern vertical clingers and leapers. Quadrupedalism was well-established during the Miocene Epoch (about 26,000,000 to 17,000,000 years ago) when the two major environmental types of quadrupedal gait—the terrestrial and the arboreal—were established, with indices in the region of 85–100 and 75–85, respectively. Brachiation, associated with a high intermembral index, was established as a way of arboreal life at the end of the Miocene and the beginning of the Pliocene.

The origin of bipedalism, which implies the appearance of manlike creatures, is indeterminate. There is direct evidence of bipedalism extending back 1,500,000 to 2,000,000 years, and certain indirect evidence (see below *Evolution and paleontology*) suggests that bipedalism might have evolved in a modified form some 10,000,000 to 14,000,000 years ago.

Locomotion of primates is an area of primate biology of great interest to scholars. It is not only that locomotion is a basic factor of primate life (primates must move to eat and must eat to live) but it is also an indicator of evolutionary progress. To study the origins of primate locomotion is to study primate evolution. Because of its immediacy for survival, natural selection has acted strongly on locomotor behaviour and the locomotor apparatus; changes in locomotor pattern may thus be said to provide principal milestones on the road to modern primates.

Bipedalism, far from being a unique possession of mankind, as is generally thought, is a basic possession of the order Primates. With one or two exceptions (one of which is the tree shrew, which may not even be a primate), all primates sit upright. Many stand upright without supporting their body weight by their arms, and some actually walk upright for short periods. The view that the possession of uprightness is a solely human attribute is untenable; man is merely one species among the 189 that constitute the order who has exploited the potential of his ancestry to his ineffable advantage.

Walking

Chimpanzees, gorillas and gibbons, macaques, spider monkeys, capuchins, and others are all frequent bipedal walkers. To define man taxonomically as "bipedal" is not enough; to describe him as habitually bipedal is nearer the truth, but habit as such does not leave its mark on fossil bones. Some more precise definition is needed. Man's walk has been described as striding, a mode of locomotion defining a special pattern of behaviour and a special morphology. Striding, in a sense, is the quintessence of bipedalism; it is a means of travelling during which the energy output of the body is reduced to a physiological minimum by the smooth, undulating flow of the progression. It is a complex activity involving the joints and muscles of the whole body in its performance and it is likely that the evolution in the human gait took place gradually over a period of 10,000,000 years or so.

The pattern of locomotion of man's ancestors immediately preceding the acquisition of bipedalism has long been a matter of controversy, and the question has not yet been resolved. The evidence derived from anatomical, physiological, and biochemical studies for the close affinity of chimpanzees and gorillas with man would imply that he evolved from a brachiating ancestry. But the many differences between the apes and man, particularly in the structure of the limbs and teeth, have persuaded the majority of leading anthropologists that the theory of a brachiating origin of man is untenable. The issue is still hotly debated, the more so since current immunological studies of serum proteins are tending to emphasize the recentness of the separation of pongid and hominid stocks (the lines that led, respectively, to apes and man) in phylogeny. An alternative to the "brachiating theory" must inevitably be some sort of "quadrupedal theory." Various authorities have proposed other solutions: semibrachiation (a form of quadrupedalism with emphasis on arm swing), a formal quadrupedal gait, and even a form of locomotion similar to that of *Tarsius* and other clingers and leapers. At the present time, there is insufficient information to elucidate the phylogeny of man's bipedal gait. It can, however, be assumed that it must have involved a large measure of truncal uprightness, a good deal of leaping, and a sizable element of arm swinging. There is no living primate that demonstrates, precisely, this combination of locomotor characteristics, although the arboreal monkeys of the subfamily Colobinae theoretically fit the bill better than most.

ECOLOGY AND DIET

Few primate species are found today in temperate latitudes. The limiting factors appear to be the general climate and the duration of the daylight hours. The higher the latitude, the greater is the fluctuation between summer and winter temperatures and the shorter are the hours of winter daylight. The combination of quiescent growth periods of fruits, leaves, and grasses, a frozen top soil, and a restricted diurnal period all make conditions extremely hard for monkeys, which depend on foraging in the trees, on the ground, or under it for their food supply. No monkey lives, or has ever lived, in the zones of permafrost, but it is probable that in times past they flourished in temperate regions. Without the harassment of man, monkeys no doubt could have survived in the temperate zones; their foraging, albeit condensed into a temperate-zone day of seven hours or so, would have supplied them with the food they required, providing they were free to forage without the threat of human persecution. Dietary adaptability of primates is greater than realized. On the Shimokita Peninsula of the Japanese Island of Honshu and in the Shiga Mountains of the same Island, Japanese macaques survive from late November until April on incredibly meagre rations. The diet of these monkeys, during the months when snow covers the ground and when the last remaining summer seeds and leaves have vanished, is bark and the fleshy cambium layer that lies beneath it. The Japanese macaques, cold and hungry, ride out the worst that winter, at the latitude of 41° N offers. Near Moscow, several species of African primates have been kept for several years in outdoor facilities in which winter temperatures go well below −18° C (0° F). It is true that they are well provisioned but, nevertheless, it is almost incredible that a tropical species should be sufficiently adaptable and possess adequately effective homeostatic mechanisms to survive in this degree of climatic adversity. Ruggedness of this sort is a primate characteristic, a survival mechanism that operates in the worst conditions, and one which provides a clue to the real reason for the primacy of the primates among mammals.

Resistance to cold

Diet. The diet of primates is a factor of their ecology, that, during their evolution, has clearly played an important role in their dispersion and adaptive radiation as well as in the development of the teeth, jaws, and digestive system. Diet is also closely related to locomotor pattern and to body size.

The principal food substances taken by primates may be divided into vegetable (fruits, flowers, leaves, nuts, barks, pith, seeds, grasses, stems, roots, and tubers) and animal (birds, birds' eggs, lizards, small rodents and bats, insects, frogs, and crustacea). The flesh of larger mammals (including primates) is not listed as an important item of nonhuman primate diet, although it is taken by certain species such as baboons and chimpanzees in special circumstances that are not yet fully understood.

While in many mammalian groups, diet is selective and specific to the order, among primates it is difficult to establish any hard and fast rules. Although there are decided preferences for certain food items, catholicity is more characteristic than specificity. Generally speaking, primates are omnivorous, as the physiology of their digestive system attests. Relatively few examples of dietary specialization are to be found. The so-called leaf-eating monkeys, a sobriquet that embraces the whole of the subfamily Colobinae, are by no means exclusively leaf eaters and according to season include flowers, fruit, and seeds in their diet. The howler monkeys of the New World have a similar dietary preference.

Broadly, however, certain overall dietary preferences are discernible. The leaf-eating langurs have already been mentioned. The apes (other than the gorilla) are substantially fruit eaters; the percentages of fruit in the diet of the gibbon and the three great apes are as follows: gibbon 62 percent, orang 50 percent, chimpanzee 67 percent, and gorilla 2–15 percent.

Many of the smaller nocturnal prosimians such as tarsiers, galagos, dwarf lemurs, sportive lemurs, the aye-aye, slender lorises, and the South American night monkey are substantially insectivorous.

The larger diurnal prosimians (*e.g.*, typical lemurs, the sifaka, and the indri) and the large nocturnal prosimians (the Asian slow loris and the African potto) are more vegetarian, including both fruit and leaves in their menu. It seems apparent that size, rather than activity rhythm, governs the nature of the primate diet. The small marmosets of the South American genus *Callithrix* have exclusively diurnal rhythms and are insectivorous, while the slightly larger, but equally diurnal, tamarins (*Saguinus*) are more omnivorous.

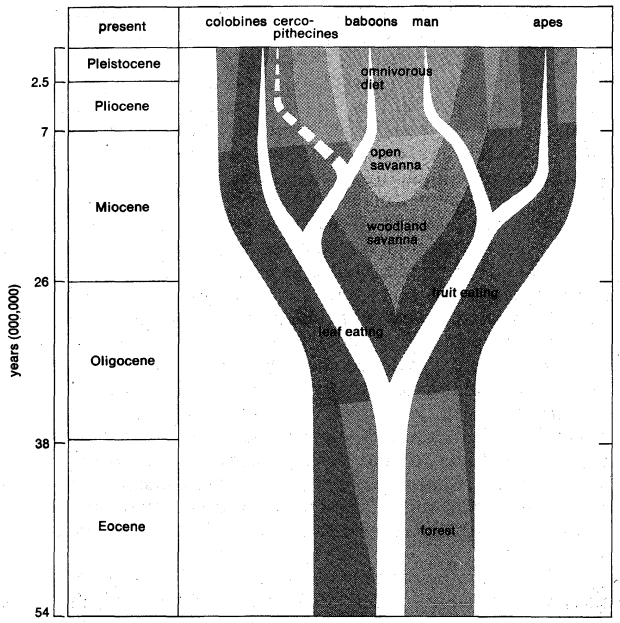

Figure 3: Hypothetical evolution of primate feeding habits in relation to vegetational areas.
From J.R. Napier and P.H. Napier, *A Handbook of Living Primates* (1967); Academic Press

The most widespread monkey populations are those of the subfamily Cercopithecinae. Many ground-living species are included in this group, the members of which are notable for the extreme catholicity of their diet; meat eating as a regular pattern, however, has not been reported among them.

Size in relation to food habits. In evolutionary terms, increase in size has probably played a large part in determining the direction of primate evolution. Fossil evidence of early primates of the Paleocene (about 65,000,000 years ago) suggests that these were small, forest-living creatures, not yet specialized as tree climbers. Their bodily form suggests that they possessed the build and the gait of squirrels. Their molar teeth bore high, pointed cusps but were neither as tall nor as pointed as those of the insectivore-like ancestors of the preceding Cretaceous epoch, whose molars were ideally adapted for cracking the hard, chitinous exoskeletons of insects. This fact suggests that the reduction of the molar cusps was associated with the adoption of a fruit-eating habit. Although this has some validity as a generalization, it should not be taken too literally. All primates include insects in their diet and there are many almost exclusively insectivorous forms, which have reduced the height and acuity of their molar cusps. Increasing body size, a trend which is clearly apparent throughout primate evolution, would have been associated with the adoption of supplementary sources of food. Insect eating is a laborious way for a large animal to obtain nourishment unless it happens to possess the extensible tongue of those mammalian vacuum cleaners, the anteaters.

The shift from insect to fruit eating

An increase in size and the gradual addition of bulk foods to the diet would, in turn, have affected the habitat and the pattern of locomotion. Fruit eating is more easily accomplished in trees than on the ground and this growing preference amongst primates may have been accompanied by the tree-climbing habit. Once such a habit was established, natural selection would have operated to espouse the suitable physical adaptations which would facilitate such a behaviour. Suitable adaptations in this case would have been the facility to climb, leap, and balance in trees.

It is noteworthy that during evolution the development of a prehensile foot preceded that of a prehensile hand. Vertical clinging primates such as the tarsiers or small squirrel-like quadrupeds like the marmosets and tamarins —all of which have prehensile feet, but not prehensile hands—by remaining small, have never been subject to the same evolutionary pressures that have impinged on larger primates. A large arboreal primate without prehensile hands is at a considerable disadvantage in moving about in the canopy of trees, but a small one suffers little disadvantage. Amid the large and firm branches, size is no particular hazard, but at the periphery of the crown, where the fruit is most abundant and the branches are slender and flexible, the risk of falling is increased. It is, therefore, likely that the combination of an increase in body size, associated with the inevitable shift towards a bulk diet, led first to the evolution of a grasping hand, then to the appearance of a prehensile hand, and finally to an opposable thumb. Four prehensile extremities are more effective than two in defying gravity.

Such adaptations of the forelimbs would have had the effect of equalizing the role of the limbs. The limbs of vertical clingers are functionally disparate, the lower pair being dominantly propulsive, the upper, secondary and purely supportive. The limbs of quadrupeds, on the other hand, are more homogeneous, both pairs having a propulsive function during running. Thus, it would seem that the transition in locomotor grade between vertical clinging and leaping and quadrupedalism came about as adaptation to increased body size. Size, diet, ecology, locomotion, and anatomical structure provide a constellation of causes and effects that are critical factors in the evolution of the primates.

Effect of forest stratification. An aspect of primate ecology that has not yet been fully investigated is the effect of the stratification of forests on the adaptations (particularly the locomotor adaptations) and on the speciation of primates. In recent years it has become apparent that forests are not simply a random consociation of trees but are an ordered system of plants under the control of climatic, photobiotic, and edaphic (soil) factors.

The chief physiognomic features of rain forests, the ancestral home of primates and the principal habitat (in numerical terms) of nonhuman primates today, are the evergreen broad-leaved trees that, collectively, form a closed canopy, so opaque to sunlight that the forest floor is in perpetual twilight. Epiphytes and thick-stemmed lianas drape the trees, linking one crown to another and providing aerial pathways for monkeys to pass from tree to tree through a continuum of interlacing branches, a three-dimensional maze that provides home, restaurant, shoping districts, and highways for primates. Three strata of the canopy of rain forests are usually recognized by botanists: an understory, a middle story, and an upper story. The understory is often "closed," the crowns of the constituent trees overlapping one another to form a dense, continuous, horizontal layer. The middle story is characterized by trees that are in lateral contact but do not overlap; and the highest story by tall trees, some 50 metres (160 feet) or more, which form a discontinuous layer of umbrella-shaped crowns. The occasional "emergent" forest giant may tower above the highest layer of the canopy. There is some evidence, much of it conflicting, that zonation of forest primates occurs within the forest canopy. The stratification of forest is extremely variable and the number of layers tends to diminish from three to two in secondary forest, dry deciduous forest, and montane forest; and from two to one as temperate zone, tropical woodland, or montane woodland supervenes.

Tropical grasslands, or savannas, are also the homes of primates in Africa and Asia; no savanna-living primates exist in South America. Tropical grasslands comprise a mixture of trees and grasses. The proportion of trees to grass varies directly with the rainfall; areas of high seasonal rainfall support single story woodlands of tall trees while lush grasses form the ground vegetation; but where rainfall is both seasonal and low, the trees consist of stubby xerophilous (dry-loving) shrubs and short, tussocky grasses. The principal primate fauna of the savanna biome are the ground-living species; in Africa, the grivet (*Cercopithecus aethiops*), baboons (*Papio* species), and the patas monkey (*Erythrocebus patas*); and in Asia the macaques (*Macaca* species) and the Hanumān langur (*Presbytis entellus*).

Tropical montane forests or tropical rain forests at high altitude also abound in primates in Africa, Asia, and South America. In equatorial Africa certain primate species have colonized the montane-savanna regions, or moorlands, where the rugged mountainous terrain and seasonal food scarcity support herds of geladas and hamadryas baboons. These high mountaineers of Africa have no ecological counterparts in Asia or South America.

As a measure of the physiological adaptability of primates it may be noted that various populations have at different times been subjected to relocation in alien environments by man. Some of these expatriates are the green monkeys (*Cercopithecus sabaeus*) of St. Kitts in the West Indies, the mona monkeys (*C. mona*) of Grenada, the macaques on Mauritius, and the Barbary apes (*Macaca sylvana*) of Gibraltar.

III. Form and function

DISTINGUISHING FEATURES

The basis of the success of the order Primates is the relatively unspecialized nature of their structure and the highly specialized plasticity of their behaviour. This combination has permitted the primates throughout their evolutionary history to exploit the wide variety of novel ecological opportunities that have come their way. Although there are a few highly specialized species among the lower primates (the aye-aye, the tarsier, the potto, and the lorises, for instance), the higher primates, the anthropoids, are extremely conservative in their structure; morphologically speaking, they have maintained a position in the evolutionary midstream and have avoided the potential stagnation of specialized life near the bank. Specialization is not always a liability; in times of environmental stability the specialized animal enjoys many advantages, but in a rapidly changing world it is the less specialized animals that are more likely to survive and flourish.

The importance of a large brain

The plasticity of primate behaviour is largely a function of the brain. The primate brain is distinguished by its relatively large size compared with the size of the body as a whole; it is also notable for the complexity and elaboration of the cerebral cortex, the function of which is to receive, analyze, and synthesize the incoming impulses from the sense organs and to convert them into appropriate motor actions, which in turn constitute behaviour.

It has been observed that there is no distinguishing feature which characterizes all primates except a negative one—their lack of specialization. St. George Mivart defined the order Primates in the following terms:

> . . . an unguiculate, claviculate, placental mammal with orbits encircled by bone; three kinds of teeth at least at one time of life; brain always with a posterior lobe and a calcarine fissure; the innermost digits of at least one pair of extremities opposable; hallux with a flat nail or none; a well-developed caecum; penis pendulous; testes scrotal; always two pectoral mammae.

When these criteria are examined one by one the inevitable conclusion is reached that, singly, none of these characters is unique to primates nor do all primates demonstrate every single character. Collectively, however, more primates than nonprimates show this particular constellation of characters. Perhaps a more meaningful way to look at primate characteristics is in the form of evolutionary trends. This approach is quantitative, inasmuch as it is recognized that not all adaptations are developed in primates to the same degree. A list of evolutionary trends with behavioral connotations is also a somewhat more functional inventory than Mivart's essentially morphological one and, furthermore, is more applicable to the study of fossil primates.

Primates are essentially arboreal animals whose limbs are adapted for climbing, leaping, and running in trees. Active arboreal life requires the mechanical assistance of a long tail and sensitive, grasping hands and feet with opposable thumbs and big toes, to aid in climbing and to ensure stability on slender branches high above the ground. Active arboreal locomotion also requires a much more accurate judgment of distances than life on the ground; this is facilitated by the development of stereoscopic vision, the anatomical basis of visual judgments in depth. The forward-facing eyes of primates are adaptations for this type of visual precision. A highly developed sense of smell is not nearly as important for animals leading an arboreal life as it is for those on the ground. Primates thus have a much reduced olfactory mechanism; noses are shorter, the turbinal (or scroll) bones of the nose are reduced in number and complexity compared with most nonprimate mammals.

Binocular vision

Primates, being on the whole omnivorous animals, have evolved a multipurpose dentition; incisors to cut, canines to pierce and tear, and molars and premolars to crush and grind. Such a dental arrangement equips its possessor with the power to cope with insect food, vegetable food, or flesh and provides a major contribution for the generalized way of life that is so characteristic of the order.

A basic adaptation for the primate way of life (including the unique specialization of man—upright walking) is verticality of the trunk. Above the level of the tree shrews, the ability to hold the body upright is a universal primate possession; indeed paleontological evidence indicates that truncal uprightness was a primate characteristic as far back as the early Eocene, some 54,000,000 years ago.

Above all, the principal evolutionary trend of primates has been the elaboration of the brain, particularly of that portion of the cerebral hemispheres known as the neopallium or neocortex. A neocortex is characteristic of higher vertebrates, such as mammals, which operate under the control of multiple sources of sensory input such as those from the nose, the eyes, the ears, and the skin. In many mammals the olfactory system dominates the senses and the cerebral hemispheres consist largely of paleocortex—the "smell brain"—of lower vertebrates. The arboreal habit of primates has led to a dethronement of the olfactory sense and the accession of a tactile, visually dominant sensory system. This evolutionary trend, combined with a progressive increase in the functional significance of the hands and feet in grasping and manipulation, has resulted in the dramatic expansion and differentiation of the neocortex.

GENERAL STRUCTURE

Vertebral column and posture. All primates retain a clavicle or collarbone (lost in many mammalian groups), a separate radius and ulna in the forearm, and a separate tibia and fibula in the lower leg. The single exception to this is the tarsier, in which the fibula becomes fused to the tibia.

The primate vertebral column shows a basic mammalian pattern of components including an "anticlinal" vertebra, situated in the mid-thoracic (upper-back) region of the spinal column and marking the transition between the forelimb and hindlimb segments. In a galloping greyhound the anticlinal vertebra is at the apex of the acute curve of the back. An anticlinal vertebra is characteristic of all quadrupeds and is seen in all primate families except the hominids and the pongids, whose posture is upright or semi-upright. The evolutionary trend in the vertebral column is toward shortening the lumbar, sacral, and caudal regions. Extreme shortening in the lumbar region, with complete loss of the caudal (tail) vertebrae, occurs in gibbons, the great apes, and man. Prehensility of the tail is a specialization of certain New World monkeys, but appears also for a brief period in the infants of many Old World monkey groups, in which it provides an important mechanical aid to survival.

Hands and feet. With two exceptions, all primates have retained five digits on hand and foot. The exceptions are the spider monkeys of South America and the colobus monkeys of Africa, which have lost or reduced the thumb. This appears to be an adaptation for locomotion, the rationale for which is not fully understood at present.

All (except tree shrews) possess prehensile (grasping) hands, and (except man) prehensile feet. The hands of Anthropoidea show a greater range of precise manipulative activity than those of Prosimii. Prosimians lack the functional duality of the hands of anthropoids. Duality in hand function has been described for man and nonhuman

Power versus precision grips

primates in terms of precision and power grips. The power grip of prosimians is very well developed but the precision grip is lacking. Among Anthropoidea, the New World monkeys show a considerable advance over prosimians in tactile sensitivity but they possess less functionally effective hands in prehensive terms than Old World monkeys.

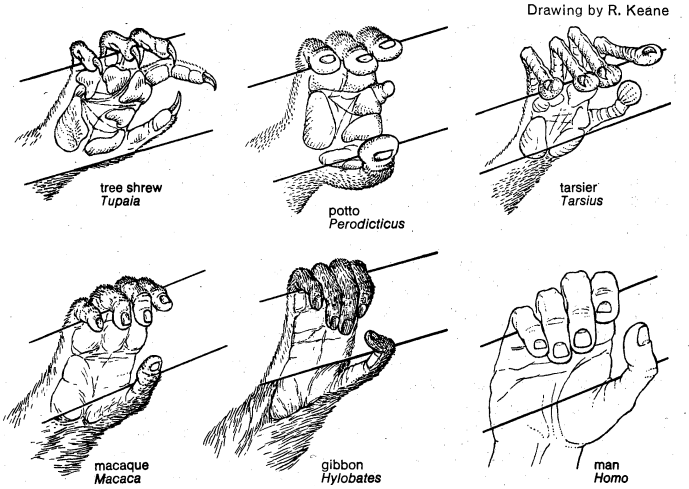

Figure 4: Shape and function of the hand in certain primates.

The critical component of the prehensile hand in terms of skilled manipulation is the opposable thumb: a thumb, that is to say, that is capable of being moved freely and independently. The movement of opposition is a rotary movement in which the thumb, swinging about its own axis, comes to face the under or palmar surface of the tips of the fingers. The opposable thumb is the basis of the precision grip which, though present to some extent in all primates, is particularly highly developed in man. Opposability is present to some degree or other in most primates but varies considerably in its functional effectiveness as an instrument of fine manipulation. The baboons and man are pre-eminent in this respect. The apes, having short thumbs and long fingers, are handicapped in relation to delicate manual dexterity but are adept in the coarser elements of hand use, particularly in relation to tree climbing and branch swinging.

Teeth. A dentition with different kinds of teeth (heterodonty)—incisors, canines, and cheek teeth—is characteristic of all primates and indeed of mammals generally. Heterodonty is a primitive mammalian characteristic and primates have evolved less far from the original pattern than most mammals. The principal changes are a reduction in the number of teeth and an elaboration of the cusp pattern of the molars.

The primitive mammalian dental formula is assumed to have been $\frac{3 \cdot 1 \cdot 4 \cdot 3}{3 \cdot 1 \cdot 4 \cdot 3} = 44$ teeth (the numbers being the numbers respectively of pairs of incisors, canines, premolars, and molars in the upper and lower jaws). No living primate has retained more than two incisors in the upper jaw and only in tree shrews is the primitive number of three incisors retained in the lower jaw. The incisors are subject to considerable variation in prosimians. Characteristically, the upper incisors are peglike, one or other pair often being absent; in the lower jaw the incisors show a peculiar conformation which has been likened structurally and functionally to a comb. The dental "comb" of prosimians is composed of the lower canines and lower incisors compressed from side to side and slanted forwards; the dental comb appears to be primarily a device for grooming the fur. Canines are present throughout the order, but show remarkable variation in size, shape, projection, and function. Characteristically the teeth of cercopithecines have a function in the maintenance of social order within the group as well as an overtly offensive role; their function as organs of digestion is relatively unimportant. They are large and subject to sexual dimorphism, being larger in males than females. Man's canines are small and are almost wholly dental in function, with no size differences between the sexes.

Evolutionary reduction of the cheek teeth

The trend in the evolution of the cheek teeth has been to increase the number of cusps and reduce the number of teeth. Both molars and premolars show this tendency. No living primate has four premolars; prosimians and New World monkeys have retained three on each side of each jaw, but at the anthropoid level two premolars are the invariable rule. The primitive premolars are uniform in shape and are unicuspid, but in primates the most posterior premolar tends to evolve either one or two extra cusps (molarization), an adaptation providing an extended tooth row for a herbivorous diet. In species with large upper canines, the most anterior lower premolar assumes a peculiar shape known as sectorial, functioning as a hone for the scythelike canine. In man, whose canines are small and unremarkable, the first and second premolars are identical in shape and two cusped.

The trend in the morphology of the molars has been to increase the primitive three cusps to four or five. The apes and man are more specialized in this feature than are the monkeys or the lower primates, having four cusps on the molar crown in the upper jaw and five cusps on the lower. A further tendency has been to reduce the molar series from three to two in both jaws, principally in the lower. Among the family Callitrichidae, which includes the marmosets, the pigmy marmosets, the tamarins and the golden marmosets, two molars are the rule, but in many other platyrrhine and catarrhine genera, as well as the genus *Homo*, the last molar (the wisdom tooth, so-called because it normally erupts in young adulthood coincidently, one might say, with the acquisition of sagacity) is frequently absent.

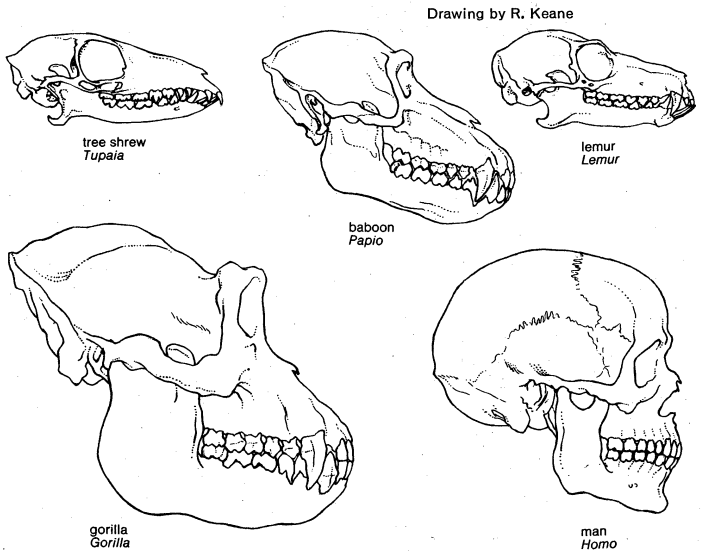

Figure 5: Skulls and teeth of primates.

Snout, muzzle and nose. The reduction of the snout in primates is a correlate of the diminution of the olfactory sense (see below *Sensory reception*). To a great extent visual acuity and manual dexterity have replaced the sensitive, inquiring nose found in so many nonprimate mammals. A marked reduction in the complexity of the "scroll" bones of the nose, the richness of the innervation of the olfactory mucous membrane, and the sensitivity of the moist tip of the nose—the rhinarium, is associated with the reduction in length of the primate snout. Although the trend in primate evolution is towards a dethronement of the primacy of the sense of smell, there are still some good snouts to be seen in those lower primates, that retain a naked moist rhinarium attached to the upper lip. The attachment of skin to gum is marked by a prominent groove bounded laterally by naked skin.

Prosimians depend for many aspects of their social and reproductive behaviour on olfactory signals which are effected by means of special scent glands distributed in different regions of the body but congregated principally in the anal and perineal regions. Marking behaviour, the placing of scent at various points in the environment, is a prominent feature of the prosimian repertoire of

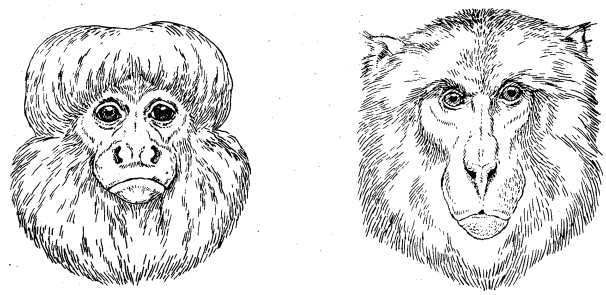
communication. Marking behaviour ceases to be of much importance above the prosimian level, and in anthropoids the structures by which olfactory signals are given and received are diminished; the snout becomes abbreviated, the scroll bones less complex, and the glandular, moist rhinarium is replaced by a dry, hairy skin, and the upper lip is free and mobile. The scent glands largely disappear. Monkeys, apes and man, though they may be lower down the scale of olfactory excellence than prosimians, rely in considerable measure on the sense of smell; all higher primates, for instance, including man, sniff at unfamiliar items of food before placing them in the mouth.

The platyrrhine–catarrhine division

The shape of the nose of higher primates is one of the most reliable means of distinguishing Old World monkeys from New World monkeys at a glance. In New World monkeys or Platyrrhines (platyrrhine means "flat nosed") the nose is broad and nostrils are set wide apart, well separated by a broad septum, and point sideways; in Catarrhines (catarrhine: "downward nosed") the nostrils are set close together, point forwards or downwards, and are separated by a very narrow septum.

Some Old World monkeys, particularly those that have adopted a ground-living way of life, such as baboons, mangabeys, and the mandrills of the subfamily Cercopithecinae, appear to have re-adopted a long snout during their evolution. This structure, however, is not primarily olfactory in function but seems, rather, to be more closely related to the large size of the jaws and the prominence of the canine teeth; it should be considered a dental muzzle rather than an olfactory one.

SENSORY RECEPTION AND THE BRAIN



Among mammals in general, the olfactory system is the primary receptor for environmental information; consequently the brain of most mammals is dominated by the olfactory centres. In primates the sense of smell is considerably less important than the well-developed visual system and highly refined sense of touch. The primate brain is enlarged in the specific areas concerned with vision (occipital lobes) and touch (parietal lobes), thus taking a characteristic shape throughout the higher primates. Associated with the central apparatus for touch and vision are the peripheral sensory endings in the skin, particularly of the hand and face, and in the retina of the eye.

Touch. The skin of the primate hand is well adapted for tactile discrimination. Meissner's corpuscles, the principal receptors for touch in hairless skin, are best developed in the apes and man, but can be found in all primates except the tree shrew; structurally correlated with a high level of tactile sensitivity are certain anatomical features of the skin of the hands and feet, such as the absence of pads on the palms and soles, characteristic of mammals in general, and the presence of a finely ridged pattern of skin corrugations known as dermatoglyphics (the basis for fingerprints).

Eyes and vision. The evolutionary trend towards frontality of the eyes has not proceeded as far in the prosimian as in the anthropoid families. Tree shrews retain set of the eyes like that of the primitive ancestor, the central axis of each bony orbit being 140° apart. In lemurs this angle is considerably less, 60°–70°, and in the anthropoid families of apes and monkeys the divergence has been reduced to 20°. It should be noted that the axes of the eyeballs (as distinct from the bony orbits) in apes and monkeys are, in fact, parallel.

Colour vision is of considerable advantage to arboreal animals living on fruits and insects. Species that have both rod and cone receptors in their retinas include all of the Anthropoidea with the exception of some of the nocturnal species (*Aotus*, the night monkey of South America, for example), and the family Lorsidae and some of the Lemuridae among the prosimians. Rods are the more primitive retinal cells and respond to low intensity light, while cones, which respond to high light intensity, have a greater resolving power, and thus provide for a finer type of visual discrimination. Cones, moreover, are adapted for colour discrimination.

Nervous integration. The elaboration of touch and vision supplements the senses of smell, hearing, and taste,

Drawing by R. Keane

providing the primate with a sensory armament of great range and flexibility. The primate central nervous system is sufficiently refined to deal with the elaborate bombardment of environmental information reaching it. Association areas provide the connections between the input and output centers of the brain—the motor and sensory cortex. Association areas are the memory banks where the memory of past experience is encoded in the infinitely complicated plexiform arrangement of the neurons, the brain cells, and their processes. All sensory impulses reaching the cortical centers of the central nervous system are routed through the association areas for conditioning, as it were, before reaching the effector side or output side where the appropriate response is initiated in the cells of the motor cortex and executed through the action of somatic (body) musculature. The more highly developed the association areas of the brain are, the more specific and appropriate is the behaviour and the more versatile is the animal in facing environmental demands.

The brain. As already indicated, the principal evolutionary trend in brain development has been towards elaboration. The neocortex of higher primates possesses highly developed associative functions, an aptitude for receiving, analyzing, and synthesizing the sensory input from visual, olfactory, auditory, gustatory, and tactile receptors and converting them into the appropriate motor responses.

Relative versus absolute brain size

The brain of Anthropoidea is larger, both absolutely and relatively, than that of prosimians. For instance, the weight of the simplest anthropoid brain, that of a marmoset, is three times greater than the brain weight of the bush baby, a prosimian of comparative size. This quantitative increase, in part, is attributable to the elaboration of the regions of the neocortex concerned with tactile and visual sensitivity; and in part to the elaboration of the intrinsic pathways connecting one part of the brain with another. The large brain of man is attributable not so much to an increased nerve cell content as to an increase in the size of the nerve cells and to a greater complexity of the connections linking one cell to another.

The external form of the anthropoid cerebral cortex is characterized by a complicated pattern of folds and fissures (sulci and gyri) in the brain surface. The fissural pattern is seen in its simplest form in the marmosets, but in the larger and more advanced members of the New World monkey infraorder, the capuchins (*Cebus*) for instance, the cerebrum is richly convoluted. Gyri and sulci are well marked in Old World monkeys and in the apes, the complexity of the pattern closely approximating the tortuous mazelike pattern seen in man.

REPRODUCTIVE SYSTEM

Male and female genitalia. The functions of the individual organs of reproductive systems are fairly uniform throughout the primates, but in spite of this physiological homology there is a remarkable degree of variation in minor detail of organs between groups, particularly in the external genitalia, which, by their variation, provide a morphological basis for the reproductive isolation of the species. There could be no more effective barrier to mating between different species than incompatability of the male and female sex organs.

Among the characteristics of the primate order as listed by Mivart, the penis is described as "pendulous" and the testes as "scrotal." In contrast to other mammals, the primate penis is not attached to the abdominal wall but hangs free. The testes, with a few exceptions among the prosimians, in which they are withdrawn seasonally, lie permanently in the scrotal sac, to which they migrate from their intra-abdominal position some time before birth (in man) or after birth (in nonhuman primates). In all primates except modern man (there is no evidence one way or the other regarding early representatives of the genus *Homo*), tarsiers, and some South American monkeys, the penis contains a small bone called the baculum, a typically mammalian character. The uterus of female primates shows all grades of transition between the two-horned (bicornuate) uterus, typical of most mammals, to the single-chambered (simplex) uterus of the higher primates and man. Broadly speaking, the prosimian uterus retains the primitive bicornuate pattern, while the anthropoid uterus is single-chambered.

Variations between primate taxa are demonstrated most strikingly by the glans penis, the scrotum, and perineum of the male, and the clitoris and the labial folds of the female vulva. The length and form of the clitoris, which when elongated mimics the penis, as in spider monkeys for instance, is a potent source of confusion in determining the sex of certain New World primates. The coloration of the male scrotum in forest-living primates, particularly of the genera *Cercopithecus* and *Mandrillus*, shows an infinite range of variations and provides a species-recognition signal of considerable effectiveness.

The external appearance of the genitalia undergoes seasonal variation in a number of primates. In the male, swellings of the testis and colour changes of the scrotum occur, and, in the female, swelling and coloration of the vulva and perineal region herald ovulation, sometimes most obtrusively. Turgidity and excessive vascularity of the tissues of the perineum are probably characteristic of all mammals, but there are certain primate species in which this engorgement reaches monstrous proportions, notably baboons, mangabeys, some macaque species, and chimpanzees. Regions other than the primarily genital areas may also be affected by the hormones circulating at certain periods of the reproductive cycle. For instance, in the gelada baboon, the skin on the front of the female chest, which normally bears a string of caruncles resembling the beads of a necklace, becomes engorged and brightly coloured. A German zoologist, Wolfgang Wickler, has suggested that this is a form of sexual mimicry, the chest mimicking the perineal region. The observation that geladas spend many hours a day feeding in a sitting posture provides a feasible, Darwinian explanation of this curious physiological adaptation.

Mimicry of bottom by chest colours

Placenta. The placenta, a characteristic of all Eutherian mammals, is a vascular structure that permits physiological interchange of blood and body fluids between the mother and the fetus and the breakdown products of the fetal metabolism; it also provides a two-way barrier preventing the passage of some, but not all, noxious substances and organisms such as bacteria and viruses from one individual to the other and is the source of hormones such as estrogens.

The placenta is a flat discoid-shaped "cake" in man, some of the other higher primates, and the tarsier. In many monkeys it is bidiscoidal, having two linked portions. The placenta is intimately attached on its outer surface to the endometrium, the lining of the uterus, by fingerlike processes (villi) that embed themselves in the endometrium where the vascular connections between the two circulations are achieved. The connection between fetal and maternal circulations appears as two distinct types among primates, a distinction which is believed to have had an important effect on the evolution of the order. In the first type (epitheliochorial), found in the prosimian suborder, several cellular layers separate the maternal and fetal bloodstreams, thus limiting the passage of molecules of serum proteins. In the second type, hemochorial placenta, the relationship is much more intimate, there being no fetal and maternal cellular layers separating the two circulations, and serum proteins can easily pass. A hemochorial type of placentation is found in tarsiers, apes, monkeys, and man.

The placenta is shed at birth in all primates, and, in all other than civilized man, is eaten by the mother.

IV. Evolution and paleontology

RENEWED INTEREST IN PRIMATE ORIGINS

The 1950s, 1960s, and 1970s were marked by a notable expression of interest in primate paleontology. Hardly a year has passed without some new major discovery being announced. New sites have been opened up and old discoveries redescribed and reallocated. New techniques in geological dating, in palynology (the study of fossil pollen), in paleoclimatology and paleoecology and in the archeological interpretation of fossil sites, have helped to lift primate paleontology into the forefront of the life sciences and have aroused public interest to an unprecedented level. The popularity of all aspects of the evolution of man is reflected, for instance, in the spate of books covering this field published during this period.

The African continent has contributed the greatest share of recent finds—Rusinga and Songhor in Kenya, Olduvai in Tanzania, and Sterkfontein, Kromdraai, Swartkrans, Makapan in South Africa are names with which every anthropology student is familiar. New names like Omo, Kanapoi, Lothagam, Napak and Moroto—all East African sites of hominid and pongid discoveries in the last few years—are now becoming as equally well known as Sterkfontein in the fifties and Olduvai in the sixties.

Important recent sites of primate fossils

Elsewhere, pieces of this colossal worldwide jigsaw have been discovered in Europe, notably in Hungary, France, and Italy; in the Siwalik Hills of northwest India; in the ever prolific middle Eocene Bridger Beds of North America, and in the La Venta deposits in Columbia and, recently (1969), in Bolivia. These latter discoveries are particularly welcome because of the poverty of fossils of New World monkeys.

While new discoveries have clarified the human story, older ones, that had only served to cloud it, have been repudiated. Piltdown man was shown unequivocally to be a fake in 1953; *Oreopithecus* of Monte Bamboli, Italy, has been relegated to a family remote from human ancestry, and Galley Hill Man in England has been shown to be a recent intrusion (a burial) into middle Pleistocene gravels. The questionable finds from the remoter geological periods of the Eocene and Oligocene have also been re-examined, with the result that a number of confusing fossils have been dismissed. *Anagale*, long thought to be a fossil tree shrew, is now regarded as a small carnivore; others, such as the supposed tarsioid–anthropoid annectent form, *Parapithecus fraasi*, have been reallocated within the order Primates.

Progress in constructing the phylogeny of higher primates and man has been bedevilled by a number of controversies concerning taxonomy and nomenclature, and, as a result, internal disagreements have developed which mitigate against the sort of international cooperation that is essential for so vast a project as the construction of a human phylogeny. New-school and old-school taxonomists have come into conflict. But with the rapid advances in genetics, in the new concepts of biological species and in population anthropology, a fresh equilibrium is slowly being acquired, as the pendulum swings between the reactionary "lumping" of such taxa as genera and the traditional "splitting," in which every new discovery was provided with a new generic name. The most extreme example of taxonomic lumping in primate paleontology was in a 1965 revision by E.L. Simons and D.R. Pilbeam of the Miocene–Pliocene genus *Dryopithecus*; from the 28 genera recognized prior to 1965, the authors recommended the recognition of three genera only: *Dryopithecus, Ramapithecus,* and *Gigantopithecus*. All the rest were absorbed into the three genera, a result initially satisfying but not yet subjected to the test of time.

THE PRIMATE FOSSIL RECORD

Cretaceous. The known range of the primate order was extended back from the middle Paleocene to the Late

Cretaceous (about 75,000,000 years ago) by the discovery in Montana of one premolar and four molar teeth, representing two species of insectivore-like primates that were assigned in 1965 to a new genus, *Purgatorius*. This diagnosis is based on the characters of four molar and one premolar tooth and is not by any means universally accepted.

Paleocene. The best known early primate species, of which, *inter alia*, a complete skull and a partial postcranial skeleton are available, belongs to the genus *Plesiadapis* from the Paleocene (about 60,000,000 years ago) of Cernay, France, and Colorado. The skull shows a number of dental specializations including procumbent rodent-like incisors in the upper and lower jaw and the absence of antemolar teeth, but the molar teeth show the unequivocal primate affinities of this species. Rodent affinities have been suggested for *Plesiadapis*, but most authorities agree that it is a primate, however aberrant.

Eocene. The known Eocene fossil families include the Tarsiidae (tarsiers), the Adapidae, considered probable ancestor of lemurs and lorises, and the Omomyidae, possible ancestors of the monkeys and apes.

Possible ancestors of the lemurs

The family Adapidae contains two North American genera, *Notharctus* and *Smilodectes*, which are well represented in the fossil deposits of the Bridger Basin, Wyoming. *Adapis*, a closely related genus, was widely distributed in Europe, as were *Anchomomys* and *Pronycticebus*. *Notharctus* and *Smilodectes* are not thought to be antecedent to living lemurs, principally on zoogeographical grounds, since egress from the North American continent for tropical species was effectively cut off by ecological changes soon after the beginning of the Eocene (about 54,000,000 years ago). *Notharctus* was not unlike the modern lemurs in size and general appearance. On both morphological and zoogeographical grounds, *Adapis* and *Pronycticebus* or *Anchomomys* could have provided the stem from which the living lemurs and lorises evolved.

Representatives of the Omomyidae have been found in North America, in Europe, and in Asia. According to American paleontologist Elwyn L. Simons, the Omomyidae are probably the key family for tracing the phylogeny of the higher primates, the apes and monkeys. The family was common to North America and Eurasia, a fact which reinforces the presently held view that omomyids provided the stock from which New World monkeys and Old World monkeys, apes, and man arose. No other Eocene primate family has a greater claim to be ancestral to the Anthropoidea. Their principal claim to antecedency (other than the circumstances of their zoogeography) is the dental formula: $\frac{2 \cdot 1 \cdot 3 \cdot 3}{2 \cdot 1 \cdot 3 \cdot 3} = 36$ teeth (18 pairs).

The Eocene Tarsiidae, represented by the European species *Necrolemur antiquus*, found in the Quercy deposits of France, are likely to contain the ancestor of the modern genus *Tarsius*. The tarsier is indeed a "living fossil" in the best sense of that overworked term. What is known of the skull and skeleton of *Necrolemur antiquus* indicates that it was almost identical with that of the living *Tarsius*.

Oligocene. Information on primate evolution during the Oligocene Epoch (about 38,000,000 to 26,000,000 years ago) rests principally on discoveries in three areas —Burma, Texas, and Egypt, and by far the most important is Egypt. From the Fayum, from the upper levels of the Qatrani Formation, has come the first evidence of the emerging Anthropoidea. A number of different genera have been described from the Fayum, including *Apidium, Propliopithecus, Oligopithecus, Parapithecus, Aeolopithecus*, and *Aegyptopithecus*. The Fayum, indeed, seems to be the cradle of the Old World anthropoids. Simons has indicated that the possible ancestors of Old World monkeys (*Parapithecus, Apidium*), of gibbons (*Aeolopithecus*), of apes (*Aegyptopithecus*) and even of man (*Propliopithecus*) are all represented in the fauna. Unfortunately, apart from a few fragmentary scraps of limb bones, there are no postcranial bones to help. From the evidence provided by the possible forerunners and probable descendants of the Fayum primate fauna, however, it is reasonable to assume that quadrupedalism was becoming established as the typical locomotor pattern, and that vertical clinging and leaping, the characteristic gait of the Eocene forebears of the fauna, was probably retained by at least some of the genera represented at this site.

Figure 7: Eocene fossil lemur *Notharctus*.
Drawing by R. Keane

Of unusual interest is the recent discovery of the cranium of a North American omomyid called *Rooneyia*; it is of particular note in view of a belief that primates had disappeared from North America by the late Eocene times. *Rooneyia* is also of considerable interest in itself. The skull possessed a mixture of primitive (prosimian) and advanced (anthropoid) features, precisely the combination that might be anticipated in a transitional form bridging the gap between the lower and higher primates.

Rooneyia, an important transitional form

Miocene. The Miocene Epoch is probably the most fruitful of all for paleoprimatology. During the 19 million years of its duration (beginning about 26,000,000 years ago), dramatic changes in geomorphology, climate, and vegetation took place. The Miocene was a period of volcanism and mountain building, during which the topography of the modern world was becoming established; of particular relevance to the story of primate evolution are the vegetational changes resulting from the orogenic ones. Grasses, known since the early Tertiary Era, flourished in the new conditions and in many areas that were previously forested. Grassland is known regionally by such names as savanna, llanos, prairies, etc. A new type of primate—the ground inhabitant—came into being during this period. Today ground-living primates, in terms of population numbers, include the most successful primate species, the macaques, the baboons, and man. The generalized nature of the bodily form of primates, combined with their specialized brain, made possible this critical step. It is probable that man owes his very being to this geomorphological revolution.

In the last few decades considerable additions to the knowledge of ape and human evolution have accrued from Miocene fossil beds in East Africa and Europe.

In Europe further discoveries of the gibbon-like genus *Pliopithecus* and the gorilla-chimp-like genus *Dryopithecus* have been made. *Pliopithecus* remains from Neudorf-an-der-March in Czechoslovakia have provided a remarkably complete picture of the habits of the Miocene apes, which, on this evidence, appear to have possessed bodily forms of a quadruped with morphological overtones of incipient brachiating specializations. Perhaps most interestingly of all, *Pliopithecus*, with its retention of numerous platyrrhine or New World monkey characters, emphasizes the phylogenetically conservative nature of anthropoid evolution.

In East Africa the excavations of the inshore islands and of the Kenyan shores of Lake Victoria by L.S.B. Leakey and a number of colleagues have illuminated man's knowledge of the evolution of the African great apes and have set up provocative questions regarding the origins of man. The *Proconsul* group (relegated to subgeneric status within *Dryopithecus* by the revision of Simons and Pilbeam) is known from three fossil species of ape, *Proconsul major, P. nyanzae,* and *P. africanus.* All three species are represented by a large number of jaw and facial fragments, but the only complete skull, discovered in 1948, belongs to *P. africanus.* Though complete, it was somewhat distorted by pressure of the surrounding rocks during fossilization. Subsequent reconstruction revealed a skull more monkey-like than apelike in its contours, an appearance which belied the unquestionably chimpanzee-like affinities of its teeth. The form of the skull and braincase of *P. africanus,* along with the forelimb skeleton, which is known in great detail for this species, indicates a body form that most closely resembles that of living monkeys. An American anthropologist, Sherwood L. Washburn, has described these creatures as "dental apes." The monkey-like characteristics of the *Dryopithecus* (*Proconsul*) group reflect the recency of the separation of the monkey and ape stocks of the Old World.

Proconsul africanus has been suggested as a possible common ancestor for apes and monkeys, but the general consensus is that *P. africanus* was already too specialized dentally to fit such a role. Be this as it may, there is no doubt that this Miocene fossil ape provides a very reasonable "model" for such an ancestor.

In East Africa two species of fossil gibbons, *Limnopithecus,* have also been discovered, closely related, if not generically identical, to the fossil "gibbon" of European deposits termed *Pliopithecus.* The taxonomic status of these fossils as "gibbons" is somewhat uncertain.

Appearance of hominids

It is towards the end of this turbulent epoch that the first probable ancestral hominids appear in the fossil record. *Ramapithecus punjabicus* was discovered in 1934 by an American paleontologist, G.E. Lewis, in the Siwalik Hill Miocene deposits in northwest India. Lewis tentatively expressed the view that *Ramapithecus* was a hominid, but the scientific climate of the period was not propitious for claims that seemed to imply such remote antecedents for man; as a result Lewis's perceptiveness was largely ignored. Recently, Simons and Pilbeam have resurrected Lewis's specimen and have demonstrated its hominid characteristics. At Fort Ternan in East Africa, meanwhile, Leakey found what at present appears to be another specimen of *Ramapithecus,* but of a different species and called by him *Kenyapithecus wickeri.* If and when it is proved (which seems probable) that *Kenyapithecus* was simply a *Ramapithecus* then it will, following the laws of nomenclatorial priority, be officially renamed *Ramapithecus wickeri.*

First ground-living monkey

It was also from the late Miocene that the first unequivocally ground-living monkey came to light. Attributed to the living subfamily Cercopithecinae of Old World monkeys, these specimens of *Mesopithecus pentelici* demonstrate the morphological transition between the ancestral monkey type (today represented by the leaf-eating monkeys or Colobinae of Africa, India, Ceylon, Malaya, Burma, and Southeast Asia) and the newly evolved adaptive type of ground-living monkey epitomized by *Macaca* or *Papio.* In its known features of skull and postcranial skeleton, *Mesopithecus* is broadly equivalent to the macaque monkeys. Although *Macaca* is now almost wholly restricted to Asia, the ancestral stock was at one time widely distributed throughout Europe as well.

Pliocene. The Pliocene Epoch (from about 7,000,000 to 2,500,000 years ago) was very similar to the present in terms of its geomorphology and climate. Discounting the effects of the recent influence of man on the distribution of forest and savanna in the tropics, the face of the land cannot have differed much from the aspect it presents today. Thus, one would expect that during the Pliocene (bearing in mind the effectiveness of environmental selection) essentially modern forms of primates would have made their appearance, but perhaps the most famous of the Pliocene fossils was far from "modern." *Oreopithecus* was first discovered, fragmentarily, in brown coal deposits in Italy in the middle of the 19th century. The most recent discovery of a complete, though paper-thin, skeleton (so grossly has it been compressed) in Tuscany has demonstrated the power of the environment acting upon the genetic structure, in once again reproducing the trade marks of two of the "inevitable" trends of primate evolution, brachiation, and bipedalism. *Oreopithecus* possessed a number of dental and bony characters that are typically hominid; it also possessed limb characteristics that are typically pongid. The canines were relatively short, the face was abbreviated, and the pelvis was broad. The foot showed characteristics associated with bipedal walking as did the vertebral column (all hominid characters), yet the arms were long and the fingers long and curved. The limb proportions are those of a brachiator (pongid characters). Finally, a number of characters of this confusing hominoid typically reflect those found in Old World monkeys. The present consensus of attitude towards this composite primate is that it is best segregated within the superfamily Hominoidea but in a family of its own, the Oreopithecidae. That the end of the *Oreopithecus* story has not yet been heard is certain; in the meantime the Tuscany fossil stands as a memorial to the primate order, the order which, of all of the class Mammalia, is most subject to environmental adaptation by virtue of its behavioral plasticity.

Few fossils referable to the ape family are known during the Pliocene, and monkey families are scarcely better known. *Libypithecus* and *Dolichopithecus,* both monkeys, were probably ancestral cercopithecines that still retained some features of their colobine ancestry; but neither genus can be placed in a precise ancestral relationship with modern members of this subfamily.

Pleistocene. The Pleistocene, which on faunal evidence is estimated to have started 2,000,000 to 3,000,000 years ago, is the epoch of hominid expansion (see HOMINIDAE). Knowledge of nonhuman primates is surprisingly sketchy. No ape fossils are known until relatively recent times and monkeys have been identified in only a few regions in Africa and even fewer in Asia: *e.g., Cercopithecoides* (a colobine-like form), *Gorgopithecus, Dinopithecus,* from South African deposits (forms of the living genus *Papio*); and *Simopithecus* (a giant, ancestral forerunner, according to one authority, of the present-day genus, *Theropithecus,* the gelada) from Olduvai Gorge and South Africa. It is possible that the *Papio-Theropithecus* divergence can be pushed well back into the Pliocene.

The special case of *Gigantopithecus*

One genus of the Pleistocene that is neither ape nor monkey in the sense that these taxa are interpreted today is *Gigantopithecus.* The romantic story of the discovery of the gargantuan molar teeth of *Gigantopithecus blacki* by von Koenigswald, the Dutch paleontologist, in a Chinese pharmacy has often been told. The boldness of the move that erected a new genus on such apparently slender grounds has been amply justified by the subsequent discovery of several massive jaws from Kwangsi in South China and attributed to this genus. The most recent discovery is of an enormous jaw in the Dhok Pathan deposits of the Siwalik Hills of India. Possibly dating back to the middle Pliocene, this discovery provides a respectably long period of existence for this aberrant giant-toothed hominoid genus. Clearly *Gigantopithecus bilaspurensis* was a member of the family Pongidae with divergent dental specializations that were possibly adaptive for the specialized form of herbivorousness recently termed graminovorous, an adaptation for foraging in grassland where tree products were unavailable and ground products available but hard to get. *Gigantopithecus* was a fossil ape that fell by the wayside on its way up to hominid status, a victim, possibly, of overspecialization.

V. Classification

DISTINGUISHING TAXONOMIC CHARACTERS

The identifying characters of the primate order have already been discussed above. The point has been made

that no single morphological characteristic distinguishes this group exclusively from other mammalian taxa. For instance, while it is possible to make the generalization that primates bear flat nails on the ends of their fingers and toes, it is not strictly accurate, for species such as the tree shrews, the marmosets, and the tamarins have either overt claws (tree shrews) or modified claws (marmosets and tamarins). One can also aver that primates characteristically possess two pectoral mammae, but it must be pointed out that the aye-aye (*Daubentonia madagascariensis*) has its nipples sited in the inguinal region (lower lateral region of the belly) and that mouse lemurs and tree shrews have multiple sets. Generalizations regarding opposability of the thumb, a "classic" primate character, are particularly vulnerable since some marsupials possess this trait and some primates do not. Examples of the generalized nature of primate specializations are too numerous to mention here. At first sight, big toe opposability provides a more promising diagnostic feature but, as with other features, there are exceptions to the rule, man for instance; moreover, it occurs in nonprimates.

As F. Wood Jones said in his book *Man's Place Among the Mammals*: "There is no single [characteristic] which constitutes a peculiarity of the Primates: for a primate animal may only be diagnosed by possessing an aggregate of them all." It was with this precept in mind that Sir Wilfrid Le Gros Clark introduced his list of evolutionary trends of primate evolution in 1959, which is amplified below:

1. The preservation of a generalized structure of the limbs with a primitive pentadactyly [i.e., containing five digits] and the retention of certain elements of the limb skeleton (such as the clavicle) which tend to be reduced or to disappear in some groups of mammals.
2. An enhancement of the free mobility of the digits, especially the thumb and big toe (which are used for grasping purposes).
3. The replacement of sharp compressed claws by flattened nails, associated with the development of highly sensitive tactile pads on the digits.
4. The progressive abbreviation of the snout or muzzle.
5. The elaboration and perfection of visual apparatus with the development to varying degrees of binocular vision.
6. Reduction of the apparatus of smell.
7. The loss of certain elements of the primitive mammalian dentition, and the preservation of a simple cusp pattern of the molar teeth.
8. Progressive expansion and elaboration of the brain, affecting predominantly the cerebral cortex and its dependencies.
9. Progressive and increasingly efficient development of those gestational processes concerned with the nourishment of the foetus before birth. (From W.E. Le Gros Clark, *The Antecedents of Man*; © 1959 Edinburgh University Press.)

Two further evolutionary trends may be added to the list:

10. Progressive development of truncal uprightness leading to a facultative (opportunistic) bipedalism.
11. Prolongation of postnatal life periods.

From J.R. and P.H. Napier, *A Handbook of Living Primates* (1967).

A British zoologist, R.D. Martin, has criticized many of these evolutionary trends as irrelevant as determinants of primate origins. In his view, many of them are either symplesiomorph characters (primate characters inherited from an ancestral mammal and therefore nonspecific for primates) or convergent characters (characters that have been acquired by many groups of primates in response to the environmental effects of natural selection). The disputed trends of primates, nonetheless, comprise characters that are of considerable significance for primate classification. Martin's point is that such characters are of little use in distinguishing the order Primates from other placental orders. Martin argues that the inadequate nature of the current definitions of primates is the principal reason why, when so much behavioral and structural evidence points to the opposite conclusion, the tree shrews (Tupaiidae) are presently included in the order. This may well be so. But until the true synapomorph characters (characters of independent acquisition) are identified by extensive comparative studies of all of the relevant characters of primates and nonprimates, there is little justification for arbitrary disenfranchisement of the tree shrews. "Possession is nine-tenths of the law," a principle that, as in this instance, supplies the highly desirable element of stability to zoological nomenclature.

ANNOTATED CLASSIFICATION

It is apparent that the taxonomy of primates is in a very fluid condition; but this state of affairs is wholly preferable to the virtual stagnation that existed during the first half of the present century. In view, therefore, of the likelihood of further major revisions taking place during the next decade that may well reveal the fallacies of certain current concepts, the informational content of this section is best served by a conservative, rather than a radical, approach to primate classification. Thus, the most widely accepted current classification is here followed, while fully admitting that it is not wholly adequate. In order to avoid some of the descriptive complications, derived from an imperfect classification, the following scheme outlines the distinguishing taxonomic characters of order, suborders, and families; intermediate taxa, such as infraorders and superfamilies, are omitted.

ORDER PRIMATES

Distinguished by the possession of a hallux (first toe) and a pollex (thumb), one or both opposable; eyes frontally placed on the face, orbit ringed by bone and, in higher members of the group, closed posterolaterally by bone. Brain relatively large. Most of the fingers and toes bear nails, not claws. Number of teeth 18 to 36; canines prominent but dentition as a whole not highly specialized. Diet omnivorous; body weight from about 100 grams (a few ounces) to 180 kilograms (400 pounds), more or less. Twelve Recent families, 55 genera and 197 species; 8 extinct families. Extinct groups are indicated by daggers (†).

†Suborder Plesiadapoidea

†*Families Phenacolemuridae, Carpolestidae, and Plesiadapidae*

Middle Paleocene to lower Eocene; North America and (except Phenacolemuridae) Europe; collectively, more than a dozen genera.

Suborder Prosimii

Usually quadrupedal and plantigrade, but some species show vertical clinging in trees and saltation on the ground; all have long tails (except *Indri*). Very small to medium in size; substantially insectivorous, but fruit- and leaf-eating common; activity rhythm nocturnal or crepuscular. Suborder characterized by possession of long or longish snouts, naked rhinarium, and naked tethered upper lip (except *Tarsius*); facial vibrissae (whiskers) present. Specialized sublingual fold, often serrated, below tongue. Eyes large, fully frontally facing in *Tarsius*, but somewhat divergent laterally in others; bony orbits not fully closed posterolaterally. Teeth characterized by special arrangement of lower incisors and canines to form a dental "comb," except in *Tarsius* (structure absent) and in *Tupaia* (canines take no part in comb); upper incisors usually small and peglike. Hallux and pollex more or less opposable, tips of all digits bear flat or flattish nails (except in *Tupaia*), second digit of hindlimb bears toilet (grooming) claw. Placenta epitheliochorial and non-deciduate (except *Tarsius*). One or more pairs of nipples. Single births are the rule.

Family Tupaiidae (tree shrews)

Small animals with elongated body and long bushy tail (scaly with terminal tuft in *Ptilocercus*). Short limbs, with fore longer than hind. Long pointed snout. Relatively large brain (compared with nonprimates) with diminished olfactory representation; turbinal bones of nasal region of skull not well developed. Tympanic ring within middle ear cavity. Primitive dental pattern, with 3 pairs of lower incisors, protuberant and arranged as modified "dental comb"; cheek teeth primitive in form. Digits of hands and feet bear claws; pollex is incipiently divergent, but nonopposable; hallux, nonopposable. Both arboreally and terrestrially adapted species occur within the family. Head and body length 10–24 cm (4–9½ in.), tail 12–14 cm; 5 genera, 17 species; India and Southeast Asia and Philippines.

†*Family Adapidae* (*Notharctidae*)

Lower to upper Eocene; Europe, Asia, and North America; about 10 genera.

Family Lemuridae (lemurs)

Size very small to medium; tail longer than head and body length combined; hindlimbs considerably longer than forelimbs; tail more developed in subfamily Lemurinae than in the other subfamily Cheirogalinae. Coat colours highly variable;

one species, *Lemur macaco*, shows sexual dichromatism (males black, females rufous). Tympanic bullae large, tympanic ring contained within middle ear cavity (contrasting with Lorisidae). Cutaneous glands on forearm and upper arm serving marking functions in *L. catta* and *Hapalemur griseus*; absent from other species. Dentition typical of Prosimii, including "dental comb" and reduced upper incisors (absent in *Lepilemur*). Diurnal (*Lemur, Hapalemur*) or nocturnal. Births seasonal; twins common in *Microcebus*. Head and body length 13–46 cm (5–18 in.), tail 17–56 cm; 6 Recent genera; about 14 species (some possibly extinct); restricted to Madagascar.

Family Indriidae (indri, sifaka, and avahi)

Arboreal animals with exceptionally long limbs, associated with specialized locomotor habit of vertical clinging and leaping. Skull with somewhat downwardly facing foramen magnum, short facial skeleton and very large auditory bullae. Dentition atypical of Prosimii; lower canines absent, first premolar somewhat caniniform, 2 premolars only. Anatomy of stomach and cecum, particularly, specialized in association with a bulky vegetarian diet. Activity rhythm nocturnal (*Avahi*) or diurnal (*Propithecus* and *Indri*). Fossils from Pleistocene. Three living genera, 4 species; Madagascar.

Family Daubentoniidae (aye-aye)

Arboreal, nocturnal family comprising single species *Daubentonia madagascariensis*. Hand specialized by markedly elongated and attenuated third digit. Dentition anomalous: central incisors reduced to single large pair having long roots and a rodent-like function; canines absent, premolars absent in lower jaw and reduced in upper. Symphysis between right and left halves of mandible is fibrous, a condition unique among the primates. Single inguinal pair of nipples. Madagascar.

Family Lorisidae (galagos, lorises, angwantibo, and potto)

Arboreal and nocturnal. Two major locomotor types comprise family: vertical clingers and leapers (subfamily Galaginae) and slow quadrupedal climbers (Lorisinae), the former possessing excessively long hindlimbs, and the latter subequal limbs. Tails short or absent in Lorisinae and long in Galaginae. Second digit of hand reduced, extremely so in Lorisinae (particularly *Perodicticus* and *Arctocebus*) and first digit of hand and foot disproportionately large. Skull globular in form with little protrusion of facial region. Tympanic bullae large, short external auditory canal with tympanic ring sited at junction of middle and external ear. Orbits large, with little lateral divergence. Dentition typical of suborder. Omnivorous (with large insectivorous element). Family comprises 5 Recent genera with about 12 species; Africa, Asia (Lorisinae); Africa (Galaginae).

†*Family Anaptomorphidae*

Upper Paleocene to middle Eocene; North America and Europe; about 10 genera.

†*Family Omomyidae*

Upper Paleocene to lower Oligocene: North America, Europe, and Asia; about 20 genera.

Family Tarsiidae (tarsiers)

Arboreal and nocturnal. Hindlimbs almost twice the length of forelimbs. Hands with 5 digits, fingers surmounted by circular digital pads and backed by tiny triangular nails; thumb opposable, but in a fashion distinct from other Prosimii. Head of femur cylindrical (not spherical as in all other Prosimii except *Galago*), and tibia and fibula fused in lower third (unique to *Tarsius*). Skull characterized by enormous, frontally directed orbits, incompletely closed posterolaterally; nasal space much compressed. Foramen magnum (opening for spinal cord) directed downwards. Short external auditory canal; middle ear with prominent bulla and tympanic ring, sited as in Anthropoidea. Dentition unlike typical prosimian pattern, lacking dental comb; central lower incisors absent; molars sharp-cusped tuberculo-sectorial. Placentation is hemochorial, discoidal, deciduate, as in Anthropoidea. Single young usually produced. One genus, 3 species; Southeast Asia.

†*Family Microsyopidae*

Lower to upper Eocene; North America and Europe; 4 genera.

Suborder Anthropoidea

Quadrupedal, brachiating or bipedal in gait. Diurnal in habit (except night monkey, *Aotus*). Omnivorous in diet. Tail present or absent, varying in length from species to species, prehensile in some. Size ranges from very small (*Saguinus* and *Callithrix*, the tamarins and marmosets) to very large (*Gorilla* and *Homo*.) Faces show varying degrees of protrusion, most marked in the baboons and mandrills and least developed in man. Neurocranium relatively large and with or without sagittal or nuchal crests or both; foramen magnum directed downwards and backwards. Orbits frontally facing and fully closed posterolaterally; nasal cavity narrow. Dentition comprising 30–36 teeth, canines are well developed except in man. Hands and feet prehensile; thumb semi-opposable or fully opposable (except in certain platyrrhine species). Hallux widely abductable (capable of being rotated inward) and capable of prehension in all species except man; flat nails on fingers and toes (except Callitrichidae); specialized toilet claws absent. Two pectoral mammae only. Placenta hemichorial, discoidal, and deciduate. Lengthy gestation period and extended life periods (compared with Prosimii) characterize the suborder. Suborder contains two geographical groups: New World monkeys and Old World monkeys: 6 families and 35 genera; both the tropical and subtropical zones of New and Old World.

Family Callitrichidae (tamarins and marmosets)

Small animals, diurnal, arboreal, and mainly insectivorous. Quadrupedal gait, hindlimbs being 25 percent longer than forelimbs. Thumb nonopposable, but hallux fully abductable; all digits bear modified claws (tegulae) except hallux, which has a flat nail. External nostrils face forwards and sideways (platyrrhine condition); nasal septum broad. Coat colour highly variable between species including wholly black and wholly white forms; one species (*Leontopithecus rosalia*) golden; distinguishing external features include a variety of ear tufts and a diversity of mustaches. Skull long and ovoid in shape with bulging occiput; tympanic bulla present; external auditory canal absent. Dentition consists of 32 teeth (36 in *Callimico*) with 3 premolars and only 2 molars. Tamarins are distinguished from marmosets by long lower canines which project beyond incisors; in marmosets canines and incisors are the same length. Head and body length 13–37 cm (5–15 in.), tail 20–39 cm; weight about 100–700 gm. Five genera, 15 species; South America.

Family Cebidae (New World monkeys)

Larger in size than Callitrichidae, with ears more or less naked externally. All digits bear flattened or curved nails; thumb imperfectly opposable. Gait quadrupedal. Prehensile tail present in *Ateles, Alouatta, Brachyteles*, and *Lagothrix*. Bony ear formation as in Callitrichidae. Nose typically platyrrhine. Dentition of 36 teeth; molars quadrangular and quadricuspid, and canines moderately developed in both sexes. Head and body length about 24–70 cm (tail usually of same magnitude), weight about 600 to 10,000 gm (1.3 to 22 lb); 11 genera, 29 species; southern Mexico to Brazil.

†*Family Parapithecidae*

Lower Oligocene; North Africa; 2 genera.

Family Cercopithecidae (Old World monkeys)

Medium to large in size. Arboreal or terrestrial. Characterized by naked callosities covering expanded ischial bone of pelvis. Quadrupedal, plantigrade, or digitigrade in gait; hindlimbs longer than forelimbs in most species, but in ground-adapted forms limbs are nearly equal. Thumb present in all genera (except *Colobus*) and functionally opposable. Cheek pouches present in subfamily Cercopithecinae and concerned with temporary storage of food; in subfamily Colobinae pouches are absent but stomach is sacculated in association with a predominantly leaf-eating diet. Tail length variable from very long (Colobinae) to very short or absent (some Cercopithecinae). Muzzle more or less prominent. Noses with external nasal opening facing forwards and downwards or directly downwards ("catarrhine" condition); internasal septum narrow (as contrasted with Callitrichidae and Cebidae). Skull of anthropoid type but without auditory bulla; external auditory canal present. Dentition of 32 teeth; canines large in males, moderate in females; first lower premolar sectorial, molars quadricuspid with transverse linking crests (bilophodonty). Head and body length about 32–110 cm; tail, when present, 2–100 cm; weight about 0.7–30 kg (1.5–66 lb); 13 genera, 72 species; Africa, India, China, Japan, and South East Asia.

Family Hylobatidae (gibbons and siamang)

Demonstrate highly specialized form of locomotion called brachiation. Arboreal, tailless catarrhines with forelimbs twice length of hindlimbs. Hands exceptionally long and prehensile; deep cleft between first and second digits; thumb fully opposable by means of unique mechanism at carpo-metacarpal (basal thumb) joint, associated with a specialized musculature. Ischial callosities as in Cercopithecidae but developing late in life. Well developed laryngeal (vocal) sac in *Symphalangus*. Skull of typical anthropoid form, orbits large, forwardly directed and having a well-buttressed lateral margin; strong brow ridge; sagittal and nuchal crests rare; mastoid processes absent. Long sabre-like canines equally developed in both sexes; molar cusp pattern similar to that of the Pongidae and Hominidae. Chromosome diploid number: 44. Head and body length about 40–64 cm (16–25 in.); weight 4–13 kg;

2 genera; *Hylobates* (6 species) and *Symphalangus* (1 species); Southeast Asia.

Family Pongidae (great apes: gorilla, chimpanzee, and orangutan)

Arboreal or ground living. Locomotion consists of brachiation and a modified form of quadrupedalism, called knuckle walking. Characterized by total lack of tail, relatively long forelimbs, elongated hands, and short but fully opposable thumbs. Brain relatively large compared with body size and showing well marked cerebral fissuration. Permanent dentition 32 teeth: incisors large and spatulate, particularly in upper jaw; canines large and conical, particularly in males; well-marked diastema present between upper lateral incisors and canines. Molars large; quadricuspid in upper jaw and quinquicuspid in lower; cusps arranged in so-called "*Dryopithecus*-pattern"; enamel much wrinkled in *Pongo;* third molar relatively small in *Pan*. Skull bears sagittal and nuchal crests in adult males (but rare in *Pan*). Ischial collosities usually absent (*cf.* Cercopithecidae, Hylobatidae). Thorax widest transversely (*cf.* Cercopithecidae); pelvis expanded in iliac region; lumbar vertebrae reduced in number (*cf.* Cercopithecidae). Life periods extended compared with New and Old World monkeys. Chromosome diploid number: 48. Family includes three genera: *Gorilla, Pan, Pongo. Distribution*: Africa and Southeast Asia.

Family Hominidae (man and fossil relatives)

Ground-living, hairless, omnivorous and bipedal. Hindlimbs longer than forelimbs (contrasting with Pongidae and Hylobatidae). Thumb fully opposable and hand capable of both precision grip and power grip; big toe aligned with other toes, foot nonprehensile. Brain relatively large and highly fissured. Neurocranium expanded particularly in parietal and frontal regions; Mastoid process of periotic bone present from birth. Facial skeleton nonprotrusive and strongly flexed relative to cranial base. Dentition of 32 teeth: canines small and blunt, lying flush with occlusal plane; premolars bicuspid; molars small, low, bearing rounded cusps; last molar in upper and lower jaw frequently unerupted. Postcranial skeleton shows adaptations to upright posture particularly in vertebral column, pelvis and lower limb. Chromosome diploid number: 46. Life periods (including growth period and life expectancy) extended as compared with Pongidae. Head and body length about 80 to more than 130 cm (30–50 + in.); total length (height) about 130 to over 220 cm; weight from about 40 to more than 120 kg; one Recent species, *Homo sapiens*; worldwide.

CRITICAL APPRAISAL

The classification of the primates by George Gaylord Simpson is the most widely used list today. Since it was published in 1945 a number of revisions at family level and below have been incorporated; the higher categories have remained unchanged, although they have been the subject of considerable criticism and doubt. W.C. Osman Hill's classification, which, with modifications, follows R.I. Pocock's list published in 1918, has not enjoyed a wide popularity, in spite of the success of "Primates," Hill's monumental treatise on the order. Hill excludes the tree shrews from the primates altogether; he also removes the tarsioids from among the lemurs and lorises and places them with the monkeys and apes. A compromise view between the classifications of Simpson and Hill has been proposed by American paleontologist Alfred S. Romer. Romer also omits the tree shrews from the order and gives the tarsioids equal status with lemurs and lorises, Old World monkeys, New World monkeys, and apes in a separate subordinal group. It seems likely that before very long Romer's classification, or one closely similar to it, will become generally accepted. Reference to the annotated classification given above (based on Simpson's) will indicate how ill-fitted is the living genus *Tarsius* to share subordinal status with the prosimians.

Several revisions of lower taxa (genus and species) have been proposed in recent years which are proving generally acceptable. It has been suggested that *Cynopithecus niger*, the Celebes black "ape," be included within the synonymy of *Macaca*, in which case this species therefore becomes *Macaca nigra*. Also widely accepted is inclusion of *Comopithecus* (the hamadryas baboon) in the synonymy of *Papio* (the common baboon), but opinions differ as to whether the hamadryas and the common baboon are not better considered a single species in view of the good evidence of hybridization in the wild. Synonymy of the genus *Mandrillus* with *Papio* has also been suggested, largely on the evidence of molecular data from blood protein studies, but has not found much support. Less controversial is the conclusion, based on field evidence, that the three generally accepted species of savanna monkeys (*Cercopithecus aethiops, C. sabaeus* and *C. pygerythrus*) actually comprise a single polytypic species, *C. aethiops*.

Less universally acclaimed is the suggestion by Simpson that the structural and behavioral differences between the chimpanzee and the gorilla are insufficient to justify continued generic separation. According to this view, which has some support, *Pan*, having nomenclatorial priority, should include two species, *Pan troglodytes* (chimpanzee) and *Pan gorilla* (gorilla). At a recent symposium on the Old World monkeys held in 1969, the synonymy of *Nasalis* (the proboscis monkey) with *Simias* (the Pagai Island langur) and *Rhinopithecus* with *Pygathrix* was recommended but, as yet, is by no means universally accepted. Field, museum, and laboratory work has led to numerous changes in classification of primates by subspecific level that need not concern us here.

VAN LAWICK-GOODALL, *My Friends, the Wild Chimpanzees* (1967), three readable accounts of the lives of individual species, based on extensive field work; V. REYNOLDS, *The Apes* (1967); and R. and D. MORRIS, *Men and Apes* (1966), well-illustrated popular books; C.P. GROVES, "Population Systematics of the Gorilla," *J. Zool.*, 161:287–300 (1970); and *Gorillas* (1970), respectively, a technical and popular work on this interesting ape; W.K. GREGORY, *The Anatomy of the Gorilla: The Studies of Henry Cushier Raven, and Contributions by William B. Atkinson and Others* (1950), a carefully illustrated, technical book.

(J.R.N.)

Primitive, Folk, and Popular Arts

The underlying unity of all man's artistic activities, at every level and in every time and place, has, during the 20th century, been widely assumed. Nevertheless, four kinds of art (each one too heterogeneous to be usefully called a style) have continued to be recognized, partly on the basis of their asserted qualities and largely on that of their supposed, intended, or actual audiences. On the one hand, with relatively small audiences, is the kind variously referred to as elite, mature, sophisticated, serious, or high—*i.e.*, the kind normally evoked when the word "art" is used without qualification. On the other hand, with relatively large audiences, are the nonelite kinds usually referred to as primitive, folk, and popular.

The four kinds of art

In this article the elite kind of art will be considered only for the sake of comparisons. The primitive, folk, and popular kinds, in that order, will be examined in terms of (1) definitions, (2) typical productions, (3) artists and patrons, (4) materials and techniques, (5) meanings and functions, (6) styles, (7) special problems, (8) external relations, and (9) appreciation and study. The grouping of the three kinds will permit comment on their occasional zones of overlap and, more important, on the way an understanding of the characteristics of one kind can shed light on the characteristics of the others. The whole discussion will be on the level of theory, introductory explanation, and general description, with specific material included only as examples.

Specific primitive arts are treated elsewhere in comprehensive articles on each of the various arts and in those on primitive cultures; single folk and popular arts are treated in similar contexts and in the separate articles FOLK VISUAL ARTS; FOLK MUSIC; POPULAR DANCE; POPULAR LITERATURE; POPULAR MUSIC; and POPULAR THEATRE.

PRIMITIVE ART

Definitions. In the literature about visual arts and about painting in particular, "primitive" has three common applications that are not wanted here and that arguably ought not to be wanted anywhere. First, with the sense "crude," the term is loosely applied to artists who do not achieve, for a variety of reasons, 19th-century European academic correctness; thus children, madmen, certain modernists, and ordinary bunglers are sometimes called primitives. Second, with the sense "naïve" and usually with the connotation "charming," the term is applied by sophisticated critics and dealers to untutored painters who make up in earnestness of ambition and in freshness of vision for what they lack in professional training; thus in the 20th century the French customs official Henri Rousseau and the U.S. housewife Anna Mary (Grandma) Moses have been called primitives and so have, to give earlier examples, a fair number of talented, ingenuous artists, many of them itinerant painters, who flourished in the United States roughly between 1800 and the Civil War. Third, with a sense that has gradually dwindled almost to zero, the term has been applied by art historians since at least the 1830s to European painters (rarely to other visual artists) of the 14th and 15th centuries; thus a refined, lyrical Sienese master such as Simone Martini may be called an Italian primitive, and a learned, courtly virtuoso of Bruges, Belgium, Jan van Eyck, may be called a Flemish primitive. In this third usage the original implication was that International Gothic and early Renaissance painting was "immature" by comparison with the art of the High Renaissance, when such aids to illusionism as mathematical perspective, the naturalistic distribution of light and shade, and the exact rendering of anatomical detail were well in hand. The growing unfashionableness of biological metaphors for the history of styles has made this implication unacceptable to most scholars but has not kept the bearer of the implication from surviving as one of the numerous fossils in the language of art analysis.

Because of the above three usages, it is necessary constantly to stress the fact that primitive art, in the sense that has been adopted by specialists in the subject, is not a product of some sort of ineptness and not a stage on the way to something presumably better. It is the fully developed art of primitive societies. And this definition is not as evasive as it may seem, for primitive societies can be described with reasonable precision: they lack written languages, cities, monumental centres, road networks, aqueducts, highly organized trade, and technology above the level of hand tools; they subsist on wild-food gathering, hunting, fishing, livestock raising, and small-scale agriculture; they are usually warlike, but without standing armies; their political organization is usually, although not quite invariably, tribal; their religions are directed more toward the successful integration of man with nature than toward the imposition of a humanly conceived order on the cosmos and on the course of universal events. Their rates of change, in all things, are normally so slow as to be practically imperceptible.

The fully developed art of primitive societies

From this description it follows that "primitive" is not at all appropriate for the art of such complex ancient societies as those of the Sumerians, the Bronze Age Chinese, the dynastic Egyptians, the pre-Classical Greeks, and the pre-Columbian Aztecs, Mayas, and Incas. The term, it would seem, may be legitimately applied to the art of prehistoric Paleolithic and Neolithic Europe and Asia, and in fact many ingenious theories try to explain prehistoric art—cave paintings, for instance—by analogy with relatively recent primitive art or relatively recent primitive art by assumptions of diffusion from prehistoric centres. But many authorities are wary of such analogies and assumptions, and in any case, of course, the amount of prehistoric art that has survived is very limited. The upshot of the whole situation is that the bulk of what professional students regard as primitive art dates from the 18th, 19th, and early 20th centuries and comes from three principal sources: African tribesmen who live south of the Sahara, especially those in the western and central parts of the continent; the Indians and Eskimo of North America; and the native inhabitants of Polynesia, Melanesia, Micronesia, and Australia. The generalization needs to be modified only slightly by reminders that diggers sometimes find much earlier material and that scattered primitive societies have been found in many places —in isolated parts of South America, for instance, in Indonesia, and in the back uplands of Asia.

Typical productions. Any attempt to grade the importance of the various primitive arts must be made against

the realizations that there are abrupt regional differences, that some elite arts have no exact primitive equivalents, that some productions are more perishable than others, and that some have been neglected by anthropologists.

Importance of sculpture in primitive visual arts

Thus, it may be safe to say that sculpture, including the carving of ritual masks, is or has been the most important of the visual arts, in terms of both quantity and quality; the statement can be supported by hundreds of brilliant examples produced by the western and central Africans, the Melanesians of the Sepik River region, and American Indians of the Northwest coast. Yet it must not be forgotten that sculpture was a minor art among most of the Polynesians (in spite of the great stone faces on Easter Island), the East Africans, and the Plains Indians. Painting and drawing rank high when one thinks of such things as the prehistoric Lascaux cave painting (if that is acceptable as primitive), Bushman and Australian rock art, Maori tattooing and house decorations, and Navajo sand designs; yet, on the whole, primitive two-dimensional arts, unlike primitive sculpture, do not have the freedom and the specific status of the major creative arts in the elite category. The importance of primitive architecture as an art has probably been underestimated, partly because most of its productions have perished and partly because the surviving ones have not been sufficiently studied. Yet there are fascinating opportunities for aesthetic analysis in the shapes, structures, and spaces of such primitive shelters as the conical-roofed hut of Africa, the lashed-together council house of the Maori in New Zealand, the barrel-vaulted longhouse of the Iroquois Indians in the U.S. Northeast, the multistoried edifice of the Pueblo peoples in the U.S. Southwest, and even the familiar tent, or tepee, of the Plains Indians.

Among the nonvisual and the performing primitive arts, all of whose productions were in theory ephemeral (although in fact quite well preserved by memory and tradition) before the arrival of the white man with his writing, notation, and eventually films and tapes, the first place should undoubtedly be assigned to music, both vocal and instrumental, and to music's practically inseparable sister art, the dance. Literature takes the form of recited prose or poetry the subject matter of which springs from the myths and legends of the tribe. The existence of primitive drama has been mildly questioned, on the grounds that what anthropologists sometimes call plays are actually ceremonies or rites, but the same point might be made about certain early forms of elite drama. Particularly elaborate examples of this sort of primitive drama have been noted in what is now Nigeria, in British Columbia among the Kwakiutl Indians, and in New Ireland in what are called the Malagan ceremonies.

Artists and patrons. Contrary to a common misconception, the primitive artist was generally a professional. (The rapid disappearance of old tribal customs makes the past tense advisable in most of this discussion.) In many places he had to earn the right to practice his art by serving an apprenticeship; in other places he could inherit the right and, with it, a religious status. The system might not prevent an ordinary tribesman or even a tribeswoman from doing some dancing, singing, and decorating.

The professional primitive artist

But important projects, especially in the visual arts, were normally reserved for the professional, and sometimes his whole creative procedure was protected by something like a sacred copyright; in Polynesia, for example, the accepted notions of taboo made it dangerous for an unauthorized person to attempt certain activities. The professional, however, was not free, in the manner of elite Western artists since the Romantic era, to produce what he liked and then look for a market. Usually he was commissioned by a knowledgeable, exigent patron to do something according to traditional rules. The patron might be a chief, a tribal elder, a person of lower rank in need of a specific work, or quite often a representative of one of the secret societies that existed in many parts of the primitive world and took charge of particularly important communal ceremonies.

Materials and techniques. The primitive visual artist was extremely dependent on local materials. If he was an Eskimo, he was not encouraged to carve in wood. If he was a Polynesian, the absence of suitable clay kept him from becoming a potter. But the dependence did not have a simple negative effect; it gave the artist a deep respect for the natural qualities of each material and made him alert to the artistic possibilities in many materials—bark, sand, feathers, shells, skins, bones, teeth, and the human body itself—that are traditionally ignored by creators in the elite category. In a somewhat analogous way the lack of efficient equipment and complex technical processes encouraged mastery of the tools and methods that were available. The widespread notion that primitive art is on the whole more crudely executed than the elite kind cannot survive an unprejudiced look at the evidence.

Meanings and functions. The fact that primitive societies are by definition nonliterate has to be taken into account in any consideration of the meaning of a work of primitive art; for, in the absence of writing as a way of storing facts and values and of communicating them across space and time, one may find these vital cultural jobs being partly done by a little wooden statue, an apparently simple piece of music, or a traditional dance. To be aware of this possibility is not to argue, as a few experts have, that the tribes of Africa, North America, and the South Pacific never indulged in sheer entertainment or pure decoration or art for art's sake. But there can be little doubt that one of the essential differences between primitive art and the other three kinds, all of which exist in literate cultures, is that the primitive kind is on the average more densely charged with symbolic meaning and, in a broadly social and religious way, more functional. The difference, although the analogy should not be pressed very far, is rather like the difference between medieval Christian and Renaissance art.

A few examples may help to clarify the point. In primitive sculpture the material itself is frequently charged with meaning; the Iroquois Indians cut some of their masks from living trees in the belief that the masks would keep some of the power residing in nature. The forms have to be read in detail and as wholes; in Polynesia a creative deity might be carved not only with a symbolically large penis and with a number of tiny offspring swarming over his body but also, to make the significance triply certain, with the overall shape of a phallus. Primitive painting shows the impulse to rate meaning as far more important than mere representing; and there are no exact primitive equivalents for such elite genres as landscape, still life, and portraiture. All of the primitive arts were at one time functional in a religious, magical, social, or economic way; they served to placate ancestors and gods, to assure food supplies, to knit the tribe together, and to accompany daily work. Often the functions were extraordinarily specific; the Tutsi of Rwanda, in East Africa, had songs to praise cows, songs to show that one ought to have cows, songs to take cows home in the evening, songs to water cows, songs for children about cows, songs to admire the royal cows, and songs to emphasize the importance of cows in history.

Functions of the primitive arts

Styles. It is perhaps worth saying again that primitive is not, properly speaking, a style. Within it, as might be expected in a kind of art produced by communities living in relative isolation, there are many sharply definable styles. Anyone with a little experience of African sculpture in a good museum soon comes to recognize the schematized, nearly abstract style of the Kota (Bakota) tribesmen of Gabon, the relative naturalism of the Fang, who are nevertheless neighbours of the Kota, and the classical, almost European naturalism of the ancient inhabitants of the town of Ife, in Nigeria. Among Pacific styles the streamlined severity of Micronesian objects is instantly distinguishable from the complex expressionism of Melanesia. In primitive literature there is a style—and sometimes several—for each of the hundreds of languages and dialects. Anthropologists and ethnomusicologists are familiar with a vast number of musical styles that range from the rhythmic polyphony of black Africa to the radical simplicity of the Sirionó Indians of Bolivia, who have no instruments and only a few two-tone or three-tone tunes, one of which is usually adopted by a singer for his entire lifetime.

It is easy to suppose that there is a relationship between style and general cultural pattern or between style and the social function of a work of art; interesting attempts to verify the supposition and systematize it have been made. Naturalistic styles, for instance, have been said to be associated with nomadic ways of life and geometric styles with settled ways. The degree of power and sacredness in primitive masks has been said to match an increasing degree of abstraction and fantasy in the styles. But not enough evidence has been sifted to make such assertions definitely acceptable, and there are always exceptions to generalizations about style.

Special problems. Considerations of style are involved in four special problems that are problems of general anthropology but that are capable of arousing particularly strong emotions among students of primitive art—partly because the solutions advanced can imply fundamental assumptions about the nature of man and of universal cultural history. The problems, inadequately but conveniently labelled, are those of evolution, diffusion, environment, and aesthetic psychology in relation to primitive art.

The problem of evolution in primitive art

The first problem has triple roots in the facts that primitive often means early, that the Darwinian theory of evolution made some injudicious converts, and that Europeans during the last half of the 19th century, when primitive art began to be seriously examined, were inclined to have a high opinion of themselves and their cultural achievements. The result, in its rawest form, was the belief in a world unilinear evolution, or progress, of art (along with other cultural elements) from an infantile, fumbling stage up to an adult, fully developed stage represented essentially by Renaissance and post-Renaissance European creations. Manful efforts were made to set forth the intervening stages and to answer such questions as which came first, naturalism or geometrism. Art that was discovered in the mostly tribal societies of Africa, America, and Oceania was classified as unevolved and as representative of some of the early stages through which Western elite art had passed. The whole theory has crumbled during the 20th century under the growing evidence of the immense variety and technical excellence of much primitive art, under the attacks of modern artists on post-Renaissance conservatism, and under the conviction that, at least in art, value judgments are relative. Anthropologists and art historians, as was pointed out earlier in this article, now agree that primitive art is not in a formative stage in relation to elite art. It is simply the art of societies that are unlike the societies that provide the audiences for elite art—and also for the folk and popular kinds.

But perhaps this conclusion does not really dispose of the problem. Granting that "evolution," with its connotation of improvement, is an undesirable term in the context and granting that 19th-century Western prejudices are no longer tolerable, many scholars nevertheless feel that the history of the various primitive arts is a legitimate field for speculation and research. One can assume (and sometimes back the assumption with archaeological evidence) that these presumably mature arts have changed, however slowly, in the past. One asks how and why they changed, how they became what they were when Europeans discovered them.

The problem of diffusion

Such questions are part of the background of the diffusion problem. Nearly all experts, of course, are willing to accept the hypothesis of diffusion from a creative centre when similar traits appear in the arts of neighbouring regions over a reasonably short period of time; no one doubts that some of the traits in the art of the natives of New Guinea derived from Indonesia. The problem arises when the traits appear in cultures that are otherwise quite different and that are separated by great expanses of time and space—sometimes by many centuries and by thousands of miles. Some ancient panpipes found in what is now Peru, for example, are tuned in the same way as some much more recent ones found in Oceania, and quite similar spiral motifs appear over a period of thousands of years in the arts of Europe, Asia, Melanesia, and North and South America. Diffusionists tend to assume that transmission, perhaps by accident, must have occurred at some unknown moment; and their assumptions are apt to be plausible in proportion to the complexity of the elements in question: the similarity of tuning systems, for instance, is harder to explain as independent invention than is the similarity of simple spirals. Antidiffusionists in such cases tend to stress whatever makes the supposed transmission improbable: the length of time involved, the difficulties of travel, and especially the lack of buttressing evidence of cultural contact. Why, they might ask, if certain stylistic motifs were diffused from the Old World to South America, did the potter's wheel fail to be diffused?

To reject, as a majority of anthropologists do, the extreme diffusionist position and to favour the idea of independent invention is to raise the environment problem, with "environment" stretched enough to mean traditional, almost natural tools as well as landscapes, climates, raw materials, and local food supplies. When primitive art is examined in the context of the environment that produced it, a critic may ask what the relationship is between a stone hatchet and a particular kind of sculpture, between the frozen landscape of the north and an Eskimo artist's conception of space, between big game and rock art, between forests and naturalism. Clearly, similar questions may be asked about any kind of art, but they are particularly important in the study of the primitive kind because of the isolation of primitive societies and their close contact with nature. And the answers are not always as obvious as they may at first seem.

The "environment" problem

The problem of aesthetic psychology may arise in connection with almost any aspect of primitive art, but it arises with a special force if it is suspected, as many investigators have suspected, that the minds of primitive artists and of their publics do not work in quite the same way as the minds of elite artists and publics. It has been argued, for instance, on the basis of incomplete but interesting evidence, that primitive societies do not possess a concept of art or that at least they do not possess anything comparable to the art concept of nonprimitive societies. One wonders then, whether they can be properly said to produce art. Again, it has been argued that the nearly abstract and schematic representations common in primitive visual art are, supposedly along with the drawings of children, "ideoplastic" in character; in other words, the artist depicts what he knows or thinks and not what he actually sees. If this is so (and, according to Gestalt psychology, it may not be), many of the criteria used in elite art are not appropriate in the primitive kind.

External relations. Evolutionism, diffusionism, environmentalism, and "ideoplasticism" are matters for the scholarly interpreter of primitive art. A problem of a different sort is posed by what happens when a primitive society undergoes modifications through contact with theoretically more advanced societies—when it undergoes, to use the technical term, acculturation. With a few temporary exceptions, the local arts in such situations have declined. They have proved to be too closely integrated with the total culture to survive. Even the forms, regarded as pure shapes and patterns, have tended to wither away, like organs deprived of function. Occasionally the forms have had a stimulating and liberating effect on elite artists, the best known example being the effect of African sculpture on European Cubists such as Pablo Picasso. Occasionally, too, the forms have been given a new content, often Christian or Western secular, in their old localities. But the effect, as a glance at the evidence can reveal, of primitive art on 20th-century elite art has been exaggerated; and the achievements of the new native workshops have been debatable. The sad rule is that primitive art, unlike the elite, folk, and popular kinds, cannot have external relations that go beyond the exchange of a few motifs.

Appreciation and study. Works of primitive art, long regarded as mere curios and then as material for anthropology, have slowly acquired the aesthetic status they deserve. Public collections of the visual productions exist in such institutions as (to name only a representative sample) the Museum of Primitive Art, the American

Museum of Natural History, and the Museum of the American Indian, Heye Foundation, all in New York City; the Field Museum of Natural History, Chicago; the British Museum, London; the Australian Museum, Sydney; the Musée de l'Homme, Paris; the Museo Preistorico Etnografico Luigi Pigorini, Rome; the Rijksmuseum voor Volkenkunde, Leiden, The Netherlands; the Museum für Völkerkunde und Vorgeschichte, Hamburg; Staatliches Museum für Völkerkunde, Munich; Museum für Völkerkunde und Schweizerisches Museum für Völkerkunde Basel, Basel; the Etnografiska Museet, Stockholm; and the museums installed in the new non-European nations. Primitive literature can be found, too rarely, in anthologies of translations; primitive music, often labelled as folk music, can be found on commercial records and in many museums on tape.

FOLK ART

Definitions. Much as a search for a usefully limited meaning for "primitive art" may be hampered by 19th-century prejudices, so a search for a merely descriptive, reasonably factual sense for "folk art" may be hampered by 19th-century sentiments. For, at about the same time that notions of "primitive" were being affected by the theory of unilinear world artistic evolution and by imperialist self-satisfaction, notions of "folk" were being affected by a fondness for the picturesque, by generous impulses toward aesthetic democracy, by the so-called arts and crafts movement, by historicism and philosophical Idealism, by nationalism and regionalism, and by an occasionally aggressive, wildly mystical sort of ethnocentrism. Thus, folk art was defined, if only by the implications of usage, sometimes as almost anything that could be considered quaint; sometimes as all non-elite art, primitive and popular included; sometimes as whatever seemed vaguely homemade; sometimes as the art of the common people, but with the latter regarded as a ghostly entity existing outside of real class structures; and sometimes as a traditional, characteristic art that preserved a cultural heritage and somehow represented the collective soul of a nation or a province.

19th-century notions of folk art

There are some more or less acceptable elements in such definitions. What is missing is a flat enough acknowledgment that folk art is the recognizable product of a nonruling, relatively unaffluent social class and that references to it except in relation to the elite art of a ruling class are meaningless. With this acknowledgment in mind, one can see that talking about a folk kind of art in primitive societies is usually not worthwhile, even though such societies have often had strongly marked class structures. Aristocracies that existed in Polynesia, particularly in Hawaii, did not have a distinct kind of art; they simply had their choice of the better artists. Royal courts in black Africa, with the exception of one at Benin, did not have court styles, although they sometimes insisted on having "noble" materials—bronze, for example, instead of wood or clay. In theory it is possible legitimately to talk about folk art in the great civilizations of the ancient world; but in practice the arts of these civilizations have usually been regarded, for good reasons, as aesthetic wholes. In modern, technologically advanced societies of the 20th century, one encounters the problem of distinguishing between folk and popular, which will be considered below in this article. For the moment it may be enough to point out that Detroit factory workers and New York secretaries are not commonly thought of as belonging to the class called the folk. Nor are city dwellers in general, including those of eras before the 20th century.

A core description of folk art

Putting all these considerations together, one arrives at what can serve as a core description. Unmistakable folk art is the art of a class of peasants, herdsmen, seamen, artisans, and small tradesmen living as a rule away from urban centres in societies that, while literate and highly civilized, are not highly industrialized. Such societies were to be found in Europe, particularly eastern Europe, until well into the 20th century, and they will still exist, of course, on other continents. Where they no longer exist, the term folk may still be appropriate for the art of social or ethnic minorities that have preserved earlier traits by living apart, culturally and often physically. More doubtfully, the term may be extended to certain traditional artistic productions—especially those associated with carnivals, national holidays, religious processions, and the like—that are the work of thoroughly unfolkish city people. But to go much further, to label as folk art everything from an American Indian buffalo robe to a comic strip, is to obliterate a valuable set of distinctions.

Typical productions. Although the folk kind of art is invariably produced, according to the only definition that makes serviceable sense, in a culture that also produces the elite kind for a ruling class, the usual elite classification of the arts into the fine, or independent, and the useful, or decorative or dependent, is pretty much ignored by folk visual artists, who are typically willing to devote their creative imaginations to the design or decoration of tools, toys, furniture, cottages, clothes, arms, banners, musical instruments, and so on. The portrait of a Spanish patron saint may appear in embroidery; narrative pictures belonging, according to the European academic classification, to the elevated "history" category are painted on Sicilian carts. Something of the same mixture of the so-called high and low is typical of folk literature, music, and dancing: tragedy takes ballad form and a noble war dance the form of a Highland fling.

Artists and patrons. In some ways the usual folk artist can be called an amateur. He lacks professional training, he normally has a second, more remunerative occupation, and he creates primarily for his own pleasure and needs or at most for those of acquaintances in his own small locality. But in other ways he is quite unlike an amateur artist in a nonfolkish social context. He is apt to work strictly within the limits of a traditional formula, he often remains anonymous, and often he is an artisan who carries over into his works of art his everyday skill. Amateur is not quite the word for a blacksmith who designs a fantastic shop sign in wrought iron nor for a baker who turns out figurines.

Materials and techniques. Works of visual folk art are rarely executed in anything except readily available, fairly inexpensive materials. A sculptor is likely to work not in marble or bronze but, rather, in wood, iron, clay, straw, ice, sugar, or whatever else is at hand; a painter may substitute an old board for the elite artist's canvas or special paper. Perhaps because of this situation and perhaps because of the already mentioned tendency to ignore the separateness of fine art, the folkish creator displays little of the elite (or, for different reasons, the primitive) concern to employ a specific technique for a specific material—to respect what a French art historian has called the vocation of each sort of artistic material. Folk wooden sculpture may be carved in a manner suitable for granite; painting may be done in an approximation of embroidery technique; pottery may bear incised patterns borrowed from metalwork or basketry; and almost any material is apt to be disguised under bright colours.

Meanings and functions. Although the folk, defined as a class, live in nonprimitive societies, they are more or less isolated from the urban centres in which cultural change may be relatively rapid; and in their predominantly rural environments they are close to nature and to the basic birth-to-death cycle of human existence. Hence folk art is strongly conservative and preservative; in fact, it is often referred to as simply traditional art (with the unfortunate implication that other kinds of art do not possess traditions). It acts as a repository for proverbial wisdom, ancient superstitions, sentimental themes, and religious beliefs that may have long since ceased to be orthodox; it accompanies and celebrates what is repetitive in the lives of individuals and of communities—baptisms, marriages, funerals, anniversaries, sowings, reapings, and the daily routine of work. Often it preserves customs the meanings of which have been largely forgotten; the colouring of Easter eggs and the decorating of Christmas trees are familiar examples. Often, too, the old meanings are given an unexpected twist by a naïve or eccentric artist. But, on the whole, folk art functions within its sphere, as does primitive art in an entire society, on the

Conservative and preservative qualities in folk art

side of continuity and social stability; and there is some justification for 19th-century talk about the expression of a collective "soul."

The "soul," however, is not so much that of a nation, a race, or a province as that of a social and economic class. The best folk art reflects the common sense, unpretentiousness, humour, and peculiar slyness of humble people in contact with small, hard realities; and not infrequently it reflects hostility toward the rich and powerful. In folk depictions of the Nativity, a gift bearer may bring not frankincense and myrrh but, instead, a jacket for the baby Jesus; in a harvest song, one may suddenly be informed that "the gentlemen," not the corn, are about to be mowed.

Styles. Encouraged by local patriotism, scholars have divided folk art into mostly national and regional styles: English, French, German, or Spanish folk music, Breton, Provençal, or Balkan costumes, Pennsylvania Dutch decorations, Mexican processional figures, and so on. This sort of classification is justified by the remarkable traditional and settled nature of much of folk art. But it should not be allowed to obscure, as it frequently does, the existence of other sorts of style, nor should it suggest that these national and regional manners are without histories. There are Jewish, Christian, Islāmic, and other religious folk styles; mountain, valley, and seaboard styles; classical, romantic, realistic, fantastic, and expressionistic styles; and naturalistic and abstract styles. There are period styles; in fact, a sizable number of vaguely ahistorical-looking provincial folk styles are arrested styles of the 18th and early 19th centuries.

Special problems. Diffusionism, environmentalism, and related theories have aroused polemicists in the field of folk art as well as those in primitive art. But perhaps stronger feelings can be, or have been, stirred among folk-art specialists by theories that attempt to answer the two rather loaded questions of how folk art is created and, second, what the difference is between a folk art and a folkcraft.

Theories about the creation of folk art

The first question has some of its roots in the facts that the adjective folk may connote "communal" and that folk art is often the work of unknown creators. Other, probably more important, roots lie in the fact that, by the beginning of the 19th century, German Romantic thinkers were committed to myths (at that time fairly harmless) about the collective spirit, or virtue, of a nation or a race. The result was the idea, set forth with varying degrees of explicitness, that folk art—in particular, poems, melodies, and dances—was a communal creation. This idea was eventually replaced by a theory of communal re-creation or communal growth in situations in which the work of an individual poet, singer, or dancer is preserved only in memories and is modified as it passes from locality to locality and from generation to generation. In the meantime another largely German idea, that of cultural sinking, was provoking argument. According to this idea, folk art—visual art in particular—is derived, after a lapse of several decades or even several centuries, from the elite art of a ruling class; thus a Crucifixion carved by a 19th-century Breton peasant is explained as a late-provincial imitation of the 17th-century Baroque of Paris and Versailles. On all these matters the opinion of a majority of modern scholars is apt to be conciliatory. Although collective improvisation is not impossible, the original creator of a work of folk art is practically always a single artist. But it is possible to grant that a good deal of communal re-creation occurs in literature, music, and the dance and that in the folk visual arts the role of the individual creator, subject as he is to the demands of tradition and function, is not as decisive as it is in elite art. Again, it can be granted that folk art is often a belated borrowing from elite. But this need not prevent recognition of the fact that the folk as a class have their own traditional themes and forms.

Difference between a folk art and a folkcraft

The question about the difference between a folk art and a folkcraft is partly philosophical (which is not a reason for neglecting it) and partly quite practical, at least for museum curators who must classify exhibits, for specialists interested in a proper division of labour, and for modern educators or animators who want to continue the 19th-century arts and crafts movement. It has been argued that, where an artist creates, a craftsman merely fabricates; that, whereas the first is a nonmaterialist who makes something for the sake of expression or of disinterested contemplation, the second is a materialist who makes something for a definite function; and that, whereas the first cannot know exactly what he is going to produce, the second has an extremely precise foreknowledge accompanied by a plan and a method of execution. On this argument many alleged works of folk art can be dismissed as works of mere craft. But the argument is challengeable, partly on the familiar ground that art is in the eye of the beholder.

External relations. Although folk art, as was pointed out above, may borrow from elite and although it may also lend motifs to everybody from classical musicians to modern dress designers, it has proved incapable of surviving in the world of 20th-century industry and communications. Like primitive art, it can live only in isolation. Unlike primitive, however, it has demonstrated, particularly in the performing arts, an extraordinary ability to transform itself into a special branch of popular—which will be discussed below.

Appreciation and study. Many of the museums of primitive art listed at the close of the previous section also have collections of folk works. Other material can be found in such institutions as the Metropolitan Museum of Art (American Wing), the New York Historical Society Museum, the Brooklyn Museum, and the Jewish Museum, all in New York City; the Library of Congress (Folklore Section) and the Smithsonian Institution, both in Washington, D.C.; the Southwest Museum, Los Angeles; various museums of American state historical societies; the Royal Ontario Museum, Toronto; the Museo Nacional de Artes e Industrias Populares, Mexico City; the Cuming, Horniman, and Geffrye museums, London; the Royal Scottish Museum and the National Museum of Antiquities of Scotland, Edinburgh; the National Museum of Wales, Cardiff; the Musée des Arts et Traditions Populaires, Paris; the Norsk Folkemuseum, Oslo; the Museu de Arte Popular, Lisbon; the Museo de Artes Populares, Barcelona; the Museo Nazionale delle Arti e Tradizioni Popolari, Rome; the Museum für Völkskunde (Staatliche Museen), Berlin; the Folk Art Museum and the National Museum of the Peoples of the U.S.S.R., Moscow; museums in all the Balkan capitals; the Crafts Museum, New Delhi; the Folkcraft Art Museum, Tokyo; and the Canton Peasants' Institute, Canton. Folk art in something like original surroundings is on view in such restored or reconstructed places as Colonial Williamsburg, Virginia; Greenfield Village, Dearborn, Michigan; the Pueblo Español in Barcelona, Spain; Pérouges, France; Skansen, Stockholm; and the "villages" that are a regular feature of world fairs. National and provincial folk music and literature have been extensively collected on records and in books. Folk dancing has been revived, or simply preserved, in many countries.

POPULAR ART

Definitions. As might be gathered from the names of some of the museums mentioned above and from countless books, articles, and conversations, it is not likely that art officials, critics, historians, and ordinary appreciators will soon be using "popular" in a very limited sense. Since the word can mean merely "commonly approved, or widely liked," it may be applied to the "Mona Lisa," the ballad "Barbara Allen," Pueblo pots, and television shows. It, or its Romance-language equivalent, has been employed frequently by English scholars, and quite regularly by French, Italian, Spanish, and Portuguese scholars, to designate what is called "folk" in the present article. In Germany the situation has been somewhat reversed, the word for "folk" being employed to embrace what many Americans are inclined to think of as "popular." Style-term coinage has added to the confusion: around 1960 the expression "Pop art" became current in the United States and Europe for what, in spite of an iconography derived from such sources as billboards and

comic strips, was distinctly a phase of elite modernism, not a whit more "commonly approved, or widely liked" than any other prominent avant-garde movement. Cultural improvers have contributed: in many places "popular" theatre does not mean an absence of elite classics but simply a lowering of admission prices. Politicians have intervened: in some totalitarian regimes "popular" means what is "commonly approved" by the government.

The examples could be multiplied. In the realm of common usage, there is not any point in even attempting to limit the sense of such a term. But there is indeed a point in the context of serious discussion of art. For there is clearly a kind of art that is neither elite nor primitive nor folkish. It is a kind whose central characteristics can be discerned, however foggy its remote frontiers may be. And the best adjective for it, in the long perspective of history and in the mind of a contemporary observer, is certainly "popular."

Description of popular art

Popular art, in this restricted sense, has probably existed ever since people began to crowd into cities and to form readily accessible mass markets; temple figurines of ancient Mesopotamia might be classified as popular, if one knew a little more about the economics of their production and distribution. But the category emerges into prominence and becomes easily distinguishable from the folk category only with the progress of reproductive technology, first with the invention of printing and then with the development of engraving, lithography, photography, the phonograph, motion pictures, radio, television, and the latest audiovisual equipment. Thus popular art can be summarily described as art intended to be popular in the usual sense—commonly approved or widely liked—among the common people in a literate, technologically advanced society dominated by urban culture. That excludes, on one ground or another, elite, primitive, and folk art. In the qualification "intended" lies the heart of the matter. The actual audience may not count at all in determining how a particular work should be classified. The sale of 1,000,000 records cannot transform a Beethoven sonata into popular art, in this restricted sense; and the box-office failure of a film concocted for millions of viewers does not transform it into elite art.

Typical productions. Although among the older surviving genres of popular art one must cite dancing, fireworks, street spectacles, circus routines, and several other sorts of almost wordless entertainment, the long-term popular trend, at least in Western countries, has been noticeably literary. This is evident not only in the success of popular fiction but also in the directions taken by nonliterary disciplines once they enter the popular category. Painting as such, for example, is relatively unimportant; what the popular audience wants are pictures that tell stories—in woodcuts, lithographs, photographs, comic strips, films, and television dramas. Music as such cannot, of course, be called unimportant; during the 20th century it has become, with the help of records, perhaps the most popular of the popular arts. But it is predominantly music with words.

Artists and patrons. There have been popular artists, including many in the 20th century, who have expressed deeply felt private convictions about the meaning of ordinary human experience; there have been not a few who have employed their talents in defense of what they believed to be justice or the cause of the common man. There have been some who have refused to grant that the customer was always right. A generalization that leaves such artists out of consideration is unfair. Nevertheless, it

Role of the popular artist

can be said that on the whole the popular artist is less committed, both to his work and to any particular set of beliefs, than are his opposite numbers in the elite, primitive, and folk categories. Unlike elite artists, he seldom starves in an attic for the sake of his art. Unlike primitive and folk artists, he is not necessarily integrated with his cultural context, and he is not encumbered with a duty to propitiate occult forces and to preserve tribal or community continuity. He is primarily a professional entertainer. He is constantly tempted to express not what he himself thinks but what he—or his immediate employer—thinks the intended audience thinks.

Materials and techniques. In the fairly remote past the materials of popular art were about the same as those of folk art, and surviving works suggest that popular artists often had a folkish lack of the primitive and elite concern to adopt specific techniques for specific materials. But the popular artist of more recent times, if he happens to be of the visual sort, is seldom in direct contact with the material of his finished creation; he is merely the first stage in a process of multiplication for a large market. He does not normally engrave the plate, run the press, or cast the statuette. Something similar to this distancing of actual execution occurs in other sorts of popular art, particularly those that have flourished in the 20th century. The singer's material and technique are partly his own and partly those of amplifying or recording equipment; the film maker's are partly people and processes beyond his firm control. The same situation may occur, naturally, in elite art, but there the creator is usually in a better position to assert himself, and so the aesthetic consequences are apt to be different.

Meanings and functions. Since popular art exists in a pluralistic society quite unlike the unified contexts of primitive and folk art and since it is normally intended as light entertainment or simply as a means of making money, all attempts to generalize about its meanings and social or cultural functions may seem futile as well as humourless. Yet it is perhaps almost as "functional" as primitive art and hence notably different, at least in this respect, from elite "contemplative" art. Popular love stories have been one of the bulwarks of monogamy in the Western world for several centuries. There can be little doubt that certain varieties of popular music, powerfully helped by modern publicity, provide young people with a satisfying conviction of belonging to an ingroup and that this conviction makes the intrinsic quality of the music a secondary matter (which is not to say that the quality is always poor). Nor can there be much doubt that a popular television show, like a Melanesian tribal ceremony, may function as a ritual to promote community cohesiveness (which is not to reflect adversely on television viewers or on Melanesians).

Styles. The "functionalism," however, of popular art differs radically from that of the primitive kind, as well as from that of folk art, by being tied, especially under modern technological conditions, to comparatively rapid changes in period style—often to short-lived fashions. In primitive Africa, America, and Oceania and in the backcountry of such a folk province as 19th-century Brittany or Pomerania, there was little that could be properly called fashion; styles might change over long periods, but they were essentially matters of tribe, race, or locality, with variations according to sex, age, class, and occupation. In popular art the situation is more or less reversed; styles are essentially matters of time. And, if 20th-century trends in mass communications, politics, sexuality, and social stratification continue, style differences other than the temporal may disappear entirely from popular art. By the 1970s the styles of popular music were already nearly universal.

Special problems. The majority of commentators would probably agree that all the special problems of popular art concern quality: how an artist can aim at a large market without aiming at the lowest common denominator; how the distancing of execution can be reconciled with the personal touch that is a usual requirement for good art; how local flavour can be preserved as globalism grows; how change itself can be kept from becoming the principal popular style as world history accelerates; and where the point is at which popular art ceases to be art and becomes an instrument for something else. By the last third of the 20th century, these perhaps too familiar, but nonetheless pressing, questions were being regularly discussed by intellectuals, by enlightened public officials, and in what was often significantly referred to as "the industry." Answers, none of which were very confidently offered, ranged from resigned proposals to let-consumers-work-things-out to exhortations to launch a cultural and hence partly economic and political revolution. Sometimes the reformers apparently overlooked the plain

fact that good popular art—the good song hit, cowboy-and-Indian film, comic strip, television series, advertisement (if that qualifies as art), social dance, magazine story, or item of house decoration—might be less rare than pessimists had alleged.

Sources of popular art

Unlike primitive and folk art, the popular kind thrives on technological advances (to which it partly owes its existence), on imported ideas, and on influences from the other aesthetic categories; and it does so not only in the sense of being able to continue an ample production. It has successfully borrowed, for instance, a large number of ideas from both traditional and modern elite painting, for use in illustrations, cartoons, magazine layouts, printed advertisements, and window displays. The latest device of an avant-garde film director is almost certain to appear, after a delay of a few years, in family movies and on the television screen. Perhaps the most effective tricks in the popular fiction of a given decade are borrowings from the elite fiction of a generation or two earlier. But the best example of this sort of aesthetic appropriation is the already mentioned incorporation and transformation of folk music; there is a vast amount of popular song and popular dance music that owes its charm and vitality to old ballads, exotic traditional tunes, and rustic rhythms. Often the content as well as the form may be adopted and adapted; thus a peasant's complaint about the Hundred Years' War may turn up as a protest song of the 20th century.

Scholarly interest in popular art is much more recent than that in the primitive and folk kinds, and much of it has been strictly sociological. Collecting has been neglected, for the evident reason that the material has seemed, until too late, to be everywhere. Many museums of folk visual art, however, have preserved examples of early popular, usualy from the 18th or 19th century. Old popular songs have been recorded or re-recorded. And of course the serious student of contemporary popular has only to look and listen.

BIBLIOGRAPHY

Primitive art: FRANZ BOAS, *Primitive Art*, new ed. (1955), stresses environment, techniques, and functions. LEONHARD ADAM, *Primitive Art*, rev. 3rd ed. (1954), defines his subject broadly enough to include both prehistoric and children's art. PAUL S. WINGERT, *Primitive Art* (1962), investigates physical, psychological, and social backgrounds and closely analyzes styles in Africa, Oceania, and North America; the result is an excellent general introduction. ANDRES LOMMEL, *Prehistoric and Primitive Man* (1966), stresses diffusion. Two useful anthologies offering a variety of viewpoints are DOUGLAS FRASER (ed.), *The Many Faces of Primitive Art* (1966); and CHARLOTTE M. OTTEN (ed.), *Anthopology and Art* (1971). CLAUDE LEVI-STRAUSS, *La Pensée sauvage* (1962; Eng. trans., *The Savage Mind*, 1966), provides fresh insights into the mentality behind primitive art. ALAN P. MERRIAM, *The Anthropology of Music* (1964), helps to correct the tendency of many anthropologists to emphasize visual material. Primitive literature is usually examined in works on folklore.

Folk art: MAMIE HARMON, GIUSEPPE COCCHIARA, and ALESSANDRO MARABOTTINI MARABOTTI, "Folk Art," in the *Encyclopedia of World Art*, vol. 5, col. 452–483 (1961), present a broad, book-length theoretical survey focussed on visual art. A comprehensive work focussed on literature is MARIA LEACH (ed.), *Funk and Wagnalls Standard Dictionary of Folklore, Mythology and Legend* (1949). BRUNO NETTL, *Folk and Traditional Music of the Western Continents* (1956), offers much general theory in the course of treating his specific subject.

Popular Art: NORMAN JACOBS (ed.), *Culture for the Millions?* (1964), presents opinions expressed in a wide-ranging symposium on the situation in the United States. MARSHALL MCLUHAN, *Understanding Media* (1964), probes in a controversial way the effects of technology. Of general interest but with a British slant are the chapters on the 20th-century best-seller and on mass communications, respectively by P.N. FURBANK and RICHARD HOGGART, in BORIS FORD (ed.), *The Modern Age* (1963). For more specific treatments, see STUART HALL and PADDY WHANNEL, *The Popular Arts* (1964); and DAVID EWEN, *History of Popular Music* (1961).

Primitive Law

Whereas civilized law is the law of societies whose cultures include writing and archaic law is the law of early civilizations, primitive law is the law of nonliterate peoples. Studies of civilized and archaic law are centuries old. Primitive law is a recent field of study, pursued to some extent by lawyers with an interest in comparative legal systems but primarily by anthropologists. Increasingly this field has also drawn the attention of political scientists and government administrators, especially those working in newly formed nations made up of several previously autonomous tribes or societies.

The general findings of anthropological jurisprudence show that all societies have legal systems. In all known societies disputes are governed by definitely understood, though frequently unstated, rules—with machinery and personnel to enforce them. Offenses are variously defined and handled from society to society, with a few "crimes" being almost universal. There are differences, also, in types of penalties and in the selection of persons responsible for the administration of justice. All legal systems, primitive and modern, are based on the social need to keep the group effectively and reasonably harmonious. All are dynamic and constantly changing in response to basic changes within the culture, although different societies show varying degrees of capacity for adaptation.

CULTURE, CUSTOM, AND LAW

Law distinguished from custom

Law is an aspect of culture. Culture as defined by anthropologists is the integrated sum total of learned behaviour traits characteristic of the members of a society. It constitutes a people's lifeway; it shapes their world view, modes of food getting, personal beliefs, government, religion, law, forms of housing, and technology. Through culture, each human society develops standardized modes of action on which individual behaviour is to be patterned. Such patterns of behaviour, called social norms, are popularly known as customs.

Customs or social norms are sanctioned; they are supported by rewards or penalties for conformity or nonconformity. While the potential range of human activities is enormous, organized social living requires restriction of the range of behaviour that may be allowed expression. Controls, therefore, are instituted to induce people to act in accordance with prescribed norms.

Law is a limited and special part of the system of social control, but it is never the entire system. This is an important and frequently overlooked point. Any discussion of law must take for granted a host of extralegal mechanisms such as child rearing, education, religious taboo, and other controls over behaviour. All are more fundamental than law. Law comes into play when there is disagreement among the members of the society over relations, rights, and duties or when individuals ignore the rights and expectancies of others to such a degree that formal steps are required to restore disrupted relations and to discourage repetition of the behaviour in question.

Although law differs from custom, not all students agree on what the distinctions are. Perhaps it is enough to say that law employs economic or physical sanctions in support of selected norms. The law has teeth that can bite. It consists of the network of social norms from which deviation—beyond that which may be allowed by the society—is controlled by the exaction of economic or physical penalties, according to norms of due process, by persons exercising the authority to carry out such processes. The norms to be enforced constitute the rules of substantive law, whereas those governing procedure and legitimacy constitute the rules of due process and allocation of authority. Substantive law comprises what is to be supported and enforced by the law; the rules of due process define how it is to be enforced. The allocation of authority determines the possessor of the legitimate authority to enforce such rules. It is this principle of legitimacy that separates legal force from mere violence.

SUBSTANTIVE AND PROCEDURAL LAW

Legal offenses

The content of substantive law varies tremendously among primitive societies. Two features, however, are

almost universal: homicide within the group is legally punishable everywhere; adultery, with a few possible exceptions, also comes universally within the scope of legal action. It should be noted, however, that what constitutes illegal homicide and adultery varies among different peoples. Among the Eskimo, the killing of infants, old people, and invalids, for example, is legally privileged if committed by a relative or close friend. Among these people sexual intercourse between a married woman and a man to whom she has been lent by her husband is not illegal adultery; on the other hand, it is definitely illegal if the husband has not given at least his implicit permission.

Sorcery, or detrimental witchcraft, is also a widespread object of legal control among primitive societies. Apparently, sorcery is seen as a form of vicarious homicide and aggression against the well-being of another.

Theft, interestingly enough, is not always a subject of major concern in primitive law. Among primitive peoples, access to economic resources is generaly open to all on an equal footing. Furthermore, food and implements tend to be shared freely. Substantive law among primitive food-gatherers and hunters is, therefore, largely concerned with such direct personal offenses as homicide, bodily assault, sorcery, and adultery rather than with goods. Among peoples who have achieved a developed level of farming or animal husbandry, however, the law of property and inheritance burgeons. In such economies there is the development of capital, or productive goods (such as plows or mills), which may be borrowed, lent, purchased—and misappropriated. Entry into contractual relations is common, and unlawful conversion (theft, misappropriation, fraud, etc.) and indebtedness are major causes of litigation in more complex primitive societies.

As cultures and environmental conditions change, new issues and conflicts necessitate different means of resolution. The introduction of the horse from Europe wrought great cultural transformations among the Indians of the American plains. Earlier norms among the Cheyenne had allowed the free borrowing of goods without permission, providing the borrower left an identifiable personal item as notice and security. Eventually, because horse borrowers could move great distances among the camps, this privilege led to abuses and resulted in the lodging of formal complaints by horse owners. This ended the practice of borrowing of horses without asking. An old general norm permitting borrowing was legally modified to accommodate new cultural circumstances.

Sanctions

Primitive legal systems focus much more heavily on ameliorating ruptured social relationships than on exacting vengeance or punishing wrongdoers. Imprisonment is an invention of civilization and has no place in any known primitive society. The death penalty, it is true, is often imposed for homicide, sorcery, and a few other extremely "dangerous" acts, such as incest. Among North American Indians, the Comanches could kill their wives or cut off their noses for adultery or desertion. Cheyennes could expose adulterous wives to mass rape. Adultery with the wife of the paramount chief of the African Ashanti was punished by an excrutiatingly long, drawn-out surgical death. Pueblo Indians severely beat minor offenders and executed serious deviants. The henchmen of Trobriand Island chieftains executed upstarts who insulted the chief. Exile is used in some tribes and some situations as a substitute for death, but rituals may be used to bring an exile back into the community.

Most legal actions in the majority of primitive societies end in a public restatement of norms and obligations and a symbolic reaffirmation of such obligations through the payment of economic damages. Valuables—be they cattle in Africa; pigs in Melanesia; fine mats in Polynesia; horses and guns among Plains Indians; shell money in Micronesia, Melanesia, and California; or yams in the Trobriands—are tokens of social esteem and rewards for social achievement. When one is deprived of "valuables" to pay damages or fines, he loses social esteem.

Thus, although physical coercion may be the ultimate legal sanction, the more usual sanctions are the exaction of damages in private law (between individuals) and of fines in public law (between the individual and society).

It has often been written that one attribute of law is its universal applicability. This is not entirely true of primitive legal systems, in which the total situation influences the outcome much more than is ideally allowed in Western law systems. Legal norms are rarely absolute; the range of deviation from prescribed norms is often called the "range of permissible leeway." Within this range, some combinations of circumstances and personalities will result in legal sanctioning whereas others will not. In private law, the esteem in which a kinship group holds each individual member is often crucial. Has he fulfilled his kinship duties well and willingly? Does he lend strength to the group? Or is he a shirker and troublemaker? The group will go all out for the valued member; it may not lift a hand for the black sheep. Permissible leeway maintains an elment of uncertainty in law and allows for adaptability in effecting justice and maintaining society.

Permissible leeway

ALLOCATION OF AUTHORITY

In primitive legal systems the authority to initiate and carry through legal actions is commonly vested in the injured party, supported by his kinship group. The private prosecutor is, for the particular occasion and for that offense, an official representative of social authority, even though he wears no constable's badge, policeman's uniform, or judicial robe. A Comanche husband whose wife had run off with another man could himself, for example, take formal legal steps to collect damages from the absconder; if he was too weak a person, a kinsman or other brave warrior could act as prosecutor for him. Although there might be much pushing and hauling in the negotiating process, every recorded Comanche case of adultery and wife absconding in the 19th century resulted in the payment of damages by the offender; and no chiefs entered into these cases.

Such social allocation of authority to private individuals and kinship groups is a primitive form of private law. In its extreme form, it exists in a number of hunting and gathering tribes as a "self-help" process without the involvement of mediators. Usually, however, it operates with a "third party," a person or group of persons who enter the dispute-settlement process as negotiators, mediators, arbitrators, or judges. The negotiator, or mediator, like the Ifugao *monkalun* in Luzon in the Philippines, facilitates settlement through persuasion. He may, however, threaten to throw the whole force of his powerful family against a disputant who violates the norms of procedure. Or he may, like the priest of the earth among the African Nuer, threaten to curse the whole kinship group that refuses to accept a reasonable settlement of a serious case. Failure to come to terms in a dispute involving a just claim that has been legitimately prosecuted may finally lead to physical compulsion. It has been reported that among the Ifugao, if the dispute is not resolved, the culprit may be slain, especially if a *monkalun* has been involved; in such a case, public opinion will usually support the action and the slain person's family usually will not retaliate.

The role of judge

The role of judge among primitive societies is usually implicit in chieftainship; indeed, decision-making authority, in both the executive and the judicial capacity, is one major attribute of "chief" and "king" as opposed to the "headman" of systems that are not politically centralized. Chiefs are infused with the symbolic identity of the corporate wholeness of their societies and as such their authority is endowed with legitimacy. The whole society may be so symbolized in the person of the chief that offenses against the person of the chief no longer are seen as private wrongs but as crimes against the society. Offenses increasingly are looked upon as breaches of the king's peace. The scope of royal courts may widen. Centralized political and judicial authority may develop, based on factors other than the dominance of a kinship group. Among the Cheyenne Indians, for example, such authority was vested in a tribal council of chieftains. The heads of military fraternities also directed legal actions on behalf of the entire tribe. Among the Pueblo Indians in the southwestern U.S., the central legal authority resides in a

high priest, cacique (chief), and in a council of ranking priests of the religious fraternities.

The foregoing discussion has dealt with legal systems that are self-determining. Each of them has been developed over time by a primitive people for its own social purposes in consonance with its own culturally defined goals. The law of such systems may be called *organic*.

There have been, however, a number of primitive states in Africa, Asia, and Middle America that have lived by conquest. Conquered tribes were incorporated into a sociopolitical structure dominated by the conquerors, who often imposed legal restraints upon the subject peoples that were not of the latter's making. Such law is *tyrannic*. By definition, tyrannic law consists of a network of regulations imposed by a social group possessing the raw power to establish norms and to enforce them. Power is seized; authority is not allocated as a socially recognized privilege or right.

Feud and law

Although primitive legal systems have well-developed concepts of due process, these do not function very well in the area of private law. Private law involves direct negotiation by parties in disagreement, and in primitive law the defendant must agree to some form of punishment or restitution or there can be no settlement. If the defendant is recalcitrant, perhaps to unreasonable demands, procedure breaks down. The defendant may deny further suit and possibly incur physical attack by the plaintiff. If the defendant has indicated that he rejects the legitimacy of the claim, he will deny the plaintiff's right to resort to force. Feud or internecine war may result.

Feud is a state of conflict between two kinship groups within a society, typified by a series of illegal killings and counterkillings between the kinship groups, usually initiated in response to an original homicide or other grievous injury. Legal historians traditionally have seen primitive society as marked by a constant state of feud, as rent by violent retaliation and blood revenge, and, in general, as an arena of violence ruled by the law of the jungle and the retaliative lex talionis ("eye for eye, tooth for tooth").

There is very limited evidence for this. Legal procedures or ritual devices such as regulated combat that are used as a means of avoiding or terminating feuds have been universally found to exist in such cultures. Even when feud is a reported institution in primitive cultures, there is usually little or no empirical evidence that it actually takes place. An example would be the case of the Trobriand Islanders, for whom it was reported that although honour made "vendetta" obligatory in cases of homicide, it was evaded by the substitution of blood money (compensation). There was much talk of feud but no evidence of specific cases.

If there are strong grounds for doubting that feud occurs with anything like the frequency so often supposed, there is no question but that the folk belief in feud is widespread. The belief is a folk phenomenon in its own right. Real feud is socially destructive and dangerous. When it does occur, it represents a breakdown of the technique of peaceful resolution of conflict. Among the Northwest Coast Indians of North America, the threat of violence was not always enough to insure the success of negotiations; often feud was the result.

Law exists everywhere to preclude the recourse to bloody battles within societies. Folk belief in the expected requirements of honour to engage in feud is often countered by a stark recognition of the effects of feud. It seems quite likely that this very fear of feud is one of the factors that nourishes and sustains primitive legal systems.

THE EVOLUTION OF LAW

The greatest contrast between primitive and civilized law is in the area of procedure and is based largely on differences in social structure. The simpler primitive societies are characterized by decentralized units of organization lacking overall political authority. Each kindred, lineage, or clan has considerable autonomy, and headmen and elders function as leaders and guides to the group's activities. When several kinship groups exist in a village, the elders may form a village council, and one of them may also serve as village headman or chief. The scope of such village or tribal authority is, however, usually limited when compared to the autonomy of the kinship groups.

In primitive law the primary authority for most legal actions is the kinship group working in support of its individual members. Hence, private law dominates most primitive law. At the same time, almost every primitive society recognizes some acts as legally punishable by the society at large or through explicitly delegated officials. Illegal acts punished by public prosecution are crimes, as against the torts of private law.

The major trend in the development of law from the most primitive societies to the most civilized is in the direction of a shift of the right to prosecute and impose sanctions; this right is transferred from the wronged individual and the kinship group to officials representing the general society. As cities emerged in the Mediterranean area, urban migrants representing a huge variety of tribal legal systems became detached from their tribal moral orders and kinship groups. The need for law generated elaborate legal systems promulgated and managed by the ruling elite of priests and warriors. The legal person became *citizen* rather than *kinsman*.

Four functions of law

All legal systems perform four functions essential to the maintenance of societies and their cultures. First, they determine obligatory relations among the members of a society, making clear which activities are permitted and which are ruled out. Second, they allocate authority and designate who may initiate and carry through legitimate corrective actions leading to economic or physical sanctions when norms are violated. Third, they dispose of troublesome cases as they arise so that social harmony may be re-established. Fourth, they continually redefine relations among the members of the society as the conditions of life change, in order to maintain adaptability in the substantive and procedural law.

Primitive law and modernization

Primitive legal systems have been strongly affected by the impact of modern legal systems. As of 1970 only a handful of primitive societies in the Amazon Basin and perhaps a hundred or more in the interior of New Guinea had not been brought under the nominal administrative control of some national state. Colonial and national administration of law with respect to tribal societies has varied considerably in policy and application.

In Africa, the British ruled by "dual mandate" through the first half of the 20th century. In native affairs indigenous headmen and chiefs were permitted to administer their own courts in accordance with tribal law and custom (except for the death sentence) and in cases that were not contrary to public policy or to "natural law and justice." Their decisions were subject to appeal and review by British authority. In later years, when people like the Nuer and Tiv had no indigenous courts, the British provided for their organization. Systems of folk law were on the whole retained and kept in reasonable consonance with the values and forms of tribal social organization.

In the Dutch East Indies, adat (customary) law was likewise continued for Indonesian village communities.

In India, following the Mutiny of 1857, law was codified for British India upon the model of English common law, modified somewhat to accommodate the social conditions of India. Religious and family law was reserved to Hindu and Muslim law, according to the religion of the disputants.

In the French colonies, the French civil and criminal codes were said to be universally applied.

In the United States, from 1832 to 1953, all Indian tribes were legally recognized as "domestic dependent nations," not subject to the laws of the states in which they were located. Except for 11 major crimes brought under federal jurisdiction by acts of Congress, each tribe retained its own legal jurisdiction over its members as long as they were within reservation boundaries. In 1968, the Civil Rights Act for Indians introduced the Bill of Rights into Indian tribal procedure for the first time.

The importance of anthropological study of tribal law systems for administrative and legislative guidance of national lawmakers should be self-evident. Much damage to family and community life could be spared if national law were adapted to the living law of the various peoples that make up the nation. The urge to use law as a unifying

force in newly developing nations raises the problem anew: it may be seen in every postcolonial nation of Africa and Asia, and it reaches bizarre proportions in the Territory of Papua and New Guinea, where a population of 2,300,000, composed of several thousand indigenously independent peoples, speaks an estimated 700 distinct languages and dialects.

World law as primitive law

International law has been termed primitive law on the level of world society. What passes as international law consists of a considerable body of substantive rules for the conduct of affairs between nations, recognized by tacit concensus or agreed upon in conventions, pacts, and treaties or verbalized in arbitration awards, rare World Court awards, and United Nations resolutions. But this body of norms has as yet no supporting sanctions other than withdrawal of reciprocal services, damage to national reputation, the threat of feud (war), and the waging of war. Force and the threat of force have not yet been brought under control by and for organized world society.

(E.A.H.)

Primitive Religion

Because of the misleading connotations of the term primitive, most present-day scholars hesitate to classify any religious phenomena as primitive. Nevertheless, for lack of a satisfactory substitute, "primitive religion" still appears in the title of many books and articles. In a study by E.E. Evans-Pritchard, an outstanding contemporary anthropologist, *Theories of Primitive Religion* (1965), primitive religion means the religion of peoples "living in small scale societies with a simple material culture and lacking literature." The term is generally used in this article in that sense, but other meanings that have been attached to it are also considered, particularly those that refer to the elements and basic forms of religious experience and behaviour, whether historical or psychological. Those beliefs and practices that have been labelled "primitive" are still of central interest to students of religion in general and, in many cases, are still very much alive today.

NATURE AND SIGNIFICANCE OF "PRIMITIVE" RELIGION

Importance and influence of the study of primitive religion. The religions considered "nonprimitive"—*e.g.*, Judaism, Islām, Christianity, and Buddhism—are characterized by literate theological and philosophical traditions, even though their adherents are often neither literate nor educated in the literature of their faiths. These religions, however, represent only a fraction of the total religious experience and expression of mankind, which have been mainly "primitive." "Primitive" religion then claims attention as representing the religions of most human beings for most of human history; and, though followers of supposedly "advanced" religions have often looked down on these "primitive" faiths, the more philosophically and sociologically minded have also sought to learn something essential about the nature of man and divinity from them.

The basic form of human religion

During the 18th- and 19th-century confrontations between a religious and a scientific view of the world, when the validity of all religious belief became a matter of general dispute, the nature of the primitive religion that supposedly underlay and preceded all formal creeds became a subject of central interest. Primitive religious belief and practice could be invoked either to demonstrate that all religion was based on delusion or that since men had always been religious, religion must relate to the deepest realities of human nature and of the universe.

Thus, many writers whose influence is still widely diffused in intellectual life made use of information about primitive religion. In theology it was notably represented in the voluminous writings of a German priest and anthropologist, Wilhelm Schmidt (1868-1954), and his school, in which it was ultimately held to corroborate orthodox Christian doctrine. In political and social theory, Friederich Engels drew upon the religions of North American Indians in *The Origins of the Family, Private Property and the State* (1902), and Karl Marx must have been acquainted with such information. His view of the essentially social nature of religious sentiment has been widely shared by students of primitive religion. Sigmund Freud and Carl Jung, the outstanding innovators in psychology, brought primitive myth and symbolism into the mainstream of psychoanalytic theory, Freud's *Totem and Taboo* (1913) in particular basing its argument upon what was then known of Australian Aboriginal religion. Through classical scholars like Jane Harrison and Gilbert Murray, the living religions of then remote societies were brought to bear on the interpretation of Greek and Roman texts; and the distinguished Sanskrit scholar and philologist Max Müller referred to African and other beliefs in his works on mythology and language. In creative literature the characteristically modern writers of this century—*e.g.*, T.S. Eliot, Ezra Pound, D.H. Lawrence, and W.B. Yeats—received some inspiration from accounts of primitive religious experience; and in more popular literature, writers of adventure stories—*e.g.*, Henry Rider Haggard, perhaps the best informed—exploited anthropological sources with varying degrees of sensationalism, as they still continue to do. Behind the use all these writers made of anthropological knowledge were scholars who collected, organized, and sifted information, especially in the English-speaking world (see below *Development of the study of primitive religion*).

Effect on imaginative literature

The problematic meanings of the term primitive and suggested substitutes. The word primitive has had pejorative overtones, intensified by 19th-century reconstructions of human evolution that placed primitive man low in a scale of human development from prehuman ancestry to contemporary civilization. Thus used, the term constantly confuses what is historically primary with what is psychologically immature, the early with the crude or simple, and for this reason various substitutes are often used in modern writings. Thus "ethnic," tribal," "preliterate," "preindustrial," "small-scale," and now "underdeveloped" and "developing" appear where once "primitive" would have unhesitatingly been accepted. Any one of these may well be somewhat more suitable in a particular study of a particular people. In a short general survey one must retain the older term, but it may still be necessary to state that, for serious students of the subject, primitive religion, far from connoting "savage" superstitions, exhibits the very basis of man's religious constitution, to which the professional theologians and philosophers have but added their own systematic rationalizations. Thus, although William James in *The Varieties of Religious Experience* (1902) has nothing to say about the religions considered below, he shares something of the spirit in which they are now studied in pleading for more attention to be paid to the religious experi-

ence of the common man, as against the highly intellectualized theological constructs of professional thinkers. Attempts to rediscover in primitive religion forms of experience that seemed to have been superseded by scientific materialism and dogmatic religious orthodoxies have also characterized the middle years of this century, two examples being the writings of Henri Frankfort and Mircea Eliade.

Observations of travellers

Development of the study of primitive religion. From classical times observations on the customs, including the religions, of the "barbarians" and "pagans" occur in anthropo-geographical writings, the most famous being those of Herodotus; but these classical and later and fuller medieval references reveal more about the outlook of their authors than about primitive religion. By the Renaissance, travellers' observations on cults and beliefs from distant parts of the world had been further assimilated, if still without much real understanding. What was known of primitive religion was fitted into the biblical and Christian context of belief, where it appeared either as a special category of religion, idolatry, or, as in Sir Thomas More's *Utopia* (1516), was introduced more sympathetically to suggest what "natural" religion without the Christian revelation would be like. The idea that primitive religion started with idolatry, or more precisely with the worship of animals and material objects called by Portuguese voyagers "fetiches," was widespread into the 18th and well into the 19th centuries.

In the 18th century also, with such work as the French Jesuit missionary Joseph-François Lafitau's comparison of the North American Indians with the ancient Hebrews and Egyptians (*Moeurs des sauvages amériquains comparées aux moeurs des premiers temps*, 1724), debate arose as to whether extant primitive religions had emerged independently or represented degenerate and fragmentary survivals of the religion of Genesis. Montesquieu, an 18th-century French philosopher, took primitive religion into account in his sociological history, and the British moral philosopher David Hume (in *The Natural History of Religion*, 1757) argued that monotheism had grown with the growth of human reason out of an original polytheism. Hume's account of the origin of religion in the personification of the unknown causes of natural events has lived on in one or another form until the present day.

But it is to the 19th-century scholars, with their vastly greater knowledge of the peoples of the world, that present-day students more particularly look back. They were obsessed with positing one or another origin for religion, with evolutionary reconstructions of human society and psychology that now have a merely historical interest; but their theories at least encouraged argument and the later effort to test them by accumulating reliable empirical evidence. Two writers who made very substantial contributions to the study were the great English scholars Sir Edward Burnett Tylor and Sir James George Frazer. Tylor, regarding the basis of religion as "a belief in spiritual beings" (a more acceptable view than earlier suppositions that primitive men worshipped material idols), coined the term animism for this primitive faith and argued that man had arrived at the conception of spirits by reflecting on the experience of incorporeality found in his own dreams and the withdrawal of a vital principle, the soul at death. Herbert Spencer, who, especially in the first volume of *The Principles of Sociology* (1896), compiled a great deal of information on primitive religion, came apparently independently to the same conclusion. In *Golden Bough* (1890), probably the most famous single treatise on primitive religion, Frazer proposed a vast scheme of psychological and theological evolution, beginning with magic, for him a primitive attempt to coerce nature by technical acts and formulas, which was replaced by religion, involving the propitiation of unknown forces controlling human destiny, and which was in turn being superseded by modern experimental science.

The great English and French scholars

Such were in principle psychological theories of the primitive basis of religion, but in France Émile Durkheim and his followers (as also W. Robertson Smith in Britain) rather emphasized its social and collective nature. In *The Elementary Forms of the Religious Life* (1915), a still indispensable work, Durkheim saw a totemic belief of the Australian Aborigines as those most elementary forms and suggested that gods, like the totemic clan animals revered by the Aborigines, symbolized and expressed social cohesion. These streams of thought, along with others concerned with the interpretation of primitive mentality, myth, and ritual, meet in the writings of later anthropologists. From early in the 20th century and increasingly during it, direct contact with "primitive" peoples by trained observers with a thorough knowledge of their languages has opened up far deeper channels of enquiry into the refinements and complexities of their thought. Among the immediate forerunners of contemporary studies may be mentioned Bronisław Malinowski, A.R. Radcliffe-Brown, Paul Radin, and Robert H. Lowie, of whom the last two wrote general works on primitive religion.

Although his work is probably less often referred to than theirs, perhaps a more pervasive influence in this century was Lucien Lévy-Bruhl, who in several books argued that primitive thought was prelogical and exhibited an interest in mystical participation with the life of the natural world quite unlike the analytic habit of thought of scientific Western man. It would now be admitted that Lévy-Bruhl underestimated the rational and empirical elements in the thought of his "primitives." He drew attention, nevertheless, to the possibility of approaching their religious propositions and symbolism in their own right as forms of mystical thought and not merely seeing them as a failure to develop the mental procedures of European natural scientists. Work done in the field since the 1940s at least has been more and more concerned with elucidating religious symbolism and (under the impact partly of the widely acclaimed contemporary French anthropologist Claude Lévi-Strauss) with the elaborate analysis of belief and myth, in an attempt, ultimately, to deepen understanding of human thought and imagination through study of its spontaneous expressions in primitive life.

RELIGION IN PRIMITIVE CULTURE

Specific characteristics and functions in primitive communities, life, and thought. The societies that most students of primitive religion have been concerned with are, or were, similar in three principal respects. First, as compared with urban and more particularly industrial cultures, they are small in scale, with a corresponding emphasis on face-to-face, personal relations between their members. Local groups of kin and neighbours play a more significant part in national or tribal life than is the case in modern states, and much of primitive religious belief and practice is bound up with the needs and structure of these local communities.

The three common characteristics

Second, with some important exceptions, they have been economically poor, without great distinctions of wealth, and technologically unable to dominate their natural environment. The close economic interdependence of their members and their ultimate dependence on the forces of nature have important consequences for their religions, which emphasize the communal aspects of human life and common subjection of all men to forces beyond their control.

Third, though often rich in oral tradition, they have lacked written traditions and, with them, the accumulative records of private introspection that eventually produce systematic and formalized philosophy and theology. It is often said, therefore, that they are religions of action rather than of reflection, though this distinction can be over-stressed.

Following from the first point, primitive religion has been said to be largely polytheistic, for there are family gods, clan gods, gods of the local community, and other gods associated with features of the locality and with the needs and shared experience of the local community. The effect of their cults is to bind believers in communions based upon kinship and neighbourhood. To take one example, the highland people of New Guinea present a pattern of many local communities, each with its different

gods; but the gods are of a basically similar kind, and belief and practice are generally uniform over the whole territory.

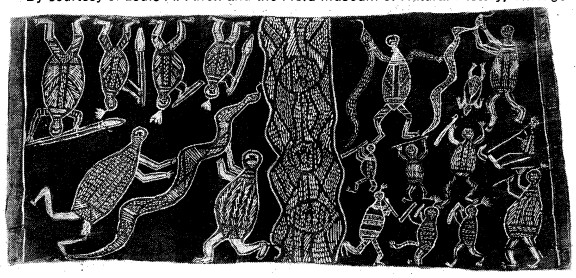
But to say that primitive religion is polytheistic is to disregard other significant and widespread characteristics. Belief in some kind of high god, a transcendent being in whom the nature of divinity in general is conceptually unified, is widely reported, and Wilhelm Schmidt devoted much attention to investigating this aspect of primitive belief. It is often reported that these high gods are too distant from men to concern themselves with local affairs, though a single inclusive concept of divinity emerges when local needs and interests give way to broader national, tribal, and intertribal concerns. It is less usual, however, to find a pantheon with gods or gods and spirits arranged in a fixed hierarchy. The god (or gods) dominant in a particular situation has first place, corresponding to a mode of belief which Max Müller called henotheism (adherence to one god, while acknowledging the existence of others).

The moral sanctions of the gods

The relative lack of centralized coercive secular power in primitive cultures leaves to the gods the important sanctions for correct behaviour. It is not that gods announce moral rules; rather, they support the moral principles traditionally taught by the ancestors with whom they tend to be closely connected. So if a man fails to carry out binding obligations to his kin, his immorality may be corrected by illness, interpreted as divine retribution, more than by other social and merely secular pressures. When the relations between kin form the fabric of local community, this idea of the retributive justice of the gods is a powerful sanction for approved behaviour. Similarly, when comparative and general poverty make for great local interdependence, the belief that the generous man has the blessing of the gods encourages the mutual economic support actually essential for communal survival.

A simple technology and the absence of extensive scientific knowledge mean that many results brought about on the modern world by purely technical acts and events explained in the modern world by tested scientific generalizations are in the primitive world part of the province of religion. Thus, rainmaking ceremonies and rites to promote fertility—*i.e.*, to promote life—are central social concerns. At the individual psychological level, too, religious action gives the reassurance of being able to deal symbolically with suffering and misfortune, of being able to divine truths that men need to know for their own well-being, and of making direct contact, often through spirit possession, with the suprahuman forces believed to affect human health and happiness. Hence the growing study of ethno-psychiatry examines primitive religious belief and ritual seriously with regard to their psychotherapeutic effects.

Various types of religiocultural configurations. In the past many attempts were made to construct typologies of religion, but with increased knowledge it has now become clear that any attempt to divide forms of belief and ritual into mutually exclusive types is bound to do violence to the facts. Thus, such terms as fetishism, animism, totemism, ancestor worship, and shamanism can no longer be regarded as denoting well-defined and distinct modes of religious belief. Rather, certain dominant themes appear in the religions of different societies. So for all peoples contemplation of the dead and, more particularly, of dead ancestors excites some sentiment of piety and often of fear, but the extent to which the ancestral dead are placed at the centre of a religious cult varies greatly from one society to another. An example of a people whose religious outlook is concentrated on the power of ancestral ghosts is that of the Manus of Melanesia, who regard the father's or sometimes some other kinsman's ghost as supervising the affairs of the living household, sometimes protecting and sometimes punishing its members. This Sir Ghost, concretely present in the skull of the person from whom it derives and which his family preserves in the home, is thought in particular to punish sexual transgressions by causing illness. When illness occurs diviners are consulted to discover which Sir Ghost or other ghost is angry. The Manus are fishers and traders, and Sir Ghost also requires the correct fulfillment of economic obligations.



Relation to the dead: ancestral ghosts

A concern with the power of ancestral ghosts, however, is also found among many African peoples whose way of life and systems of morality are very different from those of the Manus and among whom religious service to the dead is combined with cults of nonhuman spirits and gods. The Nuer of the southern Sudan, whose political system is based upon patrilineal descent and who therefore trace their ancestry much further back than do the Manus, have in common with many peoples of the Nile region a belief in the ghostly vengeance of the embittered dead. But here, despite the importance of genealogy, there is no cult of the dead, and graves are not for long remembered. Instead there is a concentration upon an entirely spiritual high god, Kwoth, and many nonhuman spirits who partake of his nature. To these prayers and sacrifice are offered, and diviners are employed to suggest which spirit has caused any particular misfortune. Here the dominant theme of the religion is belief in spirit in numerous manifestations, or "refractions," as they have been called by E.E. Evans-Pritchard. Nuer have little or no interest in the material representation of spiritual forces, in great contrast to the proliferation of images and shrines of the gods found among the Yoruba, the Akan, and many other West African peoples.

Where kingdoms have developed, the cult of kingship, as represented in the king and his ancestors, has often become the dominant theme of religious practice. It was so in ancient Egypt and remains so in many African kingdoms where, just as the kingship itself must not die, the king in person must not appear to die like other men. This sacralization of the king, sometimes as high priest of the nation as, for example, in Ashanti (now in Ghana) and other West African states and sometimes as himself divine, is one of the main interests of Sir James Frazer's *Golden Bough*, which gives examples from many parts of the world and not only from peoples who have been called "primitive."

Among many peoples the commonest cultic practices are centred round certain animals, plants or other species, and sometimes human artifacts. These species are regarded as emblems or material symbols of the spiritual vitality and integrity of particular social groups within the society, and in some cases elaborate myths explain their association with those groups, while ceremonies are performed to further their well-being. This aspect of primitive religion, called totemism (from a North American Indian word) by both past and present writers, was more particularly identified among the Australian Aborigines. There a wide range of species, the totems, are thought to link those who revere them with what they call "the dream-time," which was defined by Adolphus Peter Elkin, an eminent Australian anthropologist, as "the ancient time of the heroes . . . the eternal dream-time of spiritual reality. . . ."

Individual religious experience

But it is not only through totemic observances that this contact with spiritual reality is sought. In some primitive religions (and again, not only the religions of peoples who have been called primitive) the quest for an indi-

vidual spiritual experience that will provide guidance through the dangers of life might be said to be the dominant theme. This is particularly so among some North American Indian groups, where men will prepare themselves for this significant vision by solitude, fasting, and self-mortification. Sometimes also, as in American Peyote cults, drugs are used to produce this vital experience of the ultimate situation of the individual psyche. Widespread also are cults of spirit possession, in which the worshipper invites ultrahuman, spiritual forces to enter his body and speak through him, both to exorcise injurious spiritual influences from himself and from others and to announce truths beyond rational investigation. Emphasis on possession, ecstasy, and exorcism is characteristic of what has been called shamanism (after the Tungus word for "medicine man" in East Siberia) amongst Amerindians, Eskimos and Mongolians, but it is a widespread and apparently increasing feature of many African religions. Shamanism, however, involves special experiences and techniques in some respects different from those of African mediums (see SHAMANISM).

Salient distinctions from or similarities with the advanced religions. Not only is it impossible to differentiate mutually exclusive types of primitive religion (and still less to place them in an evolutionary hierarchy) but also what has been called "primitive" religious practice and belief has far more in common with "advanced" religions than it has apart from them. The literary heritage of the latter does indeed permit the formation of longer and more varied traditions and the incorporation into them of a wider range of individual opinions, intuitions, and experiences, but the oral traditions of nonliterate peoples (which tape recording makes more fully available than ever before) also display a greater depth, range, and consistency within the particular community than had previously been supposed. To take only two examples, *The Myth of the Bagre* from northern Ghana (Jack Goody, ed.; 1972) runs into some 12,000 lines of verse that are memorized in a fixed form as a recapitulation of man's historical relation to the gods, while the priesthood of the Maori of New Zealand has long been known as the repository of a rich historical and religious tradition. Priesthood, prayer, sacrifice, and asceticism, as well as elaborate mystical symbolism and mythological validation are found equally in those religions which have been called primitive and those which are described as advanced. Doctrinal dispute following from wider confrontations of opinion in religious matters is probably much more characteristic of literate religious traditions than of the rest, and it is widely reported of primitive faiths that they make no claim for the exclusive truth of their own teachings. Nor, on the whole, do they have any doctrinal certainty in asserting what happens beyond this life. Their emphasis lies rather on communal well-being than on the cultivation of individual virtue, and their ethical teachings are often less centrally incorporated in religious lore than those of the more moralistic "religions of the book." And as compared with the literary form in which the spiritual beings of those religions often tend to be presented, primitive religions seek and appear to provide direct experience of the power of the gods. It is, of course, a return to some such primal spirituality that revivalists of the "advanced" religions have often sought.

Tradition, institutions, and doctrine

PRIMITIVE WORLD VIEWS

Distinction between sacred and profane. It is commonly accepted in modern western society that religion is concerned with the supernatural; however, as Durkheim recognized, the notion of the supernatural depends upon a notion of the natural as being governed by scientifically established laws, an intellectual construct of a specialized and historically recent kind. Hence, like Durkheim, many students of primitive religion would still hold that religion is not concerned with the supernatural so much as with the sacred—with sacred periods in time, sacred places, and sacred persons set apart from the ordinary flow of common life for special religious attentions. Primitive (and not only primitive) religion, then, would be concerned with the knowledge of sacredness and its protection, and with distinguishing the sacred from its complementary opposite, the profane. For Durkheim, the sacred represented the collective strength and aspirations of the community, experienced in some special periods of time (as in the religious cycle of a church calendar), in some persons (such as priests and kings), and in some places (such as shrines or centres of pilgrimage). All these are connected with rituals and religious prescriptions and proscriptions that do not apply to the daily sequence of ordinary life, to ordinary men, or to ordinary places, which represent the realm of the profane. Also, of course, "to profane" may have the meaning of actively opposing the sacred and, thus, desecrating or polluting. For a comprehensive discussion of the sacred and profane, see SACRED OR HOLY.

Dynamistic, daemonistic, and theistic views of the sacred. A main point of departure for students of the sacred was the Melanesian and Polynesian concept, mana, first noted by Robert Henry Codrington, an English missionary and anthropologist, in a book published in 1891. Like the words totem and tabu (*tapu*), that indigenous term became part of the technical vocabulary of anthropological and religious studies. Mana signifies the intensity of an impersonal force or power attributed to some persons, things, and situations. Mana, Codrington stated,

> is what works to effect everything which is beyond the ordinary power of men, outside the common processes of nature; it is present in the atmosphere of life, attaches itself to persons and things, and is manifested by results which can only be ascribed to its operation.

Mana, animism, and high gods

The apprehension of this ethically neutral sacredness, a spiritually dynamic power, which in some contexts might readily be translated simply as "luck" and in others perhaps as "strong effectiveness," was regarded as the psychological basis of religion.

Closely connected with mana in earlier discussion was the idea of taboo, indicating in its original Polynesian meaning something set apart or forbidden. R.R. Marett, another British anthropologist, considered at length whether mana was a magical or a religious conception and whether taboo was "negative magic" in the sense that "to break a taboo is to set in motion against oneself mystic wonder-making power in one form or another." In any case, for him a belief in mana, a generalized impersonal power, was historically and psychologically prior to animism, a belief in spiritual beings, asserted by Tylor to be the original form of religion. Preanimism (belief in mana) thus gave way to animism, and animism and polytheism, with more advanced thought, were superseded by monotheism. As against this it was argued by some, particularly Wilhelm Schmidt, that many peoples then called "primitive," the Bushmen of the Kalahari Desert and the pygmies of the Congo, for example, had a conception of a supreme god, often associated with the firmament and, hence, a high god. Whether or not primitive religions incorporated the conception of a supreme divinity now appears more a matter of theological and missionary controversy than a scientific problem. The evidence now available shows that some peoples do emphasize the unity and transcendence of divinity more than others and that the same people will stress divine unity and transcendence in some circumstances and divine multiplicity and immanence in others, as, indeed, in the so-called higher religions.

These early attempts to define the fundamental features of "primitive," as distinct from any other religion, have little relevance to contemporary discussion, except that it is from them and from the vocabulary they adopted that the general reader is bound to take his bearings. What they were concerned with, however, were three very profound and perennial themes in religious experience, exposed, as we now see, not only in the "advanced" religions but also in a rich variety of ethnographic literature from all over the world. The first is that of divine unity and divine multiplicity. The second is what may be called the ambivalence of the quality of sacredness. Not only do sacred things, persons, and places both attract men in veneration and keep them at a distance in avoidance and

respect but also the gods themselves often have, from the human point of view, both benevolent and malign aspects. Hence they are sometimes called to help men and others to leave them untroubled. In much of what has been reported of "primitive" religion, the gods, though they may sanction morality, are themselves ethically neutral, uniting the goodness and badness that are recognized as categories of merely human experience, so that what kills men in one context cures them in another. And, finally, there is the theme of man's ultimate passiveness in relation to a universe animated by powers beyond his technical or rational control.

Primitive cosmogonies and cosmologies; sacred time and times, sacred space and places. In the absence of modern astronomy and physics, explanations of the structure of the universe and the origin of the world are incorporated in "primitive" religious teaching. All peoples have some form of cosmology, though not all have the elaborate cosmogenic myths of the evolution of the universe that are characteristic of the religious traditions of ancient Egypt and Mesopotamia. But that the Australian Aborigines, regarded by earlier anthropologists as the most primitive of living men, should have particularly complex cosmological myths that are periodically dramatized in liturgical performance is sufficient to show that primitive religion is far from impoverished (or "primitive") in this respect. Indeed, the myth of Genesis is an unusually simple account of creation, a fact that may well explain how widely men have found it possible to accept it.

Creation myths

Australian Aborigines dancing a tribal myth.

That myth, however, does provide what all cosmological myths incorporate as a central teaching—an account of how the palpable world of a particular population in a particular geographical location emerged from an earlier state regarded as more formless, more constricted, and less diversified. So, for example, in Maori cosmology from New Zealand, as also in much African cosmology, sky and earth are represented as having been originally conjoined. Only when sky and earth are separated (often through some act of the first human beings) does the world as it is now known emerge, with a clear distinction between what is above and what is below, between light and dark, and so on.

From this separation follows one of the major polarities of religious thought and symbolism—that of higher and lower powers and orders of being. With the complementary opposition of sky and earth, high and low, often go other symbolic oppositions: that between male, usually associated with the higher, and female, usually associated with the lower; the earth, often represented indeed as a mother; that between superior strength, particularly intellectual and spiritual strength, and human weakness; and that between light and dark, knowledge and ignorance. Similarly, the complementary oppositions of east and west or of what is on the right hand and what is on the left are commonly associated, respectively, with the auspicious and the inauspicious, the strong and the weak, and life and death. Consequently, in many rituals the east and the right are directions symbolizing birth and vitality, and the west and the left are reminders of death and grief.

As with space, so with time. There are not only the seasons of innumerable religious calendars, often running parallel to and sacralizing the seasonal cycle upon which the well-being of those who live at a subsistence level depends. There are also times of crisis at which special precautions of abstinence must be taken—for example, the exclusion of sexual intercourse before hunting, as among the Lele of the Congo, or in the various periods and forms of abstinence kept by the Crow and other Plains Indians of North America in preparation for their guiding visions. In a sense, as primitive religion seems at least implicitly to acknowledge, all human suffering comes from the limitations imposed upon fulfilling, in the material world dominated for human beings by time and space, the freedom of action that can be present to the imagination.

The cause of suffering

Hence, in many rituals a sacred time is represented. In the individual's experience of time, life ends with death. In the collective and religious representation of time, life and strength are recreated regularly in a repetition of the same cycle of ceremonies. And this sacred time of ritual is accompanied by the sacred spaces and places to which men attribute what values they will: the altar, the shrine, the marking out of the particular area in which rituals are to be held, and the recognized abodes of gods and spirits —all represent the imposition of a special form of order, a sacred order, upon the flux of ordinary spatial and temporal experience. Thus, in "primitive" religions of which the historical provenance is known and recent, such as the Ghost Dance religions of North America or the Christian separatist churches of Africa, the deliberate recreation of time and space in religious terms is found, so that, for example, the return of the ancestors or the coming of a messiah are imminently expected. In general it may be said, however, that an elaborate eschatology (doctrine of the final state of the soul and world) is not a common feature of primitive religions, which fix the attention on the sufferings of this life and usually pretend to little knowledge of any other.

Primitive views of man's nature, origin, vocation, and destiny. In many myths, including the biblical ones, man is represented as having been originally nearer to God than he now is. In some myths he is made by God, as a potter makes a pot, for example. Among the Nilotic Dinka and other African peoples, man at one time had easy access to God, and suffering and death were unknown. But having imagined such a state, which reflects the good fortune and well-being that men even now associate with the necessary help of the gods, many primitive religions concentrate on man's condition as it is now, rather than as it was in the past or on what it might be in some ideal future. When men die, they return to or are merged with the ancestors in conditions of "another world," which is rarely elaborately defined. Man's original destiny, myths frequently suggest, was not to die, but what happened to bring death to him in the beginning cannot be reversed. His own vocation is to live his life according to ancestral teachings and to reproduce himself so that a line of descendants will secure for him the only certain immortality. Consequently, though some peoples have quite complex representations of the composition of the human personality—the Akan of Ghana, for example, recognize in it three constituents—speculation about the qualities and fate of anything that could be called the individual human soul is minimal. Only when (as it seems from a modern standpoint) the guilty conscience of the living is disturbed by the dead, particularly when illness is attributed to their dissatisfaction, are attempts made to identify its cause. So with all the rich imagination of primitive religious exegesis, the basic view of man's place in the universe probably held by most people for most of human history has been little different

Views of the soul and afterlife

from that reported by Knud Rasmussen, explorer and ethnologist, from an Eskimo:

> We fear! . . . . And therefore our fathers, taught by their fathers before them, guarded themselves about with all these old rules and customs, which are built upon the experience and knowledge of generations. We do not know how or why, but we obey them that we may be suffered to live in peace.

PRIMITIVE MYTHOLOGY AND SYMBOLISM

The role of myth in primitive cult and culture. The form in which the knowledge of previous generations is handed on is, of course, partly in practical teaching of practical knowledge. But metaphysical truths are apprehended through myth. As H. and H.A. Frankfort wrote,

> Myth is a form of poetry which transcends poetry in that it proclaims a truth; a form of reasoning which transcends reasoning in that it wants to bring about the truth it proclaims; a form of action, of ritual behaviour, which does not find its fulfillment in the act but must proclaim and elaborate a poetic form of truth.

Malinowski and many followers have rightly pointed out that myths provide a "charter" for contemporary belief, action, and social relationships. More particularly they often explain the principles, if not all the details, of contemporary rituals. Here what modern historians would distinguish as myth, legend, saga, fable, or history shade into one another, especially in an oral tradition. But myth, which reveals and perpetuates a body of truths to live by, is a way of interpreting the essential structure of the little moral and physical universe in which many people live and, hence, is recognized as a mode of thinking about man's place in nature and society. The cosmological myths earlier mentioned, which explain how the world as a whole came to be arranged as it is, are accompanied by others establishing and validating the innumerable local forms of social and religious order.

Symbolism in primitive thought and action. With mythical thought, which connects the past and the present to representations of the human condition that transcend them both, go symbolic thought and action, which reorder the given world according to principles both intellectual and affective. Sir James Frazer had already identified two elementary features of symbolic thought and action in what he called "homoeopathic or imitative magic" and "contagious magic," though his interpretation of them as misunderstandings of the relation between cause and effect would no longer be accepted. In the former, objects and experiences that were in one sense similar were related by the mind so that one could stand for (or as it would now be said, symbolize) the other. The Arunta, a group of Australian Aborigines, have as their totem the witchetty grub and perform ceremonies to multiply it. "A long narrow structure of branches," wrote Frazer, "is set up to imitate the chrysalis case of the grub. In this structure a number of men, who have the grub for their totem, sit and sing of the creature in its various stages. Then they shuffle out of it in a squatting posture, and as they do so they sing of the insect emerging from the chrysalis." In "contagious magic" things which have been in intimate contact and thus are united in thought are treated as though one could stand in belief and ritual for the other. Thus, in sacrifices a part of the sacrificial beast is often offered to the gods as substitute for the whole, or a relic of a holy man is venerated (for example, the Buddha's tooth) in commemoration of all the man has stood for. This use of a part to symbolize the whole is a very common feature of symbolic thought and behaviour. More complex are whole systems of symbolic classifications that increasingly command attention. Here the basic features of the spatial ambience and of human social life—what is "higher" and "lower" in nature, for example, and what is socially or spiritually superior and inferior are assimilated to one another in thought. Hence, to take the simplest example, priests, kings, and temples are often associated with high places. Of great interest to students of primitive religion are also the variety and permutations of colour symbolism: white often representing enlightenment, peace, and life (with its association sometimes also with sap and sperm); black representing danger and misfortune; and red representing blood and physical vitality. The general principle behind all this symbolic activity is to bring experiences of the natural and material world together with the "inner" moral and imaginative experience of man and, thus, to express, in a form accessible to the senses, truths accepted on the moral and mental plane.

Symbolism in imitative and contagious magic

Primitive art and iconography. The extent to which spiritual realities are represented in man-made material forms (whether "art" forms or not) varies greatly from one culture to another. Peoples whose sacred objects are few, simple, and produced with little artistic or craftsmanlike effort, such as the Nilotes and the Bushmen of Africa, often have a wealth of verbal art at the service of their religions; therefore, the richness of a religious tradition is not to be judged by the complexity of its iconography. Further, where images of the gods are numerous and deploy the talents of specialized craftsmen, they are often produced less for aesthetic effect than to preserve a material impression of divinity that may be so placed in the home or the temple that it can rarely be fully seen, like the supposedly "magical" pictures of prehistoric cave art. Primitive iconography is thus, from the primitive point of view, less a form of art than an effort to give physical form to realities of the religious imagination. Since the evocation of divinity, whether in words or in materials, is a form of creation, those who are skilled in the activity are often accorded a special religious status under the auspices of the divinities they reveal. The forms in which divinities are depicted vary from schematic and abstract diagrams and pictograms to the fully rounded forms most familiar in West African or Melanesian carving, but both abstract and representative forms are found in the religious art of both these areas; their purpose, decorative as they may be, is less one of decoration than of bringing vividly to the mind and the senses the direct impact of the divine on men.

Non-aesthetic functions of primitive art

PRACTICES, INSTITUTIONS, PERSONAGES

Primitive religious experience and its expressions. In earlier European writings of primitive religion, much was made of a supposed contrast between the fear that inspired primitive religious practice and the hope, love, and confidence preached by the "revealed" religions, Christianity in particular. But even in biblical teaching "the fear of the Lord is the beginning of wisdom," and it is now accepted that the societies formerly called "primitive" are no more obsessed with fear of the unknown than are the advanced societies of today. Nevertheless there can be no doubt that anxieties, which in scientifically and technologically advanced societies are dispelled for some by a sense of scientific and technological competence to deal with their causes, are the therapeutic province of primitive religion. Only when the spiritual cause of suffering is diagnosed and named can proper action be taken to remove it by prescribed ritual action. As a result, in much of the world today, where both "primitive" religion and modern medical science are available, it is common to find that patients turn for relief both to medical science, which deals with their symptoms, and to their own religious practitioners, who deal with the cause of those symptoms. For them, the phenomena of their world are not, as theoretically in some modern science, simply "objects" to be controlled by technical and scientific knowledge: the world is also a living subject, and its life is to be respected, as when, for example, North American Indians objected to the injury done to the earth itself by the metal implements of rationalized agriculture.

Basic religious actions. Thus, a sacramental view of man's relation to his world is implied in primitive belief and ritual, in that the nonhuman creatures and phenomena with which he shares the world (and especially those he regards as vitally affecting his own life) are regarded as signs of a further spiritual reality. They are to be understood and propitiated, even bargained with, rather than dominated as in rationalistic scientific tradition. A central act in man's relationship with the divine is sacrifice, often blood sacrifice, when the life of the sacrificial

Sacrament, sacrifice, and prayer

victim, be it a beast, a vegetable, or even a human being, is offered in exchange for the lives of those who sacrifice and, often, also to augment their own fertility and vitality. Formerly, the essence of primitive sacrifice was thought to lie in the notion of communion with the god through eating the flesh of the sacrificial victim, but it is clear now that this interpretation was strongly influenced by the Christian doctrine of the Eucharist. The commonest sacrificial rituals are probably piacular (expiatory), involving giving satisfaction to the ancestors and the gods so that men may live in peace and health. Thus, sacrifice may be seen as a form of exchange relationship, in which, basically, a superior vitality is received from the gods in exchange for an inferior form of life. In hymns and prayers, the suprahuman powers thought to determine human well-being are praised, exhorted, and sometimes cajoled to come near to men to help them or, as frequently, to accept the offerings men make to them and leave the human sufferers in peace.

Salient rites. Since what is sought from primitive religious practice is "life," ritual develops primarily around critical periods in the life of the individual or the community. These critical periods may be times in the natural cycle when rain is needed for the crops and herds, when game is migrating and may be more or less accessible to the hunter, or when the harvest, with its promise of future plenty or its threat of future deprivation, is gathered in. The local communal cycle of yearly rituals is often complemented by other cycles covering several years, which draw together and affect the welfare of many local communities normally living in comparative isolation from one another. Also there are the "rites of passage," performed when the persons are passing from one social role or status to another. Such major crises are birth and the purification of the mother when the child seems likely to live, initiation when children and youths are recognized as having grown to the status of adults, marriage, and death, sometimes accompanied by exhumation and reburial when the dead person is finally accepted in human memory as having left the community of the living. Similarly, there are rites to mark the passage of an heir to the kingship itself or of a neophyte to the assumption of the full priestly role.

Worship or veneration centred on natural objects or forces. Modern students of primitive religion, not unlike its own practitioners, are concerned with the different forms in which "Nature" is sacralized and brought into contact with human life. Therefore, the innumerable forms in which sacredness is thought to manifest itself, itemized at length in Frazer's *Golden Bough,* are matters for detailed symbological investigation in each particular culture. It helps little, however, to learn that people "worship" animals, plants, and celestial phenomena; what counts is how the religious imagination apprehends the relationship of these phenomena to human affairs. So, for example, totemism, the intimate association of natural beings and forces both with a transcendental world of spirit and with specific social groups, may be seen as the systems of ideas and metaphors in which particular peoples conceive the relation of the natural to the social and mental world. The totemic species, be they species of animals, plants, or trees, are symbols of invisible, intellectual, and affective realities. Hence, in an oft-quoted aphorism, Claude Lévi-Strauss wrote "that natural species are chosen not because they are 'good to eat' but because they are 'good to think'."

Totemism

Worship or veneration centred on human or ex-human beings and qualities. Many writers, following Durkheim, have seen some analogy between the material emblems of totemic spirits and heraldic devices, national flags, and the like that also symbolize communal solidarity of different kinds. All such symbols call to mind a community embracing past, present, and future members, and, where the more strictly totemic representations are found, they are usually closely associated with the ancestors. But, as with the Manus of Melanesia, the ancestral dead may themselves provide the main focus of religious attention. Among the Tallensi and LoDagaa of northern Ghana, the main emphasis seems to be upon the spiritual authority of the dead, a reflection of the moral and legal authority of living parents. On the other hand, Maurice Freedman, a contemporary British anthropologist, writing of the filial piety for which the Chinese are particularly well known, refers to "the relative ineffectiveness of Chinese ancestors, their general air of benevolence, and . . . the lack of strong feelings of hatred or guilt towards them on the part of their descendants."

But in either case the dead command religious veneration and are commemorated by sacrifice. To attend properly to their burial, their graves, and their supposed postmortem wishes is an important religious duty. A single Chinese text quoted by Freedman serves to suggest the spirit and intention of such piety:

> I, Ling Kwang . . . presume to come before the grave of my ancestor . . . Ling Kung. . . . Cherishing sentiments of veneration, I look up and sweep your tomb. Prostrated I pray that you will come and be present, and that you will grant to your posterity that they may be prosperous and illustrious. . . . Always grant your safe protection. My trust is in your divine spirit. . . . Reverently I present the fivefold sacrifice . . . earnestly entreating that you will come and view them.

The special quality of dead kings

In general, the wider the community for which the dead are significant, the more elaborate the ritual and ceremonial surrounding them and the more they are assimilated in idea to a transcendental divinity. Thus, the kings of the Shilluk of the Sudan have the title *jwok piny* ("god on earth") in their lifetime, and, like many other kings in whom divinity itself is held to be manifest they must not be thought to die like ordinary mortals. Their spirits, like the spirits of national or tribal heroes, do in fact continue to inspire the communities which they serve and which serve them, and their immortality suggests to their followers that they themselves, not as individuals but as generation after generation of the same people, are immortal.

Special disciplines and practices to attain religious states. The assumption of important social roles, such as those of king or priest, is usually accompanied by special forms of self-discipline, as are also initiation and mortuary rites. Commonest among these are abstentions from certain foods and from sexual intercourse, fasting, and periods of seclusion or withdrawal from the normal round of social life. The theme of "rebirth" is frequently stressed. Similarly, the officiants at important religious ceremonies may prepare themselves by various forms of purification involving self-mortification in order to achieve a special religious condition. In addition to this, there are the deliberate and positive efforts of individuals to make personal contact with divinities. These are most strikingly exemplified in spirit mediumship and shamanism, when the medium or medicine man sets out, as it were, to relinquish his own personality so that he may become the vehicle for divine activity. Mediums and shamans get their "call" very commonly through illness, during which they receive divine instructions about the particular forms of self-discipline they are to practice. This very prominent feature of primitive religious experience continues to assert itself in syncretic religions, so that leaders of Melanesian Cargo Cults, African separatist churches, and other millenarian movements have revealed to them forms of self-abnegation considered necessary for a new and more satisfying way of life. In Cargo Cults, this has often taken the extreme form of the wholesale destruction of traditional forms of wealth. The objective of such disciplines is to acquire a deeper insight into spiritual reality and to lift the practitioner, if only temporarily, to a state of being that partakes in the divine transcendence. Many American Indian tribes are specially noted for this deliberate visionary quest, undertaken with fasting and other forms of self-inflicted suffering and accompanied by the use of drugs. Such practices, like the persistent dancing and drumming of voodoo rituals, appear to produce a state of dissociation in which the ordinary human personality subordinates itself to the gods.

Magical, divinatory, and spiritualistic practices. The religious practices summarized above are concerned basi-

cally with an effort to perceive the true nature of human vitality and human suffering, so that the former may be augmented and the latter diminished. Consequently, the occasional arbitrariness of the taboos, rules, and procedures by which this supra-rational truth is approached may itself appear as a guarantee of its divine origin. In this respect it is no longer easy to draw a firm line, as was common in the past, between magical and religious practices; for if "magic" involves, as was once maintained, the attempt to influence events by a quasi-scientific knowledge and "religion" involves the attempt to do the same through the supplication of higher powers, both are commonly represented in the very same rituals. This is most clearly seen perhaps in the immense range of divinatory practices throughout the world, one famous example being the complex system of divination called Ifa among the Yoruba of Nigeria, where spiritual guidance is sought through the systematic manipulation of 16 palm nuts. Here the truth, usually about a client's illness or misfortune, is arrived at by precise, quasi-scientific procedures, but it is a truth which is thought to have divine sanction and authority: "Truth is the character of Olodumare [God]. Truth is the word that cannot fall. Ifa is truth. Truth is the word that cannot spoil. . . . 'Those who speak the truth are those whom the gods will help.' " Similarly, in the voice of the spirit speaking through its human medium and manifested commonly by violent trembling and shaking of the body followed by entry into trance, the true nature of the condition about which it is being consulted is thought to be announced. It should be recognized, however, that such primitive religious practices leave room for a good deal of skepticism about individual mediums, whose possible fraudulence is well-known to their clients. Nevertheless, as Raymond Firth has noted, "scepticism about the validity of the performance of some spirit mediums [does] not extend to the performances of all." E.E. Evans-Pritchard made the same point about the Sudanese Azande's consultation of oracles and "magicians" about witches.

The divinatory and spiritualistic paths to truth

Religious personages; types of religious authority. Contact with truths hidden from other men thus confers religious authority, and knowledge of those truths permits the religious leader to restore and maintain health and harmony, whether in the body of the individual patient consulting a diviner or in the body social in which a sacred king reigns. The Mughal emperor Akbar (1542–1605) claimed that ". . . a king possesses, independent of men, the ray of Divine wisdom which banishes from his heart everything that is conflicting" (quoted by Max Müller, *Introduction to the Science of Religion*, 1873), and it is essential in many religious ceremonies that the congregation and officiants should be at peace with each other. This peace may encompass more than a single tribe or nation where, as commonly in reaction to foreign rule, prophets have arisen who claim to speak for God on behalf of all their followers. From the family elders serving their own ancestors, to the minor priests officiating for local gods at local shrines, to the national or tribal cult, and finally to intertribal unions under the auspices of an inspired prophet, religious authority embraces larger and larger communities. As it does so, it claims to define truths that have more and more general application. The teachings of primitive religions, profoundly relevant in their specialized social and natural environments, here begin to give way to intuitions of more universal significance.

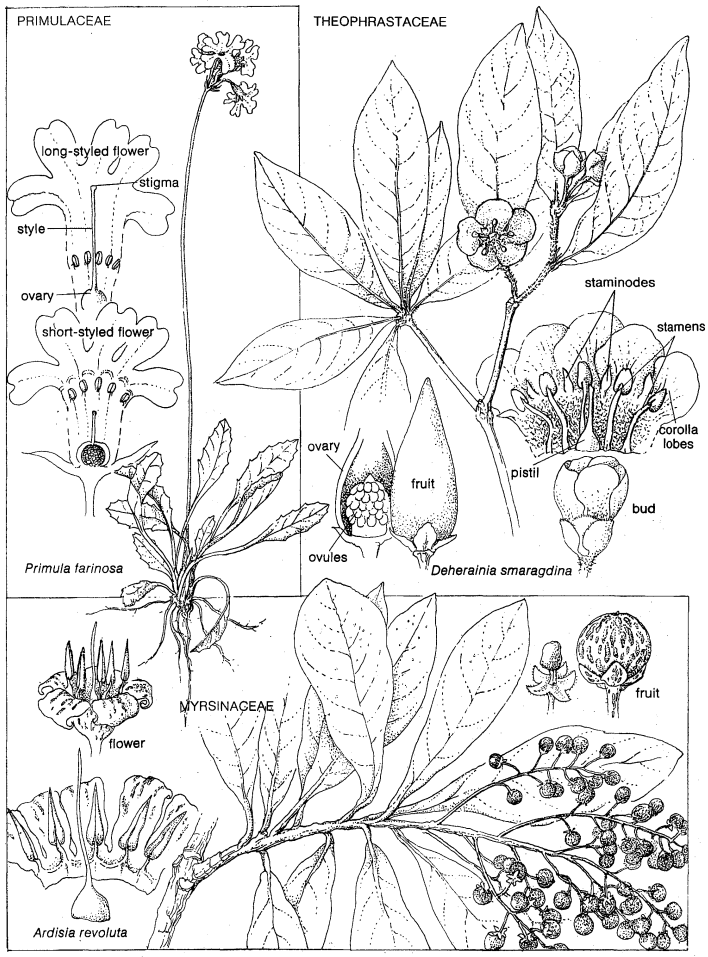
(R.G.Li.)

Primulales



The primrose order of flowering plants (Primulales) contains three families, about 64 genera, and nearly 2,000 species. The group has long been of popular interest because of the attractiveness of many of the wild plants, such as shooting star (*Dodecatheon*) and loosestrife (*Lysimachia*), and the beauty of the cultivated members, such as cyclamen (*Cyclamen*) and primrose (*Primula*).

Two of the families (Theophrastaceae and Myrsinaceae), which contain about half of the species in the order, are composed entirely of trees or shrubs. A few species of these families are climbers or epiphytes (plants that grow upon other plants instead of being rooted in soil). The order is worldwide in distribution, although the two woody families have a much more restricted range than the third, the primrose family (Primulaceae), which is composed of herbaceous (nonwoody) plants.

The economic importance of the order lies almost entirely in its ornamental value. Very few of the woody

representatives are in cultivation and then only infrequently. In the tropics some of the woody species are used to poison fish and as a tapeworm remedy (*e.g.*, the pea-sized fruits of *Myrsine africana*).

Drawing by M. Pahl

Representative plants from the three families of the order Primulales.

Cross-pollination ensured by flower structure

Natural history. In the wild the plants reproduce mostly by seed, and in cultivation this method is also common. Cross-pollination in the woody families is attained by the occurrence of species with separate male and female flowers. In some species of the family Primulaceae, however, cross-pollination is effected by heterostyly, a condition in which some flowers have differently sized or positioned sexual structures (male stamens and female pistils) than others of the same species. Heterostylous flowers appear superficially identical, but some have short styles (the narrow, upper part of the pistil) and elevated anthers (the saclike pollen-producing part of the stamen); others have long styles and anthers near the inner base of the tubular corolla (fused petals). Self-pollination is almost entirely prevented by the different lengths of styles and stamens. Cross-pollination is practically ensured when an insect visits the flowers because it transfers pollen only between male and female structures of similar length, which are in different flowers. An insect (usually a bee) visiting a short-styled flower, for example, could encounter long stamens and pick up a load of pollen from them. This pollen would then be deposited on the stigma (the sticky, pollen-receiving region at the tip of the style) of a long-styled flower on a subsequent flower visit, but not on a short-styled flower because the pollen is not carried in an appropriate place on the insect to reach the stigma of a short-styled flower. A similar restriction operates when an insect picks up pollen from the short stamens of a long-styled flower. The pollen can only be deposited on the stigma of a short-styled plant. The centre, or "eye," of the corolla is often a different and brighter colour than the rest of the flower and is thought to function as a guide for the insect.

The family Primulaceae occurs primarily in cool climates and damp, usually acidic soils. A large number occur in mountainous regions, and many grow in the arctic tundra or in alpine communities at high elevations. The two woody families are subtropical and tropical.

Form and function. Few morphological characters other than the flowers and fruits make the order readily distinguishable. The leaves are simple, lack the small basal appendages called stipules, and are generally alternately arranged along the stems; but this combination of traits is by no means unique. The location of the stamens in front of the corolla lobes, rather than in the usual position of being alternate with them, and the unusual free-central placentation—the attachment of the ovules to a short column that arises from the interior base of the ovary—make the order completely distinctive. The pistil is composed of five carpels, or ovule-bearing segments, which is not unique but is sufficiently unusual to make it useful in recognizing members of the order.

The two woody familes differ morphologically from each other in two characters. The Theophrastaceae has, in addition to the five stamens, five petallike staminodes, or sterile stamens, that lie alternately with the corolla lobes. The seeds of this family are large and yellowish. The family Myrsinaceae lacks staminodes—at least petallike ones—and the seeds are small and dark coloured. In both families the fruits are more or less fleshy. The family Primulaceae, being herbaceous (rarely a little woody at the base), is readily differentiated from the other two families. The fruit, a capsule, is not fleshy.

Evolution and classification. The two woody families, which are included in the order chiefly because of the structure of the flower and fruit, may have had a different evolutionary origin from that of the herbaceous family. The form and structure of the flowers in the three families, however, are so striking and similar that their placement in one order is widely accepted.

There is strong evidence that the more or less immediate ancestors of the order had ten stamens and a five-celled pistil. Loss of the five outer stamens and of the septa forming the five cells readily explain the present type of flower. The carpel number of five contrasts with the usual two-carpelled condition of other plants with petals fused into a tubular corolla (sympetalous plants). On the widely held supposition that the larger the number of parts a flower has the less evolved it is, this order is considered primitive within the sympetalous group. Sympetalous plants are, however, considered to be evolutionarily advanced over most plants with free-petalled flowers.

Similarities to other plant orders

The primrose order seems to be related to the ebony order (Ebenales), but neither is considered to have been derived from the other, and the two orders may have had a common origin. The origin has been sought among flowering plant groups with separate, free petals. The Caryophyllaceae (pink family), consisting primarily of herbaceous plants, has several characters remarkably similar to the Primulaceae, including the unusual free-central placentation. For this reason there is widespread opinion that this group is ancestral to the Primulaceae. Because woody plants are considered more primitive than herbs, however, and therefore the woody families of the order would not likely be derived from herbaceous families, it has been considered logical to look for a woody ancestor. Some authorities have recently suggested relatives of the woody, free-petalled tea or camellia order (Theales) as likely ancestors. A classification has been proposed that derives the families Theophrastaceae and Myrsinaceae from the order Theales, and removes them from the Primulales. This leaves the family Primulaceae in the primrose order; it is considered to be derived from the Caryophyllaceae.

Evidence from chemical studies of plants is not yet definitive. Leuco-anthocyanin pigments occur in the order Theales and the family Myrsinaceae but not in the Theophrastaceae. Although infrequent in sympetalous families, they do occur in the Primulaceae and in the possibly

related family Plumbaginaceae (leadwort family). But in the putative ancestor, the Caryophyllaceae, they are lacking.

Fossil leaves and flowers have been found representing the family Myrsinaceae in the Northern Hemisphere from Tertiary (2,500,000 to 65,000,000 years ago) and upper Oligocene (about 26,000,000 years ago) deposits. These are from regions in which living species of the family no longer occur.

Annotated classification. The following descriptions are generalizations; some are true in all instances and some have exceptions, usually rare ones. The superior-fruit (*i.e.*, an ovary positioned above the attachment point of the other flower parts) character finds an exception in the genus *Samolus* (family Primulaceae) in which the capsule is half-inferior, or partly enclosed by the basal parts of the sepals, petals, and stamens. The genus *Coris*, of the same family, with a single species in the Mediterranean region and northeast Africa, has a bilaterally symmetrical corolla. It has been suggested that this aberrant species does not belong in the order Primulales.

Some exceptions to general characteristics of order

ORDER PRIMULALES

Trees, shrubs, or herbs with leaves usually alternate, simple, and lacking stipules. Flowers usually radially symmetrical; with the basic parts (sepals, petals, stamens, and carpels) 5 in number (rarely 4 to 8). The 5 petals united into a radially symmetrical corolla, the 5 stamens arising from the inner surface of the corolla tube and opposite the corolla lobes. Ovary superior, of 5 fused carpels, but only 1 interior chamber, with few to numerous ovules attached to a centre axis rising from the base of the ovary. Three families, about 64 genera, and more than 2,000 species.

Family Theophrastaceae

Trees or shrubs with leaves characteristically crowded at ends of branches. Flowers often large and showy; with a whorl of 5 petallike staminodes (sterile stamens) alternating in position with the corolla lobes in addition to the 5 fertile stamens that are opposite the corolla lobes. Fruit a fleshy drupe (stony-pitted fruit) or berry with few to many seeds. Seeds large and yellowish or orange red in colour. Four genera and 60 to 110 species, depending on the authority consulted, distributed in the American tropics and Hawaii.

Family Myrsinaceae

Evergreen trees or shrubs, often with leathery leaves. Leaves glandular-punctate (with glands, translucent or coloured dots, depressions, or pits dotting the surface) and with resin ducts, which are also present in the stems. Calyx (sepals) and corolla of 4 to 6 parts or lobes; staminodes absent or small. Fruit a fleshy berry or drupe; ovules numerous; seeds small and dark-coloured. Thirty-two genera and 1,000 species widely distributed in the tropics and subtropics of the world; they are especially abundant in Africa, Malaysia, and Australia.

Family Primulaceae (primrose family)

Herbaceous plants (rarely woody at the base) with leaves often in a basal rosette or, when on an aerial stem, frequently opposite or whorled. Flowers often on leafless stalks (scapes). Calyx persistent (remaining attached into fruiting season). Fruit a several-seeded capsule, opening by 5 apical valves or teeth. Seeds angular. Twenty-eight genera and 800 to 1,000 species (half of which are in the genus *Primula*) distributed mostly in mountainous, northern temperate regions.

Critical appraisal. There are serious differences of opinion concerning what families ought to constitute the order Primulales. The most widely accepted viewpoint is that presented here, which recognizes the three families described in the annotated classification section above.

Another taxonomic system, gaining in acceptance, recognizes the families Myrsinaceae, Theophrastaceae, and Aegicerataceae (consisting of the single genus *Aegiceras*, here placed in the Myrsinaceae) to constitute a separate order, the Myrsinales. In that system the primrose order contains the two families Primulaceae and Plumbaginaceae. The main division between the two orders is based on woodiness versus the herbaceous habit, the Myrsinales containing the woody plants, and the Primulales containing the herbaceous ones.

Still other systems accept all the above mentioned families (and sometimes also the family Plantaginaceae) into a more broadly defined primrose order.

The order is thus distinctive morphologically; its evolutionary origins and whether or not its families came from one or more than one ancestral stock still are not clear. Continued anatomical and phytochemical studies may provide the answers.

(G.J.G.)

Prince Edward Island

A thin crescent of land nestling on the southern shores of the Gulf of St. Lawrence, Prince Edward Island is Canada's smallest province, its serenity attracting hundreds of thousands of summer tourists. A mild climate and fertile soil favour agriculture, while its location makes the island a base for lobster and groundfish operations. Despite these natural assets, the provincial economy has lagged appreciably behind national averages for productivity, employment, and per capita income, and the emigration of its young people has been a perennial concern. As a result, a 15-year development plan—the only one of its kind in the political subdivisions of North America—was instituted in 1969. The province's small size and limited resources have precluded its having a major role in the political and economic life of the Canadian nation, though many island natives have become distinguished citizens of other parts of Canada and the United States.

From North Cape to East Point, the curving island is about 140 miles (225 kilometres) long, and varies from four to 40 miles in breadth. It lies between 46° and 47° north latitude, and 62° and 64° west longitude. On the south, the Northumberland Strait separates the island by a minimum of nine miles from the mainland of the provinces of Nova Scotia and New Brunswick. Narrowings of the island roughly mark off the three counties—Prince in the west, Queens in the centre, and Kings in the east. The total land area of 2,184 square miles (5,657 square kilometres) was inhabited by 110,200 people at the 1971 census, making the island the most densely populated of Canadian provinces (for related information, see CANADA; CANADA, HISTORY OF).

History. Before the European explorations, Micmac Indians from the mainland used the island for fishing, hunting, and some planting in the warmer seasons. They called the place Abegweit, which meant "Cradled on the Waves." By the 1970s, only a small island in Malpeque Bay, on the north shore, was reserved for their descendants.

Legend suggests that John Cabot, the English-sponsored Venetian explorer, may have seen the island in 1497, although historians credit its discovery to Jacques Cartier, the French navigator, in June 1534. Claimed for France in 1603 by Samuel de Champlain, the first gover-

nor of French Canada, and designated on his maps as Île St. Jean, it was not colonized until 1720 when 300 settlers from France, sponsored by the commercial company of the Count de St. Pierre, established Port la Joie at the entrance to the harbour of Charlottetown, the present capital. In addition, fishermen and trappers from the French-speaking mainland colony of Acadia established several other small communities on the island. The French regime lasted only 38 years, and then the British occupied the island in 1758, dispersing over 3,500 of the settlers.

British administration

The island was formally ceded to Great Britain in 1763, and six years later the colony was separated from Cape Breton and its first governor appointed. In 1799 St. John's Island was renamed in honour of Edward, duke of Kent, who was then commander of the British forces in North America.

Under British administration the island was surveyed and divided into three counties, each with a townsite and "royalty," and 67 lots or townships of about 20,000 acres each. In 1767 these lots were awarded by ballot to grantees or proprietors who were expected to promote settlement, and for the next century absentee-landlord problems beset the colony. Representative government reached the island in 1851, and the Land Purchase Act of 1875 brought to an end this unique system of land tenure. By 1900 the population reached 100,000. It has fluctuated within 15 percent of that figure for the past 70 years.

In 1864 a conference intended to discuss the possible union of the three Maritime Provinces fortuitously prepared the way for the confederation of all the provinces in the Canadian nation. This Charlottetown Conference was the historic forerunner of the Quebec Conference of 1864, which actually resulted in the founding of the Dominion of Canada. Prince Edward Island has thus been known as the "Cradle of Confederation," even though it did not finally join the union, as Canada's seventh province, until 1873, when forced to do so by severe financial troubles. Resourceful politicians then persuaded the federal government to make concessions that enabled the province to purchase the lands still held by foreign proprietors and resell them to resident farmers; to transfer to the federal authority financial responsibility for the heavily-indebted island railway; and to obtain assurance of continuous communication with the mainland.

By 1970, after a century of chronic economic depression in the area, relieved occasionally by flourishing markets for wooden sailing vessels, silver fox furs, potatoes, or lobsters, Prince Edward Island had joined with Nova Scotia and New Brunswick in a renewed study of Maritime union. At the same time, the island had embarked on its own comprehensive development plan.

The landscape. Numerous streams, bays, and tidal estuaries indent the irregular coastline. On the north side, the bays are generally blocked by dunes; but on the east and south there are good natural harbours. Along the 1,100 miles of pink, sandy beaches, red sandstone cliffs average about 20 feet in height but sporadically exceed 50 feet. Most of the island is within five miles of the sea or tidal inlet and no place is more than ten miles from salt water. Water pollution is not extensive, but effluents from processing plants, pesticides, erosion, and sedimentation have seriously degraded some water resources.

With an average mean temperature of 42° F (5.6° C), and an annual mean precipitation of 39.5 inches (1,003.3 millimetres), the island climate is conducive to forests. The original stands were mainly deciduous, but coniferous trees are as common as they are elsewhere in the region. Besides the native birch, maple, pine, and spruce, foreign species include linden, horse chestnut, black walnut, and European mountain ash. Tall trees line the streets of the towns, as well as the country lanes.

Though a gentle undulation is most characteristic, the landscape ranges from rolling hills in central Queens County to level stretches in western Prince County. The highest elevation is nearly 500 feet above sea level. The soils are classed as podzols, comparatively low in plant nutrients and high in acidity. In over half the island, the red, sandy loam is suitable for clover and timothy hay, oats and barley, and turnips and potatoes. Dairying, mixed farming, and crops for canning and freezing are found in the more central parts of the island, and tobacco is grown in southern Kings County. The average family farm is about 137.4 acres, and the growth period is from mid-May through mid-October.

The people. Most residents are descendants of early settlers from the British Isles: Highland Scots, Englishmen, and southern Irish. Other ancestral strains include several hundred Loyalists who settled here after the American Revolution, and about thirty Acadian families, recorded in the census of 1765, who are the progenitors of over 16,000 island residents today. Many original settlement patterns can still be traced in the place names and family names of the island. People of Scottish ancestry, constituting one-third of the population, are found everywhere, but particularly along the north shore from East Point to Malpeque Bay, throughout Kings County and eastern Queens County; many are descendants of the Glenaladale settlers who arrived at Scotchfort and Tracadie in 1771–72, and the Selkirk settlers who came to the Orwell District in 1803. Somewhat less than one-third of the people claim Irish ancestry and are found mainly in areas of later settlement, notably western Prince County and the interiors of Kings and Queens. English and Loyalist descendants are found mostly in villages and towns in Queens and in eastern Prince County. The Acadians are found in large numbers south of Rustico, near Cape Egmont, and west and north of Cascumpeque Bay. Since 1945, about 120 Dutch families, as well as a sprinkling of Americans, Belgians, Lebanese, and Germans, have settled in this province.

Population

In 1971 the population of Kings County was 18,100; Prince County (including Summerside's 9,300), 41,700; and Queens County (including Charlottetown's 18,600), 50,400. Apart from Charlottetown, the one city, the province has six towns and seventeen incorporated villages. In 1966 the urban population stood at 39,747, and the rural population at 68,788, including 30,841 farm residents. In the 1961 census, 95,564 called English their mother tongue; 7,958, French; and 1,107, another language. At that time, Roman Catholics numbered 48,256; United Church members, 27,395; Presbyterians, 12,744; Anglicans, 6,085; and Baptists, 5,942.

Economy and social conditions. In 1966, the labour force was estimated at 35,400, out of a total population of just over 109,000. Unemployment rates were three to seven percent above the national average and output per worker was below the average—close to 50 percent in agriculture. Per capita income amounted to between 60 and 70 percent of national averages.

During the late 1960s, the government proposed a series of reforms, aimed at enabling the people to create viable economic enterprises for themselves. These included full exploitation of agriculture; development of tourist facilities; better use of forest assets; improvement of fisheries; expansion of manufacturing; public investment in housing, health, and welfare services; and extension of programs of education and training. Federal authorities subsequently designated the province a Special Rural Development Area under the Fund for Rural Economic Development Act, and the two governments entered into a 15-year agreement starting April 1, 1969. The agreement covers the entire province in a comprehensive and coordinated plan intended to promote economic and social development, to increase income and employment opportunities, and to raise standards of living.

Development plan

This plan will cost approximately $745,000,000, of which the federal contribution will be approximately $225,000,000. A Federal-Provincial Advisory Board approves all projects, recommends all programs and budgets, evaluates progress, and suggests amendments. The plan is administered by the province and the federal office of Plan Co-ordinator, but the responsibility for the progress of the plan belongs to the provincial Department of Development headed by the premier.

Agriculture will continue to be the base of the island's economy. Through the Land Development Corporation, low-income farms may be purchased and resold or

leased, one objective being consolidation of the area into a resource base of about 2,500 commercial farm units. Such transactions may involve upward of 400,000 acres. This strategy, along with improved farming and marketing methods, is expected to double the 1966 net agricultural value added to $48,000,000 by 1976 and to $68,000,000 by 1983.

The tourist industry in 1968 had a net value of $14,618,491, but the growth rate has been 10 percent annually since that date, and the objective of the plan is a net value of $18,000,000 by 1979. In 1967 there were 375,000 visitors, and gross revenue was slightly over $13,000,000; by 1970 the visitor count had risen to 557,000, and the gross revenue was estimated at $18,000,000.

The fishing potential is to be developed by consolidating processing plants, reducing both the number of inshore fishermen and the number of ports, and by maintaining the normal growth rate in offshore fisheries. The object is to increase efficiency, quality, and productivity, and thereby effect some increase in total returns and substantial increase in individual incomes. Island fisheries were valued at $9,300,000 in 1970, and the Irish moss industry added another $1,300,000.

Economic growth potential

The net provincial product in 1966 stood at a total of $133,000,000 and was expected to increase to $205,000,000 by 1978 and to $270,000,000 by 1983; under the development plan, the net provincial product is projected to reach $330,000,000 by 1978 and $440,000,000 by 1983. Per capita income, averaged from 1963 to 1965, was $1,236 and could normally be expected to rise to $2,140 by 1983; but in the same period, the plan aimed at boosting per capita income to $3,070.

At the start of the 1970s, the Prince Edward Island Lending Authority was established; the Health Services Commission was appointed to administer the provincial plan for socialized medicine; agencies were set up for housing and pollution control; welfare services were being reorganized; and the Department of Education had embarked on reducing 308 administrative units to five jurisdictional districts by 1972. In addition, the 17 regional high schools were being changed to several comprehensive high schools that would offer academic, general, commercial, and industrial arts courses.

Transportation. As over 90 percent of the travel between the province and the mainland is by automobile, proposals for a causeway over the Northumberland Strait are frequently reviewed. Meanwhile, the Northumberland ferries sail, except in the winter months, between the province and Nova Scotia, while Canadian National Railways icebreakers provide year-round service for both automotive vehicles and freight trains between the island and New Brunswick. The Canadian National Railways, extending the entire length of the island, remains the leading carrier of bulk commodities, though passenger service has been discontinued. By 1970, over 1,400 miles of paved and 1,900 miles of unpaved roads laced the island. Potatoes and pulpwood were shipped out from ports on the island's south and east coasts. Eastern Provincial Airways provides daily jet plane services between Charlottetown, the other Atlantic Provinces, and Montreal.

Administration. The province is represented in the Federal Parliament by one member from each of four electoral districts as constituted in 1968: Cardigan, Hillsborough, Malpeque, and Egmont. Four Senate appointments also are allotted to the province.

The provincial government consists of the lieutenant governor, and an Executive Council chosen from the 32 members of the Legislative Assembly. Two assembly members are elected from each of the sixteen districts, as constituted in 1966. The premier heads the Executive Council of ten ministers, whose responsibilities range from education, agriculture, and fisheries to tourism, industry, natural resources, and development.

Cultural life and institutions. Both amateur and professional productions are fostered at the Fathers of Confederation Memorial, a complex containing a large auditorium, art gallery and museum, children's theatre, and various studios. This centre, which adjoins historic Province Building in Charlottetown, also houses a public library and legislative library and archives.

Holland College, an institute of applied arts and technology, and the University of Prince Edward Island were both chartered in 1968, replacing two institutions that originated over a century earlier, Prince of Wales College and St. Dunstan's University. At the start of the 1970s, Holland College enrolled about 250 students yearly, while the new university enrolled almost 4,000, including part-time and summer-session students. The campuses are located in Charlottetown, but extension courses are offered in several other island communities.

Throughout the province, such handicrafts as weaving, pottery-making, and woodworking are encouraged by government agency and the Women's Institutes, and the annual music festival attracts thousands of participants from the schools of the province. There are radio stations and daily newspapers in Charlottetown and Summerside and a television studio in Charlottetown.

As Prince Edward Island continues its efforts to achieve prosperity while maintaining independence, the programmed economy recently adopted is expected to transform many of the accustomed ways of doing many things. The people, on the other hand, seem determined to preserve their rural and insular heritage, their traditional values, and their humane mode of life.

Printing

Printing traditionally has been defined as a technique for applying under pressure a certain quantity of colouring agent onto a specified surface to form a body of text or an illustration.

Certain recently developed processes for reproducing texts and illustrations, however, are no longer dependent on the mechanical concept of pressure or even on the material concept of colouring agent. Because these processes represent an important development that may ultimately replace the other processes, printing should probably now be defined as any of several techniques for reproducing texts and illustrations, in black and in colour, on a durable surface and in a desired number of identical copies. There is no reason why this broad definition should not be retained, for the whole history of printing is a progression away from those things that originally characterized it: lead, ink, and the press.

It is also true that, after five centuries during which printing has maintained a quasi-monopoly of the transmission or storage of information, this role is being seriously challenged by new audiovisual and information media. Printing, by the very magnitude of its contribution to the multiplication of knowledge, has helped engender radio, television, film, microfilm, tape recording, and other rival techniques. Nevertheless, its own field remains immense. Printing is used not merely for books and newspapers but also for textiles, plates, wallpaper, packaging, and billboards. It has even been used to manufacture miniature electronic circuits.

The invention of printing at the dawn of the age of the great discoveries was in part a response and in part a stimulus to the movement that, by transforming the economic, social, and ideological relations of civilization, would usher in the modern world. The economic world was marked by the high level of production and exchange attained by the Italian republics, as well as by the commercial upsurge of the Hanseatic League and the Flemish cities; social relations were marked by the decline of the

landed aristocracy and the rise of the urban mercantile bourgeoisie; and the world of ideas reflected the aspirations of this bourgeoisie for a political role that would allow it to fulfill its economic ambitions. Ideas were affected by the religious crisis that was due primarily to the links between the Catholic Church and the older feudal society, links that would lead to the Protestant Reformation.

The first major role of the printed book was to spread literacy and then general knowledge among the new economic powers of society. In the beginning it was scorned by the princes. It is significant that the contents of the first books were often devoted to literary and scientific works as well as to religious texts, though printing was used to ensure the broad dissemination of religious material, first Catholic and, shortly, Protestant.

The significance of the Western alphabet to the use of movable type

There is a material explanation for the fact that printing developed in Europe in the 15th century rather than in the Far East, even though the principle on which it is based had been known in the Orient long before. European writing was based on an alphabet composed of a limited number of abstract symbols. This simplifies the problems involved in developing techniques for the use of movable type manufactured in series. Chinese handwriting, with its vast number of ideograms requiring some 80,000 symbols, lends itself only poorly to the requirements of a typography. Partly for this reason, the unquestionably advanced Oriental civilization, of which the richness of their writing was evidence, underwent a slowing down of its evolution in comparison with the formerly more backward Western civilizations.

Printing participated in and gave impetus to the growth and accumulation of knowledge. In each succeeding era there were more and more men who were able to assimilate the knowledge handed to them and to augment it with their own contribution. From Diderot's encyclopaedia to the present profusion of publications printed throughout the world, there has been a constant acceleration of the rate of change, a process highlighted by the Industrial Revolution at the beginning of the 19th century and the scientific and technical revolution of the 20th.

At the same time, printing has facilitated the spread of ideas that have helped to shape alterations in social relations made possible by industrial development and economic transformations: the works of the 18th-century philosophers, the United States Constitution, the Declaration of the Rights of Man and of the Citizen of the French Revolution, and 19th-century social doctrines.

By means of books, pamphlets, and the press, information of all kinds has reached all levels of society in most countries.

The advantages of print

In view of the contemporary competition over some of its traditional functions, it has been suggested by some observers that printing is condemned to disappear. On the other hand, this point of view has been condemned as unrealistic by those who argue that information in printed form offers particular advantages different from those of other audio or visual media. Radio scripts and television pictures report facts immediately but only fleetingly, while printed texts and documents, though they require a longer time to be produced, are permanently available and so permit reflection. Though films, microfilms, punch cards, punch tapes, tape recordings, holograms, and other devices preserve a large volume of information in small space, the information on them is available to human senses only through apparatus such as enlargers, readers, and amplifiers. Print, on the other hand, is directly accessible, a fact that may explain why the most common accessory to electronic calculators is a mechanism to print out the results of their operations in plain language. Far from being fated to disappear, printing seems more likely to experience an evolution marked by its increasingly close association with these various other means by which information is at man's disposal.

  The future of printing

I. History

ORIGINS IN CHINA

By the end of the 2nd century, the Chinese apparently had discovered, empirically, a means of printing texts; certainly they then had at their disposal the three elements necessary for printing: (1) paper, the techniques for the manufacture of which they had known for several decades; (2) ink, whose basic formula they had known for 25 centuries; and (3) surfaces bearing texts carved in relief. Some of the texts were on classics of Buddhist thought inscribed on marble pillars, to which pilgrims doubtless applied sheets of damp paper, daubing the surface with ink so that the parts that stood out in relief showed up; some were religious seals evidently used to transfer pictures and texts of prayers to paper. It was probably this use of seals that led in the 4th or 5th century to the development of ink of a good consistency for printing.

A substitute for these two kinds of surfaces, the marble pillars and the seals, that was more practical with regard both to manageability and to size appeared perhaps by the 6th century in the wood block. First, the text was written in ink on a sheet of fine paper; then the written side of the sheet was applied to the smooth surface of a block of wood, coated with a rice paste that retained the ink of the text; third, an engraver cut away the uninked areas so that the text stood out in relief and in reverse.

To make a print, the wood block was inked with a paintbrush, a sheet of paper spread on it, and its back rubbed with a brush. Only one side of the sheet could be printed.

Early wood-block works

The oldest known printed works were made by this technique: in Japan about 764–770, Buddhist incantations ordered by the Empress Shotoku; in China in 868, the first known book, "The Diamond Sutra"; and, beginning in 932, a collection of Chinese classics in 130 volumes, at the initiative of Fong Tao, a Chinese minister.

Invention of movable type (11th century). About 1041–48 a Chinese alchemist named Pi Sheng appears to have conceived of movable type made of an amalgam of clay and glue hardened by baking. He com-

posed texts by placing the type side by side on an iron plate coated with a mixture of resin, wax, and paper ash. Gently heating this plate and then letting the plate cool solidified the type. Once the impression had been made, the type could be detached by reheating the plate. It would thus appear that Pi Sheng had found an overall solution to the many problems of typography: the manufacture, the assembling, and the recovery of indefinitely reusable type.

In about 1313 a magistrate named Wang Chen seems to have had a craftsman carve more than 60,000 characters on movable wooden blocks so that a treatise on the history of technology could be published. To him is also attributed the invention of horizontal compartmented cases that revolved about a vertical axis to permit easier handling of the type. But Wang Chen's innovation, like that of Pi Sheng, was not followed up in China.

In Korea, on the contrary, typography, which had appeared by the first half of the 13th century, was extensively developed under the stimulus of King Htai Tjong, who, in 1403, ordered the first set of 100,000 pieces of type to be made of cast bronze. Nine other fonts followed from then to 1516; two of them, in 1420 and 1434, were made before Europe in its turn discovered typography.

Transmission of paper to Europe (12th century). Paper, the production of which was known only to the Chinese, followed the caravan routes of Central Asia to the markets at Samarkand, whence it was distributed as a commodity across the entire Arab world.

The transmission of the techniques of papermaking appears to have followed the same route; Chinese taken prisoner at the Battle of Talas, near Samarkand, in 751 gave the secret to the Arabs. Paper mills proliferated from the end of the 8th century to the 13th century, from Baghdad and then on to Spain, then under Arab domination. Paper first penetrated Europe as a commodity from the 12th century onward through Italian ports that had active commercial relations with the Arab world and also, doubtless, by the overland route from Spain to France. Papermaking techniques apparently were rediscovered by Europeans through an examination of the material from which the imported commodity was made; possibly the secret was brought back in the mid-13th century by returning crusaders or merchants in the Eastern trade. Papermaking centres grew up in Italy after 1275 and in France and Germany in the course of the 14th century.

But knowledge of the typographic process does not seem to have succeeded, as papermaking techniques had, in reaching Europe from China. It would seem that typography was assimilated by the Uighurs who lived on the borders of Mongolia and Turkistan, since a set of Uighur typefaces has been found that date from the early 14th century and are carved on wooden cubes. It would be surprising if the Uighurs, a nomadic people usually considered to have been the educators of other Turco-Mongolian peoples, had not spread the knowledge of typography as far as Egypt. There it may have encountered an obstacle to its progress toward Europe, namely, that, even though the Islāmic religion had accepted paper in order to record the word of Allah, it may have refused to permit the word of Allah to be reproduced by artificial means.

Contribution of the Uighurs

THE INVENTION OF PRINTING

Thus, the essential elements of the printing process collected slowly in western Europe, where a favourable cultural and economic climate had formed.

Xylography. Xylography, the art of printing from wood carving, the existence and importance of which in China was never suspected by Marco Polo, appeared in Europe no earlier than the last quarter of the 14th century, spontaneously and presumably as a result of the use of paper. It had been observed that paper was better suited than rough-surfaced parchment for making the impressions from wood reliefs that manuscript copyists used to reproduce the outline of ornamental initial capital letters.

The process was extended to the making of religious pictures. These at first appeared alone and later were accompanied by a brief text. As engravers became more skillful, the text finally became more important than the illustration, and in the first half of the 15th century small, genuine books of several pages, religious works or compendiums of Latin grammar by Aelius Donatus and called *donats*, were published by a method identical to that of the Chinese. Given the Western alphabet, it would seem reasonable that the next step taken might have been to carve blocks of writing that, instead of texts, would simply contain a large number of letters of the alphabet; such blocks could then be cut up into type, usable and reusable.

It is possible that experiments were in fact made along these lines, perhaps in 1423 or 1437 by a Dutchman from Haarlem, Laurens Janszoon, known as Coster. The encouraging results obtained with large type demonstrated the validity of the idea of typographic composition.

But the results were disappointing with regard to type destined for use for text of the usual size. The letters of the roman alphabet were smaller than Chinese ideograms, and cutting them from wood was a delicate operation. Moreover, type made in this way was fragile, and it wore out at least as quickly as blocks carved with a whole text. Further, since the letters were individually carved, no two copies of the same letter were identical any more than when the text was engraved directly on a wood block. The process, thus, represented no advance in ease of production, durability, or quality.

Metallographic printing (1430?). Metallographic impression is more likely to turn out to be the direct ancestor of typography, although the record is far from clear. Several medieval craft guilds, notably the metal founders, the die-cutters, and goldsmiths and silversmiths, were familiar with the technique of using dies. Masters of this technique apparently realized that it could be applied to a process that would enable texts to be set in relief more quickly than by carving wood blocks, probably in three steps: (1) a set of dies, each bearing a letter of the alphabet, was engraved in brass or bronze; (2) using these dies, the text was struck letter by letter to form a mold on the surface of a matrix of clay or of a soft metal such as lead; (3) lead was then poured over the surface to form a small plate that, once hardened, would bear the text in relief.

Steps in metal relief printing

The theoretical advantages of this process were that only one engraving per letter, that of the die, was required to make the letter as often as desired, and any two examples of the same letter would be identical, since they came from a single die; sinking the matrix and casting the lead were rapid operations; the lead had better durability than wood; and by casting several plates from the same matrix the number of copies printed could be rapidly increased.

Metallographic printing appears to have been practiced in Holland around 1430 and next in the Rhineland. Gutenberg used it in Strassburg (now Strasbourg, France) between 1434 and 1439.

But the experiments were not followed up because of problems created by the cast plates. It was difficult to strike each letter die with the same force and to keep a regular alignment, and, worse, each strike tended to deform the adjacent letter. It may well be that the major value of metallographic printing was that it associated the idea of the die, the matrix, and cast lead.

The invention of typography—Gutenberg (1450?). This association of die, matrix, and lead in the production of durable typefaces in large numbers and with each letter strictly identical, was one of the two necessary elements in the invention of typographic printing in Europe. The second necessary element was the concept of the printing press itself, an idea that had never been conceived in the Far East.

Johannes Gutenberg is generally credited with the simultaneous discovery of both these elements, though there is some uncertainty about it, and disputes arose early to cloud the honour.

It is true that his signature does not appear on any printed work. If masterpieces such as the 42-line Bible of

1455 rather than the imperfect products of a nascent typography such as the *donats* of 1445 or the "Astronomic Calendar" of 1447–48 are attributed to him, this is because of deduction and historical and technical cross-checking. The basic assumption is that, since Gutenberg was by profession a silversmith, he would have retained the role of designer in an association set up at Mainz, Germany, with the businessman Johann Fust and Fust's future son-in-law the calligrapher Peter Schöffer. The assumption is based solely on the interpretation of obscure aspects of a lawsuit that Gutenberg lost against his associates in 1455.

Evidence supporting Gutenberg's claim

Apart from chronicles, all published after his death, that attributed the invention of printing to him, probably the most convincing argument in favour of Gutenberg comes from his chief detractor, Johann Schöffer, the son of Peter Schöffer and grandson of Johann Fust. Though Schöffer claimed from 1509 on that the invention was solely his father's and grandfather's, the fact is that in 1505 he had written in a preface to an edition of Livy that "the admirable art of typography was invented by the ingenious Johan Gutenberg at Mainz in 1450." It is assumed that he had inherited this certainty from his father, and it is hard to see how a new element could have persuaded him to the contrary after 1505, since Johann Fust died in 1466 and Peter Schöffer in 1502.

The first pieces of type appear to have been made in the following steps: a letter die was carved in a soft metal such as brass or bronze; lead was poured around the die to form a matrix and a mold into which an alloy, which was to form the type itself, was poured.

Spectroscopic analyses of early type pieces reveal that the alloy used was a mix of lead, tin, and antimony—the same components used today: tin, because lead alone would have oxidized rapidly and in casting would have deteriorated the lead mold matrices; antimony, because lead and tin alone would have lacked durability.

It was probably Peter Schöffer who, around 1475, thought of replacing the soft-metal dies with steel dies, in order to produce copper letter matrices that would be reliably identical.[1] Until the middle of the 19th century, type generally continued to be made by craftsmen in this way.

The typographer's work was from the beginning characterized by four operations: (1) taking the type pieces letter by letter from a typecase; (2) arranging them side by side in a composing "stick," a strip of wood with corners, held in the hand; (3) justifying the line; that is to say, spacing the letters in each line out to a uniform length by using little blank pieces of lead between words; and (4), after printing, distributing the type, letter by letter, back in the compartments of the typecase.

The Gutenberg press. Documents of the period, including those relating to a 1439 lawsuit in connection with Gutenberg's activities at Strassburg, leave scarcely any doubt that the press has been used since the beginning of printing.

Perhaps the printing press was first just a simple adaptation of the binding press, with a fixed, level lower surface (the bed) and a movable, level upper surface (the platen), moved vertically by means of a small bar on a worm screw. The composed type, after being locked by ligatures or screwed tight into a right metal frame (the form), was inked, covered with a sheet of paper to be printed, and then the whole pressed in the vice formed by the two surfaces.

This process was superior to the brushing technique used in wood-block printing in Europe and China because it was possible to obtain a sharp impression and to print both sides of a sheet. Nevertheless, there were deficiencies: it was difficult to pass the leather pad used for inking between the platen and the form; and, since several turns of the screw were necessary to exert the required pressure, the bar had to be removed and replaced several times to raise the platen sufficiently to insert the sheet of paper.

It is generally thought that the printing press acquired its principal functional characteristics very early, probably before 1470. The first of these may have been the mobile bed, either on runners or on a sliding mechanism, that permitted the form to be withdrawn and inked after each sheet was printed.

Next, the single thread of the worm screw was replaced with three or four parallel threads with a sharply inclined pitch so that the platen could be raised by a slight movement of the bar. This resulted in a decrease in the pressure exerted by the platen, which was corrected by breaking up the printing operation so that the form was pushed under the press by the movable bed so that first one half and then the other half of the form was utilized. This was the principle of printing "in two turns," which would remain in use for three centuries.

IMPROVEMENTS AFTER GUTENBERG

Several of the many improvements in the screw printing press over the next 350 years were of significance. About 1550 the wooden screw was replaced by iron. Twenty years later, innovators added a double-hinged chase consisting of a frisket, a piece of parchment cut out to expose only the actual text itself and so to prevent ink spotting the nonprinted areas of the paper, and a tympan, a layer of a soft, thick fabric to improve the regularity of the pressure despite irregularities in the height of the type. An engraving of an early printing shop is shown in Figure 1.

The Dutch press

About 1620 Willem Janszoon Blaeu in Amsterdam added a counterweight to the pressure bar in order to make the platen rise automatically; this was the so-called Dutch press, a copy of which was to be the first press introduced into North America, by Stephen Daye at Cambridge, Massachusetts in 1638.

About 1790 an English scientist and inventor, William Nicholson, devised a method of inking using a leather-covered cylinder (later replaced by a compound of gelatin glue and molasses), the first introduction of rotary movement into the printing process.

The metal press (1795). The first all-metal press was constructed in England in about 1795. Some years later a mechanic in the United States built a metal press in which the action of the screw was replaced by that of a series of metal joints. This was the "Columbian," which was followed by the "Washington" of Samuel Rust, the apogee of the screw press inherited from Gutenberg; its printing capacity was about 250 copies an hour.

Stereotypy and stereography (end of 18th century). An increasing demand for printed matter stimulated the search for greater speed and volume. The concepts of stereotypy and stereography were explored. Stereotypy, used with notable success around 1790 in Paris, consisted in making an impression on text blocks of type in clay or soft metal in order to make lead molds of the whole. The stereotyped plates thus obtained made it economically possible to print the same text on several presses at the same time. The plates left the pieces of type

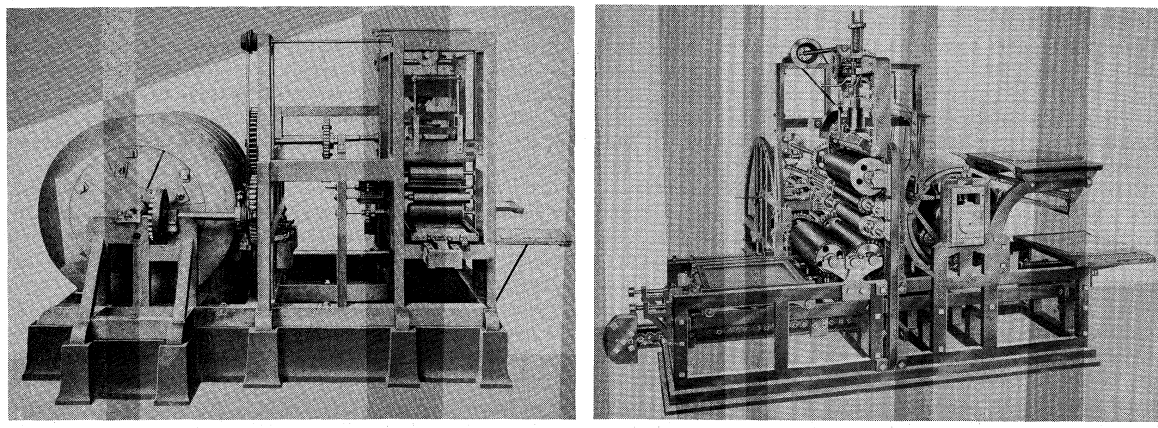

Figure 2: (Left) Friedrich Koenig's mechanical platen press, 1811, and (right) the first stop-cylinder printing machine, 1811, built by Koenig and Andreas Bauer.
By courtesy of Koenig and Bauer AG

in the form immediately available for further use and thus accelerated the rate at which they rotated.

A variation of stereotypy was the application, after 1848, of galvanoplastic metallization, in which process plates of thin metal lined with a base of lead alloy were made by placing a coat of copper on a wax mold of the typeform.

Stereography aimed at bypassing the composition of the type in making the mold. Attempts to perfect the old metallographic method of preparing a clay matrix by stamping with dies brought no better results. In 1797 a variation was tried in which sets of copper matrices of each letter were made in large numbers. The matrices were then assembled according to the wording of the text, so that they covered the whole surface of the bottom of a mold in which the lead plate was then cast. Once the cast had been made, the matrices were available for further use.

Koenig's mechanical press (early 19th century). The prospect of using steam power in printing prompted research into means by which the different operations of the printing process could be joined together in a single cycle.

In 1803, in Germany, Friedrich Koenig envisaged a press in which the raising and lowering of the platen, the to-and-fro movement of the bed, and the inking of the form by a series of rollers were controlled by a system of gear wheels (see Figure 2, left). Early trials in London in 1811 were unsuccessful.

Presses with a mechanized platen produced satisfactory results after the perfection, in the United States, of the "Liberty" (1857), in which the action of a pedal caused the platen to be held against the bed by the arms of a clamp.

Though Nicholson very early took out patents for a printing process using a cylinder to which the composed type pieces were attached, he was never able to develop the necessary technology involved.

The cylinder was in fact the most logical geometric form to use in a cyclical process. It was also the one capable of providing the greatest output. Given an equal amount of energy, the pressure exerted by a platen had to be spread over the whole of the surface to be printed, whereas the pressure exerted by a cylinder could be concentrated on the strip of surface actually in contact with the cylinder at any one instant.

A limited demonstration of the efficiency of the cylinder had been made as early as 1784 on a French press for books for the blind.

In 1811 Koenig and an associate, Andreas Bauer, in another approach to the rotary principle, designed a cylinder as a platen bearing the sheet of paper and pressing it against the typeform placed on a flatbed that moved to and fro. The rotation of the cylinder was linked to the forward movement of the bed but was disengaged when the bed moved back to go under the inking rollers (see Figure 2, right).

In 1814 the first stop-cylinder press of this kind to be driven by a steam engine was put into service at the *Times* of London. It had two cylinders, which revolved one after the other according to the to-and-fro motion of the bed so as to double the number of copies printed; a speed of 1,100 sheets per hour was achieved.

The London *Times* press of 1814

In 1818 Koenig and Bauer designed a double press in which a sheet of paper printed on one side under one of the cylinders passed to the other cylinder, to be printed on the other side. This was called a perfecting machine. In 1824 William Church added grippers to the cylinder to pick up, hold, and then automatically release the sheet of paper.

The to-and-fro movement of the bed that was retained in these early cylinder presses constituted an element of discontinuity; to make the cycle completely continuous, not only would the platen have to be cylindrical but the typeform also. In 1844 Richard Hoe in the United States patented his type revolving press, the first rotary to be based on this principle. It consisted of a cylinder of large diameter, bearing columns of type bracketed together on its outer surface; pressure was provided by several (six, eight, or ten) small cylinders, each of which was fed sheets of paper by hand. This system gave speeds of more than 8,000 copies per hour; its only drawback was its fragility; faulty locking up of the forms caused the type to fall out of the cylinder.

This defect was remedied by applying stereotypy to the production; that is, forming curved plates by making an impression of the typeform on strong pasteboard, the flong, or mat, which was fixed against the inside surface of a rounded mold, which was injected with lead alloy. In France, from 1849 onward, experiments were conducted with this process; it was regularly used in London by the *Times* from 1856 onward and after 1858 was in general use.

But feeding the press with paper still remained outside the mechanized cycle. Mechanization of this step was accomplished by the use of a continuous roll of paper supplied on reels instead of sheets. Techniques for producing paper in a continuous roll had been known since the beginning of the century. The first roll-fed rotary press was made by William Bullock of the United States in 1865. It included a device for cutting the paper after printing and produced 12,000 complete newspapers per hour. Automatic folding devices, the first of which were designed by Bullock and Hoe, were incorporated into rotaries after 1870.

Later, numerous other types of curved stereotype plates were used on rotary presses. These included electrotype plates that are curved before being backed; rubber or plastic plates made by molding or by a photomechanical process; and metal wraparound plates made by photoengraving or electronic engraving.

Attempts to mechanize composition (mid-19th century). Unlike the mechanization of the printing process, mechanization of the composition process was difficult to achieve in the 19th century. The invention of a compression mold in 1806 opened prospects for the mechanization

of the production of type. In 1822 in Boston, William Church took out a patent for a typesetting machine consisting of a keyboard on which each key released a piece of type of the corresponding letter stored in channels in a magazine. The pieces of type thus obtained had to be assembled by hand and the line justified. Church had avoided the problem of distribution and shown an intuition as to its solution by annexing to the magazine a device for constantly casting new pieces of type.

Numerous machines based on the same principle and with the further addition of a mechanism that placed the type pieces selected the right way round appeared in the course of the next 50 years. On one of these the more than 10,000 pages of the ninth edition of *Encyclopædia Britannica* were composed. These machines produced type at the rate of 5,000 to 12,000 pieces per hour, as opposed to about 1,500 by hand composition. But in all of them the type was simply delivered in a continuous row, which had to be divided into lines and justified.

These machines were completed by the introduction of a mechanical distributor, which was a sort of reverse compositor: pieces of type from lines that had been used passed before the operator, who pressed the corresponding key on his keyboard for the appropriate channel in the magazine to be opened up. The speed of mechanized distribution did not exceed 5,000 pieces of type per hour and was, thus, no faster than hand distribution.

Mechanization of letterpress composition faced two difficulties: first, justification, which required intelligent estimation of the size of spaces to be provided between words; and, second, the time taken during which the pieces of type were used for printing, which delay kept composition and distribution from being integrated into one cycle.

Mergenthaler's Linotype machine

Typecasting compositions (1880s). Finally, in the 1880s in the United States, German-born Ottmar Mergenthaler invented the Linotype, a typecasting compositor that cast a solid one-piece line, or slug, from movable matrices of each letter. Each of the matrices was individually notched so that it could return only to its proper slot in the magazine after use. Justification was carried out by inserting wedged spacebands between groups of matrices immediately after making up the words of a given line. Here the matrices rather than type pieces went through the four basic operations of letterpress composition; cast lead was used for printing. The Linotype can produce the equivalent of 5,000 to 7,000 pieces of type per hour.

In 1885, also in the United States, Tolbert Lanston invented the Monotype, which casts individual pieces of type for a line and justifies each line by a system of counting in units the width of the spaces taken up by the pieces of type. The matrices are indefinitely reusable, and the pieces of type, which are used only for the impressions, are returned to the caster. The contemporary Monotype typecaster is controlled by a ribbon of paper perforated on a separate keyboard. It can produce 10,000 to 12,000 pieces of type per hour.

In 1911 another American, Washington I. Ludlow, perfected a typecasting machine for the large display type that bears his name, in which matrices are assembled by hand in a composing stick, which is then inserted above the opening of a mold; the matrices are also distributed by hand.

19TH-CENTURY INNOVATIONS

In the course of the 19th century several important innovations laid the foundation for a number of printing techniques which were not directly related to Gutenberg's invention.

Reproduction of illustrations. The first process for reproducing illustrations was xylography, woodcuts that printed in relief and that therefore could be used together with letterpress, the picture blocks and the pieces of type for texts being locked into the same form. As early as the second half of the 15th century, xylography faced competition from engraving on metal that printed by intaglio; the metal plate (copper, sometimes brass, zinc, and even steel after 1806), engraved with a tool (burin) or etched with acid, was inked and carefully wiped so that ink remained only in the incisions and was transferred to paper under pressure in a cylinder press derived from the rolling mill. Since the intaglio method of printing was not compatible with woodcut printing, sheets of text and of illustrations for the same book had to be printed separately.

Presses for printing curved intaglio-engraved plates were perfected during the 19th century with mechanized inking with the use of rollers and wiping with the use of revolving cloth bands or rotating disks covered with calico. Their printing capacity was limited.

As early as the end of the 18th century, however, intaglio printing had inspired a method for continuous printing of textiles by passing them under an engraved and inked cylinder from which excess ink had been removed by a scraper. In France in 1860 this technique was applied to printing paper for school-book covers. A solid copper cylinder was engraved not with continuous lines but with a multiplicity of tiny cavities in such a way that they retained the ink uniformly despite gravity, centrifugal force, and the action of the scraper. The process was suitable only for simple graphics.

Lithography: Senefelder (1796). A third printing process that had undergone significant development was lithography, neither relief nor intaglio printing but based on the principle that water and grease will not mix. In 1796 Aloys Senefelder of Prague investigated the properties of a stone with a calcium carbonate base and a fine, homogeneous, porous surface. A design drawn on its surface with greasy ink, wetted with water and then brushed with ordinary ink, retained the ink only on the design. This could consequently be reproduced on a sheet of paper pressed against the stone. Senefelder also established that a design drawn on such a stone and printed on paper could be transferred to another stone in as many identical copies as desired, side by side, which made it possible to obtain several copies at a time by printing a single large sheet. He further established that a metal such as zinc had the same properties.

Senefelder envisaged a press in which the stone, secured to an undercarriage, was inked, covered with the sheet of paper with a sheet of pasteboard above it, and submitted to pressure. By 1850 the first mechanized lithographic press with a cylinder, flannel-covered rollers for wetting, and rollers for inking was perfected.

The fact that it was possible to replace the stone by a zinc plate that could be curved made it possible to build rotary presses (the first in 1868) in which the paper passed between the plate-bearing cylinder and the impression cylinder.

Photosensitivity: Niepce (1820s). It was while searching for a means of automatically inscribing an image on a lithographic stone, then on a tin plate, in order to engrave it in intaglio, that Joseph-Nicephore Niepce in the 1820s established that certain chemical compounds are sensitive to light. This discovery marked the origins of photogravure (see also PHOTOENGRAVING) and led to both the invention of photography (between 1829 and 1838) and the use of photographic processes for the printed reproduction of photographs.

In 1852 Fox Talbot, a British scientist and inventor, placed a piece of black cloth (tulle) between the object he wanted to reproduce (the leaf of a tree) and the photosensitive coating spread on a steel plate and obtained a picture that retained the fine mesh of the tulle. Consequently, etching with acid resulted not in an extensive and uniform erosion of an area but in tiny juxtaposed pits all over the photosensitive coating and varying in depth according to the degree of exposure. Talbot simultaneously had invented the screen and also had opened the way for a new development in intaglio printing: rotogravure.

The screen was perfected in the 1880s by substituting for the cloth two sheets of glass with uniform parallel lines that crossed perpendicularly. The screen made possible letterpress and lithographic reproduction of the full range of tones of a photographic document by using the effect of the diffusion of light through the mesh of its grid and

converting the different intensity of tones into the different thicknesses of the printing surface.

Gravure and rotogravure (1890s). The circular mechanization of intaglio engraving, meanwhile, came up against two associated difficulties: the need to engrave an infinite number of tiny cells and the need to engrave them directly onto a cylinder. There were problems, because the rubbing of the squeegee to remove excess ink excluded the use of a curved plate that would not have provided a uniform surface in the area in which it was attached, and it was not possible to get photosensitive solutions to adhere to a cylinder.

In 1862–64 J.W. Swan of Britain invented carbon tissue, which was coated with a photosensitive solution and could therefore be exposed to light before being applied to a metal surface of any shape.

The Klietsch process

In about 1890 a Czech, Karl Klič (also spelled Klietsch), thought of copying a grid screen directly onto carbon tissue, which could be used to transfer the cells necessary for intaglio printing to a cylinder at the same time as the image to be reproduced. In 1895 Klič, with English colleagues, founded the Rembrandt Intaglio Printing Company, which published reproductions of pictures, on paper, by rotogravure. They kept their process a secret.

In a parallel way, patents for a slightly different process, in which the image to be reproduced was screened before making the impression on the carbon tissue, were taken out in Germany and the United States. But a workman from the Rembrandt Intaglio Printing Company emigrated to the United States in 1903 and there revealed Klič's secret, and rotogravure, using his method, became widespread.

THE 20TH CENTURY

Beginning with the invention of the offset technique, the 20th century saw the steady development of innovations in the direction of mass production, speed, and economy.

Discovery of offset (early 20th century). At the same time, lithography was undergoing a new evolution. After the first mechanical presses had been perfected, this process had developed along two lines: (1) printing on thin sheets of metal (for example, tinplate for packaging canned foods) using a transfer process (1878) in which the impression cylinder carrying the metal sheet to be printed did not come in contact with the stone but did with an intermediary cylinder covered with rubber, the blanket, which transferred the image from the stone to the metal; and (2) printing on paper, which was done only comparatively infrequently in the last years of the 19th century, on cylinder or rotary presses.

In 1904 at Nutley, New Jersey, an American printer, Ira W. Rubel, discovered that an image accidentally transferred from the plate cylinder of his rotary to the rubber blanket of the impression cylinder during a paper-feed stoppage could itself be used for printing and in fact produced a superior impression. Rubel and an associate constructed a three-cylinder press, the first offset press, the term since used to describe this constantly expanding printing process.

Dry offset (1920). A few years later a problem arose in connection with printing the background of checks with a water-soluble ink to prevent forgeries. It was proposed that the lithographic plate of the plate cylinder be replaced with a stereotype plate or with a letterpress wraparound plate. This process, which combines the relief of letterpress, which does not require wetting, with the transfer of offset, is known as dry offset, or letterset. Its area of application is not limited to check backgrounds but is used in all areas of conventional printing.

Since 1950 another process has been developed, particularly in the United States, which combines rotogravure with the transfer of offset for printing wallpapers, plastic floor coverings, paper plates, and other products.

Colour printing. As early as 1457 a psalter, which Peter Schöffer signed but which some researchers now attribute to Gutenberg, included, in imitation of the contemporary illuminated manuscripts, paragraphs beginning with ornamental capital letters printed in two colours. This was accomplished by the use of two wood blocks that fitted one inside the other and could be separately inked.

Early colour experiments

Experiments to reproduce pictures in several colours on wood blocks were made in Germany in the 16th century. In the 17th century, different inks were applied to the different parts of the same engraved metal plate in such a way that all the inks were transferred to the paper in a single pressing. In 1719 a painter, Jacques-Christophe Le Blond, took out a patent in England for a process that used the three primary colours, blue, yellow, and red, and black for outlining shapes. Using a dense grid, he engraved four metal plates, bringing out on each plate the relative importance of the colour involved. The same sheet of paper then went through four successive impressions, each in a different colour.

In the 19th century the scientific definition of the principles of trichromatism, the enunciation of the fundamental theories of three-colour analysis and synthesis of colours by photography, the perfecting of coatings selectively sensitive to colours, and finally the use of the screen, instead of Le Blond's hand-drawn grid, established the modern trichromatic technique (which is called quadrichromatic when black is also used).

Automation of composition (after 1929). The search for maximum efficiency had from the very beginning posed the problem of both the mechanization and the automation of composition. The Monotype system, with its separation of keyboard and caster, had constituted one approach to the solution, since the same caster could work at full speed when fed with perforated tapes produced on several keyboards.

The perfection of teletypesetter remote-control composing equipment in the United States by about 1929 permitted widespread application of the principle of separation of human function on the one hand and mechanized function on the other. The operator produces a tape on which each letter, symbol, and space is represented by a combination of perforations. A translator device reads the tape and, according to each combination of holes, orders the release of the necessary matrices for letters, signs, and justifying spaces. Machines casting one-piece fully spaced lines or slugs are able to produce more than 20,000 characters per hour.

Programmed composition (1950s). The production of the perforated tape remained relatively slow, however, because of the time taken by the operator to decide where to make the division in a word at the end of a line. Eventually, in the second half of the 20th century, electronics provided the means of automatically making this decision.

In the 1950s the BBR system, named by the initials of three inventors in France, introduced programmed composition. Starting with a perforated tape continuously produced by the operator, a computer takes over the task of determining the length of lines, the places where words are to be divided according to grammatical rules and typographic usage, the integration of corrections, and even the presentation of the text according to the layout. The speed at which a final tape bearing this information can be produced is limited only by the performance of the perforator, which is the outlet device of the computer. Operating speeds have exceeded 300,000 characters per hour, or ten times the capacity of the most modern slug-casting machines.

Introduction of magnetic tape

During the 1960s, perforated tape began to be replaced by magnetic tape, which is even more rapidly made, at a rate of about 1,000 characters per second, or 3,600,000 per hour. Although magnetic tape is useless for mechanical composers casting pieces of type or lines in lead, such speed is practical for other types of machines not burdened with the weight of lead and the inertia of their mechanical devices.

Photocomposition. In preparing cylinders for rotogravure, offset plates, or letterpress wraparound plates, it is illogical to use the vast weight of lead in letterpress composition to produce a reproduction proof that will then be photographed. Before the end of the 19th century this consideration led to consideration of machines for composing headings by photographing the images of the let-

ters in succession. In 1915 the Photoline, a photographic equivalent of the Ludlow, assembled matrices of transparent letters in a composing stick in order to film each line of the heading.

First generation of phototypesetters: mechanical. The next idea to be tried involved the adaptation of existing typesetters by replacing the metal matrices with matrices carrying the image of the letters and replacing the caster with a photographic unit. The industrial application of this idea resulted in the Fotosetter (1947), a phototypesetter, and its variant the Fotomatic (1963), controlled by a perforated tape, both derived from the Intertype slugcasting machine; the Linofilm (1950), derived from the Linotype; and the Monophoto (1957), derived from the Monotype. Retaining the mechanical limitations of machines intended to shape lead, they could not achieve appreciably higher rates of performance. Photocomposition had to be rethought in functional terms. This approach was explored as early as the 1920s with the Uher typesetter, built in Germany, whose photographic matrices were attached to a rotating disk.

Second generation of phototypesetters: functional. The second generation of phototypesetters is characterized by the maximum elimination of factors of inertia, the number of moving parts having generally been reduced to only two: a disk or drum carrying the photographic matrices and revolving permanently and an optical device of prisms or mirrors allowing directional action on the stream of light provided by an electronic flashtube.

The first revolutionary application of this notion was the Lumitype, invented as the Lithomat in 1949 by two Frenchmen, René Higonnet and Louis Moyroud, who applied for patents in the United States. Executed entirely by phototypesetting, *The Marvelous World of Insects* was done on their machine in 1953. The first model had an attached keyboard. On later models with a separate keyboard production speed exceeded 28,000 characters per hour.

A new Linofilm (1954), functional and electronic, was fitted with a device for selecting matrices by the action of the blades on the photographic shutter, producing 12 characters per second or 43,200 per hour. The model that succeeded it (1965) is equipped with a drum and is capable of double the output.

The Photon-Lumitype 713 (1957) also performs at the rate of 70,000 to 80,000 characters per hour. But at this speed the technique of using a rotary matrix case reaches its limit because of the problems posted by centrifugal force.

The Lumizip 900 (1959) introduced a further revolutionary change by retaining as moving parts only the lens, which scans in a single movement the fixed series of light matrices so as to photograph at one time the whole line of 20 to 60 letters. Output reaches 200 to 600 characters per second, or more than 2,000,000 per hour; this machine required magnetic tape.

The first book composed with a Lumizip, the *Index Medicus*, published in the United States in 1964, was as much of a landmark in the history of phototypesetting as the 42-line Bible had been in printing. Its more than 600 pages were completed in 12 hours. To produce the same work on a typecasting machine would have taken almost a year.

Third generation of phototypesetters: electronic. But magnetic tape was capable of production speeds even higher than those obtained on the fastest phototypesetters. To narrow this gap, a third generation of phototypesetters appeared in the 1960s, in which all mechanical moving parts were eliminated by omitting the use of light and therefore omitting the moving optical device responsible for operating in its field.

Cathode-ray-tube phototypesetters (RCA, Linotron, etc.) operate on a principle analogous to that of television: a narrow pencil of electrons analyzes an image matrix of each letter and commands the modulation of another pencil of electrons on a luminescent screen, which leaves an impression on photographic film. Performance exceeds 500 characters per second and even approaches 1,000, or over 3,000,000 per hour.

Digiset, a German development that appeared in 1965, pushed the use of the electron to its logical conclusion by suppressing even the image matrix of the character, simply keeping the binary analysis of its design available in its magnetic memory; this is, in fact, all that is needed to modulate the pencil of electrons on the final screen.

Speed of phototypesetters

Phototypesetters of this kind (called alphanumerical) have theoretical performance rates exceeding 3,000 characters per second, or more than 10,000,000 per hour, and should be able to approach 30,000,000.

Speeds such as these exceed even the production rate of magnetic tape. Consequently, to work at its most efficient output, such a typesetter must be directly connected to a computer with a similarly high rate of output.

Toward direct impression. The number of characters thus composed now approaches the number of characters printed on a press in the same time (for example, 5,000 sheets per hour, each with 100 lines of 60 characters per sheet, equals 30,000,000 characters). The narrower this gap becomes, the more a still further revolutionary possibility looms—that of eliminating the press itself, since the typesetter can be made to deliver each page as quickly as the press would have done.

To accomplish this it would be necessary only to replace the photographic film that the photographer imprints when it is conventionally used, with an inexpensive carrier capable of receiving an image in the same way without pressure.

Several pressureless printing processes have already been perfected. In 1923 an electrostatic onset system drew the ink of a cylindrical typeform to the paper by means of an electrical charge. In 1948 two Americans conceived another type of electrostatic printing in which the colouring agent is not ink carried on a typeform but a powder or a solution sensitive to the pull of an electric charge inscribed in a plate. This technique gave birth to xerocopy in office duplicating (see below *Office printing*) and, at the industrial level, to xerography for producing posters and maps.

Printing without pressure can also be accomplished on papers impregnated with photosensitive preparations and passed in front of a cathode-ray screen of a phototypesetter. The first experiment using this facsimile printing process was carried out in Japan in 1964 by the *Mainichi Shimbun*, a Tokyo daily newspaper. The image of the newspaper page formed on the cathode-ray screen was transmitted by radio waves, as in television. It was reproduced using the electrostatic system, which does not require chemical treatment of the paper after its exposure.

The Tokyo newspaper experiment

Serigraphy and collotype: a renaissance. Parallel to the evolution of the three major printing processes, letterpress, offset, and lithography, various other techniques have experienced a similar evolution, which has allowed them to survive or to establish themselves in the course of the 20th century and to preserve or win a place in printing.

The art of reproducing a design by forcing ink through the mesh of a silk screen partly blanked out with a stencil plate (serigraphy) had been practiced by the Chinese and Japanese long before the invention of letterpress. In the 19th century the textile manufacturers of Lyons, France, adopted it for printing textiles. In the 1930s in Great Britain and the United States the most varied materials (glass, wood, plastic) and even the most varied shapes (round objects, for example) were printed by serigraphy, which from a handcraft progressed to an industrial technique, with the screen prepared by photosensitization and printing carried out by semi-automatic or automatic machines.

Another process, patented in France in 1855 under the name Photocollography, was modified in 1865 under the name Phototypy (still used in France) and in Germany in 1868 under the name Albertypy (still used in Germany). This process used photosensitive substances not as agents in making plates for printing but to serve directly as the effective surface of such plates. Known elsewhere as the collotype process, the technique was in great favour between 1880 and 1914, was then neglected, and has recently been revived and mechanized for printing posters and transparencies in black and in colour.

Flexography is a letterpress process using rubber plates on the plate cylinder; it occupies a special place in printing on account of the fluidity of its inks. The first patents were taken out in England in 1890, and it was perfected in Strassburg a few years later. Flexographic printing is only of medium quality but is particularly suited to relatively coarse surfaces (pasteboard, wrapping paper, plastic or metal film). It can be carried out by sheet-fed machines but is chiefly used on powerful rotaries.

Three-dimensional printing (1960s). In the 1960s a three-dimensional print was developed, essentially an illustration bearing two views, superimposed, of the same image taken from slightly different angles, on a transparent mount striped with a multitude of imperceptible parallel strips (Xograph process.) On account of these strips, each eye, looking at the print from a different angle, sees only one of the two images selectively. The three-dimensional illusion is produced when this binocular vision is interpreted by the brain.

Office printing. The development of industry and commerce, in the 19th and 20th centuries, accompanied by an increase in administrative activity, created a demand for an abundance of printed information at various levels. In the field of office printing the first tool was the typewriter, perfected in 1867 (see TYPEWRITER). Thereafter, machines appeared that would reproduce large or small numbers of copies of typewritten texts and, later, texts or illustrations of every kind. Some of these machines rely on techniques very close to those of conventional printing; others turned to original techniques that were in turn extended into modern printing. In 1881 in England appeared the stencil duplicator, basically similar to the serigraphic technique. In 1900 a photocopying machine invented in France opened the way to facsimile printing. The offset printing process spread into the area of business printing with small offset duplicating machines whose simplified methods for preparing plates had repercussions that led to the simplification of the preparation of normal plates.

Stencil, facsimile, and xerography

The application of the electrostatic printing process to xerocopy, perfected in 1938, has since been taken over by industry.

All the various processes of duplication and reproduction of documents make up reprography, a name bestowed during the first congress devoted to these techniques, which was organized at Cologne in 1963. If its boundaries with conventional printing are poorly delimited, to the extent that reprography can compete with conventional printing when a medium number of copies are concerned, reprography nevertheless represents an original field. In response to the increased need for quality reprography, the typewriter has been improved since the 1950s and given the capability of providing justified composition suitable for conventional printing.

II. Modern printing techniques

COMPOSITION AND TYPESETTING

Mechanical composition and typesetting. In the first decades of the 20th century all type was set and composed into columns and pages by hand or by mechanical means. These methods are still widely used.

Letterpress composition by hand. The font, which constitutes a complete set of characters of a given typeface, with duplicate numbers of each letter in proportion to the frequency with which each is used, is stored in the compartments of a case; capital letters, proportionately less frequently called for, are in the upper compartments, whence their name, uppercase, and the small letters in the lower compartments, which are more easily accessible and whence their name, lowercase.

The typographer works standing in front of the case. His principal tools are the composing stick, a metal angle iron with one fixed end and a "knee" with a screw or lever for locking; the line gauge, a ruler graduated in units of typographic measurement; and tweezers.

He locks the knee of the composing stick at the justification; that is, at the length of the line to be composed. Against the inside edge of the stick he places a lead, a strip of nonprinting lead alloy that later enables him, using a second lead, to grip the finished line in order to remove it from the composing stick. Holding the composing stick in one hand, he uses the other to select the individual type characters from the case. He can tell by touching which way up they should go, thanks to a nick indicating the top or bottom of the body (the bottom in English-speaking countries and Germany; elsewhere, the top), and he places them side by side in the composing stick. Having completed the proper number of characters to fill the length of the line with a whole word or at the correct division in a word, he adds as necessary to the nonprinting pieces already in place to mark the spaces between the words until the exact justification is obtained.

Having composed and justified the line, the typographer takes it, gripped by its two leads between the thumb and forefinger of both hands, to place it in a galley, a wooden or metal tray with a raised edge on two or three of its sides.

Semimechanized composition. The Ludlow is considered a combination machine; though it automatically casts slugs, it is related to hand composition by the way the matrices are assembled. The matrices are bronze blocks bearing the letter or sign engraved in intaglio on their lower side and with two shoulders on their upper side.

Operations of a Ludlow caster

The composer gathers them individually from the case, which is one of the drawers of a desk, and arranges them side by side in a special composing stick. This steel composing stick is hollowed out in the middle to receive the matrices supported on their shoulders with an adjustable stopscrew for fixing the length of the line. Justification is ensured by blank unengraved matrices in various sizes equally distributed between the words.

The caster resembles a steel workbench with a hollowed-out slot on its surface in which the composing stick is inserted with the matrices face down. A lever starts the casting process by turning on an electric motor. A mold with an opening rises and positions itself under the aligned matrices; a plunger in the melting pot containing the molten alloy forces enough alloy into the mold to cast one line; casting is completed in less than ten seconds, the mold withdraws and releases the solidified line, and the lever, which releases the composing stick, rises automatically.

Since the body size of the font is a uniform size, the upper part of characters whose body size exceeds its measurement projects beyond each side and has to be supported, when it is being used, with leads.

Since the width of the slugs is also uniform, when shorter lines are being cast the composing stick is furnished with thick, blank matrices; once cast, the line is clipped off to the proper length. For longer lines, composing sticks are used with justifications in multiples of that of the mold. Fractions of the line are cast one after another and fit together exactly. The Ludlow is used especially for casting lines of large type for use as titles and subtitles, using typefaces varying from 12 to 144 points (one point equals 1/72, or 0.0138, inch).

The Ludlow caster is complemented by an Elrod caster. This automatically casts nonprinting leads and rules, narrow pieces of nonprinting alloy; both items come in various thicknesses.

Another type of mixed typecaster with manual assembly of the matrices is represented by the All-Purpose Linotype, a sort of Linotype from which only the casting part has been retained (see below *Linotype*). It is used primarily in United States printing establishments. An Italian equivalent, the Nebitype, is used, though less widely, in Europe.

Mechanical composition: slugcasting typesetters. The Linotype and Intertype slugcasting typesetters produce lines of letterpress composition in a single operation, starting with the assembling of the movable matrices. The letter matrices are thin, brass 19 × 32-millimetre (0.7 × 1.3-inch) plates, with two ears and a system of 14 notches arranged in a V on the upper surface and two heels in their lower part. The letter is engraved in intaglio on the face surface; usually two copies of the same letter are superimposed (duplex matrices)—one normal, or ro-

man, the other a variant, either italic (sloping design) or boldface (stronger design). Thus, their thickness varies according to the letter and the body of the character.

The set of matrices is stored in a magazine, a flat, trapezoid metal box consisting of 90 channels in which the matrices are aligned one behind the other, duplicates of 20 or 24 for each letter or sign, lying face down, resting on an ear and a heel.

Introducing blanks into the line is done in two ways: either by using unengraved blank matrices, included in the magazine in three standard sizes, or by using spacebands designed to ensure justification.

The operator sits in front of a keyboard with 90 keys, corresponding to the channels in the magazine, on the left the lowercase letters, on the right the uppercase letters, in the middle the small capitals, numbers, and various symbols. A special bar operates the release of spacebands.

The nine steps in slugcasting

Slugcasting typesetters function as follows: (1) Touching a key releases the matrices, which are brought in proper order on a conveyor belt to a composing stick made of slide-bars and held by their ears. The spacebands, which are stored directly above the composing stick, fall into place between the words. (2) When the matrices and spacebands in the composing stick visibly take up the amount of space planned for the length of the line, the operator completes the line, either with a whole word or by dividing the last word, and pushes a lever to move the line. Since the remaining operations are done automatically he can go on to set the next line. (3) The assembled matrices and spacebands are moved three times in succession: vertically upward on the composing stick; sideways to the left on a transfer slide rest; vertically downward on an elevator that puts them in front of the opening of a mold mounted on a cogwheel called a mold wheel, connected to an electric melting pot containing the molten lead alloy. (4) A justifying hammer forces the long pieces of the spacebands upward, forcing them to separate by equal spaces until all the matrices and spacebands are locked between two steel jaws fixed at the precise justification of the line (see Figure 3). A piston plunges

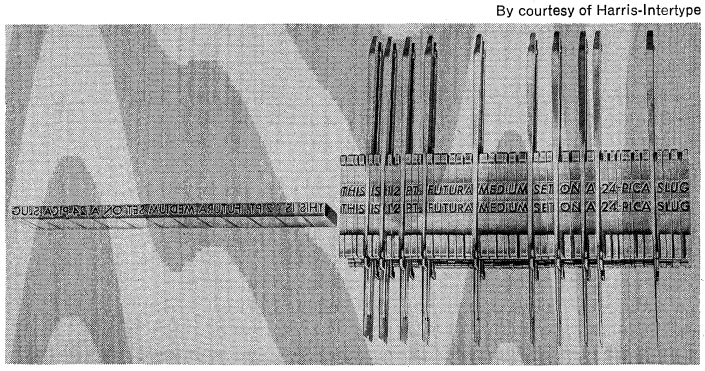

Figure 3: Lineup of matrices and justifying spacers (spacebands) and a cast line of type in a linecasting operation (see text).

into the melting pot and forces the alloy into the mold to cast the line. (5) While the mold wheel rotates three-quarters of a revolution and the solidified line is finished to its exact letterpress height before it is ejected into a galley, the matrices and spacebands are again moved upward by the elevator. (6) They are pushed to the right toward a triangular bar bearing 14 grooves corresponding to the 14 notches in the matrices. (7) Raised by a catcher arm, this bar removes the matrices, which are caught by their notches; the unnotched spacebands are released and immediately return to the place where they are stored. (8) When the catcher arm is at its highest position, the matrices are pushed to the right toward another triangular bar with 14 grooves along its length and flush with the top part of the magazine; this is the distributor bar. (9) The matrices move along the distributor bar until at a certain point the arrangement of grooves ceases to provide support for the notches, which of course are different for each letter or sign. Each letter's matrix is then released at the opening of its own channel in the magazine.

The automatic cycle of the typesetter is controlled by several large cams mounted on a single shaft driven by an electric motor.

Modern typesetting machines are equipped with several magazines of varying type sizes that can be used alternately. Some so-called double-distribution machines permit two magazines to be used at once by pressing a supplementary key.

The performance of recent models has been improved by accelerating the revolution of the matrices, intensifying the cooling system of the mold, and increasing the number of molds on the mold wheel to six.

The slugcasting typesetter, which furnishes solid, easy to handle, composed type, is particularly suited to printing newspapers. It has the disadvantage that to correct any error, however trivial, the whole line must be recomposed.

The All-Purpose Linotype is a combination manual and automatic machine that retains only the casting part of the Linotype. Special matrices, solidly rectangular or with notches, ears, and heels, are assembled by hand in a composing stick. Justification is done with blank matrices of various sizes. The line of matrices, held by the composing stick, is placed against two set squares fastened to the bedplate of the machine and manually pushed on a slide rest, which takes it to the elevator. The elevator places the matrices in front of the opening to the mold for the casting operation, which delivers the slug. The matrices are then distributed by hand.

Typesetter casting aligned characters. The operation of the Monotype typesetter, which casts individual aligned characters, is based on a system of measuring the width of characters, called the set. In each font, letters and symbols have sizes determined in units of set, from five units for the narrowest, such as the "i" or the "l," to 18 units for the largest, such as the "W" or the "M."

The Monotype keyboard

The Monotype keyboard, separate from the caster, consists, on the standard model, of 274 keys, 30 of which, in two rows numbered from 1 to 15, are called justifying keys. Typing out the text results in the perforation, by an automatic punch, of one or two holes, each letter or symbol having its own pattern, in the width of a paper tape that allows 31 possible arrangements. An automatic calculator adds the widths of the letters and symbols typed out. Moving his forefinger across a scale that he has before him, the operator knows when the end of a line is near. Once he has finished a line, he places his other forefinger on the justifying drum, which indicates which two justifying keys he must now press. This move results in the perforation of one or two holes whose position indicates the quotient of the number of units lacking for the line to be completed by the number of spaces between the words of this line, plus a third hole in a position specifically fixed for the justification process.

The typesetter is composed of an electric melting pot containing molten alloy situated under a mold in the shape of a vertical chimney, the internal dimensions of which can vary according to the measurement in units of set of the characters or spaces to be cast.

The matrices are in the form of small bronze cubic blocks measuring five millimetres (0.2 inch) square, arranged in a steel frame nine centimetres (3.5 inches) square containing 15 rows of 15, enough for five complete alphabets, typically uppercase and lowercase in roman, italic, and boldface, and small capitals, as well as double or triple letters, numbers, and punctuation marks. Each row includes only matrices of letters and symbols of the same unit of set, from the smallest (five units) in the first row to the largest (18 units) in the back row.

The frame can slide horizontally in either direction to place any matrix from any row above the opening to the mold.

The process of setting and casting type on the Monotype is as follows: the roll of perforated paper tape is placed in the pneumatic tower of the typesetter—a row of 31 pipes circulating compressed air. As it unrolls, the tape prevents the compressed air from entering all pipes except those corresponding to the perforations.

The tape unrolls in the direction opposite to that in

which it was rolled up—that is, in the opposite order to the way it was typed, the last line appearing first and the justifying perforations being inserted into the pneumatic tower before those for the letters and symbols. The compressed air that the perforations allow to pass into three (or two) of the pipes causes pieces of metal (justifying quoins) to fall into position in such a way as to control the internal measurement of the mold each time that the spaces between the words of the next line are to be cast.

The perforations for each letter or symbol allow the compressed air to pass into two (or only one) of the pipes connected to two blocks, each of which also contains a series of graded pins. Compressed air raises a pin in each block and halts the movement of the matrix frame in either of its sideways movements. In this way the matrix's row and the matrix's place in its row are selected. Selecting the row is the same as selecting a measurement given in units of set. Positioning the row is automatically linked to setting a piece of metal (the set quoin) whose position regulates the dimensions of the mold for casting the letter or symbol.

For the casting, a centring device places the selected matrix precisely against the opening of the mold, and a plunger in the melting pot forces the alloy up to cast the character or the space (that is, the unengraved matrix).

The composed line emerges from the machine completely assembled and justified and is placed in a galley.

The Monotype can cast type ranging in body size from five to 24 points (with a special mold for each). The addition of a speed-reducing device enables it to cast in 48 points. The maximum width of lines assembled is 60 picas.

In the early 1970s Monotype models could be equipped with a frame carrying 15 rows of 17 matrices (255) or 16 rows of 17 (272), with six or seven complete alphabets. The keyboard then has 310 keys.

A special model of the keyboard permits simultaneous perforation of two tapes for composing the same text in identical or different kinds of type and lengths of line.

Advantages of Monotype

The advantages of the Monotype system are the quality of its composition and the ease with which corrections can be made without having to reset the whole line. It is not well suited to newspaper printing because of the difficulty of handling lines of movable type and because, since typecasting begins with the end of the tape, composition must wait until all the type has been cast.

Automatic composition (perforated tape). The Teletypesetter (TTS) system extends to slugcasting machines the principle of separation of function originally characteristic of the Monotype: it enables Linotype or Intertype machines to be controlled by a perforated tape produced on a separate keyboard, even situated in a different city, since the combination of the perforations on the tape can be sent telegraphically.

The Teletypesetter tape is six-channelled; that is, it contains six possible positions for perforations across its width. This allows 64 different combinations of from one to six perforations.

Ths limited capacity, less than the number of keys on the keyboard of the typesetter, is corrected by an arrangement whereby each combination of perforations may have two different uses (for example, the uppercase and the lowercase of the same letter) according to whether it follows one or other of two special signals (themselves represented by combinations of perforations) that control passage of one or other of these uses.

The Teletypesetter keyboard

The keyboard for preparing the Teletypesetter tape looks like a typewriter with, in addition to the usual 44 keys and the space bar, 20 special keys. Striking each key establishes contact with the electric circuit or circuits that operate the perforators and at the same time acts on a calculating mechanism: a needle moving across a screen warns the operator of the end of each line.

Usually, as the tape is perforated the text is also typed out on a sheet of paper, which allows the work to be checked, reread, and corrected. For use with a Teletypesetter, the typesetting machine is equipped with a mechanism that translates the tape. In this mechanism the tape passes under six sensors that register electric contacts as the perforations pass. In accordance with the combination of electric contacts thus established, relays control the action of the keys or of the bar that causes the spacebands to drop and, at the end of each line, the starting of the casting cycle.

The most recent typesetters specially designed for use with the Teletypesetter offer such technical refinements as the elimination of the composing stick and immediate dispatch of the line to the elevator, simplifying the path taken by the matrices; and electromagnetic, rather than mechanical coupling, which speeds the starting up of the casting cycle.

Programmed composition (prepared by computer). The use of a computer eliminates manual intervention in preparing the perforated tape, in assessing the length of the lines, and even in deciding how to end them; *i.e.*, whether by completing or dividing a word.

Normally, the operator types out a continuous tape called idiot tape in the United States (kilometre tape in France) without concern for the length or division of lines. This band is inserted into the computer's input device, a tape scanner, which operates by means of either electric sensors or photoelectric cells and converts letters, signs, and orders into combinations of electric impulses. The computer semi-automatically or automatically processes this raw information in accordance with its programmed instructions and immediately communicates the result to an electromagnetic perforator, the output device, that produces a second tape, like the first but that also bears, in the proper places, perforations ordering the ends of lines.

A general program establishes the operation of the computer in its application to the work of composition. Individual programs adapt it to the machinery of the company concerned (models of typesetters, available magazines of matrices) and to the kind of work carried out (usual length of line, method of indenting paragraphs, etc). Finally, special instructions punched on the tape by the operator at the same time as the text can interrupt the execution of the programs registered in the computer with directions valid for this text alone, in its entirety or in certain parts: choice of typeface among those available, transition from one kind of typeface to another available for the same typesetter, length of line and changes in the length, alignment to right or left, squaring of lines, indentations for ornamental capitals, spaces for borders or illustrations, and other details.

Having identified the combinations of the perforations on the tape and separately retained the service signals addressed directly to it, the computer proceeds to estimate the amount of the space occupied in a line by its letters and symbols, referring to instructions registered in its memory regarding each. In the same way, it determines a justification zone in which a division in the line is necessary and possible, the minimum and maximum limits of this zone being fixed by the limits of expansion of the spacebands on the typesetter.

If the end of a whole word comes within the justification zone, the computer itself signals the end of a line after this word and suppresses the space that would normally follow it. Otherwise, the last word must be divided. The process is said to be semi-automatic if a special operator, seated at a keyboard linked to the computer, must intervene to decide where to place the division in the word submitted to him on, for example, a cathode-ray viewing screen. The process is automatic if the computer is designed and programmed to make the decision itself; the operation then is carried out by starting a subprogram in which all the divisions possible in the word considered are listed (after a prefix, between syllables). This list is tested against prohibited divisions (according to the rules of etymology, phonetics, typography) stored in the rapid-access memory of the computer. From among the positions that are not eliminated during this test, the computer chooses the one situated nearest the end of the word. It automatically inserts the signal for the hyphen and orders the end of the line.

Computerized division of words

The computer can also carry out the correction of mistakes before composition. Various methods are possible,

of which two will be described briefly. In one, the perforation of the justified tape delivered from the computer includes the introduction at the beginning of each line of a numbered signal and is accompanied by a proofing copy of the text with a corresponding reference number for each line. When the mistakes have been corrected on the proofing copy, an operator prepares another, much shorter correction tape, which consists of the corrections preceded by the reference to the line on which they occur. The justified tape and the correction tape are jointly introduced into a double reader, the mixer, which determines anew the length of the line and where the division should occur, as well as for such succeeding lines as need to be modified, before producing a final tape.

In the second method, the proofing copy can be typed out or shown on a cathode-ray viewing screen with the lines numbered but without the tape. At a keyboard connected to the computer, an operator types out the corrections, preceded by their line reference. If a viewing screen is used, the text reappears immediately in its corrected form, and the output perforator immediately delivers a justified and corrected tape.

The computer is usually programmed to sort out and correct even mistakes or anomalies in typing, such as the presence of two consecutive spaces, in which case it cancels one. It can, if its capacity allows, receive a makeup program independent of the tape of the text; following the specifications of the layout (positioning and size of headings, text, and illustrations) coded in binary language, the computer itself introduces onto the perforated tape the special instructions concerning kinds of typeface, length of lines, changes in lines, etc.

Because of the quantity of information needed for composition, the six-channel Teletypesetter tape is being increasingly replaced by seven- and eight-channel tape.

Computer processing using a continuously typed tape can be applied equally well to the Monotype system. The programmed operation for dividing lines is in this case carried out by the automatic calculation of the width of the spaces between words and by the perforation, before the end-of-line signal, of a signal signifying the appropriate position of the justifying quoins. To enable the text to be read by the pneumatic tower of the typesetter, a converter transcribes the perforations from a narrow six-, seven-, or eight-channel conventionally perforated tape to the wide tape of the Monotype system.

The use of computers is now widespread in preparing photocomposition jobs, with programs adapted to the specifications. The computer's output device can produce magnetic tape instead of perforated paper tape.

Optical scanning devices

One intake device no longer reads perforated tape but is an optical mechanism for scanning a typewritten text. The Retina reader, for example, is a sort of artificial retina made up of a group of photosensitive units able to identify each letter typed by a special typewriter, using only three data: height, width, and gray value; that is, the surface area occupied by the outline of its design.

Cold type. Cold type is the expression used, particularly in the United States, to describe a simple and economic method of preparing text by machines resembling ordinary typewriters but capable of producing justified lines in type the width of which varies according to the letter involved. Justification is achieved in several ways by different versions of the machine. In the IBM Multipoint, a first typing calculates the total measurement of the type pieces up to the beginning of the justification zone and causes a coded sign to appear. A button is set in position over the coded sign thus assigned to each line before a second, final typing is done. The position of this button determines the automatic adjustment of the spaces between the words to the amount needed to obtain justification.

In the Justowriter, the keyboard on which the uncoded, unjustified proofing copy is typed simultaneously perforates a paper tape with the code for the letters, as well as, for each line, the code for the amount of space between the words as indicated by a calculator. The tape then controls, on a second unit of the machine, the electric typing of the final justified copy.

In the IBM Multipoint with magnetic tapes, a magnetic tape produced at the keyboard is processed by a computer for justification and, if necessary, for corrections. The final tape delivered by the computer controls the action of an output unit, which carries out the final typing.

If the copy thus produced on paper is to be photographed to prepare printing plates by photogravure, cold type cannot be directly incorporated into photocomposition because of the intermediate operation.

Optype is a hybrid process that simultaneously carries out the operation of justifying a text typed directly in cold type and transmits it to photographic film. By means of optical distortion, each line is stretched to the exact length of line projected on the film. The same mechanism also enables the line to be magnified or reduced or set in italics.

Phototypesetting. Using phototypesetting, a direct image of the text is obtained, positive or negative, according to need, on a photosensitive, usually transparent surface by exposing the surface to light through transparent matrices, negative or positive, of the letters and symbols.

Manual phototypesetters. Several small machines permit phototypesetting of short texts and titles in conditions to a greater or lesser degree short of automation. Among them are the following:

Dantype uses separate transparent plastic matrices, which are assembled in a composing stick and placed in direct contact with the photosensitive film inside the machine.

Typro makes use of letters and symbols on a negative film that moves to and fro to place the desired type piece in contact with the photosensitive film.

Headliner incorporates letters and symbols that appear in negative on an interchangeable plastic disk whose position is controlled from outside. The film is exposed by contact.

Hadego uses plastic matrices assembled in a composing stick, exposure taking place through an adjustable photographic lens that permits enlarging or reducing. With just two series of 350 matrices, one with a 20-point body, the other with a 48-point body, all sizes of type from eight to 110 points can be obtained.

The Starlettograph, comparable to an ordinary photographic enlarger, can be used only in a darkroom. The type, inscribed on a semirigid plastic tape, is set in position one piece at a time, using red light that does not affect the photosensitive film.

Letterphot works on the same principle as the photographic enlarger but on a luminous table. A first projection is made of all the characters of a line without the sensitive surface. Then the sensitive surface is placed on the luminous image of the line, which appears transparently and cannot therefore make an impression. Letters are successively printed in a two-part operation. First the letter is projected in normal light to cause it to coincide with its luminous image; the normal light does not make an impression on the sensitive surface, because the latter has a special composition. After this adjustment has been made, the letter is projected in actinic (photographically active) light, which exposes the sensitive surface.

Diatyp and the Monotype photoheadliner (as well as the Varityper, which is similar in composition) are more elaborate phototypesetters, easier to operate and permitting production speeds of nearly one character per second. The image of each character on the matrix disk is controlled by a symbol that is read by photoelectric cells and which automatically moves the film forward the same amount as the space taken up in the line by the character. A totalizing calculator informs the operator of the rate at which the line is being completed, and justification can be achieved by a first typing without having the source of light in operation; in a second typing, the spaces between the words are adjusted the necessary amount. Adjusting the lens of the Diatyp produces characters ranging in size from four to 36 points and, using the Monotype, from five to 84 points.

Automatic phototypesetting. The first Linofilm was a direct adaptation of the Linotype. Its photographic matrices were the normal Linotype matrices, the only difference being that, instead of bearing an intaglio engraving

of the character on their face, they bore its outline in black on a white background. Lines were composed in exactly the same way as on the typesetter, justification being carried out by expanding the spacebands. The justified line is then passed a single time in front of a lens to be photographed.

Fotosetter operations

The Fotosetter is an adaptation of the Intertype machine but with functional differences. The matrices resemble matrices used for casting; they have the same notching and different thicknesses, depending on the character. But the outline of the character, instead of being inscribed on the face, is a transparency (*i.e.*, a photographic negative), in a capsule set into the level surface of the matrix. These special matrices are called fotomats. In place of spacebands there are space fotomats of different thicknesses.

The Fotosetter is equipped with magazines of 117 channels, 27 more than the typesetters, with an enlarged keyboard of 114 keys.

Once the line has been assembled and justified, using space fotomats of the necessary sizes, the fotomats move inside an optical apparatus that sends a brief flash of light toward the sensitive film. After each exposure, the support of this film is moved slightly sideways by a rack-and-pinion system commanded by the withdrawal of the next fotomat from its alignment; the matrix moves in proportion to the thickness of this fotomat. When all the type pieces in a line have been photographed, the film unwinds the correct amount to present a clean surface ready for the phototypesetting of a new line, while the fotomats are carried off to the distribution bar.

Equipped with a turret of 14 different lenses, the optical apparatus produces 14 sizes of type from three to 72 points, from the same set of fotomats of uniform 12-point size.

The Monophoto is a direct adaptation of the Monotype system with, on the one hand, an independent keyboard that produces a wide perforated tape in the Monotype code and, on the other, a phototypesetter operated by inserting this tape. The type pieces are chosen by positioning a frame, which carries 17 rows of 20 cubelike matrices in which the letter or symbol appears as a transparency, in negative, in the path of a beam of light (see Figure 4). This beam, after proper processing, is directed toward the sensitive film, on which it makes an impression. It first travels through a combination of magnifying glasses and prisms whose position in relation to each other is adjusted to obtain the desired ratio of enlargement or reduction. The sensitive film remains stationary on the drum carrying it as a composed line, while the element that enables the beam of light to move from letter to letter is a set of two mirrors placed face to face at a 90° angle and mounted on a mobile carriage. Before each exposure, this set of mirrors shifts, parallel to the direction of the sensitive film, the same amount of space as the width of the character about to be composed. This amount of space depends also on the number of units of set of the letter or symbol and on the ratio of photographic enlargement or reduction. The movement of the mirrors is thus subjected to the command mechanisms of two factors: the position of the frame, since the matrices are arranged in rows of the same units of set, and the adjustment of the combination of magnifying glasses and prisms.

Justification is accomplished, as on the typesetter, by predetermining the width of the spaces between the words. Since the justification perforations appear before those for the type pieces, they establish for the line to come the amount of space the set of mirrors has to shift at each space command punched in the perforated tape.

After all of the type in a line has been photographed, the set of mirrors returns to its original position, and the drum bearing the sensitive film turns the amount necessary to continue on to the composition of the next line according to the degree of line spacing (leading) chosen.

Using matrices of a single eight-point size, the Monophoto makes available the whole range or type size from six to 24 points. For perfect photographic reproduction it is usually found preferable to use two or three sizes of matrices to cover this range. Given the quality of its

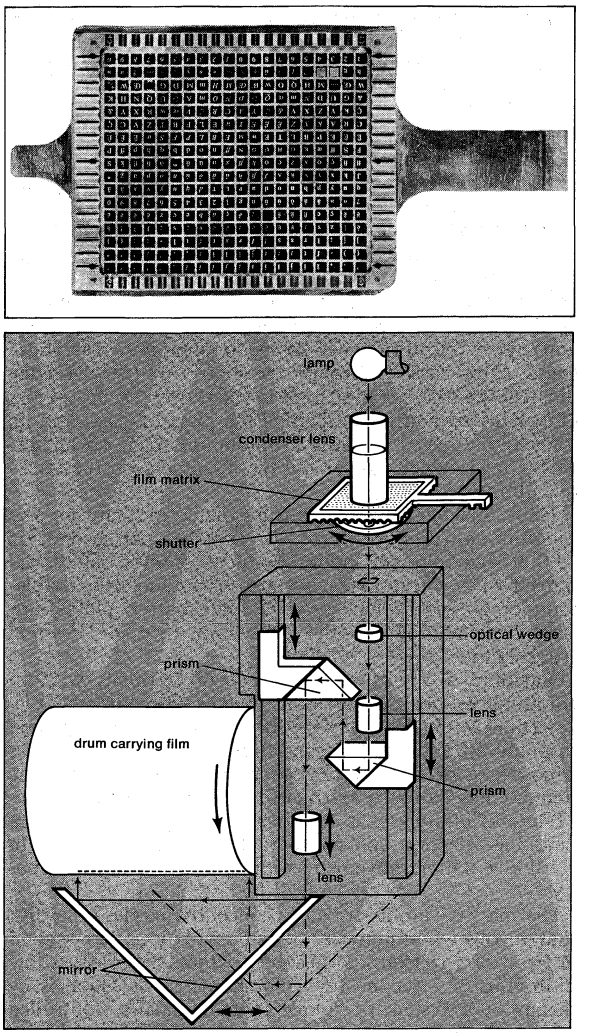

Figure 4: Basic operation of the optical system used in Monotype photocomposition (see text). A film matrix is shown at top.
By courtesy of Monotype

production, the Monophoto, sometimes linked to a unit programmed to prepare the tape, is popular for work that demands careful composition.

Functional phototypesetters. A second generation of phototypesetters consists of functional machines that are analogous neither in structure nor in operation to typesetters using lead. Outwardly they resemble metal chests comparable to office furniture. Their design aims at reducing mechanical parts, inertia, and friction to the minimum. Their technical characteristics vary according to model, use, and cost.

The keyboard, which is hardly more complex than that of an ordinary typewriter, can be attached or separated; in the latter case, information regarding the text to be composed is inserted by perforated tape. Computer units can be integrated, either merely to direct the machine's operations or to ensure completion of the justification process, division of words, and correction, whether from the adjoining keyboard or from a continuous perforated tape. Selection of the matrix image of each character can be done either by using a mobile support for the matrices (plastic tape, disk, drum) in front of a fixed source for the beam of light or by using a mobile beam of light in front of a fixed support for the matrices (glass or plastic plate); alignment of type pieces is carried out in either case by mobile prisms or mirrors.

Versatile capabilities of the phototypesetter

In addition to enlargement or reduction, the optical apparatus can be designed to carry out special effects, such as converting roman to italic type or stretching a line to make it longer or higher. The photographically composed text can be delivered either on paper or on film, in

positive or negative, or in straight reading or reverse reading. The source of light is usually an electronic flash the intensity of which can, if necessary, be made proportionate relative to enlargement or reduction.

Some of the characteristics of phototypesetters are outlined below.

Linofilm (new method): The matrices of the 88 characters in a set are inscribed on a plate of glass that remains stationary during composition. The character is chosen by the shutter of the photographic lens. This shutter consists (as in a commercial camera) of very thin, overlapping metal blades, eight in number. Instead of always opening at the same point at the moment of exposure, it opens facing the desired character, each being set in position by an electromagnet so as to obtain this arrangement. After passing through the matrix of the character thus chosen, the beam of light is taken over by one of the 88 small lenses arranged behind the plate of glass and its trajectory directed towards a mirror mounted on an undercarriage, which carries out the alignment on the sensitive film.

Using this very light electromagnetic mechanism, the Linofilm can produce up to 12 exposures per second, or 43,000 symbols per hour. Eighteen matrix plates arranged in a turret magazine are instantaneously usable, producing 1,584 characters. Three matrix plates are enough to photograph the same type face in 16 sizes, from six to 36 points.

Diatronic, a phototypesetter made in Germany with an adjoining keyboard, uses matrix plates with 126 symbols. Selection is made after the beam of light has passed through all the symbols on the plate, through prisms which take up the position necessary to retain only the light coming from the matrix of the chosen character.

Continuous high-speed photo-typesetting

Photon-Lumitype was the first phototypesetter to introduce the selection and photographing of the character in a rapid circular movement without interrupting continuity.

The matrices are inscribed in concentric circles on a disk that revolves continuously at ten revolutions per second in front of an electronic flashtube whose light lasts a few millionths of a second for each character. Selection is by means of a system of rotary contact makers, controlled by the telegraph system. A nylon drum is integrated with the matrix disk and turns with it in the same movement; the drum is encircled with as many tracks as there are channels in the binary code used to define the characters. These tracks are the transmitting and isolating elements that pass under a row of electric sensors. A special combination of transmitting and isolating elements corresponds to each character matrix positioned ready to be photographed.

Whether by striking a keyboard or by perforating a tape, selecting a given character consists of the precise formulation of the combination that establishes the electrical contact and initiates the flash of light. This selection can be acted on only at the precise moment when, as the disk revolves, the matrix of the desired character moves into position to be photographed.

Whether textual information is fed into the machine on an adjoining keyboard (as on the early Linotypes) or on a keyboard directly connected to the photographic unit or whether it is done on perforated tape, this information is in every instance preserved, line after line, in a memory, formerly mechanical but magnetic on the later models, which at the same time permits calculation of the size of the spaces between the words and ensures that the character's binary signal is presented during the 1/10-second period of time available.

It is possible to attain a production speed of ten symbols per second, or, theoretically, about 36,000 per hour; in practice the figure averages less.

Each of the eight concentric circles on the matrix disk contains two complete sets of 90 characters, which can be filmed in 12 sizes, from five to 72 points. In other words, a total of 17,280 characters are immediately available.

Another Photon-Lumitype model operates on the same principle, but the disk is replaced by a drum revolving 30 times per second around an axis that coincides with the source of light. The type matrices are inscribed in negative on two films carried on the surface of the drum, and the source of light consists of two electronic flashtubes, one for the upper, the other for the lower half of the drum (see Figure 5, right). The lens and mirror system for producing images of the matrices on a moving light-sensitive film is shown at the left in Figure 5.

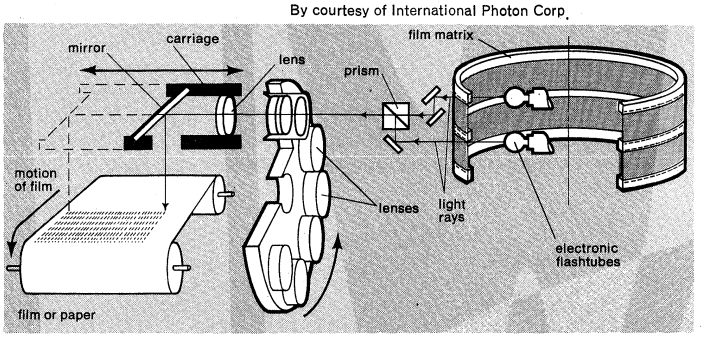

Figure 5: Basic operating principle of the Photon 713-10.

This model's total capacity in characters (four complete sets and eight ratios of enlargement or reduction) is three times smaller, but its speed of composition is three times faster: it can attain 80,000 symbols per hour.

By putting the same films of type matrices in the upper and the lower part of the drum—that is, by cutting in half the number of characters stored—speed of production can be raised to 120,000 symbols per hour.

Europa-Linofilm is similar in design to the Photon-Lumitype just described, with a permanently revolving drum but with an electric type-matrix selection system. These matrices are small individual plates bearing not only the negative image of the letter or symbol but also a series of transparent marks whose arrangement constitutes its binary identification code. In the revolving drum this coded part of the plates passes in front of a scanner made up of a series of photoelectric cells. As soon as the scanner picks up a coincidence between the code of the type matrix and the code of the character selected for composition, it activates the shutter release of the electronic flash.

The Europa-Linofilm drum is composed of four superimposed levels, each containing 120 duplex type matrices —for example, with the same letter in both roman and italic—easily interchangeable in order, since their identification is not linked to their place.

The Photon-Lumizip

Photon-Lumizip is based on a different principle. The performance speed of drum phototypesetters can hardly be increased because of the technical problems posed by the rapid rotation of the drum. To increase speed, the Lumizip abandoned rotary movement. The type matrices are stationary and are aligned in negative on a large-sized plate. There is an individual electronic flash behind each type matrix. The sensitive film is stationary while a line is being composed. The only moving element is the component of the lens placed between the plate and the film, which carries out a rectilinear to-and-fro movement, parallel to them. The flashtube situated behind a given matrix emits its beam of light each time that the component of the lens finds itself, in the course of its to-and-fro movement, in the axis that joins this matrix to the position where the letter to which it corresponds is to appear in the line to be composed on the sensitive film. Thus, the order in which the characters are photographed is neither that in which they appear in the text nor that of the matrices on their plate but that determined by an angular relationship between them both.

A computer is built into the Lumizip. As soon as the coded signals for a line to be composed reach the computer, it determines the order and the exact moment when each flashtube is to operate, synchronized with the movements of the component of the lens.

In practice, the type matrices are aligned on the plate not in a single row but in 11 horizontal rows. The component of the lens always moves in the same horizontal

plane, which is the same as that of the line to be composed and also that of the median row, the sixth, of the matrix plate. Alignment of characters from the other rows is achieved by means of two level, horizontal mirrors placed on either side of this horizontal plane, parallel to it and face to face at a small distance from one another. The beams of light coming from the flashtubes of the matrices of the median row pass between these two mirrors without touching them. But the beams of light coming from the flash tubes of the matrices of the other rows strike these mirrors at an angle that is sharper, depending on how far the row is from the median row, and between these mirrors they are repeatedly reflected, the number of reflections depending on the angle: one for rows five and seven, up to five for rows one and 11, the last reflection falling into alignment on the sensitive film.

Mechanical movement in the Lumizip is reduced to the extreme minimum, because the component of the lens is the only moving part. Since it depends on an alternating, rectilinear movement and is therefore handicapped by factors of inertia, its speed, which cannot be as great as that of a continuous rotary movement, is only ten to-and-fro movements per second. But during a single one of these to-and-fro movements all the several dozen characters for one line are photographed. Thus, the Lumizip attains a performance rate perhaps 20 times superior to that of the Lumitype. Theoretically, it can perform at a rate exceeding 2,000,000 symbols per hour and in practice has produced over 1,000,000.

Electronic phototypesetters. In phototypesetters of the third generation, the beam of light is replaced by a flow of electrons, which offers the advantage that the electrons can be deflected by means of magnetic fields without the intervention of mechanical parts such as mirrors and lenses. Television systems are based on this characteristic, and an early type of electronic phototypesetter is structurally comparable to a closed-circuit television system. A reading device analyzes, by fine scanning, the outline of the matrix of the letter to be composed and converts the luminous information it obtains into electronic signals. The cathode-ray screen of an output device reconstitutes, in accordance with these signals and by a fine scanning device synchronized with the reading device, a luminous image of the letter, which makes an impression, through an optical reducing device, on a photosensitive surface. A computer, depending on the text to be composed, directs the position of the reading device's scanner towards that part of the matrix plate that bears the matrix of the letter selected, and simultaneously directs the position of the output device's scanner toward that part of the screen that corresponds to the position of this letter in the line being composed.

On some models, the scanning device consists of the equivalent of a television camera whose electron beam is selectively deflected towards the chosen matrix and directly analyzes the luminous information coming from it. On others, a cathode-ray tube takes the place of the emitter of a regular beam of light by scanning behind a plate on which the matrices appear in transparency. On the other side of the plate, photoelectric cells collect this beam at the moment it passes through the matrices and react by emitting electronic signals directed to the output device.

Electronic matrix selection

For matrix selection, the face of the emission tube is divided into 16 square sections (four by four), of which only one is illuminated at a time by selective scanning directed towards it. There are 16 photoelectric cells arranged in a square (four by four), only one of which is in operation at a time. Thus, there are 256 (16 by 16) possible arrangements of the chosen section and of the chosen cell. Each combination corresponds to an optical trajectory belonging to one or the other; that is to say, to the precise positioning of one of the matrices over the plate.

On the screen of the output device, the letters have a definition of 650 lines per inch for ordinary work and 1,300 lines per inch for quality work. The line structure is invisible after the letters have been reduced for photographic reproduction.

A more complex model of the Linotron scans, on the screen of the output device, the surface of a whole page, composing as it goes all examples of the same letter in all the places where it occurs on the page. Composition of the page is completed after all the matrices have been exposed once. The average speed of production is on the order of 1,100 symbols per second, or almost 4,000,000 per hour.

Carrying the system of electronic composition to its logical conclusion, designers have replaced the matrices, whose outline had to be repeatedly electronically analyzed, by the results of analyses previously carried out and preserved in binary form in a magnetic rapid-access memory, setting up for each letter the output program for its luminous image on the cathode-ray screen when it is selected for composition. Electronic phototypesetters of this kind are called alphanumeric.

Hell-Digiset carries out a preliminary analysis by inscribing the outline of each letter on a very dense grid of 3,000 to 6,000 small squares, according to the body size of letter envisaged. Those squares covered by the outline are assigned the symbol 1 of the binary code; the others are assigned the symbol 0. The result of the analysis is first inscribed in perforations on an eight-channel tape. Tape containing perforations for an entire set of type in a given style is inserted into a special Digiset reader to instruct the magnetic memory, in a few dozen seconds, concerning type production. All that is necessary to change the style of type is insertion of the tape belonging to another set.

The Digiset 50 T 2 can reach a production speed of 3,000 characters per second, or more than 10,000,000 per hour. One Digiset is designed to permit a whole newspaper page to be composed photographically in a single scanning operation; not only the words but also the illustrations are analyzed in binary code.

Fototronic-CRT and APS (Alphanumeric photocomposition system) reduce the amount of coded information by interpreting each letter as a series of closely packed adjacent vertical lines whose distinguishing parameters are their height and their position. Vertical scanning on the screen of the photographic output device reproduces these lines one after another according to these parameters (see Figure 6).

The number of lines varies from about 50 to 90, depending on the width of the letters, and the number of units calculating the measurement of parameters of height can go up to 80, which amounts to a definition perceptibly as fine as the Digiset grid, or 800 lines per inch in two dimensions on the screen of the output mechanism.

The APS electronic phototypesetter has a production speed of 3,000 to 10,000 characters per second, the latter figure amounting to 36,000,000 per hour.

Makeup of letterpress copy. Preparing a form suitable for use in printing from letterpress copy, whether in individual type pieces or in lines of lead alloy, is an operation called makeup. This is preceded, if the same form is to include several smaller pages to be printed together, such as a book, by an operation called imposition, which consists in laying out the pages in the form so that they are in their numerical order after the printed sheet has been folded into a signature of eight, 16, or 32 pages.

Newspaper makeup

In the case of a daily newspaper, one form is generally used for each page. When the manuscript or typescript copy containing information regarding the type and the justification required arrives at the printing plant, it is divided among several Linotype machines. The titles are handed over to be composed, depending on their body size, in movable type on a Ludlow or Linotype machine. When ready and corrected from galley proofs, the titles and columns of text arranged in galleys are brought to the compositor, together with, where relevant, plates of illustrations or advertising matter mounted on lead blocks the same height as the type. Standing at a level casting table, the stone, and following the instructions on a layout, the compositor arranges the elements inside a rectangular steel frame, the chase, usually equipped with a locking system using quoins that slide along the inside of two of its adjacent sides.

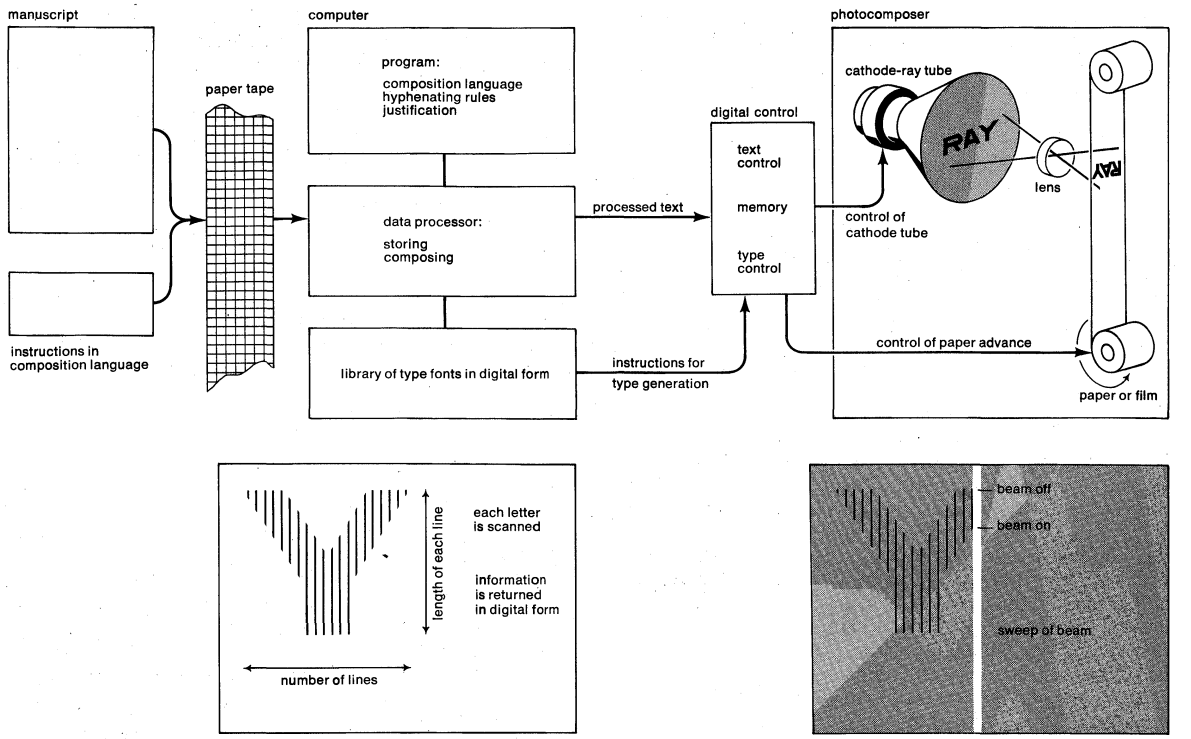

Figure 6: Basic components of the Alphanumeric photocomposition system (see text).
By courtesy of Alphanumeric Inc.

The compositor inserts leading between paragraphs to bring each column on the page to its proper height. He separates columns and articles using leading or rules cut to the desired dimensions. Once the chase has been locked, proofs are taken to check the page for final corrections before it is pressed on to a metal frame to be brought to the press.

Mounting composition on film. Composition on film consists of a mounting operation carried out on a luminous table. Films of the text and titles and positives or negatives of the screened or unscreened photographs, depending on the printing method to be used, are arranged on a sheet of transparent plastic of the dimensions indicated on the layout, placed under the plastic sheet and lighted from beneath. The film is glued or fixed using pieces of transparent adhesive.

Conversion systems. One composition process can be converted to the other. A page composed on film, in negative, can be used for photogravure plates or for metal or engraved plates intended for letterpress printing (see below *Printing*). Contrariwise, a page composed in type can be converted to a positive or negative, direct or inverted transparency by any of a number of techniques.

The whole page, including the screened plates or photographic illustrations, can be subjected to conversion, or the text can be taken alone, leaving the positioning of illustrations until the positives or negatives of the illustrations, screened or not, according to the printing process to be used, are included in the makeup at a later stage.

PRINTING (PRESS OPERATION)

Printing in the second sense of the word—that is, press operation—is the technique by which ink or other colouring agent, transferred to paper or any other material, is localized on printing surfaces delimited by the composition of texts or the making of illustration material.

Colour printing. Juxtaposition of colours is achieved by submitting each sheet to successive impressions by typeforms each of which prints only on areas designed to carry a single colour and inked only in that colour.

There are sufficient wavelengths in the three primary colours, blue, red, and green, to reconstitute all the colours of the spectrum. The colour perceived from an inked impression results from the fact that the ink reflects some waves of the range of colours of the spectrum and absorbs the others; that is, prevents them from being seen. Thus, three colours of ink can reconstitute the visual effect of all the range of colours by combining them appropriately. Yellow totally absorbs all waves of colour that are basically blue and reflects waves of colour that are basically red and green; magenta (deep crimson) totally absorbs green and reflects red and blue; cyan (close to turquoise) absorbs red and reflects blue and green.

Effects of combining coloured inks

When two of these inks combine, each annuls in the other the capacity to reflect that one of the two primary colours that it cannot itself reflect; the eye then perceives only the one primary colour that both inks reflect; for example, red, by combining yellow and magenta inks. All three inks combined no longer reflect any of the three primary colours but appear as black.

In trichromatic printing the screened plates necessary for each of the three colours of ink are prepared by selecting the colours through filters. A fourth plate is usually used for making a print in black ink to accentuate the contours and modelling in the picture, making the process quadrichromatic.

Printing colours by superposition requires the exact positioning on top of one another of the successively printed constituent parts of the picture (usually printed in this order: magenta, yellow, cyan, black). The finer the definition of the screen, the more precise this positioning must be.

Letterpress printing. Letterpress printing consists of transferring a thin film of ink from the printing surface of the typeform to that of the paper by pressing the two together.

Letterpress presses are thus made up of two principal elements, one bearing the type form, the other exerting the pressure. These elements may be either flat or cylindrical. There are three principal types of presses, according to the way these elements are combined: (1) plane to plane; (2) cylinder to plane; and (3) cylinder to cylinder (see Figure 7). In all types of letterpress presses the printing surface must be coated with a uniform layer of ink before receiving the paper. This inking is carried out by a mechanism composed of up to 20 rollers: take-up rollers carry the paste ink from the ink supply to the distributing and sliding rollers, which operate with a longitudinal to-and-fro movement to crush and spread the ink in an even

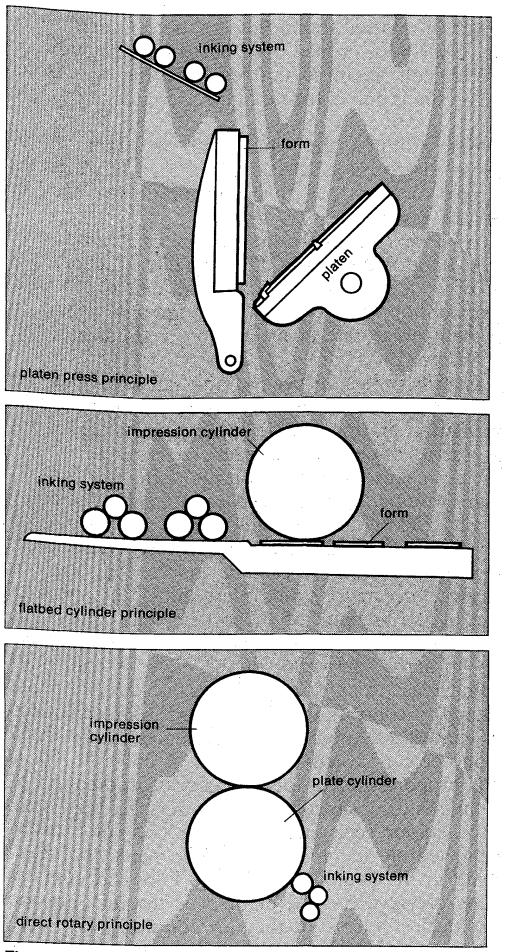

Figure 7: Operating principles of the three principal types of letterpress presses (see text).
From J.S. Mertle and G.L. Monsen, *Photomechanics and Printing*

layer on a level or cylindrical metal surface and finally contact rollers that transfer the ink to the printing surface of the typeform.

The first two kinds of presses are sheet fed. The third can be either sheet fed or roll fed (web fed), depending on the model and type of work. Sheets of paper must be fed into the press in a sequence synchronized with the movement of the press. Most modern presses are equipped with an automatic feeder that functions in conjunction with the movement of the press. The feeders operate by either friction or suction. In a friction-operated feeder, the sheets of a pile of stock on a slightly slanting surface are fanned out so that each sheet projects over the one beneath in such a way that the friction of a cylinder can dispatch them individually one after another toward the feedboard of the press, where three pegs guide each into position. In a suction operation the sheets remain piled up vertically; a wheel brushes a corner of the top sheet and separates it from the others, enabling a compressed-air blower to inject a cushion of air underneath the sheet. A system of vents connected to a suction pipe lifts the paper and carries it towards the press's feedboard. An automatic device lifts the pile of sheets continuously into place. On all letterpress presses, slight irregularities of the surface of the typeform are compensated for by packing the platen with a material soft enough to absorb the irregularities.

As the sheets leave the press, a powder is sprayed onto their surface to form a separative coating that prevents ink from one sheet being transferred to another. An alternative in modern high-speed presses is the incorporation in the ink of a special quick-drying agent.

Platen presses. Presses that operate plane to plane are called platen presses. A vertical clamping contrivance clamps the bed, which carries the form into which the composed type is locked, and the platen, which carries the sheet of paper while it is being printed. When this clamping contrivance is open, the typeform is inked by a series of rollers that descend and then reascend, and the printed sheet is removed and a new sheet placed in position on the platen.

The pressure exerted during impression is about 40 kilograms per square centimetre (570 pounds per square inch). A platen press can reach a production speed of 5,000 sheets per hour.

Cylinder presses. In presses that operate cylinder to plane, called flatbed presses, a cylinder provides the pressure while the typeform retains its flat surface, generally in a horizontal position. Generally, too, the bed is mobile to allow the typeform, as it moves back and forth, both to pass under the rollers of the inking system and to pass under the impression cylinder around whose outer surface the sheet of paper is wrapped, attached by a set of clamps. Flatbed presses fall into various categories, depending on the cylinder's operation.

The stop-cylinder press

In the stop-cylinder press, a toothed rack incorporated in the bed engages a cogwheel incorporated in the cylinder while the bed is moving forward. As it moves back again, the cogs disengage. A shallow cavity in the cylinder makes it possible for the typeform to be slid underneath. Printing speeds can reach 5,000 sheets per hour.

In the two-revolution press, the cylinder never stops revolving but is raised on its bearings as the bed moves back again in order not to touch the form. In its lowered position the cylinder's cogwheel engages a low-toothed rack incorporated in the bed; in its raised position the cogwheel engages a parallel high-toothed rack, which enables the cylinder to continue revolving in the same direction. Printing takes place during the first revolution; during the second revolution the cylinder runs free. Printing speeds are about the same as for the stop-cylinder press. But, by avoiding the mechanical jerkiness due to the stopping of the cylinder, the two-revolution press has a much smoother, more regular, and quieter action.

On a single revolution press, the cylinder does not stop revolving but must be raised while the bed moves back. Its diameter is twice that of the two-revolution cylinder press, but one half of its surface is hollowed out in order not to touch the form. Printing, then, takes place in the first half of the cylinder's revolution.

A perfecting press is a combination of two two-revolution presses bracketed together. It has two cylinders and a single bed bearing two different type forms. Thus, as it moves back and forth the bed prints two impressions, one for each form. The same sheet of paper is passed from one cylinder to the other and is thus printed on both sides. The padding on the second cylinder is constantly cleaned by a kerosene-coated roller to prevent a transfer from the first side of the paper to be printed. In fact, the second impression is better than the first, and the part of the job requiring a better quality is reserved for the second cylinder.

The two-colour press also combines two bracketed two-revolution presses, but a small auxiliary drum is interposed between the two cylinders to ensure that a single sheet of paper presents the same side to be printed twice. The typeforms, which are designed to complement one another, are each inked with a different colour.

Contrary to the general design of cylinder presses, the vertical cylinder press is composed of a vertical bed, and both bed and cylinder move vertically with a reciprocating motion, each in an opposite direction. The cylinder revolves only while it is moving up and down, which makes this kind of press similar to the stop-cylinder press.

Printing speeds exceed 5,000 sheets an hour for paper up to about 2,000 square centimetres (300 square inches).

Rotary presses. Presses that operate cylinder to cylinder, usually described as rotary presses, consist of two cylinders turning in opposite directions. The typeform is attached to the surface of one cylinder, and the impression cylinder provides the pressure.

Sheet-fed rotary presses produce the same kind of work as flatbed cylinders, but the size of paper can be slightly larger, and production speed is three times higher using the same size of paper. The inking system is much the

same as in flatbed cylinder presses. In both models the sheet of paper is held to the impression cylinder by a set of clamps. On the largest models passage of the paper between the cylinders is controlled only by precise positioning and presentation of the paper.

The two-colour rotary press combines two plate cylinders, each bearing a different typeform and each provided with its own inking system against a single impression system, in a so-called satellite arrangement. Thus, the same side of the same sheet of paper receives two successive impressions of two different colours in a single revolution of the impression cylinder.

The rotary perfecting press uses the same arrangement as the previous machine, but a second impression cylinder of smaller dimensions is interposed between the first impression cylinder and one of the plate cylinders. Thus, the sheet changes sides between one impression and the other and so is printed on both sides.

The two-colour cylinder and flatbed press combines a rotary and a single-revolution press by using the same impression cylinder. Clamped around this cylinder, the sheet of paper first moves against the curved form on a plate cylinder inked by the first inking system; then it moves against a flat form on a mobile bed inked in another colour by a second inking system.

Polychrome rotaries permit three, four, or five colours to be printed on the same sheet without handling the pile of paper. Some of these are designed on the planetary principle, using as many plate cylinders as colours, each being fed by its own inking system and grouped around a single impression cylinder. This type of machine is much more popular in North America than in Europe. Others are designed as a row of identical units each printing one colour, the paper moving from one unit to another by means of a transmission drum or a conveyor contrivance.

The planetary colour press

Roll-fed rotaries are exceptionally large, with high rates of production, and are used almost exclusively for printing daily newspapers. Their principle is extremely simple; the continuous roll of paper drawn from a reel moves between a plate cylinder and an impresssion cylinder. In practice, the cylinders of some have a circumference twice the height of a page of newsprint. Thus, each revolution of the cylinder prints two copies of the same page. On others the circumference of the cylinders corresponds to the width of four pages of newsprint side by side; each revolution prints eight copies of the same page.

In another type, the basic unit of the rotary, called the group, is composed of a symmetrical arrangement of two plate cylinders with their impression cylinders. Within the same group the roll of paper moves from one of the plate cylinders, where it is printed on one side, to the other cylinder, where it is printed on the other side. Each revolution of the machine thus produces a group of two times eight pages of newspaper printed on both sides. Inking is effected by distributing, sliding, and contact rollers that receive ink from dozens of openings distributed across the width of the cylinder, each of which can be precisely adjusted. In each group paper is fed in by a barrel-like device with three axes for supporting the reels, which makes it possible to move over from a finished roll to a new one by a simple gluing operation and a 120° revolution. The reels weigh up to 600 kilograms (about 1,300 pounds). The rotary press is made up of a certain number of identical groups in alignment.

Folding and cutting operations

After printing, the roll of paper is automatically folded down the middle so that on both sides only two pages remain face to face. Moving along a triangle with rounded sides and then passing between rollers, each half roll is folded in the middle to form a newspaper. A cutting mechanism, synchronized with the action of the rotary, separates each newspaper from its neighbour.

Depending on the number of pages of the newspaper, various arrangements are possible: rolls coming from different groups can be added to by accumulation to produce two issues in a multiple of four pages. A roll half as wide as the others coming from one of the groups can be added to the middle of one or more of the usual rolls, producing two issues in multiples of four pages, plus two. Two parallel rollers, called turning bars, arranged at an angle of 45° in relation to the flow of the roll, enable the roll, after it has been printed and folded in the middle, to be folded in half again so that each of the two issues produced by the group is formed into a signature of eight pages.

For colour printing, the same roll of paper moves through several groups in succession, in each of which the plate cylinders carry typeforms appropriate for each of the colours necessary.

Modern rotaries can revolve at the rate of 35,000 revolutions per hour (500 metres [1,600 feet] of paper per minute), or at a theoretical production rate of 140,000 newspapers an hour in two issues from the final group. In practice, the average rate of production is about half this figure.

At speeds such as this, inspection and safety precautions are more reliably carried out by electromagnetic devices based primarily on the use of photoelectric cells; for example, a series of cells on the track, over which a roll of paper moves, react to tearing by stopping the machine.

In colour printing, photoelectric cells ensure matching by selectively picking up the guide marks printed in each colour as they go by and by reacting to any irregularities in the distance between these guide marks. Any error is automatically corrected by modifying either the speed of one group or the pressure of the rollers that control the tension of the paper between one group and the next. Matching up across the width of the paper is controlled by cells that react to any lateral digressions as the paper moves along by controlling a lateral-shifting mechanism.

Quality control of colour reproduction is also carried out by photoelectric cells that emit a current whose strength is proportional to the intensity of impression of the guide marks for each colour. By comparing this intensity with a colour scale, an electronic computer determines from minute to minute the adjustments that need to be made in the composition of the inks and controls the opening of valves to add pigment if the inks are too light or colourless varnish if they are too dark.

Preparing stereotypes and plates. The curved shapes with which the printing cylinders of the rotaries are fitted are the stereotypes, or plates. These may be produced from ordinary flat typeforms by reproducing the relief surface of the type copy and of the plates for illustrations made from halftone photoengravings and line engravings. Alternatively, screened photographic illustrations are used to make plates from mounted positives of transparencies by means of photoengraving.

Casting stereotype plates

In making stereotype plates, a flong, or mat, a thin sheet of pasteboard, pliant enough to register an impression and sufficiently heat-resistant to tolerate the molten type metal, is placed on the type form with paper and cotton packing. It is subjected to heavy pressures in a press at a moderately high temperature to ensure that it dries; it retains an intaglio impression of the relief surface of the type form and is placed against the inside wall of a curved casting box into which a lead alloy is injected. The cooled stereotype plate resembles a rigid shell, solid or ribbed according to its thickness.

The plate is mechanically finished to ensure uniform thickness and to provide properly bevelled edges; metal from nonprinting areas is routed out to avoid ink smudges. Finally, the plate is electroplated with a thin layer of nickel to increase resistance to wear.

Though it is rarely done, stereotype plates can equally well be cast flat, then curved while heated after being finished.

The stereotype process is the fastest and most economical process for obtaining curved plates, but such plates are not suited to the precise matching up necessary in colour printing because of the irregular behaviour of the mat; its performance depends heavily on humidity and temperature conditions.

In making electrotype plates, an impression is made of the typeform using a substance that is a conductor of electricity or can be made conductive by treating with black lead or dusting with a powdered metal such as silver. Any of the following may be used: a sheet of wax submitted to heavy pressures in the press; a sheet of lead

submitted to extra heavy pressure; a sheet of Tenaplate, a kind of vulcanized plastic covered with a film of black-lead wax, submitted to pressure only slightly less than that for lead; a sheet of celluloid or a sheet of plastic (Vinylite, tenalite composed of a layer of aluminum between two layers of Vinylite, etc.).

After metallizing to ensure conductivity, these molds are electroplated with a thin copper shell, delicately reproducing the relief surface of the type form. This shell is stripped from the mold and reinforced with a backing of lead alloy poured over its underside. Nickel plating can again be employed to increase its wear resistance.

Electrotype plates can be curved while cold after they have been backed or while hot, during leading, when the lead has not yet solidified. There are also impressions that can be curved before electroplating to obtain curved copper shells. The plate is then reinforced by spraying molten metal against the shell while it is fixed against the inside wall of a rapidly spinning drum.

Making electrotype plates, especially in a curved shape, is a costly process, but they produce the best quality print. An impression made with a sheet of lead is best suited to printing in colour because it is least sensitive to variations in humidity and temperature. Metal-shell plates are attached to the plate cylinder mechanically.

Stereoplastic plates are made in two successive moldings. A hot mold is made in the press from the typeform in a thermosetting material; that is, one that can be melted only once and can thereafter tolerate high temperatures without damage, such as Bakelite. This first molding itself serves as the mold into which is pressed the hot material for the plate—usually cellulose acetate, vinyl resin in sheets or in powder to which a plasticizer has been added to make it more durable, or a sheet of rubber gum that will be vulcanized when pressed. New liquid plastics can also be employed using a method similar to casting.

The plates are trued up by milling or filing to the desired thickness and glued either to the plate cylinder of the rotary or to a metal plate wrapped around it.

Stereoplastic plates are light and easy to use, particularly on small rotaries. Their printing quality is good enough for texts and line illustrations, although they are ill suited for fine-screened halftone illustrations.

Whether wraparound plates (wraproud plates in Great Britain) are made of metal or of plastic, they utilize photosensitive materials in their preparation.

Metal wraparound plates may be of copper, magnesium, or zinc. Only one type of zinc, microzinc, whose molecular structure permits finer prints than ordinary zinc, is used. The plates are covered with a layer of photosensitive material and processed like photoengravings, using negatives of the pages on which the photographic illustrations have already been screened. Because the engraving is only half as deep as letterpress engraving, ink rollers of a larger diameter are used.

The plate can be curved after engraving, but curving is usually done beforehand, both to avoid breaks in the metal and to obtain an absolutely uniform degree of bend in the various plates for colour printing.

Plastic wraparound plates

Plastic wraparound plates utilize the property of photosensitive polymers to lose their solubility in certain solvents when exposed to light. Exposure to light through the negative of a page fixes the insolubility of the polymer and limits it to the areas that are to constitute the printing surfaces. A suitable solvent then eliminates all the nonprinting areas and sets off the type in relief.

New polymers with this property and with new qualities are constantly being perfected. Among the better known examples are nylon, Dycril, and KRP. Nylon is sensitized in bulk by immersion in a solution of acetone containing the sensitizing agent. The plate is exposed to ultraviolet light, and the nonprinting areas are dissolved by a bath of methyl and ethyl alcohol. It takes 24 hours for the plate to attain its maximum hardness. Dycril is sensitized by immersing it for 24 hours in a carbon dioxide atmosphere. The nonprinting areas are removed by sprinkling with a solution of sodium hydroxide. Because it is preferable for the plate to be curved before being engraved, exposure takes place on a rotary drum turning in front of an arc lamp and the bath on a rotary drum turning in a trough. The total amount of time required to make a plate is about 45 minutes.

KRP (Kodak Relief Plate) is a sheet of cellulose acetate that is superficially sensitized by the deposit of a thin coat of photographic emulsion. After exposure to light, this emulsion remains only on the printing areas, which it protects from the action of the solvent. Engraving the KRP plate can also take place on a rotary drum.

The polymer of the plastic wraparound plates is usually mounted on a base consisting of a metal sheet. The depth of the engraving can equal the actual thickness of the polymer. The type therefore stands out in sharp relief. Whether metal or plastic, the wraparound plates are easily and rapidly attached by means of register hooks, which ensure perfect tension of the plate on the surface of the rotary's plate cylinder.

Scope of letterpress. Letterpress printing is characterized by the sharpness and strength of bite of the type. It produces good reproduction of illustrations on sheet-fed machines, with these two reservations, that screening prevents the reproduction of pure white, and it is not possible to use more than four colours without risking a speckled moiré pattern. Roll-fed printing still preserves a good sharpness in the text but produces only an acceptable or average photographic illustration, depending on the quality of paper, and then only in black. Colour printing of illustrations on roll-fed rotaries can hardly rise above the mediocre level, even with the use of special rotaries in which the printing groups are drawn as close together as possible.

Rotogravure. Rotogravure is a system of intaglio printing. It consists of transferring to paper fluid ink contained in the cells of the printing cylinder, while the projecting nonprinting areas on the surface of this cylinder are kept free of ink by constant wiping.

The density of the print at each point depends on the depth of the cell at that point and the quantity of ink it contains, rather than on the printing surface, as in the letterpress process. The screen no longer plays an optical role. It is used to establish the partitions that separate all the cells of the honeycomb from each other and that form a surface of uniform height, while the cells are all of different depths, so that the ink is taken up on the engraved surface in an exactly defined quantity. The screen also prevents the wiping mechanism from penetrating the cells of the cylinder and withdrawing the ink. For this reason, line drawings and even the text type must be screened, as well as the photographic illustrations.

Rotogravure rotaries are thus composed of two principal elements: the cylinder bearing the printing form and the impression cylinder; the paper moves between these two cylinders either in sheets or from a roll.

The nature of the ink used in rotogravure and the operation of the wiping mechanism make the use of plates technically more delicate because of the indentation that would be necessary in the places where they were affixed to the cylinder. Plates are used only on certain sheet-fed machines, because they are easier to prepare and stock. Generally speaking, the image is etched directly onto the printing cylinder, which must therefore be easily handled.

Ink of sufficient fluidity is used to allow direct inking of the engraved cylinder without the use of a roller to spread and distribute it. While the paper tangential to its upper surface is being printed, the lower part of the cylinder is bathing in the pool of ink. In fast-working machines the ink can be poured on through a spout or sprayed onto the surface of the cylinder, to avoid flying ink. On the plate machines, inking must be done by roller to avoid filling the hollows of the clamping system with ink.

The operation of the doctor blade

Between inking and printing, the wiping mechanism comes into action. It consists of a thin blade of soft steel, the scraper, or doctor blade, which moves slowly to and fro lengthwise. By rubbing against the cylinder with a precisely regulated degree of pressure, it causes the excess ink to drop off before the cylinder moves over the paper.

In sheet-fed machines the impression cylinder is like that of a letterpress press, with a diameter large enough

to carry the sheet wrapped around its surface, gripped and released by a system of articulated clamps. Production speed can attain 6,000 sheets per hour.

Roll-fed rotaries generally consist of several printing units in line (up to as many as 18), each composed of a printing cylinder, an inking system, and a hard-rubber impression cylinder of small diameter. Each unit can turn in either direction to allow the paper to move through in any combination.

When printing both sides, the same roll of paper must pass through two successive printing units. In colour printing the same roll must move through as many printing units as there are colours used on each side of the paper. Several rolls coming from different printing units can be added together by accumulation.

Rotogravure rotaries normally include the same folding and cutting systems as letterpress rotaries, along with the electronic devices necessary for controlling the operation. Because of the fluidity of the ink, all rotogravure machines, whether sheet-fed or roll-fed, require a drying process. The paper passes over a heated drum or over sources of infrared rays or through a compartment ventilated with hot or cold air.

Preparing rotogravure cylinders. The printing cylinders or plates are prepared from positives of pages on which neither text nor illustrations are screened. The photosensitive substance necessary for carrying out the photoengraving operation, carbon tissue, is separately packaged to permit it to be treated before being affixed to the metal. Carbon tissue is paper, in sheets or on rolls, coated with a layer of gelatin. This layer is sensitized before use by being plunged into a solution of potassium bichromate. The carbon tissue is first exposed to intense light through a glass plate bearing a transparent screen on an opaque background and then exposed a second time through a positive of the pages. During these two exposures the gelatin is hardened by the light, completely in the white and screened areas, more or less deeply in the halftones of the photographic illustrations, and not at all in the areas covered by text and lines.

The carbon tissue is then applied to the copper surface of the cylinder (or plate). The tissue is then peeled off, leaving the gelatin film fused with the metal. The cylinder (or plate) is plunged into a warm-water bath, which dissolves the gelatin in inverse proportion to the degree to which it was hardened: totally in areas where it received no light like the text and line drawings, more or less deeply in the halftone photographic illustrations, and not at all in the screened areas.

The etching of the copper is begun by sprinkling it with an acid solution (ferric chloride), which attacks the metal in the areas where the gelatin is totally dissolved and bites into it more or less deeply depending on the thickness of the surviving gelatin that it must penetrate. After being etched, the printing surface can be reinforced by chromium plating.

Improvements on this classic method of preparing the rotogravure plate are continually being made. The carbon tissue may be replaced with silver emulsions on a plastic base; a direct copy without carbon tissue may be made by dusting the cylinder with a photosensitive substance and projecting the image on the surface of the cylinder by optical means and finally by electronic engraving.

Plates for rotogravure are made of solid copper, and after use they are discarded unless preserved for reprinting. Rotogravure cylinders consist of a steel mandrel on which a layer of copper has been deposited by electroplating. After printing, the etching is removed by grinding and a thin film of copper deposited to restore the cylinder to its original diameter. Restoration is simplified if the film can be prevented from adhering to the cylinder so that it can be ripped off after printing. This can be done by coating the surface of the cylinder with a copper–mercury amalgam before electroplating. After plating, the new copper film is then polished. Some electroplating baths produce a shiny copper finish, dispensing with the polishing operation.

Scope of rotogravure. Even in long runs, rotogravure produces quality illustrations with rich colours. It is less suited to printing small typefaces because they are cut up by the screen.

Offset. The first characteristic of offset printing is that, in principle, there is no appreciable physical difference between the printing and the nonprinting surfaces. The difference is simply that the printing surfaces repel water when moistened but absorb the ink with which they are coated, whereas the nonprinting surfaces absorb the water and repel the ink. The form used in offset printing is a metal plate on which the surfaces have been prepared to give them these opposite properties.

The second characteristic of offset printing is that the ink is not transferred directly from the printing form to the paper but is first transferred to a rubber blanket. It is the ink retained by the blanket that is transferred to the paper.

The three-cylinder offset press

Offset presses utilize three principal elements: the plate cylinder; the blanket cylinder; and the impression cylinder, which applies the paper, in sheets or a roll, against the blanket cylinder.

The plate cylinder is like the cylinder for wraparound plates on a letterpress rotary, with a groove in which the attaching and tension mechanisms are housed. A moistening system and an inking system are connected to this cylinder. The inking system is similar to that on letterpress presses, with a series of alternating hard and soft rollers that grind, spread, and evenly distribute the ink in a uniform thickness.

The wetting system, which dampens the plate before it is inked, consists of a series of rollers that transmit regularly controlled quantities of water taken up by puddling in a tank or sprayed from rotary brushes grazing its surface.

The blanket cylinder also has a groove containing the mechanism for attaching and controlling the tension of the blanket, which consists of several layers of fabric and rubber. During printing the groove of the blanket cylinder and that of the plate cylinder coincide at each revolution.

On sheet-fed machines the impression cylinder has a cavity in which a system of articulated grippers is recessed. The movement of the machine is synchronized so that at each revolution the slightly projecting grippers enter into the groove in the blanket cylinder in such a way as to cause no damage to the latter. This problem does not arise on the impression cylinders of roll-fed rotaries, and their movement does not therefore have to be synchronized with that of the other cylinders.

In sheet-fed presses the three cylinders, usually placed side by side, are of the same diameter and turn at the same speed. The movement of the cylinders is synchronized by meshing sprocket wheels. Paper is fed in by a feeder similar to that of letterpress presses.

Offset machines can be used to print very large sheets. The fastest reach a production speed of 10,000 sheets per hour.

In printing two or more colours, during the offset process the dampness of the plate is partly transferred, via the blanket, to the paper. This slightly alters the paper's dimensions, causing difficulties in register. The separate colours are therefore printed as simultaneously as possible.

On some two-colour machines a single impression cylinder applies each sheet successively against two blanket cylinders, which receive a transfer from their own plate cylinders.

More generally, sheet-fed offset machines printing in two or more colours are designed as a series of printing units each consisting of three cylinders with their wetting and inking systems, the sheet being transferred from one unit to the next on drums of large diameter with a system of articulated grippers. Size of paper and speed are the same as for the one-colour machines.

Blanket-to-blanket machines

In the offset process an unusual arrangement, without impression cylinders, is possible. Simultaneous printing is done of both sides of the sheet as it passes between two juxtaposed blanket cylinders. Each receives a transfer from its own plate cylinder and prints one side of the sheet while at the same time acting as an impression cylinder for printing the other side of the sheet. Thus, the

blanket-to-blanket machine consists of a total of only four cylinders.

The various kinds of machines can be used in combination: for example, three one-colour printing units and one blanket-to-blanket machine can print one side of the sheet in four colours, the other side in black.

Roll-fed rotaries work on the same principle as sheet-fed presses, with two differences—the groove for the plate fasteners on the plate cylinder is very narrow, and the impression cylinder, lacking grippers, has an entirely level surface.

In-line rotaries are designed as a succession of one-colour printing units or, more frequently, blanket-to-blanket units. On these, as on the others, printing in several colours is done by sending the paper directly and horizontally through several successive units.

On blanket-to-blanket rotaries, the back is printed simultaneously with the front. On rotaries made up of one-colour units, a turning bar reverses the direction in which the roll of paper presents itself. Feeding the paper into and taking delivery of it from the machine can be combined so that the rolls are superimposed to form a signature.

Satellite rotaries (drum presses) work on the principle of a single impression cylinder of very large diameter that has arranged around its outer surface four, five, or sometimes six blanket cylinders. Each receives a transfer from its own individually moistened and inked plate cylinder. Thus, colour printing one side of a roll of paper is accomplished in a single revolution of the impression cylinder.

Drum cylinders are most often made up of two symmetrical groups printing one side after the other. For quality colour printing with a heavy thickness of ink, rapid drying is necessary to prevent smudging. The roll therefore moves horizontally into a drier heated by a ramp of gas burners or hot-air blowers and is cooled as it passes over metal drums refrigerated by circulating water.

Offset rotaries work at a speed of 15,000 to 20,000 revolutions per hour and have the same cutting and folding systems as letterpress rotaries.

Preparing the plates used in offset involves defining and fixing the joint presence of two mutually repellant materials, one water-receptive for the nonprinting areas, and the other ink-receptive for the printing areas. As in letterpress the screen is necessary to translate the halftones of photographic illustrations into surface densities.

Even though there is no question of creating reliefs, the preparation process is very similar to that of photoengraving. But, because the blanket intervenes between plate and paper, text and illustrations appear on the same offset plate in straight rather than in reverse reading as on letterpress plates.

Offset plate making. Depending on the work they are intended for, various kinds of plates and processes for preparing them exist.

Monometal plates are made of a metal with hydrophilic (water-receptive) properties, such as zinc or aluminum, the surface of which is treated to make it more porous. The plate is coated with a thin layer of a photosensitive substance, covered with a negative of the texts and previously screened photographic illustrations, and exposed to intense light. This hardens the photosensitive substance in the areas of the negative where the light passes through; that is, in those corresponding to the printing areas. The photosensitive substance is then washed away from the nonprinting areas, where the metal, now stripped, is wetted; the hardened photosensitive substance is inked.

Presensitized plates are monometal plates coated with a photosensitive layer that has a life-span, away from light, of up to six months. Certain presensitized plates for use in short runs can be made of paper or plastic.

Deep-etch plates are monometal plates prepared by inversion. The plate is coated with a photosensitive substance and then exposed to light through a positive of the text and screened photographic illustrations. This exposure hardens the photosensitive substance on the nonprinting areas. Washing eliminates the photosensitive substance on the printing areas, exposing the metal. The plate is then given a mild acid bath, which etches the metal of the printing areas to a shallow depth. An ink-receptive lacquer is spread over the surface of the plate; that is, over the hardened photosensitive substance wherever it still survives, as well as over the etched-metal areas. The hardened photosensitive substance and the lacquer are both removed at the same time by dissolving and brushing, exposing the metal of the nonprinting surfaces to be wetted. Lacquer remains in the cavities of the etched areas, ready to be inked. Plates treated by this process are suitable for longer runs (up to 250,000 copies).

Bimetal or trimetal plates are composed of two superimposed metals, one of which is hydrophilic (aluminum, stainless steel, chromium, nickel) and the other ink-receptive (copper, bronze). Whichever of the two covers the other in a microscopic film is partly eliminated by the photoengraving operation. In the case of a hydrophilic metal, photoengraving is carried out using positives of the text and illustrations. In the opposite case, negatives are used.

Among the combinations used in various commercial plates are chromium on copper or nickel on bronze for use with positives and copper on stainless steel or copper on aluminum for use with negatives.

The combination of two metals can, in certain plates, take the form of a double film deposited on a third metal (steel or zinc), which simply serves as a base. Bimetal or trimetal plates are very durable and can be used to produce an average of 500,000 copies.

Alongside these various types of conventional offset plates, special processes are being developed that tend to further simplify the work of preparation. Electrostatic (or xerographic) transfer plates were developed from the principle that certain materials (such as selenium) that are insulators while in the dark become conductors of electricity when exposed to light. A selenium plate is given a positive electric charge in the dark and then exposed to light through the positive of the text and illustrations. In the areas touched by the light, the plate becomes a conductor, and the positive charge disperses. A fine, negatively charged powder is sprinkled over the plate and is attracted by the positive charge in those areas of the plate where it still remains. The image thus revealed is transferred to an aluminum plate, which is positioned on the selenium plate and then given a positive electrical charge. The powder transferred to the aluminum plate is fixed by heating to constitute the ink-receptive printing surface.

Innovations in offset plates

This whole operation, which is carried out automatically in a compact apparatus, takes only three minutes. Xerographic plates are used only on small machines.

"Immediate" offset plates consist of a polymer layer that is sensitive not to light but to heat, which makes it become hydrophilic. Those areas not touched by heat retain the opposite property. The plate is then ready for printing without further treatment.

Scope of offset. In offset printing the letters print a little less sharply and strongly than in letterpress, except on special qualities of paper. The reproduction of photographic illustrations, in black and in colour, also depends on the quality of the paper and may rival rotogravure reproduction when printed on offset rotaries with driers.

Other printing processes. *Letterset.* This process, also called indirect letterpress, or dry offset, is a combination of letterpress and offset. Like offset, it has a blanket cylinder as the transfer element between typeform and paper, but, like letterpress, it uses a relief typeform. Thus, letterset presses use the same three cylinders as offset, but there is no dampening system.

Because of the use of a blanket, the text and illustrations appear on the typeform straight and not reversed. Consequently, the use of plates is excluded, since these would be made by making a mold of a conventional typeform. On the other hand, all types of metal or plastic wraparound plates, prepared using positive or negative transparencies, can be used. These plates are thinner than those used for letterpress, and the height of their relief is less. Rollers of a quite large diameter must be used for inking, and con-

tact between plate and blanket cylinder must be extremely light.

All the combinations that the blanket allows on offset machines are equally possible on letterset machines: blanket-to-blanket and drum press. Machines are manufactured that can be used interchangeably, both for offset and for letterset; in the latter case, the action of the dampening system is suspended. The size of paper and performance rates are the same in letterset as in offset.

Serigraphy (screen printing). Serigraphic printing consists of forcing an ink, by pressing with a squeegee, through the mesh of a netting screen stretched on a frame, onto the object to be printed. The nonprinting areas of the screen are protected by a cutout stencil or by blocking up the mesh.

Silk and other screens

The screen is usually made of fine but strong silk gauze (available in different mesh sizes) but can also be made of synthetic gauzes (nylon, tergal) or of wire gauze (phosphor bronze, stainless steel, nickel) or of combinations (nylon–copper, nylon–bronze).

Preparation can be carried out by hand. The design to be reproduced is transferred to the screen by drawing with a benzene-soluble ink, spreading glue over the whole surface of the screen, then dissolving the ink so that the glue remains only on the nonprinting areas. The nonprinting areas can also be covered with glued paper or film, cut out in the shape of the desired image and attached either by heat or by a solvent.

Direct or indirect photomechanical processes are being more and more widely used, however. In direct photomechanical processing the screen is covered with a photosensitive layer and then exposed under a positive, the photographic illustrations having been screened previously. In indirect photomechanical processing, the printing and the nonprinting areas are prepared by exposure under a positive (screened, if necessary) of a photosensitive film (carbon tissue, the same as that used in rotogravure, or presensitized film), which is then bonded to the screen.

Screen printing is still done largely by hand, the frame being lifted up after each operation, but semi-automatic and automatic machines driven mechanically or by compressed air can carry out the series of operations: positioning the object to be printed, moving the frame, inking, spreading the ink with the squeegee, delivering the printed sheet or object, and transferring it to a drying apparatus.

Serigraphic printing can be applied to a wide variety of surfaces—paper, cardboard, glass, wood, plastic, posters, bottles, electronic circuits, etc.—and to varied shapes: for printing cylindrical objects, the squeegee is stationary, while the screen revolves under it at the same time as the object to be printed.

Modern machines reach speeds of from 1,000 to 6,000 copies per hour.

Collotype. A photosensitive layer, spread on a plate of glass and exposed under a negative, hardens and loses its hydrophilic properties in the areas where it receives light and in proportion to the intensity of the light received through the halftones of the photographic documents. It is then able to retain both ink and water in all areas, the ink repelling the water in inverse proportion to the intensity of the exposure.

Collotype printing, which is based on this property of mutual repulsion, is thus related to lithography. But it is also related to rotogravure in the fact that the thickness of the film of ink is not uniform but in proportion to the shades of tone in the original image. Collotype, the only printing process that can reproduce photographic documents without a screen, is characterized by its fidelity of reproduction.

Collotype presses consist essentially of a bed bearing the glass plate prepared for printing, an impression cylinder carrying the sheet to be printed on its outer surface, and a system of ink rollers. The photosensitive preparation retains its own moisture, so no dampening system is necessary.

Speed of collotype printing

Printing speed is slow, rarely more than 200 copies per hour, and the useful life of the printing surface is very limited. from 2,000 to a maximum of 5,000 copies. Increasingly, the glass plate is being replaced by a cellophane film as the surface to which to apply the photosensitive layer. The prints can be cut out and, when glued onto wooden or metal blocks of type height, can be placed alongside a typeform for a limited number of copies to be printed from a flat surface.

Collotype is used for printing limited editions of works that require an excellent quality of photographic reproduction in one or more colours, such as reproductions of documents or pictures, posters, and transparent illustrations for advertising or various artistic uses.

Flexography. Based on letterpress-printing principles, flexographic presses are composed of the same basic elements as letterpress cylinder-to-cylinder presses; that is, the impression cylinder covered with a rubber packing and an inking system, which is simplified, owing to the fluidity of the ink used. Although several sheet-fed models exist, flexographic presses are usually roll-fed rotaries that can reach large dimensions and high printing speeds. They consist of a group of several identical units that print an equal number of colours (up to six).

Flexography provides poor- or average-quality economical printing, either of solid lines or with quite a coarse screen, on unfinished surfaces, wrapping paper, cardboard, or plastic film.

Electrostatic printing. Electrostatic printing is a process of printing without contact, without a typeform, and without ink. The paper is coated with a very thin layer of zinc oxide, which makes it an insulator while in the dark and a conductor of electricity when exposed to light.

This paper is given a negative electrical charge in the dark. It is then exposed by light projected through a positive film of the document to be reproduced. The zinc oxide layer becomes conductive wherever it is illuminated, and the negative charge is dissipated in those areas that correspond to the blank surfaces of the document. Finally, the paper goes through a bath containing pigmented particles that are attracted by what remains of the negative charge and are fixed by drying.

Electrostatic machines have been designed for printing geographical maps. These are composed of five successive units, each carrying out the same complete cycle of processing the paper to produce an edition in five colours at speeds of about 2,000 copies per hour.

Improvements in the bath of pigmented particles are making possible the application of the electrostatic process to printing small books.

Printing inks. Printing inks contain three components, the vehicle, the colouring ingredients, and the additives. The vehicle, responsible for transferring the colouring ingredients from the ink fountain to the typeform, can be either a vegetable base (linseed, rosin, or wood oils), which dries by penetration and oxidation and at the same time ensures fixation, or a solvent base derived from kerosene, in which case drying takes place by evaporation. The colouring ingredients come in several forms: pigments, which are fine, solid particles manufactured from chemicals, generally insoluble in water and only slightly soluble in solvents; agents made from chemicals but soluble both in water and in solvents; and lacquers, obtained by fixing a colouring agent on powdered aluminum. The additives stabilize the mixture and give the ink additional desirable characteristics.

The nature and proportions of the ingredients vary according to the printing process to be used and to the material to be printed. The proportions must be checked and sometimes modified during printing.

Letterpress and offset use greasy inks. For printing on sheet-fed presses, thick greasy inks are used in which the vehicle is generally made of vegetable oils with the addition of hard natural or synthetic resins dispersed in mineral oils. Roll-fed rotaries use fluid greasy inks in which the vehicle is made up of heavy mineral oils.

Sources of ink pigments

The colour black is generally obtained from an organic pigment, carbon black, derived from the incomplete combustion of oils or of natural gas. Colour pigments are made from chrome (yellow, green, and orange), molybdenum (orange), cadmium (red and yellow), and iron (blue).

Inks for offset are more highly coloured than those used in letterpress, because they must be transferred to the blanket before they reach the paper. Furthermore, the pigments must resist being picked up by the water from the dampening system.

Inks with various special qualities exist for both letterpress and offset. In high-gloss inks, the vehicle is not homogeneous, as with ordinary inks, but heterogeneous, based on synthetic resins dissolved in a solvent, with lead and cobalt additives. This ink glazes as it dries. When printing several colours, the whole series of operations must be finished before the ink has time to dry so that the inks can attach themselves to the surface.

Quick-setting inks utilize a vehicle that also has a base of resins dissolved in a quick-drying solvent.

Heat-set inks require the application of heat to facilitate both the oxidation process and the evaporation of the solvent, as well as the penetration of certain elements that had rendered the ink more fluid.

Cold-set inks are hardened by chilling after printing, having been kept fluid by heat until they were applied to the typeform.

Moisture-set inks dry when moistened, either by the paper or by being sprayed with water. In these inks, which are used more in the United States than in Europe, the vehicle is a solvent, soluble in water, that, on contact, penetrates the paper, leaving the pigment on its surface. Odourless, they are used for printing food packaging.

Among other special-characteristic inks are metallic inks containing powdered copper, bronze, aluminum, or gold mixed with the pigment; magnetic inks, containing a powdered magnetized iron mixed with the pigment for "recognizing" the shape of printed characters as they pass before electronic reading equipment; and fluorescent inks.

Rotogravure uses fluid inks in which the colouring agent, fixed on a natural or synthetic resin, is integrated in a fluid solvent to which, just before printing, a second, extremely volatile solvent is added.

Flexography also uses fluid inks whose pigments or colouring agents are dissolved in pure alcohol, in alcohol solutions, or in water.

Serigraphy uses inks of extremely varied consistency, depending on the surface to which they are to be applied; some are little different from ordinary paint, except that their composition must not be such that rapid drying would clog the mesh of the screen.

THE FUTURE OF PRINTING

Economic considerations determine the direction of the present evolution of printing and indicate its probable short- and long-term aims. The elimination of lead, now technically possible, has begun and can only accelerate. Up to the present, this has been demonstrated by the advance of offset at the expense of letterpress. There is a movement toward offset daily newspapers when for a long time the flexibility of letterpress composition and makeup and the simplicity of stereotype plates guaranteed the least delay between event and publication. The high performance rate of photocomposition, the success of the computer, and the simplified processes for preparing plates have all reduced and even removed this advantage of letterpress.

Letterpress has reacted by borrowing some of offset's advantages, by turning to the use of metal or plastic wraparound plates, or by developing indirect letterpress. The superior sharpness of reproduction of texts still attributed to letterpress indicates that competition between the two processes is far from ended.

The convenient use of rapidly made, easily replaceable plates to obtain the best quality of image reproduction has also enabled offset to gain ground at the expense of rotogravure, preparing the cylinders for which is a long and difficult job. It does not appear that even electronic methods for engraving cylinders can halt the recession in rotogravure.

Phototypesetting has seen considerable growth in its programmed applications. The only obstacles it has encountered were the large investments in lead-composing equipment and the uncertainty of printers when faced with equipment that might not pay back its purchase price, given the explosive rate of technical advance. In the 1970s phototypesetting promises to become widespread and expand at a regular rate. The most important problems that it poses in the future are on the human level: the preparation of idiot tape means the mechanization of a human activity; that is, the downgrading of a trade that was considered an art by those who practiced it. On the other hand, to make a profit from phototypesetting machinery capable of very high output, a great volume of work is necessary. It is thus likely to stimulate competition and create difficulties at the level of medium-sized establishments. The enlarged range of offset equipment and its facility in use help these medium-sized establishments to continue to compete. Furthermore, at their level, cold type augurs well as a supplement to letterpress that is in harmony with offset printing.

In the longer run a completely new development may be foreseen: the rise of home printing. Owning or renting an electrostatic printing machine could allow any person, without the slightest training in printing, to produce his own magazine or book simply by using diapositives that might be obtained by subscription and distributed by mail.

Also to be considered is the possible presence in each house of an electronic image maker, at the moment used only to receive television broadcasts. Such a device might be justified in the future by extending its range of uses. Among these would be electrostatic printing by facsimile, following the principle of the homemade newspaper with which the *Mainichi Shimbun* of Japan experimented in 1964. Transmission of print would obviously not be confined to reproducing a newspaper. The subscriber might be offered, on different channels and following a programmed timetable, a choice of magazines, novels, and books that would not take longer than a few minutes to print and that would be made up automatically before being delivered from the machine.

Home printing presents no major technical difficulty. The only obstacle, cost, will disappear under the conditions of mass production and distribution of such equipment for printing written and illustrated information. Such a development would be a response to the conditions of the times, similar to and with the same objectives as Gutenberg's printshop in his.

BIBLIOGRAPHY. The history of printing has been the subject of many volumes. See D.C. MCMURTRIE (ed.), *The Invention of Printing: A Bibliography* (1962). Books retracing the origins of typography include: L.P.V. FEBVRE and H.J. MARTIN (eds.), *L'Apparition du livre* (1958); P. BUTLER, *The Origin of Printing in Europe* (1966); E.G. DUFF, *Early Printed Books* (1893, reprinted 1968); and T.L. DE VINNE, *The Invention of Printing* (1876, reprinted 1969). Biographical works on contributors to the invention of printing are: S. JENNETT, *Pioneers in Printing* (1958); J. GUIGNARD, *Gutenberg et son oeuvre* (1963); G.P. WINSHIP, *Gutenberg to Plantin* (1968); and A. VAN DER LINDE, *De Haarlemsche Costerlegende* (Eng. trans., *The Haarlem Legend of the Invention of Printing, by Lourens Janszoon Coster*, 1871, reprinted 1968). The subject of an entire family devoted to the typographic art is treated by A.J. GEORGE in *The Didot Family and the Progress of Printing* (1961). The various stages of evolution of the techniques of printing are developed in: S.H. STEINBERG, *Five Hundred Years of Printing*, 2nd ed. rev. (1962); M. AUDIN in M. DAUMAS (ed.), *Histoire générale des techniques*, 3 vol. (1962–68; Eng. trans. of vol. 1–2, *A History of Technology and Invention*, 1965–69); I.B. SIMON, *The Story of Printing from Wood Blocks to Electronics* (1965); J. WATSON, *The History of the Art of Printing* (1713, reprinted 1965); C.A. CLAIR, *Chronology of Printing* (1969); and I. THOMAS, *The History of Printing in America, with a Biography of Printers* (1874; 2nd ed., 2 vol., reprinted 1967). One particular aspect of the history of printing is treated in C.H. BLOY, *A History of Printing Ink: Balls, and Rollers, 1440–1850* (1967). Both history and technology are covered in P. LUCKOMBE, *The History and Art of Printing* (1771, reprinted 1965); G. BAUDRY and R. MARANGE, *Comment on imprime*, 3rd ed. (1966), and also in G.A. STEVENSON, *Graphic Arts Encyclopedia* (1968). The specialized language of the profession and the technical terms that are appropriate to it are collected in the following dictionaries: *Pocket Encyclopedia of Paper and Graphic Arts Terms* (1960); W.M. PEPPER, *Dictionary of Newspaper and*

Printmaking

To the modern reader, the word print might suggest mechanically mass-produced commercial products, such as books, newspapers, and textiles. In this article the print refers to the original creation of an artist who, instead of the paintbrush or the chisel, has chosen printmaking tools to express himself.

The fine print is a multiple original. Originality is generally associated with uniqueness, but a print is considered original because the artist from the outset intended to create an etching, woodcut, or other graphic work and thus conceived his image within the possibilities and limitations of that technique. Without doubt, early printmaking was strongly influenced by a desire for multiple prints. Artists quickly discovered, however, that when a drawing is translated into a woodcut or engraving it takes on totally new characteristics. Each technique has its own distinctive style, imposed by the tools, materials, and printing methods. The metamorphosis that takes place between drawing and print became the strongest attraction for the creative artist. It is important to understand that the artist does not select his printing method arbitrarily but chooses the one in which he can best express himself. Thus, any of the proofs printed from an original plate is considered an original work of art, and, although most fine prints are pulled in limited quantities, the number has no bearing on originality, only on commercial value.

Difference between a reproduction and an original print

What is the difference between a reproduction and an original print? In the very early days of printmaking this was not a serious problem because the print was not looked upon as a precious art object, and prices were low. The question of originality became an issue only in the 18th century, and, in the 19th century, artists started to hand sign their prints. Since then, the signed print has been accepted by most people as the proof of its originality.

With regard to the name with which he signed his works, the Japanese artist followed a bewildering custom: he adopted and discarded names at will. If he admired another artist, he simply adopted his name. Thus, in the art history of Japan, it is common to find several unrelated artists bearing the same name and one artist bearing many names; during his long life, Hokusai, for example, used some 50 different names.

In fact a signature by itself means little or nothing. For instance, Pablo Picasso has issued many signed reproductions of his paintings; on the other hand, many of his original etchings have been published in split editions, some signed, some not. These unsigned etchings are original, while the signed reproductions are not. The crucial difference is that Picasso made the plate for the original print, while the signed reproduction was photomechanically produced.

In 1960 the International Congress of Plastic Arts drafted a resolution intended to regulate contemporary prints. The crucial paragraph reads:

> The above principles apply to graphic works which can be considered originals, that is to say to prints for which the artist made the original plate, cut the woodblock, worked on the stone or any other material. Works that do not fulfill these conditions must be considered "reproductions."

Although this is a straightforward statement, recent developments have proved it to be highly controversial. Since the rise of the Pop and Op movements, a great number of photographically produced prints have been published and sold as signed originals. Because museum curators, art critics, and artists did not take a firm stand on the question, any print that the artist declares to be original is now accepted as such, regardless of how it was made. Although the art world is divided on the solution, nearly everybody agrees that something should be done to clarify the situation.

Many artists believe that the answer lies in the giving of honest information. In the 17th and 18th centuries in the West, most prints carried all the relevant information on their margins. The name of the individual was followed by a Latin abbreviation indicating his role in the work. Common examples are *del.* (*delineavit*): "he drew it"; *imp.* (*impressit*): "he printed it"; and *sculp.* (*sculpsit*): "he engraved it." This type of information, together with the total edition number, should be furnished by the artist or the dealer to the buyer. Clearly, it is impossible to make completely rigid rules to define originality. Probably the most realistic solution is to establish degrees of originality, based on the degree of the artist's participation in the various steps in the creation of the finished print.

Numbering editions and signing prints

There may also be confusion about edition numbering. In contemporary printmaking, an original print in limited edition should carry information about the size of the total edition and the number of the print. A problem can arise because, in addition to the regular edition, there are "artist's proofs" or the French "H.C." (*hors de commerce*) proofs. These were intended for the artist's personal use and should be no more than 10 percent of the edition; but, unfortunately, this practice is often abused, and additional quantities are printed. All the prints pulled between working stages are called "trial proofs." These can be of great interest because they reveal the artist's working process and of great value because the number of proofs is small.

With prints of old masters in the West, originality is a very complex and difficult issue. These artists did not publish their prints in limited editions but printed as many as they could sell and without signing or numbering their works. There are arguments even between experts about the authenticity of many old prints. Important works of the masters are documented in catalogs and, although these must be revised from time to time, they furnish the only firm information available.

After the edition is printed, the modern artist usually either destroys the plate or marks ("strikes") it in a distinctive manner to guarantee that any reprint from the plate is identifiable.

The 19th-century American painter and etcher James McNeill Whistler was one of the first Western artists to hand sign his prints. Signing is now regulated by a convention. Upon completing the edition, the artist signs and numbers each print. Usually the signature is in the lower right corner; the edition number is on the left. Some artists put the title in the centre.

Printmaking in the 20th century

I. Major techniques of printmaking

The techniques of printmaking are divided into three major categories: relief processes, intaglio processes, and surface processes. The surface processes are subdivided into two categories: planographic (lithography) and stencil methods. The methods can be and often are combined.

RELIEF PROCESSES

In relief processes, the negative, or nonprinting part of the block or plate, is either cut or etched away, leaving the design standing in relief. Or, instead of cutting away the background, the relief print can be created by building up the printing surface. The relief is the positive image and represents the printing surface. The most familiar relief-printing materials are wood and linoleum, but many other materials can be used, such as aluminum, magnesium, and plastics. Any metal or plastic plate incised or worked in relief can be first inked in the depressions (intaglio inked) and then surface rolled, thus combining relief and intaglio processes.

Relief printing lends itself particularly to a bold conception of design, expressed more in areas than lines. This varies, however, depending on the material used: metal allows more intricate detail than wood, for example.

Woodcut. Woodcut, which appeared in the 8th century in the East and in the early 15th in the West, is the earliest relief-printing method. In this method, the design is first either painted directly onto the wood block or pasted on it. Then the surface of the wood is cut away around the design. For fine details and outlines the knife is used; larger areas are removed with gouges. The depth of the relief depends on the design: open areas must be cut deeper than the fine details so that the roller will not deposit ink in these areas. Although woodcuts are generally conceived in bold lines, or large areas, tonal variations can be achieved with textures, a variety of marks made with gouges, chisels, or knives. In contemporary woodcuts many other methods such as scraping, scratching, and hammering are also used to create textures.

Originally, woodcut was a facsimile process; *i.e.*, the cutting was a reproduction of a finished design. With most contemporary woodcuts, however, the artist creates his design in the process of cutting.

Wood for blocks

As wood is a natural material, its structure varies enormously and this exercises a strong influence on the cutting. Wood blocks are cut plankwise. The woods most often used are pear, rose, pine, apple, and beech. The old masters preferred fine-grained hardwoods because they allow finer detail work than softwoods; but modern printmakers value the coarse grain of softwoods and often incorporate it into the design.

The printing of woodcuts is a relatively simple process because it does not require great pressure. Although presses are used, even hand rubbing with a wooden spoon can produce a good print. The ink used to print woodcuts must be fairly solid and sticky, so that it lies on the surface without flowing into the hollows. The printing ink can be deposited on the relief either with dabbers or with rollers. Japanese rice or mulberry papers are particularly suitable for woodcuts because they make rich prints without heavy pressure.

Colour woodcut. The standard procedure for making a woodcut with two or more colours is to cut a separate block for each colour. If the colour areas are distinctly separated and the block is large, one block can be used for more than one colour. All blocks must be the same size to assure that in the finished print the colours will appear in their proper relation to one another, that is, properly registered.

"Head of Ludwig Schames," woodcut by Ernst Ludwig Kirchner, 1918. 58.4 cm × 26 cm.
By courtesy of the Museum of Modern Art, New York, gift of Curt Valentin

The first, the key block, is generally the one that contains most of the structural or descriptive elements of the design, thus serving as a guide for the disposition of the other colours. After the key block is finished and printed, the print is transferred to the second block. This procedure is repeated until all the blocks are finished.

The registering system depends on the method of printing used. On a press the registering presents no problem: the wood block is locked into position and the uniformly cut paper is automatically fed into the proper position by the press. For hand rubbing, several registering methods can be used. One method uses a mitred corner nailed to a table or special board. A sheet of paper is attached to one side of this corner, after which the wood block is placed securely in position and the print is made. Once the first colour has been printed, the paper is folded back and the first block is replaced with the second, and so on.

In woodcut colour printing, the artist must consider whether he can print wet on wet or whether the print should dry before it is overprinted. Usually a second colour can be printed immediately but, if the ink deposit is heavy, the print will have to dry before additional colours can be printed. This problem arises mainly with oil colours, which dry more slowly than water-base colours.

Use of small movable blocks

Movable small blocks are also used today by a number of printmakers. These involve some planning in order to print them in register with the large blocks. The easiest way is to put a light cardboard, exactly the size of the main block (the key block), in position. Once the small blocks are registered, their location can be marked on the cardboard. Then the small blocks can be glued down to the cardboard in order to avoid the danger of shifting.

The conception and technique of the Japanese colour woodcut was totally different from that of the European woodcut. Except for chiaroscuro prints, no real colour

woodcut existed in Europe before the 19th century. In the West, the woodcut was primarily a reproductive facsimile process: usually, the artist made a completed drawing that was copied by the cutter. The Japanese print, on the other hand, was the result of intricate, perfectly coordinated effort by the designing artist, the cutter, and the printer. Instead of painting a complete picture to be copied, the artist furnished a separate drawing for each colour. The engraver or cutter pasted each drawing on a wood block and cut away the white (negative) part. In this process the drawing was destroyed. Printing started only after all of the blocks had been cut. As the Japanese used water-base colours, often blending tones, printing itself was a very delicate and crucial operation, requiring perfect coordination and speed. Only after the completion of this process could the artist see the total image.

Wood engraving. Wood engraving is a variation of woodcut. The main difference is that, for wood engraving, the block—usually pear, apple, cherry, sycamore, or beech—is cut cross-grain rather than plankwise; on the end-grain block the artist can thus cut freely in any direction, allowing him to do much more intricate work with much finer tools. The image is created by fine white lines

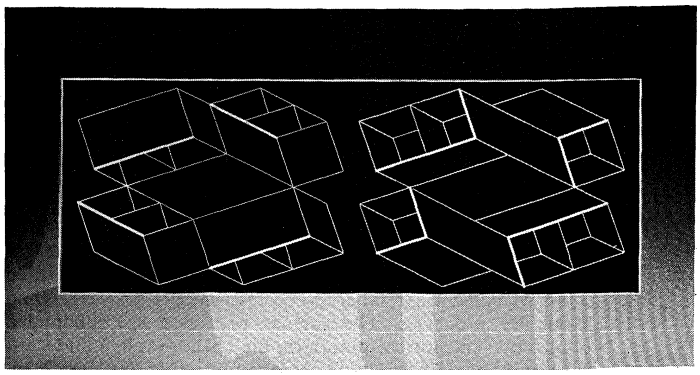
Wood engraving by William Blake, 1820–21, for R.J. Thornton's *Pastorals of Virgil.* 3.5 cm × 7.2 cm.

and textures. On most wood engravings, the whites appear as the positive image against a dominant black. The blocks are usually cut at the same height as printing type so that they can be printed on a press. Invented in the 18th century, wood engraving was primarily used by illustrators.

Linoleum cut. Since linoleum is easy to cut and does not have a grain, the linoleum cut is used often to introduce children to printmaking. The process was held in low esteem until, in the 1950s, Pablo Picasso made a series of brilliant colour linoleum cuts.



The printing of linoleum cuts is similar to the printing of woodcuts or wood engravings. They can be printed by hand rubbing or, properly mounted, can be printed on a press. The colour printing process follows the woodcut principles.

Metal cut. At times artists have used soft metals, such as lead or zinc, to make prints similar to woodcuts or wood engravings. In the 19th century, lead cuts were often used for newspaper illustrations. The distinguished Mexican artist José Guadalupe Posada, for example, used lead frequently for his prints. Lead was used primarily because it was inexpensive and easy to work. Because metal cuts were printed like woodcuts or wood engravings, it is often difficult to tell from the print which material was used.

Cardboard (paper) cut. Elementary school children are often introduced to printmaking by making cardboard cuts, and sophisticated artists use the same material to print complex abstract images. Cardboard and paper

Advantages of cardboard and paper

are not only inexpensive, readily available, and workable with simple tools but, when properly prepared, have also proved to be remarkably durable. Cardboard cuts can be made either by building up or cutting out. In the first process, cut-out pieces are glued to a support. When the plate is finished, it is coated with a plastic varnish to make

"Duo H," inkless intaglio print (relief of design etched on plastic and mounted on Plexiglas) by Josef Albers, 1966. Image 34.3 cm × 12.7 cm.

sure the surface is tough and nonabsorbent. In the cutting-out method a heavy laminated cardboard is used and the cut out sections are simply peeled off to the desired depth. When finished, the cut is varnished. The printing of cardboard plates follows the same principle as woodcuts or linoleum cuts.

Relief etching. When large areas of a metal plate are etched out (see below *Etching*), leaving the design in relief to be surface printed, the process is generally called relief etching. Usually the method is used for areas, but it can be also used for lines. The English artist and poet William Blake was the first printmaker to experiment extensively with relief etching. He devised a method of transferring his handwritten poems onto the metal plate to be etched together with the illustrations. In contemporary printmaking, relief etching is used extensively for colour printing. The different levels of the plate can be inked with different colours. Relief etching is also a popular method of making inkless intaglio prints (shallow bas-reliefs on paper).

Rubbings. Simply by inking the surface, placing a fine paper over it, and rubbing, practically any surface can be used for printing—including, as in Japan, the body of a fish. Rubbings were probably the earliest prints made by man. In India and China rubbings were made of tombstones and temple bas-reliefs. In addition to fish rubbings, the Japanese made rubbings of metal ornaments. Today

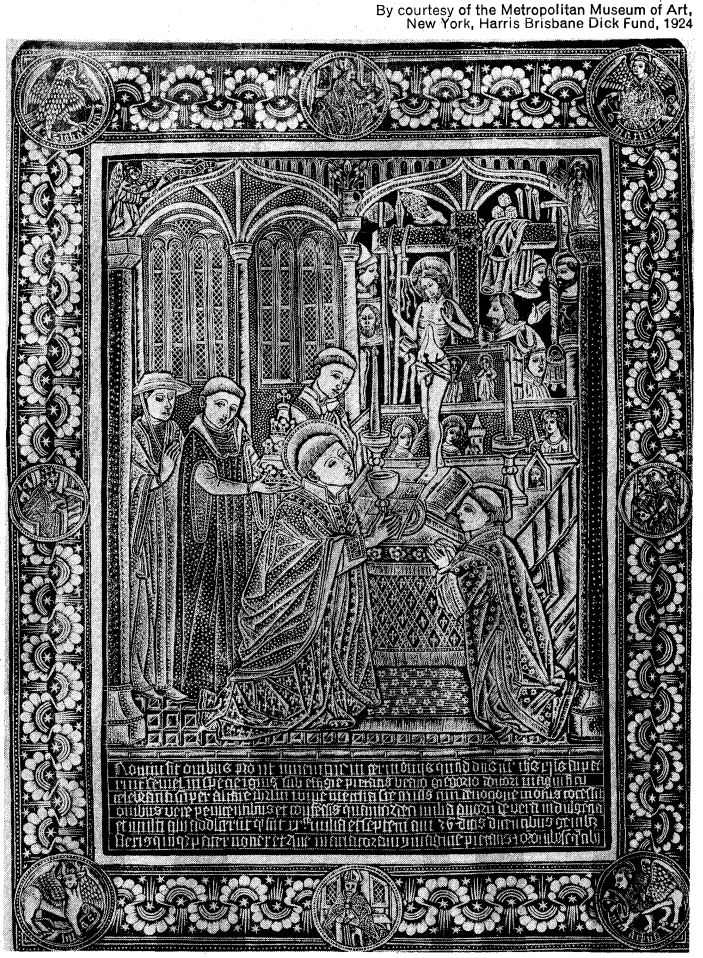
Scenes from the tomb of the Wu family in Shantung, China, stone rubbing, AD 147 (Han dynasty). 7.5 m × 6.3 m.

many museums sell rubbings of bas-reliefs in their collections. Rubbings can be made with the simplest tools and materials: rice, mulberry, or any other woodcut paper; water-base inks (because they can be washed off, avoiding permanent stains on porous surfaces); a hard rubber roller to deposit the ink, and a wooden spoon or small polished wood block for rubbing.

Dotted print (criblé). A traditional technique of the goldsmith long before engraving for printing purposes was developed, criblé was also used to make the earliest metal prints on paper. Criblé was a method of dotting the plate with a hand punch; with punch and hammer; with a serrated, flatheaded tool called a matting punch; with various gouges; or sometimes, with a hollow, circular-headed ring-punch. Criblé plates were relief printed like woodcuts. On most dotted prints, a black background dominates a fine lacelike design.

INTAGLIO PROCESSES

Intaglio printing is the opposite of relief printing, in that the printing is done from ink that is below the surface of the plate. The design is cut, scratched, or etched into the printing surface or plate, which can be copper, zinc, aluminum, magnesium, plastics, or even coated paper. The printing ink is rubbed into the incisions or grooves and the surface is wiped clean. Unlike surface printing, intaglio printing—which is actually a process of embossing the paper into the incised lines—requires enormous pressure. The major working methods for intaglio printing are engraving, etching, drypoint, and mezzotint. Intaglio processes are probably the most versatile of the printmaking methods, as various techniques can produce a wide range of effects, from the most delicate to the boldest. The intaglio print also produces the richest printed surface, as it is three-dimensional.



Pressures required for intaglio printing

Engraving. In engraving, the design is cut into metal with a graver or burin. The burin is a steel rod with a square or lozenge-shaped section and slightly bent shank. The cutting is done by pushing the burin into the metal plate. The deeper it penetrates into the metal, the wider the line; variations in depth create the swelling–tapering character of the engraved line. After the engraving is finished, the slight burr raised by the graver is cleaned off with a scraper. The engraved line is so sharp and clean that it asserts itself even if cut over a densely etched area. In the print, the engraved line is notable for its precision and intensity. In engraving, the hand does not move freely in any direction but pushes the graver forward in a line; change of direction is achieved by the manipulation of the plate with the other hand. Although copper, zinc, aluminum, and magnesium plates are used—and in the past, soft iron and even steel were used—the best all-around metal is copper. It is preferred because it has the most consistent structure and is neither too soft nor too hard.

"St. John on the Isle of Patmos," engraving by Master E.S. (active c. 1440–c. 1467). 20.6 cm × 14.1 cm.

"The Mass of St. Gregory," criblé, or dotted, print by an unknown German artist, 15th century. 35.2 cm × 25.1 cm.

Drypoint. Next to engraving, the drypoint is the most direct of the intaglio techniques. In printing, however, it represents the opposite end of the spectrum. Engraving is precise, drypoint is rugged, warm, and irregular.

Drypoint is made by scratching lines into metal plates with steel- or diamond-point needles. In this method the penetration into the plate is negligible; it is the metal burr raised by the point that holds the ink. As the burr is irregular, it prints as a soft velvety line. The angle of the needle has much more effect on the width of the line than the pressure does: if the needle is perpendicular to the plate it throws burr on both sides, which then produces a thin double line; for wide lines the optimum angle is 60 degrees.

Importance of needle angle

Copper plate is the best for drypoint. The plates are fragile because the burrs are easily flattened down by the printing pressure. Even a too vigorous wiping can damage a plate. Thus, unless the artist is satisfied with a very limited number of proofs (three or four), the plate must be faced with steel, a process in which steel is deposited by electrolytic means on the copper plate. This coating is

"Self-Portrait with Bowler Hat," drypoint by Max Beckmann, 1921. 31.3 cm × 24.5 cm.
By courtesy of the Museum of Modern Art, New York

very thin and if it is properly done, the burrs are hardened without affecting printing quality. Zinc and aluminum, however, cannot be steel-faced.

Mezzotint. In mezzotint the metal plate is roughened with fine burrs until it prints a rich, velvety black. The plate is then worked back toward the lighter values with scrapers and burnishers. For this reason, mezzotint is also called *manière noire*, or the "black manner."

Mezzotint flourished throughout the 18th and 19th centuries and was primarily used for portraits or to reproduce paintings. None of the important printmakers of the past used the technique. After the invention of photoengraving, mezzotint was nearly forgotten, but in recent years a few printmakers have started to work again with this exotic medium.

Use of the rocker

The first step in preparing a mezzotint plate is to rough up the whole plate surface as evenly as possible. The tool used is the rocker, a blade with a curved serrated edge. The rougher the rocker, the heavier is the burr. The rocker is held with its cutting edge at a right angle to the plate, and the curved edge is rocked systematically over the entire surface. If this is properly done, the entire plate is covered with uniform burrs. Then the work with scrapers and burnishers begins. Where lighter tones are desired, the burr is gradually removed, and in the white areas the plate is burnished back to its original finish.

As with drypoint, mezzotint plates must be steel faced if a large edition is desired. The printing of mezzotints differs slightly from the printing of etchings or engravings. Since the layer of burr on the mezzotint acts as a blotting paper, the ink must be selected with this fact in mind. The inking and wiping must be done gently with soft rags. Printing pressure should be considerably less than that used for engravings or deeply etched plates.

Crayon manner and stipple engraving. Invented in the 18th century, crayon manner was purely a reproduction technique; its aim was the imitation of chalk drawings. The process started with a plate covered with hard ground (see below *Etching*). The design was created using a great variety of etching needles (some of them multiple). After the design was etched in, the ground was removed and the design further developed with various tools. Fine corrections and tonal modifications were made with scrapers and burnishers. Finally, engraving was used for additional strengthening of the design. Pastel manner is essentially the same as the crayon manner except that it is usually used to imitate pastel drawings.

Stipple engraving, also a reproduction method, is closely related to the crayon manner. The exact date of its invention is not known, but it is reasonably certain that it came after the crayon manner. The first step in stipple engraving was to etch in the outlines of the design with fine dots made either with needles or with a roulette, a small wheel with points. The tonal areas were then gradually developed with tiny flick dots made with the curved stipple graver. For very fine tonal gradations, roulettes were also used. The only artist of any importance to use pure stipple engraving was Giulio Campagnola in the 16th century.

Etching. Etching is a process in which lines or textures are bitten (etched) into a metal plate with a variety of mordants (acids). The metal plate is first covered with an acid-resistant coating (ground). The design is then scratched or pressed into the ground, exposing the metal in these areas. Finally, the plate is submerged in an acid solution until the desired depth and width in the exposed areas is reached.

Although the basic principle of etching is very simple, there are many possible variations that have a strong influence on the final result. The materials themselves offer a wide range of possible variations; for example, copper, zinc, aluminum, or magnesium plates can be used; and nitric acid, hydrochloric acid, or ferric chloride can be used for the etching process. Other variations include the strength of the mordants, the biting time, the kinds of grounds and the ways in which they can be worked, and, finally, all the possible methods of printing.

Although all these matters seem purely technical, every tool or material used, every step followed, is an integral part of the creative process. The biting action of the acid is just as much part of the drawing as the incising into the ground. The selection of the paper or the method of wiping the plate can completely change the nature of a print.

Hard-ground etching. Any acid-resistant coating used to make an etching is called a ground. In the past a great variety of different grounds were used, and each master had his own formula. Most of them had wax as a basis, combined with various oils and varnishes. Today, the most commonly used ground consists of two parts Egyptian asphaltum, two parts beeswax, and one part resin. These ingredients are either dissolved and mixed or fused by heat. Ground comes either in lump or liquid form.

The plate is cleaned before the ground is applied because grease or dirt can affect the ground's adhesion, making it peel or crack. If ground in solid form is used, it is melted on low heat and rolled out evenly. Liquid ground is brushed on the plate, then heated to make it more even and to evaporate the solvents. In both cases, after the plate cools, the ground should be solid (not sticky).

By courtesy of the Museum of Modern Art, New York

"Minotauromachy," etching by Pablo Picasso, 1935. 49.5 cm × 69.7 cm.

Normally, a good ground is dark enough to offer sufficient contrast with the plate to see the work. If, however, a black ground is desired, it can be achieved by darkening the ground with the smoke of a candle.

Variety of modern etching tools

In etching the ground, any number of tools and instruments may be employed. The old masters were restricted, but the contemporary printmaker uses a whole arsenal, including electrical drills and gravers. The line produced by the etching needle is threadlike and uniform in thickness. Other instruments are used to introduce a great variety of marks. The character of the etching is further influenced by the choice of the metal and the type of acid used. For controlled, regular bite, it is common to use Dutch mordant (nine parts of water saturated with potassium chlorate to one part of hydrochloric acid) on copper. For a rugged, irregular bite, nitric acid (one part to nine parts of water) is used on zinc. A plate can be etched in stages by covering some of the already etched areas with stop-out varnish (rosin dissolved in alcohol), which resists the acid, and then etching the rest for a longer period. This procedure can be repeated many times. Most artists develop their plates by repeated bites. After the etching is finished, the ground is removed with solvent (such as kerosene or benzene), and the plate is printed.

The first print is a state, or trial, proof. If further work is desired, the plate is cleaned and covered again with ground, the previous work remaining visible through the new ground. The whole process is repeated as many times as is necessary.

Soft-ground etching. Soft-ground etching is basically the same as hard-ground etching except that the ground contains about one-third grease, which keeps it in a semihard, or tacky, condition.

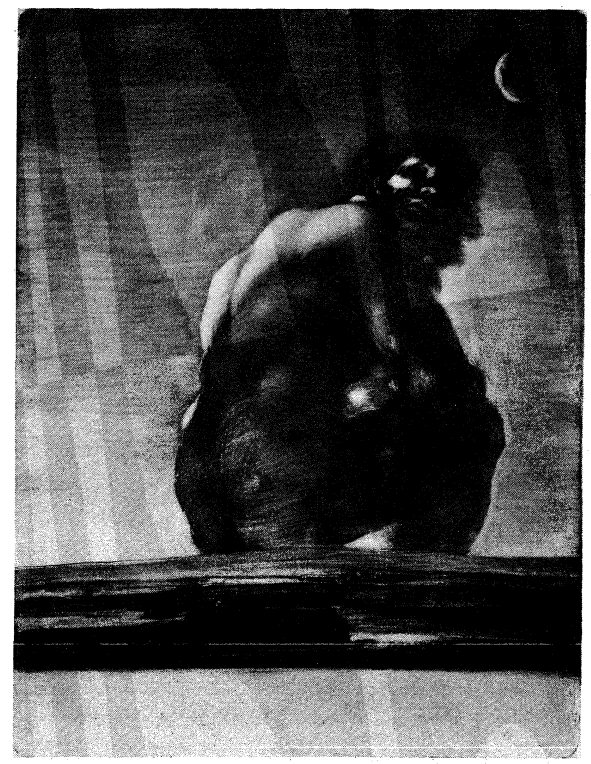
Initially, in the 19th century, soft ground was used primarily for offset drawings. The artist placed a paper on the grounded plate and made his drawing on the paper with a sharp pencil or other drawing instrument. Under the pressure, the paper picked up the ground and produced a soft granular line. Then the plate was etched normally with a fairly weak acid.

At the present, soft ground is used more often to etch various textures into the plate. Textured materials are placed on the soft ground and the plate run through the press. A thin, even ground picks up the finest textures. The design is controlled by applying a stop-out varnish to areas that should not be etched. The remaining textures are etched into the metal in the same way as in conventional hard-ground etching. This technique lends itself well to collage-type effects on the plate.

Relief etching. To make a relief etching, the areas not to be removed by acid are protected with liquid ground or varnish. The varnish used has to be tough (asphaltum, or ground) because the relief bite takes a long time, and when large areas are bitten, the plate has a tendency to heat up. If various levels are desired, relief etching can be done in stages, as in regular etching.

Aquatint. Aquatint is a process used to etch tonal areas on the plate. The first step is to give the plate a porous ground by dusting it with rosin powder and fusing the powder to the plate by means of heat. When the plate is etched, the acid goes through the pores in the ground and bites tiny cavities in the metal. These cavities hold the ink. A variety of tones and textures can be created, depending on the density, width, and depth of the cavities.

The aquatint method was invented in the 18th century, and, although a great number of pure aquatint plates were done, the technique was mainly used with line etching. Theoretically, there is no limit to the range of tones that can be etched with aquatint.



For aquatint, the plate is cleaned, as in hard-ground etching, and then dusted with rosin. Care in this step is crucial, as an incorrectly distributed rosin ground will produce uneven, spotty tones. To achieve even tones, a fine-grain rosin is used. The quantity should cover about 50 percent of the surface, neither too thin nor too thick. The dusting can be done either with a dust box or with dust bags.

Use of the dust box

The dust box is a completely enclosed container with a sliding tray (usually made of steel mesh) that holds the plate in position above the dust tray, which is filled with fine rosin dust. After the plate is placed in the box, the rosin dust is agitated either by a bellows, by an electric fan, or by shaking.

Dusting bags are made of various materials; the finer the material, the finer the dust coming through. The dusting bags have the advantage of allowing the artist to visually control the amount of dust deposited and also to use different textures in different areas.

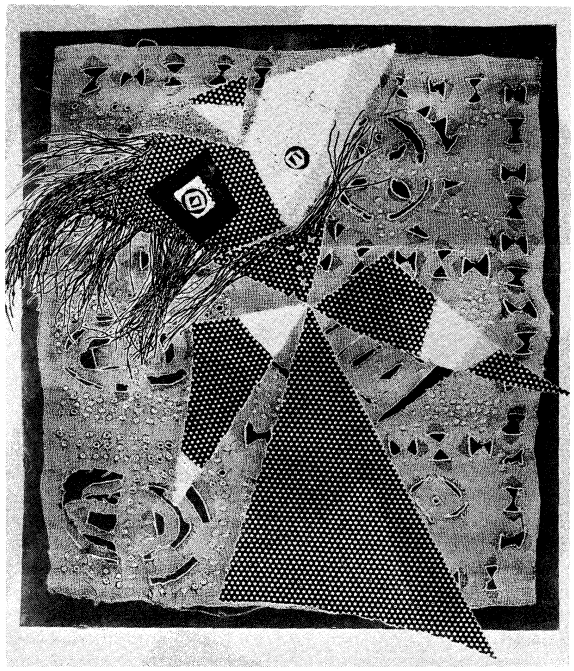
By courtesy of the Metropolitan Museum of Art, New York, Harris Brisbane Dick Fund, 1935

"The Colossus," aquatint by Francisco de Goya (1746–1828). 29.3 cm × 21.6 cm.

After dusting, the plate is placed on the heating plate, and the rosin is fused to the metal. When the plate has cooled, the design is applied with a stop-out varnish. To achieve various tones the plate is bitten in stages, much as in hard-ground etching but with one important difference: aquatint is much more delicate, and the time element is more critical. A biting time of a few seconds can produce a fine gray, but a proportionately longer time is needed as the artist proceeds toward the darker tones.

Plastic sprays are also used to make aquatints. These lacquers and enamels are sold in pressurized spray cans and are sufficiently acid resistant to use for moderately long bites. They are easy to control and simpler to use, but they must be used in spray booths or other well-ventilated places.

Lift-ground etching (*sugar-lift aquatint*). In lift-ground etching, a positive image is etched on an aquatint plate by drawing with a water-soluble ground. In the conventional aquatint technique, the artist controls the image by stopping out negative areas with varnish, thus working around the positive image. But for lift-ground etching, he uses a viscous liquid (such as India ink, gamboge, or ordinary poster paint mixed with sugar syrup) to paint directly on the plate. After the painting is finished and dried, the whole surface is covered with thin, liquid hard ground. When dry, the plate is placed in lukewarm water that dissolves the painted design, lifting the ground and dislodging it from the places that had been painted, thus exposing the metal surface to be etched. Aquatinting can be handled two ways: either the whole plate can be aquatinted before painting with lift ground or it can be aquatinted after the design is lifted. Lift-ground etching is particularly well-suited to free, spontaneous, calligraphic designs.



Action of nitric acid and Dutch mordant

Acids and the etching process. The acid bite of the plate is a critical stage in making an etching. The printmaker must be familiar with the characteristics of the materials he is using. On a zinc plate, nitric acid is used. In the process of biting, this acid develops air bubbles over the bitten area. Under the bubbles, the acid action is slower, and, therefore, if the bubbles are not constantly moved around by brushing, the etched line will be uneven. Nitric acid also has a tendency to underbite, that is, to bite not only straight down but sideways. For this reason, areas of dense texture must be watched closely.

Nitric acid also can be used on copper, but, except to bite out large areas, Dutch mordant is much better suited for this metal. The action of hydrochloric acid on copper is much more even and controlled than that of nitric. Thus, for a bold, rough bite, nitric on zinc is fine; but for delicate, controlled etching, Dutch mordant on copper is preferred.

Metal graphic. This method was originated by Rolf Nesch (1893–), the German-Norwegian printmaker. In all the intaglio methods previously discussed, the artist's design was created by making incisions in the plate. Nesch's method is the reverse of this process: the design is built up like a montage, by cutting out metal shapes and soldering them on the plate surface. Instead of the etching needle and the graver, the tools are shears, wire cutters, and a soldering iron. These plates are in deep relief

"Sort Dame" ("Dark Lady"), "metal graphic" print by Rolf Nesch, 1953. 57.1 cm × 50.2 cm.

and thus produce a heavily embossed print. Often such plates are combined with conventionally etched or engraved sections. In addition to metal shapes, wood and plastics may be used. Because of the extremely high relief, the printing of the plates requires specially prepared presses. A few contemporary artists work in such a high relief that the ordinary etching press cannot print their work and standard printing papers cannot be used. In some cases, the high relief is created by compressing paper pulp into molds with hydraulic presses.

The use of embossing is not new. Some Japanese woodcuts have sections decorated with "goufrage" (blind pressing). In contemporary printmaking, embossing has become a major interest, and many artists are exploring the possibilities of the intaglio print by using shallow paper bas-reliefs to exploit the interplay of shadow and light.

Printing by intaglio processes. The most important piece of equipment in intaglio printing is the etching press, a simple machine whose basic principle has not changed for centuries. Motorization and the use of pressure gauges are the only major improvements. The press consists of a solid steel plate (bed) driven between two rollers; a screw mechanism on both sides of the top roller adjusts the pressure. Large modern presses are motor driven.

The etching press

The print is made by placing the inked plate face up on the bed. Dampened paper is placed carefully on the plate and covered with several layers of pure wool printing felts. The bed is then driven through the rollers. The felts, squeezed between the metal rollers and the plate, are pushed into the crevices of the plate, forcing the paper into contact with the ink and thus transferring the image.

A fairly heavy pure rag paper is normally used. It is soaked until its fibres are softened and then, before printing, it is blotted until no surface water is visible.

Inks for intaglio printing are especially made for this purpose. The consistency of the ink must be such that it comes off the plate cleanly during the wiping operation, but at the same time it must have enough body to retain its relief on the paper. The printing ink must also have sufficient viscosity to stick to the damp printing paper to produce a clear and rich image. For inking, the plate is placed on a heater and kept warm throughout the inking and wiping steps. Heat makes the ink looser and thus facilitates both of these processes.

Wiping is the operation in which the ink is removed from the surface of the plate, while leaving it in the recesses. Usually a carefully folded starched cheesecloth (tarlatan) is used. When a clean, crisp print is desired, the plate is given a final wiping with the palm of the hand.

After the print is pulled, it is dried, either between blotters or taped to a large, stiff board. This choice depends on the size of the print and the type of paper used.

Intaglio colour printing. The intaglio colour print is made with two or more intaglio plates successively overprinted on the same paper. Each plate represents one colour and its possible graduations. In principle, it is possible to take four plates—the three basic colours, yellow, red, and blue, plus black—and make a print that will have the full range of colours. If the colour areas are distinctly separated, more than one colour can be printed from one plate. This method involves an extremely meticulous inking and wiping process.

Problems of colour registration

One of the greatest problems with intaglio colour printing is registering the successive colours in their precise location. If the colours can be printed immediately, wet on wet, then it is relatively simple, but often this is not possible. If the first plate has high relief and is overprinted while wet, the second plate will crush it completely. In this case the first print must be thoroughly dried and then rewetted for the second printing. Because the paper shrinks in the drying process, it is difficult to get it back to the original size when rewetted.

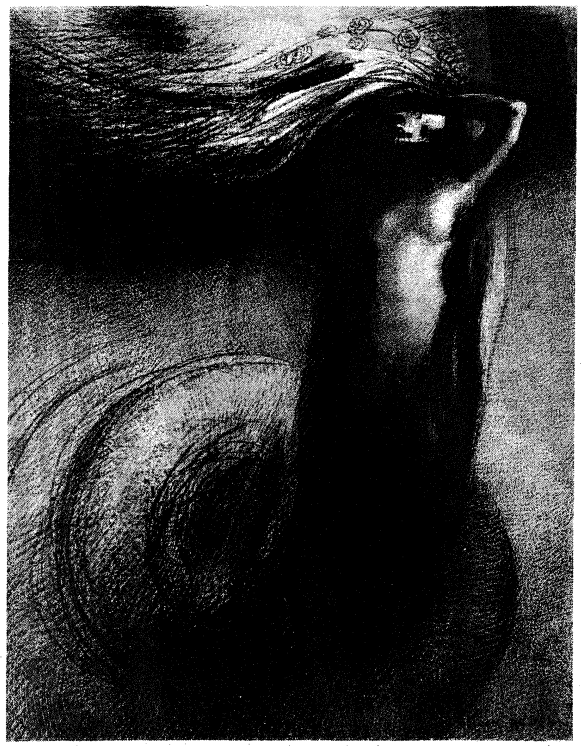
Several methods of registering can be used, depending on the particular problem. For wet-on-wet printing the process is simple. After both plates are inked, the first plate is placed on the press bed and its position is marked. Paper is placed over the plate and secured at one end with masking tape, or, if there is enough margin, the paper is run through so that one end remains caught under the printing roller. The print is then folded back and the first plate is replaced with the second.

Another method uses mats. The paper to be used in the edition is cut to the same size. A cardboard or metal mat is cut, corresponding to the size of the wet paper. The plate position is either cut out or marked on the mat. Registration consists of lining the paper up with the mat.

The most precise registering is with pinholes. Two pinholes are punched in the opposite corners of the mat. Corresponding pinholes are punched through all the printing papers. In printing, the paper is picked up with two heavy needles through the already punched holes. The needles are then inserted in the corresponding holes on the mat and the paper is released. The holes should be placed close to an edge that will be trimmed after the print is dry.

Stencilled colours with an intaglio plate. Stencilling is one of the simplest ways to use a number of colours

combined with an intaglio plate. This method has advantages and also limitations. The main advantage is that it eliminates the registering problems of intaglio colour printing. On the other hand, it is limited to flat, sharply defined colour areas. One method does not replace the other, but each may be used to solve a particular problem.



The procedure itself is very simple. The intaglio plate is inked and wiped normally. The desired colour shape is cut out on a stencil paper. The stencil is placed on the already inked plate and the colour is rolled onto the surface of the plate using a gelatin or soft rubber roller. For surface rolling, regular artist oil colours can be used. The use of stencils allows a great number of colours to be printed with a single run on the press. This is done by surface rolling colours through stencils onto the intaglio inked and wiped plate surface.

For more complex colour combinations, it is possible to combine colours stencilled directly on the paper with colours offset from the intaglio plate. For more sophisticated stencilling, silk screen can be used also in combination with the intaglio plate. When intaglio and stencilling are combined, the process is often designated as mixed or combined technique. This is essentially the same procedure as conventional stencilling except that with silk screen more complex designs and textures can also be stencilled on the plate (see below *Stencil processes*).

Intaglio and surface colour with relief etching. In this technique the main colour structure is defined by the plate surface, which is etched to different levels. The linear or textural elements moving from one level to another bind the whole together.

Inking to different levels

The sequence of printing begins with the intaglio inking and wiping of the plate. Next, the first surface colour is rolled on with a soft gelatin roller that penetrates the lower levels of the relief. The high areas are inked with a hard rubber or composition roller. The sequence of rolling can change, according to the demands of the particular colour problem.

SURFACE-PRINTING PROCESSES

Surface printing comprises those techniques in which the image is printed from the flat surface of the metal, stone, or other material. The major surface method is lithography, a planographic process. Although many experts place silk screen and stencilling in a separate category, they can be considered surface-printing processes. In lithography, the control of the design is achieved by the chemical treatments of the drawing surface. In stencilling, the design is created by holes in the stencil and the printing ink is either rolled or squeezed through the stencil onto the paper. Silk screen is a special form of stencilling.

Lithography. Lithography is based on the fact that water and grease do not mix. The image is drawn or painted on the stone or metal plate with greasy litho crayon or a greasy black ink (tusche). Once the drawing is finished, it is fixed with an etch to prevent the spreading of the grease. A heavy, syrupy mixture of gum arabic and a small quantity of nitric acid, the etch is used to protect the drawing from water and to further desensitize the undrawn areas to printing ink. The nitric acid opens the pores of the stone, enabling the gum and the grease to enter easily. The gum arabic surrounds the greasy sections, forming an insoluble surface film which sticks to the negative areas and crevices of the grain. This coating around the image repels the water applied during printing and establishes a grease reservoir. It does not smear, and it prevents seepage that would blur the image.

The etch in lithography

Because of the antipathy of grease and water, the image attracts oily ink, but repels water. Thus, when the stone is dampened with a sponge and an ink-charged roller is passed over it, the ink is deposited on the greasy drawing but not on the wet stone.

In lithography, the assumption is that the drawing made on the stone or plate will be closely duplicated on the print. While intaglio processes produce prints unlike any drawing technique, lithography is quite reproductive. Although a complex method, if lithography is well done, the effect of the print is deceptively simple and direct, making the technique attractive to artists who wish to avoid the more idiosyncratic printmaking methods.

A highly skilled technician is needed to produce a good lithograph, and most lithography is done in workshops where well-trained men are available. The artist usually works on the stone or plate under the guidance of master printers. When the artist finishes his drawing, the master printers etch the stone and do the printing.

In the basic technique, the first step is the preparation of the stone or plate. If a stone has been used before, its surface must be reground. The stone is placed in a sink, thoroughly wetted, and carborundum powder sprinkled over it. Then, either with a levigator (a heavy steel disc with a handle) or by rubbing two stones together, the surface is thoroughly reground. From time to time the surface should be tested with a steel straightedge to make sure it is level, otherwise it will print unevenly. After the stone has dried, it is ready for work. It is very important to keep the stone clean because any dirt, particularly grease, would show up on the print. Smudges and dirt can be cleaned off with erasers and abrasives.

Metal plates (zinc or aluminum) can also be used and these, too, may be reground. Although metal plates are satisfactory, stone is far superior, particularly for producing subtle tones and details.

Use of crayons and tusches on stone

With litho crayons and tusches the artist can work on the stone as he would on paper. A whole arsenal of effects is available, including pen, pencil, splashing, sprinkling, spraying, texture transfers, and scraping. After the drawing is finished and before etching, the image must be protected from the etching solution by rubbing rosin and then talcum powder on the stone. The acid-resistant rosin protects the drawing; the talcum absorbs the excess grease, allowing the adhesion of the gum etch to the edges of the drawing.

Next, the whole surface of the stone is coated with undiluted gum arabic, applied with a wide, soft brush. The subsequent etching process is done in stages. The weakest acid solution is usually brushed first on the lightest areas of the drawing. After an appropriate interval, the next strength solution is brushed on, and this continues until the strongest etch has coated the darkest areas.

After the allotted time has elapsed, the excess etch solu-

tion is blotted with newsprint paper. The surface is then wiped down and buffed with cheesecloth to a smooth, even layer. When properly handled, the stone should appear dry. It should be allowed to stand for two hours before washing out, the next step.

The wash out is done by pouring a small amount of turpentine or Lithotine over the drawn areas. Gently rubbing the drawn areas with a clean dry rag removes the drawing through the gum-etch coating. The image is preserved by the absorbed grease in the porous limestone.

Next, the stone is rubbed with liquid asphaltum or printing ink dissolved in turpentine. This procedure saturates the image and protects it at the same time.

After the stone is dry, it is ready to be inked (rolled up). First, it is dampened with a wet sponge. (In between the rollings, the stone should be redampened.) Ink rolling should be carried out according to a set pattern, gradually building up the image. To facilitate the even distribution of ink it is important to use a roller wider than the image.

The lithographic press prints with scraping pressure. The press itself consists of a metal frame that accommodates a travelling steel plate (the bed), which passes with the stone under a scraping bar (or yoke). The bed can be lowered (to position the stone) and raised (to print). The pressure on the scraping bar can be adjusted.

Lithographs can be printed on either dry or damp paper. The advantage of dampening is that it is possible to use less ink and less pressure, thus minimizing the risk of clogging the image.

To print, the printing paper is first placed on the stone, then a newsprint paper, then a blotter. Last comes the tympan, a sheet of smooth, tough material that can withstand great pressure without stretching. After the bed is raised to printing position, grease is spread evenly in front of the scraping bar on the tympan to allow it to slide easily. Then the print is made.

The prints of the French artist Henri de Toulouse-Lautrec demonstrate that lithography offers endless possibilities in colour printing. Because the effect of lithography is much more painterly than either woodcut or intaglio printing, it is natural that the strong preoccupation with pure colour in contemporary art has created a revival of interest in this medium. The planning and the principle of colour separation are similar to those for the colour woodcut or intaglio colour.

Stencil processes. In stencilling, one of the simplest methods of duplication, the design is cut out of paper (or any other suitable thin, strong material) and is then printed by rubbing, rolling, or spraying paint through the cutout areas.

The silk-screen process

Silk screen is a sophisticated stencil process, developed around 1900 and first used mainly for advertising and display work. About 1950, fine artists started to use the process extensively, giving it the name serigraphy.

The silk-screen process got its name from the fine mesh silk which, when tacked to a wooden frame, serves as a support for a cut paper stencil. The stencil is glued to the silk. In the basic process, the open mesh of the silk lets the paint through, while the paper stencil blocks it out. A design can also be blocked out on the screen with glue or other suitable substance.

By courtesy of the Kennedy Galleries, Inc., New York

"Pleiades," silk-screen print by Ben Shahn, 1960. 52 cm × 67.3 cm.

A common method of stencil preparation is to cut the stencil with a knife. In this method the artist can use commercially produced screen process printing plates or conventional stencil papers. For fine, accurate work, process plates, which consist of a film on a backing, are preferred. Areas to be printed are cut out of the film and peeled off, leaving the rest of the film on the backing paper. After the plate is attached to the screen, the backing paper is removed; thus, the screen is covered with film except in the printing areas. Process plates are available in different colours to make registering easier, and they are attached to the screen either by heat or by the use of a special solvent.

Another common method is the so-called tusche-and-glue method, which is similar to lift-ground aquatint etching. The design is painted on the screen with tusche and when dry the whole screen is covered with glue. When the glue dries, the design is washed out with either kerosene or turpentine. The tusche comes in liquid form for brushing or in solid crayon form. The use of the crayon results in screen prints deceptively resembling lithographic prints.

Stencil plates can also be made photographically. These plates are made by placing a photographic positive on a photosensitized gelatin stencil plate in a vacuum printing frame. Exposure to light hardens the gelatin under the transparent areas but leaves the gelatin soft under the dark areas. In warm water the soft areas wash out. The stencil is attached to the screen in the same manner as other stencils.

Silk-screen prints

To make a silk-screen print, the wooden frame holding the screen is hinged to a slightly larger wood board. The printing paper is placed on the board, under the screen. The consistency of the ink is important: it must be liquid enough to pass through the screen but not so liquid that it runs. The ink is pressed through the screen with the squeegee (a rubber blade set in a wooden handle, usually the same width as the screen). Any number of colours can be used, a separate screen for each colour.

SPECIAL TECHNIQUES

Monoprint (*monotype*). A monoprint is a unique print. The artist paints on various surfaces such as metal, plastic, and glass and then transfers the wet design to paper, either by rubbing or with an etching press. The primary reason for making a monoprint is that, in offsetting the image from the plate to the paper, the print achieves a separate quality and luminosity totally unlike a painting made directly on paper.

Cliché-verre. The method of printing known as *cliché-verre* was used by a few artists in the 19th century during the period when photography was a new and exciting invention. The *cliché-verre* follows the principle of photography but does not have its tonal variations. The print was made by covering a piece of clear glass with an opaque pigment or emulsion; the design was then scratched through with a sharp etching needle or stylus. When the drawing was finished, the glass plate (negative) was placed on a photosensitized paper, exposed to light, and developed. The result was a (positive) print with strong black and white contrasts.

The cellocut. The cellocut method was named by its originator, U.S. printmaker Boris Margo (1902–), one of the first to experiment extensively with plastics.

In this method, liquid plastic dissolved in acetone is poured onto a rigid support backing, such as fibre board or cardboard. The solidified plastic can be textured, raised into relief, and worked with various tools. It can be engraved, scratched, sanded, and filed. The resulting plastic plate can be printed either as a relief or as an intaglio plate, or even both. It can be printed alone or in combination with other techniques. Thin layers of plastics can easily be placed on top of intaglio plates and printed together.

Collagraphy. Like the metal graphic process, collagraphy is an additive method; the printing surface is built up. It is essentially an intaglio method, but it can be combined with relief printing. The printing surface is created by gluing various materials and textures to a support. Today, with the variety of new material available, the possibilities are limitless.

The support (plate) for collagraphy must be thin and strong. A porous material, such as cardboard, must be treated with a sealer. To build up a tough, durable printing surface, a strong adhesive such as polyvinyl acetate must be used.

Among the materials that can be used for tonal areas are sawdust, sand, carborundum, sandpaper, and ground walnut shells. For specific textures, materials such as tarlatan, laces, and crushed paper can be glued into the adhesive.

After the plate has been constructed, the surface is sealed. The sealer can be either brushed or sprayed on. Plastics are preferred because they are tough and are not dissolved by the solvents generally used to clean the plate.

The printing of collagraphs is essentially the same as for intaglio printing.

Making a plaster print

Plaster print. Good proofs of an intaglio plate can be made by plaster casting. Fine plaster of Paris will pick up the most delicate details and can be particularly attractive if the plate has deeply etched or engraved sections.

To make a plaster print, the plate is inked in the same manner as it would be for normal printing. The inked and wiped plate is placed face up on a glass plate, and a precut wood frame is placed around the plate to contain the plaster. After the plaster is poured, it is allowed to cool and set, after which the plate is gently removed.

PROCESS PRINTS

Process-printing methods are primarily used for commercial reproduction. Today, however, many artists use commercial methods to produce fine art. Silk-screen printing itself began as a commercial process, and today it is one of the most popular techniques in printmaking because its character is well suited for hardedge geometric images. Photomechanical processes are incorporated in the work of many contemporary printmakers.

Linecut. The linecut technique is the simplest and least expensive of all the photoreproductive processes. As it cannot register tone, it is used mostly to reproduce black-and-white line drawings. If tones are needed in a linecut, they are achieved with the use of screens consisting of dots (Ben Day screens). The linecut is similar to the woodcut in that both are used in relief printing.

Linecuts are usually made on zinc plates coated with an emulsion of albumin or gelatin mixed with potassium bichromate. This emulsion hardens on exposure to light. The light passing through the transparent part of the negative hardens the emulsion. The areas of the emulsion that are protected by the black on the negative remain in their soluble state.

The plate is then rolled with greasy ink and soaked in water. The unexposed soft emulsion is washed out by the water. The plate is then dried and dusted with powdered rosin, which adheres to the remaining inked emulsion areas. Heating causes the rosin to melt, forming an acid-resistant coating. The plate can then be etched so that the design stands up in high relief.

Halftone cut or plate. Halftone is more sophisticated than linecut, since it is capable of reproducing fine tonal variations. The subject is photographed first through a glass plate that has fine lines printed on it at right angles. The result is an image broken up into tiny dots corresponding to the openings in the screen. When printed, these dots create the optical illusion of continuous tones. There are great variations in screens from coarse (50 lines per inch) to very fine (175 lines per inch). The selection of the screen is dictated by the paper to be used for printing.

After the photonegative of the image is finished, it is printed on a sensitized copper plate. For halftone work, copper is used because of its ability to record fine details. The procedure of wash out and etch is similar to that used with linecuts.

Rotogravure. To make a gravure plate, a screen is used that is the reverse of the halftone screen, in that the lines are

By courtesy of the Brooklyn Museum, New York

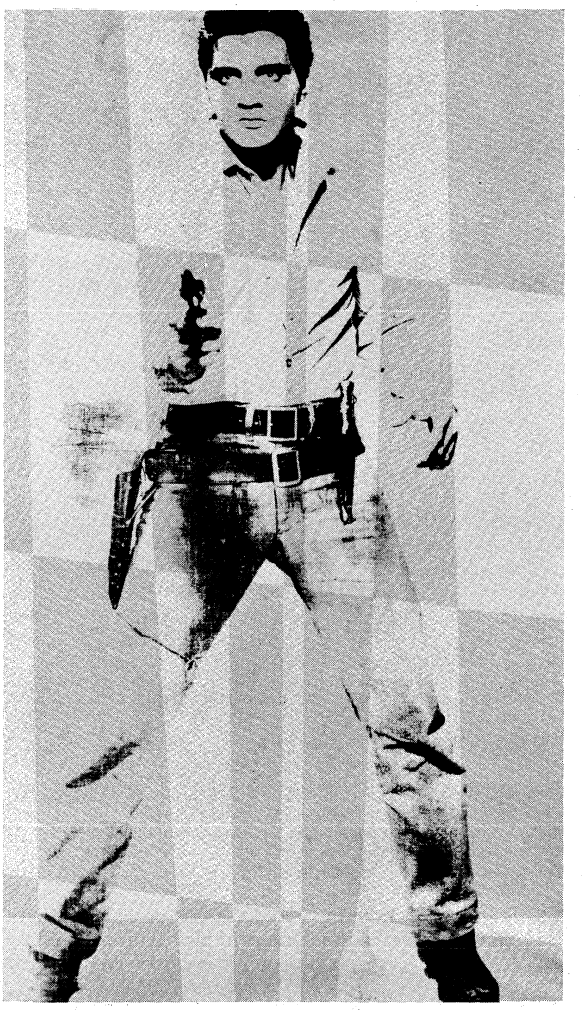
"The Alchemist, No. 2," cellocut by Boris Margo, *c.* 1947
85.3 cm × 58.3 cm.

Function of the gravure screen

opaque squares. When the sensitized plate is exposed to light through the screen, the emulsion on the plate hardens under the lines, but leaves the squares soft. Then the plate is exposed again through a diapositive (a positive transparency) of the subject. This time the soft emulsion squares harden in proportion to the range of grays. In etching, the softest squares are affected by the acid first and the hardest ones last. The result, after the etch, is a plate covered with squares of equal size but varying depth. As the deep squares hold more ink than the shallow ones, the tones in the reproduction are controlled in the same manner as in all intaglio printing methods. The rotogravure plate is inked by an ink-carrying cylinder and wiped by a steel blade that removes all the excess ink from its surface.

Although rotogravure is an intaglio printing process it is printed on dry paper with light pressure and thin ink. Hence, there is hardly any embossing.

Offset lithography. Offset lithography is the application of lithography to commercial mass production. The plate, instead of being a stone, is of specially treated zinc or aluminum, suitable for mounting on a cylinder. The image is photographed on the sensitized lithoplate through a screen. The offset method involves double printing. The image from the plate is printed on another roller covered with a rubber blanket, and from this roller it is transferred to the paper. Because the image is reversed twice, the final print corresponds to the original plate. Since the litho offset ink is thin, to speed up inking and facilitate transfer, the tonal areas lose some of their richness and tend to print gray. Litho offset is often used for colour printing. The colour separation is made photographically.



CONTEMPORARY EXPERIMENTATION

One of the most crucial changes in the 20th century involved the size of the print. All through its history, with few exceptions, the print was considered an intimate art form, enjoyed by the few. The change started with the Lautrec posters: the print started to grow until it became mural size. As the dimensions of the print changed, so did its character. It became increasingly bolder and more colourful. Today, the print often competes with painting, a situation deplored by many people who feel that in the process the print is losing its particular character and beauty. A result is that major print shows tend to exhibit a limited number of small, delicate prints.

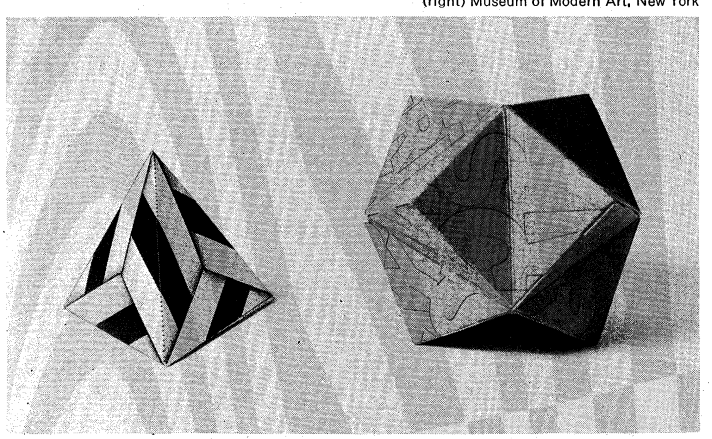
Next to the size of the print, the greatest change has been in the technology of colour printing. In this area, techniques have become so varied that practically any effect is possible. This development has contributed to the vitality of printmaking, because it has encouraged the participation of colour-oriented artists. The combining of

Combining media

various media is closely related to the experimentation in colour printing. Each medium has its own capabilities and limitations; combined, the media often complement each other. It is now common to see three or four different techniques combined.

Use of photography shown in "Elvis Presley," silk-screen print on canvas by Andy Warhol, 1964. 2.08 m × 1.2 m.
By courtesy of the Leo Castelli Gallery, New York

Another area of experimentation is in three-dimensional surfaces. The trend started with embossing, and today artists are creating completely three-dimensional printed objects.



The shaped print is a printed paper sculpture, made by cutting and folding the printed paper, or by assembling precut printed surfaces. Many of these surfaces are metal or plastic objects with printing, usually done by the silkscreen process.

Instead of using rectangular painting surfaces, many painters now work on shaped canvasses. In the same way, printmakers, instead of using rectangular plates, are using many different shapes. Printing with movable plates, which became particularly popular in intaglio colour printing and with colour woodcuts, was the logical extension of this freedom. In this method cut out small plates are placed on top of larger plates and printed together, or they can be assembled on a cardboard support and printed. This procedure facilitates the use of many colours and also offers great freedom in composing.

Photography is profoundly affecting printmaking. Photographic methods can be combined with intaglio, lithography, or silk screen to enrich their vocabulary. The possibilities are nearly limitless. Yet photography can be corrupting when it reintroduces reproductive ideas, and, unfortunately, it is often used for this effect.

Kinetic (moving) art, such as the mobile, is a major contemporary preoccupation in painting and sculpture. At the present there are few attempts in this direction in printmaking, but there will probably be more. The prob-

lem in such works is how to combine the print with motion without destroying its very nature.

MOUNTING AND CARE OF PRINTS

Very few people know how to display prints and how to take care of them properly. It is heartbreaking to see a great master's print glued to a cheap cardboard or the border of a fine print ruined with tape.

Because paper, particularly old paper, is fragile, it should be handled as little as possible and never picked up with one hand since this might put too much stress on the paper and tear it. To protect it, a print should be mounted as soon as possible.

The surface of the print, especially an intaglio print, is delicate, and rubbing might permanently injure it. Prints should not be stacked without protective layers of tissue paper between them. Wood-pulp papers should not be used, as the acid content in these might burn the print. A print should not be exposed to intense sunlight; this is true particularly of colour prints, for very few colours are stable enough to withstand long exposure to direct sun. Light can also affect the paper. Because wood-pulp board contains chemicals that in time could burn or discolour the paper, a permanent mat should be constructed out of pure rag board. A properly constructed mat consists of two parts: the backing board to support the print and the covering frame to display it. The width of the mat frame should be related to the print's dimensions so that the mat does not overpower the image. The window size of the mat should never obscure the printed image itself, or the signature and edition number.

Temperature changes in a damp climate might cause condensation and the print could develop fungi, so prints should be kept from direct contact with the glass. The simplest protection is a deep enough pure rag mat. If this is not sufficient, a filler should be inserted into the frame to increase the space between the mat and the glass.

The backboard of the frame should be also rag board, or at least faced with rag paper, although the latter is not the perfect solution. The back of the frame should be sealed with tape to prevent the penetrating of dust. In damp climates it is advisable to keep the frame away from the wall by placing corks on its four corners. This facilitates the free circulation of air. Air conditioning and humidity controls are the best protection.

II. History of printmaking

Engraving is one of the oldest art forms of man. Engraved designs have been found on prehistoric bones, stones, and cave walls. The technique of duplicating images goes back several thousand years to the Sumerians (*c.* 3000 BC), who engraved designs and cuneiform inscriptions on cylinder seals (usually made of stone), which, when rolled over soft clay tablets, left relief impressions. They not only conceived the idea of multiplication but also the mechanical principle, the roller, which in more sophisticated form became the printing press.

On the basis of stone designs and seals found in China, there is speculation that the Chinese may have produced a primitive form of print—the rubbing—about the 2nd century AD. The first authenticated prints rubbed from wood blocks were Buddhist charms printed in Japan and distributed between AD 764–770. It is believed that the first wood-block prints on textiles were made by the Egyptians in the 6th or 7th century; but the earliest printed image with an authenticated date is a scroll of the *Diamond Sūtra* (one of the discourses of the Buddha) printed by Wang Chieh in AD 868, which was found in a cave in eastern Turkestan.

In Europe, stamping (to imprint royal seals and signatures) preceded printing by rubbing or with a press. The earliest documented impressed royal signature is that of Henry VI of England, dated 1436.

Textile printing, however, was known in Europe in the 6th century, the designs consisting largely of repeated decorative patterns. Printing on paper developed from textile printing, following the introduction of paper from the Orient. The first European paper was made in 1151, at Xativa (modern Játiva), Spain. Soon afterward paper manufacturing began in France and then in Germany and Italy, notably by Fabriano, whose enterprise was established in 1276.

The first woodcuts on paper, printed in quantity, were playing cards. The term *Kartenmahler* or *Kartenmacher* ("painter or maker of playing cards," respectively) appears on a German document dated 1402; and documents from both Italy and France from the middle of the 15th century mention wood blocks for the printing of playing cards. The earliest dated woodcut is a "Madonna with Four Virgin Saints in a Garden" from the year 1418. Woodcuts of playing cards

Many documents from the 15th century indicate that a clear distinction was made between the designer and the cutter of the wood blocks. From the outset, woodcut was primarily a facsimile process: the cutter copied a drawing provided by the designer.

Printing from a metal engraving, introduced a few decades after the woodcut, had an independent development. The art of engraving and etching originated with goldsmiths and armour makers—men who were thoroughly professional craftsmen, practicing an art that had a long, respected tradition. Since the armour makers and goldsmiths were designers themselves, the whole process was controlled by the creative artist.

PRINTMAKING IN THE 15TH CENTURY

Germany. Single prints (in contrast to those printed in a series or as part of an illustrated book) of the early 15th century were not signed or dated, and, because they were religious images carried by pilgrims from one place to another, it is nearly impossible to establish with certainty their place of origin. Their style alone must be relied upon for some indication of origin.

The first phase of woodcut, from about 1402 until about 1425, was dominated by boldly designed single figures against a blank background. Most of the cuts were made to be hand coloured. In the second half of the 15th century the cuts became more complex: architectural and landscape elements came into use, and often the image was framed in an elaborate border.

The first metal prints (criblé, or dotted, print) were made in the second half of the 15th century. The design was created by tiny dots punched into the metal and intermingled with short cuts. Surface printed, the whites are the positive part of the design, which is dominated by the dark background. Tiny holes in the borders indicate that most of these plates were intended as decorations to be mounted rather than as printing plates.

The earliest dated intaglio-printed engraving is from 1446: "The Flagellation," of a Passion series. Around this time, the first distinct personality to have great influence on German engraving appeared. He is known as the Master of the Playing Cards. His style was simple, nearly monumental; unlike the printwork of goldsmiths, his engravings lack ornamentation. For shading he used slightly diagonal parallel cuts. The Master of the Playing Cards heralds the beginning of a century of great printmakers in Germany. Another significant engraver, the Master of the Banderoles, was named after the ribbon scrolls characteristic of his prints, which are more decorative than those of the Master of the Playing Cards.

In the second half of the 15th century, the outstanding printmaker was Master E.S., who flourished about 1440–67 and was one of the first to use initials as a signature on his plates. Little is known about him, but the personality that emerges from approximately 317 plates is forceful and distinct. Although it is evident from his prints that, like most early engravers, he was first trained as a goldsmith, his work has strong pictorial quality. Engravings of Master E.S.

Martin Schongauer was the first great engraver who is known to have been a painter rather than a goldsmith. Although Schongauer's style was still Gothic in character, he composed with much greater freedom than his contemporaries, thus representing a transition into the Renaissance. He made about 115 plates, mostly of religious subjects, and was a powerful influence on the young Albrecht Dürer (see below *Printmaking in the 16th century*). During the second half of the 15th century, a group of brilliant engravers known only by their initials

"Blumen-Dame" ("Cyclamen Queen"), engraving by the Master of the Playing Cards, *c.* 1440. 13.9 cm × 9.2 cm.
Deutsche Fotothek Dresden

emerged in Germany. They are the Masters B.G., B.M., L.G.S., A.G., B.R., and W.H. The controversial figure of Israhel van Meckenem appeared at the end of the 15th century. A superb and extremely prolific engraver, he was a rather eclectic artist, borrowing from other masters and often copying them.

Italy. In the 15th century, Italian printmaking was dominated by the northern cities: Florence, Venice, and Milan. Throughout the century, printmaking was mainly concerned with playing cards and book illustrations, with a few single prints appearing in the second half of the century. While in Germany and the Netherlands the art was completely dominated by devotional, religious subject matter, Italian printmaking covered a relatively broad range. The awakening Renaissance attitude made the artists much more receptive to purely aesthetic, decorative, sensuous experience. In addition to religious subject matter, Italian prints included mythology, pure ornamentation, and some of the finest early portrait engravings.

Giorgio Vasari, the chronicler of the Renaissance, credited the Florentine goldsmith Maso Finiguerra with the invention of printed engraving, but present knowledge indicates that, at the same period in Germany and the Netherlands, printmaking was in a more advanced stage. In spite of the fact that book printing was originally introduced from the northern countries into Italy, engraving remained a national, regional development, free of strong foreign influence until the beginning of the 16th century.

Broad manner and fine manner engraving

Two methods of engraving were practiced in Italy, the broad manner and the fine manner. The fine manner, associated with the Finiguerra school, is characterized by closely cut and extremely fine lines combined with crosshatching intermingled at times with dots. The broad manner is less dense, and forms are modelled using diagonally cut parallel lines, interlaid at times with short cuts or dots. In shading, the spacing between the lines is wider than in the fine manner and there is no crosshatching.

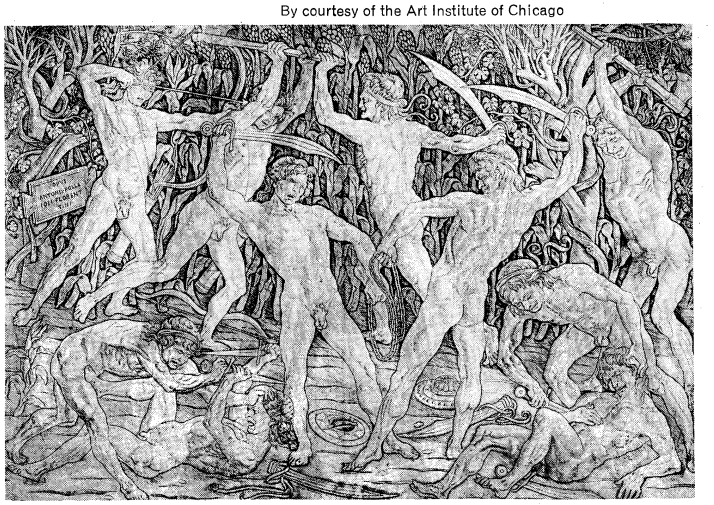
Finiguerra himself was not an important artist. His significance lies in his influence on Antonio Pollaiuolo, a Florentine painter, sculptor, and architect whose reputation as one of the most distinguished engravers of the 15th century is based on his one authenticated print, "The Battle of the Nudes" (*c.* 1465)—a powerful image, beautifully engraved in the broad manner.

While Pollaiuolo worked in Florence, Andrea Mantegna, a great painter and certainly the most eminent Italian printmaker, lived and worked in Mantua. Mantegna produced approximately 20 plates (only seven of which are completely authenticated), all line engravings in the broad manner. A superb draftsman and a virtuoso engraver, Mantegna could achieve, in spite of the limitations of his method, an incredible range of colour in his prints, a quality lacking in the work of most of his followers.

In addition to the masters, talented engravers included Cristofano Robetta, a Florentine who made some rich, intricate engravings in the fine manner; and the Venetian Jacopo de' Barbari, who travelled in Germany and whose refined engravings show the influence of Albrecht Dürer.

Other countries. *The Netherlands and Burgundy.* The first half of the 15th century in the Netherlands and Burgundy was dominated by woodcut book illustrations. Although no single prints of great importance were produced, beautiful books were published. Antwerp and Delft were the main printing centres.

Parallel with, if not even a little earlier than, the emergence of distinguished printmakers in mid-15th-century Germany, a group of great engravers emerged in the Netherlands and neighbouring Burgundy. Superb artists, they are identified only by the subject of their most characteristic work: the Master of the Death of Mary, Master of the Gardens of Love, and Master of the Mount of Calvary.



Toward the end of the century, the Netherlands produced a brilliant artist—rivalling Master E.S.—known as the Master of the Amsterdam Cabinet or Master of the Hausbuch, who worked between 1450 and 1470. He is known by this name because the finest collection of his extremely rare prints is in the Print Cabinet of the Rijksmuseum. His prints are painterly and almost expressionist in power. His role in the technical development of printmaking is also significant, as he was the first major artist to make drypoints.

Dominance of book illustrations in France

France. In France, book illustrations dominated printmaking throughout the century. Paris, the cultural centre, led in book publishing, although other prosperous cities, such as Lyon, produced many illustrated books. The publications printed by Dupré and Pierre Le Rouge are the glories of French medieval graphic art.

Strangely enough, there was little engraving of importance. Most of the French engravings of this period were either rather crude, provincial illustrations or playing cards.

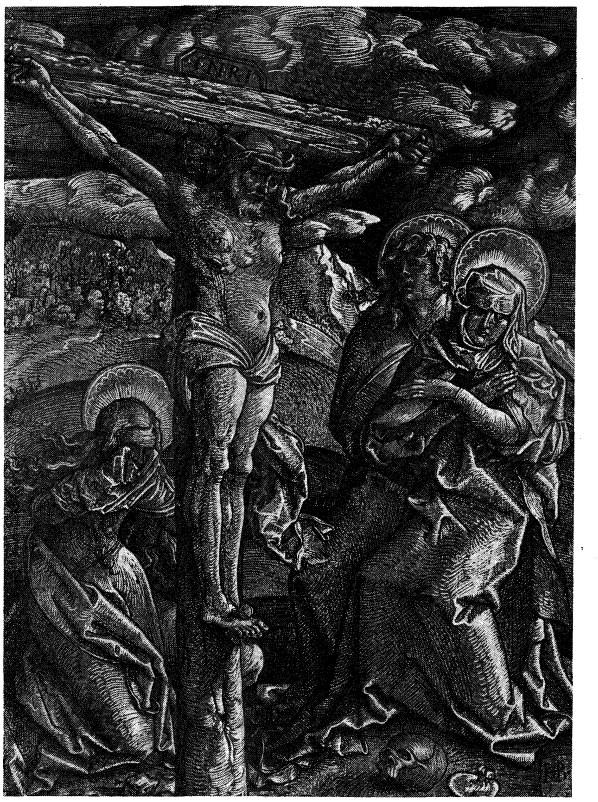
"The Battle of the Nudes," engraving by Antonio Pollaiuolo (*c.* 1431/32–98). About 40 cm × 61 cm.

PRINTMAKING IN THE 16TH CENTURY

Germany. Albrecht Dürer was the master of 16th-century German graphic arts. One of the towering figures in the history of printmaking, he was a complex, truly Renaissance man, interested in philosophy and science as well as art. He was one of the first to break the provincial isolation of Germany by travelling to Italy, where he learned from the Italians and in turn influenced them.

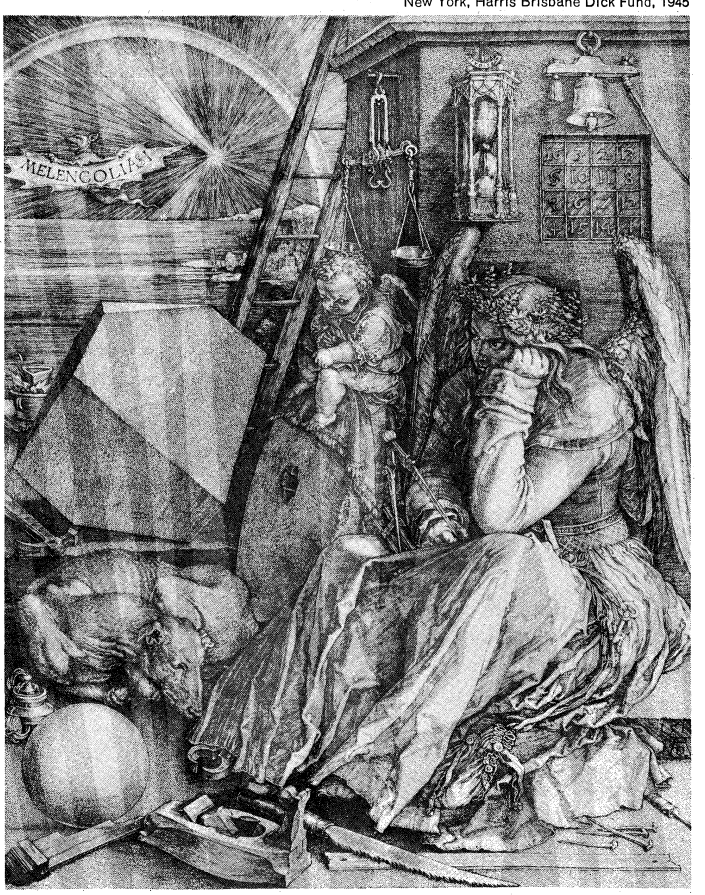
Dürer's subject matter mirrors his thoroughly European intellectual orientation. His prints deal with religion, history, mythology, and folklore. He is also one of the first great portrait engravers.



Dürer was one of the supreme draftsmen of all time and an artist of enormous imagination and sensibility. As a technician he raised the art of engraving to a height it never reached again. As an experimenter, he produced, in addition to his engravings and woodcuts, etchings and drypoints. His best works are metal engravings, which he cut himself. His woodcuts are perfect reproductions of his superb drawings.

Hans Baldung-Grien, another great German printmaker and one of the most original artists of his time, worked with Dürer. In his images of witchcraft and magic, Baldung expressed the medieval mysticism that lingered in the German Renaissance. Besides his black and white work, he produced fine chiaroscuro woodcuts in which light and shadow are produced by using different wood blocks for different tones of the same colour.

Lucas Cranach the Elder was a typical representative of the German Renaissance—much less affected by the Italian Renaissance influence than Dürer. He had a vivid imagination and an earthy imagery that was full of vitality. He made many woodcuts and relatively few metal engravings.



Landscape etchings of Altdorfer

Albrecht Altdorfer was one of the first great landscape artists and one of the first to make landscape etching and woodcuts for their own sake, rather than as backgrounds for figures. Under his influence, two other artists made fine landscape prints: Augustin Hirschvogel and Hans Sebald Lautensack. The spontaneity and directness of their work foreshadows the lyrical landscapes of the 18th century.

"The Crucifixion," chiaroscuro woodcut by Hans Baldung-Grien (1484–1545). 36.8 cm × 25.8 cm.

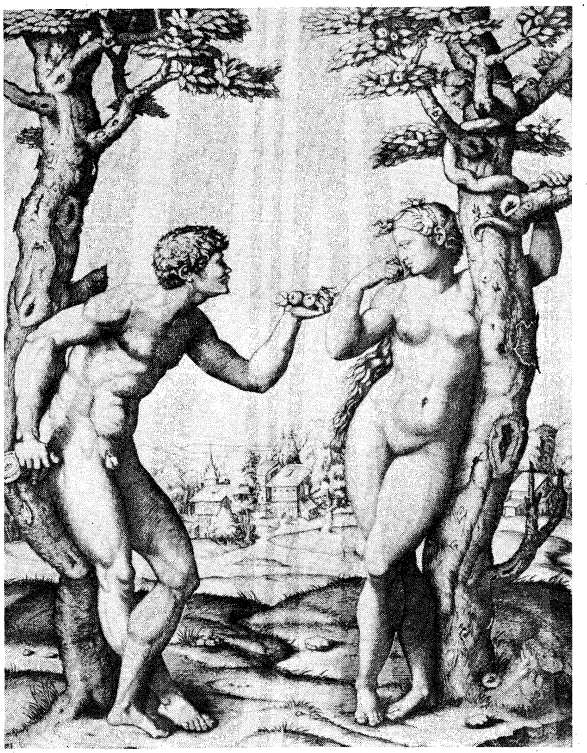
"Melencolia I," engraving by Albrecht Dürer (1471–1528). 24.1 cm × 20 cm.

The 16th century also included the artists referred to as Little Masters, so called because of the size of their prints, not their stature as artists. They were Barthel Beham, Hans Beham, Georg Pencz, and Heinrich Aldegrever.



Other countries. *The Netherlands and Flanders.* The outstanding Dutch printmaker of the period was Lucas van Leyden (1489/94–1533). If the latter birth date is correct, at the age of 14 he was already an accomplished engraver. In maturity, he was a superb engraver, in many respects rivalling Dürer. Besides his metal engravings, which are characterized by a very delicate touch, van Leyden designed many wood blocks and also made a few etchings.

A virtuoso of the burin, the Flemish engraver Hendrik Goltzius (1558–1617) developed an incredible variety of cuts and textures to imitate the surface qualities of materials. Other printmakers of the period include Allaert Claesz and Cornelis Matsys.

Italy. After the death of Mantegna in 1506, Italian printmaking of the 16th century was dominated by lesser figures. During the 16th century the few etchings produced in Italy have only historical interest.

The most influential engraver of the century was Marcantonio Raimondi. Under the influence of Dürer, Raimondi became a virtuoso engraver; technically Dürer's equal, he lacked his master's originality. Raimondi eventually became the engraver of Raphael, organizing a workshop dedicated primarily to making reproductions of his work. Thus, Raimondi won the dubious honour of being the first of the many printmakers who ultimately were influential in turning the art of engraving into mere reproduction. He was followed by a whole generation of competent engravers devoted solely to reproduction.

One of the exceptions was Giorgio Ghisi of Mantua, who in his isolated regional development escaped the corrupting influence of Rome. His 1550 visit to Antwerp made Ghisi an important link between Italian and northern engraving.

"Adam and Eve," engraving by Marcantonio Raimondi (*c.* 1480–*c.* 1534). 23.8 cm × 17.6 cm.

Engravings of Duvet

France. The only major figure in 16th-century French engraving is Jean Duvet, whose predilection for excessive ornamentation indicates that he was trained as a goldsmith. Although Duvet's style was influenced by Mantegna, his imagery was completely original. His greatest work, "The Apocalypse," reveals a feverish, mystical imagination.

Apart from the work of Duvet, ornamental engraving was the most significant achievement of 16th-century French printmaking. Although these elegant engravings cannot be ranked with the work of the great masters, they represent a genuine expression of the French spirit. The outstanding figure of this school was Étienne Delaune. Although his motifs were influenced by those employed by Raphael for his fresco wall paintings in the Vatican, Delaune nonetheless achieved a personal style.

Trends in the late 16th century. By the second half of the 16th century, the quality of printmaking, particularly engraving, had gone into a severe decline. Masters like Dürer and Mantegna were replaced by skilled craftsmen. The trend toward reproduction that had begun with Raimondi gained ground, sapping the vitality of engraving. Yet at the same time, the quantity of production increased. Except for the modern era, this was probably the most prolific period of printmaking. Since it was the beginning of the age of travel, discovery, and religious upheaval, the demand for maps, religious pictures, illustrations, and portraits was enormous.

One after the other, print publishing houses opened all over Europe. Dutch and Flemish families dominated the new profession: in the Netherlands, the firms Cock, Galle, and Passe; in Augsburg, Dominicus Custos; in Antwerp, Brussels, Prague, and Venice, the Sadeler family. In Italy, Antonio Salamanca cornered the market and flooded it with bad reprints of Raimondi engravings.

The publishers of this period usually bought the original plates outright from the artist and issued prints on demand in unlimited quantities. If the plates wore out, they were reworked in the publishers' own workshops, a practice that was responsible for the destruction of many fine artworks. In many cases, it is no longer possible to identify the creator of the original plate.

Map engravers

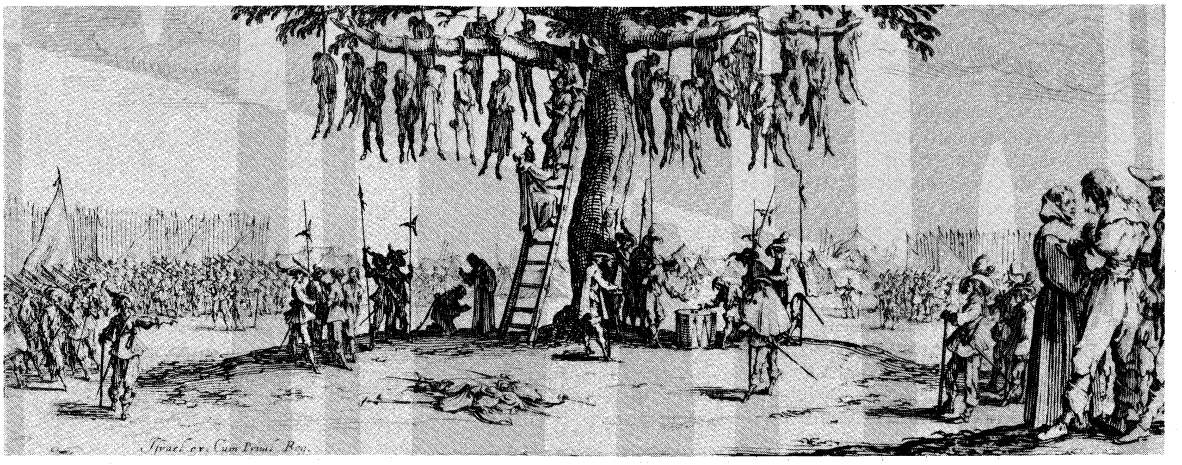
In this period, map engravers were particularly important: the maps of Abraham Ortelius were engraved by Franz Hogenberg; Gerardus Mercator engraved his own map designs; and Jodocus Hondius bought the Mercator plates after their use in the edition of 1596 and introduced them in England, along with some of his own work.

PRINTMAKING IN THE 17TH CENTURY

Portrait engraving. *France.* The end of the 16th century and the beginning of the 17th were dominated by ornamental engravers and illustrators, working under Flemish influence; by the middle of the 17th century, however, a distinctly French school of portrait engraving had emerged. Although this school did not produce a major master, it represents a significant phase of European printmaking.

Michael Lesne, a French portraitist whose influence was considerable, worked for a time in the Rubens workshop, later returning to France. Claude Mellan, another major influence, was trained in Rome. Technical virtuosity dominated his prints; for example, the modelling of a face with one continuous spiral.

A superb engraver and a fine draftsman, Robert Nanteuil is considered the undisputed master of French portrait engraving. His style is simple, elegant, and free of the mannerism characteristic of his contemporaries. He and his two rivals—Gerard Edelinck, who was born in Antwerp but studied and developed his style in France, and Antoine Masson, who engraved portraits in the grand style—represented the dominant forces in 17th-century French portrait engraving.



Germany. After the glories of the 15th and 16th centuries, German graphic genius was dormant for nearly three centuries. Historically, Ludwig von Siegen, a minor painter and medalist, is important for his invention of the mezzotint printing method. But the perfecting of this tonal technique increased the reproductive facility of printmaking, thus contributing to the decline of artistic creativity.

Like France, Germany produced a school of portrait engravers; but, although competent technicians, they failed to develop a distinctly national school comparable to the French. Of this group, two are significant: Jeremias Falck, a student of Hondius, and Bartholomäus Kilian, who studied in Paris and later introduced French influence into German printmaking.

The Netherlands. Portrait engraving in Holland was on a higher level than in Germany. Cornelis van Dalen was a fine engraver who emigrated to England and died there. More gifted than his father, Cornelis van Dalen II was an artist of considerable stature, who engraved some of the most powerful portraits of his time.

Abraham Blooteling, a pupil of van Dalen II, was also a fine portrait engraver. His major contribution, however, was in the development of the new technique of mezzotint—specifically, the invention of the rocker, the tool used in the technique. He also introduced the mezzotint into England, where it was adopted with such success that it later became known as the "English Manner."

The development of mezzotint

England. In the 17th century, English printmaking produced a portrait engraver of considerable stature, William Faithorne. He studied in France and initially was under the influence of Mellan and Nanteuil; in his late work, however, he developed a style independent of theirs. Faithorne was England's only major native printmaker during this period, when most prints were reproductive engravings. By the end of the century, engraving was in total decline, replaced by the fashionable mezzotint.

Flemish printmaking. One of the dominant figures of European art was Peter Paul Rubens, a painter, diplomat, and businessman. Quickly recognizing the commercial potential of printmaking, he organized a graphic workshop where, under his supervision, reproductions of his work were produced. Only one etching, "St. Catherine," is considered as his own. The quality of this one print indicates how great was the loss to the art of printmaking that this great draftsman did not make more original etchings.

Rubens' pupil Anthony Van Dyck was one of the most distinguished portrait painters of his time. At age 27 he undertook a very ambitious project: the etched portraits of the 100 most famous men of his day. For this set of prints, known as the "Iconography," he completed 18 portraits. But only five of these ("Peter Breughel the Younger," "Snellinx," "Erasmus," "Suttermans," and "Josse de Momper") remained unchanged; another five were retouched by professional engravers, and the rest were completely reworked by them.

Etching. Like the Van Dyck portraits, nearly all of the outstanding prints produced in the 17th century were etchings. Etching emerged as the dominant technique for many reasons. The fact that engraving had become a completely commercialized, reproductive method and that mezzotint had never been anything else alienated many artists. As an unexploited and relatively unexplored medium, etching intrigued the experimentally oriented. Furthermore, the fluid, flexible technique of etching was a lure for the creative painter, whose own medium had become freer and more spontaneous.

Italy. At the beginning of the 17th century, there was more etching in Italy than in any other European country. Strangely enough, probably the three most important etchers—Jacques Callot, Claude Lorrain, and José de Ribera—were foreign-born.

The Bolognese school was formed around Guido Reni, whose delicate etching style of light lines and dots became a standard technique for most Italian etchers of his time. His school, however, produced no superior printmakers.

The Spanish painter José de Ribera was the dominant figure of the Neapolitan school. Though he was the first major realist painter in Italy and a strong influence against the idealizing trend, both his paintings and his etchings were outside the mainstream of Italian art.

Next to Ribera, Salvator Rosa, an Italian, was the most notable artist of the Neapolitan school, producing a large number of etchings that are full of charm but of no great importance.

Born in Nancy, France, Jacques Callot ran away from home as a boy to study art in Italy. Of all the artists engaged in 17th-century Italian printmaking, he was historically the most significant; for he was one of the first to use repeated bitings on his plates to achieve tonal variations. His drawing style represented a transition between engraving and etching: using a specially shaped etching needle of his own invention, he imitated the swelling and tapering characteristics of the engraved line. His illustrations record and ironically comment upon the customs, historical events, and morals of his time. Callot's work was often decorative and manneristic; but, at his best, as in the series "The Miseries and Disasters of War" (1633), he transcended mere illustration and achieved powerful images of universal significance.

Callot's etching technique

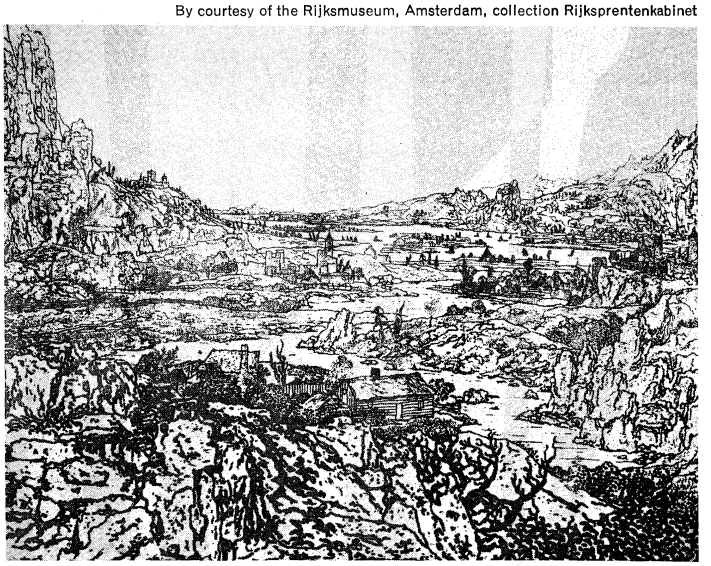
Claude Lorrain, also French-born, was one of the finest landscape painters in Italy, and he had an intuitive understanding of the etching medium. His spontaneous interpretation of the atmospheric quality of his subject foreshadows the Barbizon school and Impressionism in the 19th century.

The Netherlands. In the beginning of the 17th century, Holland suddenly exploded into a frenzy of creativity in etching. The sensitive, atmospheric etchings of the brothers Esaias and Jan van de Velde can be considered the beginning of the Dutch landscape school. Others were Adriaen van Stalbent, Pieter de Molijn, and Willem Buytewech—all fine printmakers, but all eventually overshadowed by the dramatic personality of Rembrandt. Before him, however, another artist appeared who was so original that no historical precedent could anticipate him. Hercules Seghers is one of the most interesting and mysterious figures in the history of printmaking. He was a lonely, tragic man, an experimenter who was so far ahead of his time that it took centuries for the real significance of his work to become apparent. It is known that Rembrandt appreciated his work. He owned some of Seghers' prints and even reworked one of his plates, "Tobias and the Angel" (*c.* 1633); keeping the landscape, he changed the figures, making it "The Flight into Egypt" (1653).

Seghers was the first real experimenter in intaglio colour printing. His methods were completely unorthodox: he printed on tinted canvas, tried light lines on a dark background, and also mixed printing with hand colouring. Seghers' etching technique was itself very unorthodox. His eroded lines, so well suited to his subject matter, are unlike any etched line made before him, which has led some experts to the conclusion that Seghers invented the lift ground, an aquatint technique.

Most of Seghers' etchings represent craggy, arid landscapes. Everything he drew—landscapes, still lifes, even figures—seem to be made of stone. It is a world suspended in the timelessness of death.

The graphic distinction of Rembrandt



Even among the supreme artists of the world, Rembrandt van Rijn occupies a very special place. One of the most eminent painters of all time, he also left a graphic oeuvre of heroic proportions both in quantity and quality. A great innovator, he was the first artist to fully explore the possibilities of the etched line.

Rembrandt made approximately 300 plates. His subject matter represents practically every aspect of human existence: he rendered religious and historical subjects; he explored themes of love and death; and he created profound portraits and sensitive landscapes. Everything that was part of life concerned him, from the highest ideals to the most mundane bodily functions.

While Rembrandt's early prints are pure etchings, his later works frequently combine etching and drypoint. Since he often reworked his plates between printings, there are sometimes enormous variations between proofs. Rembrandt's immediate influence on his students and followers was not very productive, for his personality was so overpowering that those close to him fell under his spell and simply imitated his style. Artists like J.G. van Vliet, who copied and reworked many of the master's plates, and Jan Lievens were mere shadows of Rembrandt. Of the group closely associated with Rembrandt, probably Ferdinand Bol was the strongest, but even he is dwarfed by the inevitable comparison.

Also active during Rembrandt's time and somewhat overshadowed by him was Adriaen van Ostade, one of the most gifted of Dutch genre painters. The subjects of both his paintings and prints were taken mainly from the daily lives of simple people, usually peasants. In spirit, his work represented an important departure from the heroic orientation of historic and religious painting, reflecting a crucial social change—the emergence of a middle class in Europe. For the first time, common people replaced the clergy and the nobility as a source of inspiration for an artist. Van Ostade's etching technique was influenced by the early Rembrandt, but his drawing style was personal. It was simple, undramatic, and direct—well suited to his intimate subject matter.

'The Rocky River Landscape," 17th-century etching by Hercules Seghers. 17.6 cm × 21.7 cm.

"Tamatori" ("Getting the Pebble"), colour woodcut by Hishikawa Moronobu, 17th century. 30.5 cm × 40 cm;
By courtesy of the Sakai Collection, Tokyo

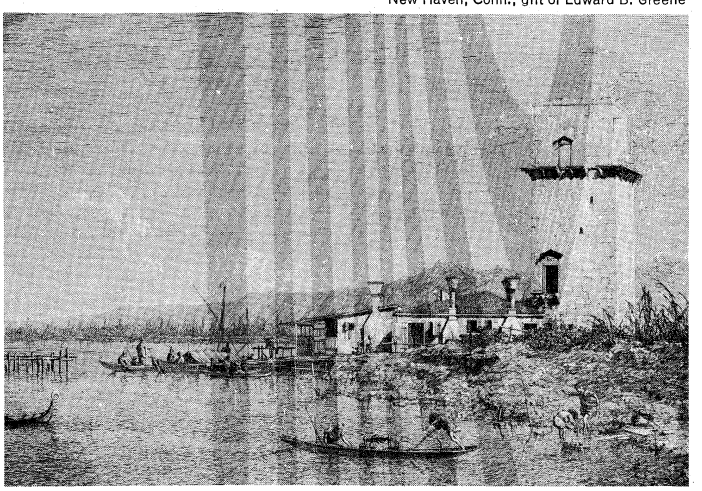
Throughout the 17th century, landscape painting and etching thrived in Holland. Jan van Goyen and Roelant Roghman both made fine landscape paintings and etchings. In this group the most interesting figure is Jacob van Ruisdael, whose sensitive, luminous landscape etchings foreshadowed the Barbizon school.

Toward the end of the century, a strong Italian influence invaded Holland. Since the earthiness of the Dutch temperament did not mix well with the Italian tendency toward idealization, the result was an eclecticism that drained Dutch art of much of its vitality.

Japanese Ukiyo-e prints. Until the 17th century, Japanese painting was completely dominated by Chinese influence. The Japanese silk paintings and screens of idealized landscapes were hardly distinguishable from their Chinese counterparts. Then, in the early 17th century, an artist of aristocratic origin, Iwasa Matabei, started to paint images related to his environment and personal experience. Although this era of Japanese art history is rather obscure, he is credited with being one of the founders (along with Iwasa Matabei II and Iwasa Matabei of Otsu) of Ukiyo-e, whose woodcuts of the transient world or the world of everyday life represented a drastic break with the classical tradition. Of the three artists Matabei of Otsu was the most original and had the strongest influence on the development of Japanese printmaking. By standards of Western taste, the images the Ukiyo-e school produced are highly stylized and thoroughly refined. Cultured Japanese, however, found them shockingly vulgar. The very fact that ordinary landscapes and the daily life of common people, actors, and courtesans were the inspiration for the Ukiyo-e artist represented a startling departure from tradition. Just as the emerging middle class revolutionized taste in Europe, the prosperous city dwellers of Edo, Kyōto, and Ōsaka developed their own aesthetic subculture. The development of the popular Kabuki theatre, as distinct from the aristocratic Nō drama, parallels the blossoming of Japanese printmaking.

Foundation of the Ukiyo-e school

The first great master of Japanese printmaking was Hishikawa Moronobu. A creative innovator, he was the first to use street scenes, peddlers, and crowds as his subject matter and to make his prints available to the common people. As a result, he was looked upon by many as the inventor of printmaking. He illustrated more than 100 books, mirroring the culture and customs of his time. Moronobu's style was a perfect harmony of rhythm, delicacy, and monumental simplicity, leading the way toward the great flowering of Japanese printmaking in the 18th century.



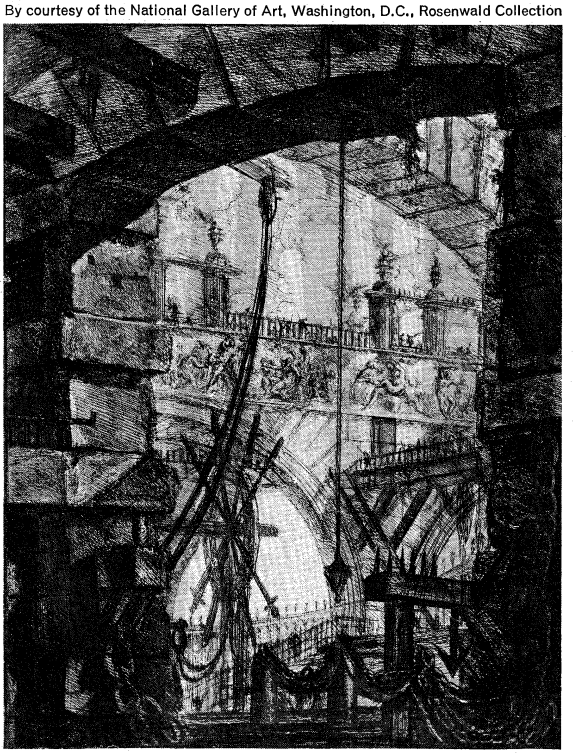
PRINTMAKING IN THE 18TH CENTURY

Italy. In the 18th century, Italy was the most fertile soil in Europe for printmaking. The first outstanding printmaker of the century was the Rococo master Gio-

vanni Battista Tiepolo. His lightly bitten, spontaneous plates reveal superb draftsmanship. With rhythmic, delicate textures, he created a living, luminous space. His 50 plates represent a major contribution to the development of etching—a contribution further enhanced by his influence on Goya (see below *Spain*). Giovanni Domenico Tiepolo, the son of Battista, made more prints than his father but remained under his influence all his life.

One of the most original printmakers of the period, Canaletto (Giovanni Antonio Canal) created lyrical etchings charged with the misty atmosphere of Venice.

By courtesy of the Yale University Art Gallery, New Haven, Conn., gift of Edward B. Greene



"La Torre di Malghera," etching by Giovanni Antonio Canal (called Canaletto) (1697–1768). 29.8 cm × 43 cm.

Inexhaustible in linear and textural invention, they are perfect examples of the simulation of colour and light by purely graphic means. His nephew and pupil, Bernardo Bellotto (Canaletto), who assumed his name, was a prolific printmaker but remained under his uncle's influence.

Giambattista Piranesi was the greatest architectural printmaker of his time and probably of all time. Trained as an architect, he was passionately interested in Roman antiquities. Of the approximately 3,000 large etchings completed by Piranesi, all are brilliant, and many rise above documentation. His most important work is the *Carceri d'invenzione* (imaginary prison scenes). The plates, which were made in his youth (published *c.* 1750), are personal, rich, and evocative, far surpassing anything he created after them.

By courtesy of the National Gallery of Art, Washington, D.C., Rosenwald Collection

Carceri d'invenzione ("Prisons"), plate 4, etching by Giambattista Piranesi, 1750(?). 55 cm × 41 cm.

England. Until the 18th century, English printmaking was dominated by foreign influences. William Hogarth, the first major English printmaker, created not only a personal style but a national school. He was a gifted pictorial satirist, belonging in some respects to the tradition of Callot and Goya. He is, however, more earthy than Callot and lacks the savagery of Goya. Hogarth was a printmaker of the people, whose work was so popular that to protect it from imitators he instigated the first engraving copyright act of 1735. Although his drawing was rather pedestrian, Hogarth's prints reveal a sharp observation, projected with robust vitality.

Pictorial satire of Hogarth

Next to Hogarth, Thomas Rowlandson is the most significant representative of English satire. A brilliant draftsman and a deft caricaturist, he spoofed the moral and social life of England with great humour.

William Blake is by far the most interesting figure in English printmaking. Poet and experimental printmaker, he was a visionary, creating his works totally outside the mainstream of art history. His printed work consisted primarily of book illustrations. Original and inventive in technique, he used a great range of media, from wood and metal engraving to relief etching. In the latter he devised a transfer method that enabled him to etch the text and the illustration on the same plate. Many of his prints were hand coloured, but he also printed colour by an offset method of his own invention.

Thomas Bewick was a provincial illustrator who made a great number of charming wood engravings, primarily of animals and rural genre scenes. He was a pioneer in the technique of wood engraving, introducing tonal variations by slightly varying the level of his blocks.

To reproduce the fashionable paintings of the day, commercial engravers perfected a whole arsenal of reproduction techniques, such as mezzotint, stipple engraving and etching, and crayon manner.

Spain. Spanish printmaking in the 17th century had been dominated by Flemish and French influences, and no printmaker of importance emerged during the period.

In the 18th-century artist Francisco de Goya, Spain had not only its first truly great printmaker but also the only printmaker whose etchings rival Rembrandt's. Moreover, he is the most eminent satirist printmaking has produced. His visual comments on human folly, war, and religious persecution are devastating.

Goya created four major cycles of prints. The first, "Los caprichos" (1797–98), consists of 80 enigmatic prints commenting on all phases of life. In 1810 he began the 83 plates of "Los desastres de la guerra," a strong visual protest against the brutality of war. After this came "La tauromaquia" (1815–16), a brilliant series on bullfighting. The last important series was "Los disparates," or "Proverbs" (*c.* 1820–24), a biting, though often humorous, interpretation of human folly.

Technically, the Goya etchings are simple and direct. He usually combined line etching with aquatint; his masterful control of the latter, a relatively new technique, has never been surpassed. Toward the end of his life, he also made a few rich, powerful lithographs.

Goya's technique

France. Most 18th-century French etchings were drawings transferred to copper, in which the effects of pencil, pen, or chalk were imitated. Although some distinguished painters, such as Antoine Watteau, made etchings, no prints of importance were produced. Jean-Honoré Fragonard made a few lovely etchings reminiscent of Tiepolo. They have a luminous, transparent quality and express the Rococo spirit but are nevertheless minor works of a major painter. Two artists are notable for technical achievements: Jean-Charles François developed the crayon manner, and Jean-Baptiste Le Prince is credited with the invention of aquatint.

Japan. The first Japanese artist to produce single prints in quantity was Torii Kiyonobu, who specialized in por-

traits of actors and theatre posters. His school, the Torii, dominated printing for the theatre for two centuries. Another imaginative innovator of the early 18th century was Okumura Masanobu, who experimented with inks, embossing, and gold and silver overlays. He also invented the two-colour print and generally standardized colour printing. His studio greatly influenced the evolution of colour woodcut. Suzuki Harunobu, one of the most charming masters of Japanese woodcut, created prints of infinite delicacy and grace. In this respect he is a forerunner and rival of Utamaro. A highly gifted colourist, he was one of the first to exploit the *nishiki-e*, or full-colour print. He was also the first to colour print backgrounds and to use blind embossing extensively to give his prints three-dimensional textures. Katsukawa Shunshō is notable for his austere portraits of actors, which he designed with much strength and intensity. Some of his portraits are among the finest in Japanese printmaking.

"Two Lovers Under an Umbrella in Snow," woodcut by Suzuki Harunobu (1724–70). 26.7 cm × 19.7 cm.

The period from 1780 to 1790 was dominated by Torii Kiyonaga, whose work represents the Ukiyo-e at its height. He was a great draftsman and designer and could harmonize in his prints the two seemingly contradictory qualities of elegance and power. Kiyonaga was one of the first to experiment with the compositional possibilities of the diptych, triptych, and pentaptych formats. Although he conceived each block as a self-contained unit, they functioned together in harmony. Kitagawa Utamaro can justly be called the supreme poet of Japanese art. Utamaro's prints are the most perfect expression of a tender, loving contemplation of nature, which included not only birds and flowers but women as well. At the age of 50, he was put in jail for an offending print; broken in spirit, he died shortly after his release. During his lifetime he produced over 600 series of books and albums. Toshusai Sharaku is not only one of the most distinguished but also one of the most mysterious figures of Japanese art. Seemingly out of nowhere, his magnificent, powerful portraits of actors suddenly appeared on posters. The boldness of the portraits, verging on caricature; their psychological insight; their richness in colour all represented a daring new attitude. The originality of these prints disturbed the authorities to such an extent that the police prohibited them. In less than two years of working life, Sharaku had produced approximately 145 portraits; then the prodigious flow of work stopped, and he disappeared again.

Late 18th-century Ukiyo-e

PRINTMAKING IN THE 19TH CENTURY

The 19th century was a turbulent period of art, one aesthetic revolution following the other.

France. French domination of 19th-century art is comparable to northern domination of 15th-century printmaking. Few graphic artists of importance worked outside France.

The great French painter Jean-Auguste-Dominique Ingres made only a few etchings, mainly portraits; but, as demonstrated by the lithograph "L'Odalisque" (1825), his draftsmanship was incomparable. Eugène Delacroix left a much more extensive graphic oeuvre: 24 etchings and 131 lithographs. Both in subject matter and style, Delacroix's prints are eloquent expressions of the Romantic spirit. In his tragically short life, Théodore Géricault made a series of powerful lithographs; his horses are considered classics in their genre.

At midcentury, a rebellion against studio painting took place. A group of young landscape painters, most of whom were also printmakers, formed a group that became known as the Barbizon school. The etchings of Charles-François Daubigny, Théodore Rousseau, and Jean-Baptiste-Camille Corot were close to the spirit of the 17th-century Dutch landscapes. Corot made prints whose spontaneity foreshadowed Impressionism; he also experimented with the newly discovered photographic method of *cliché-verre*.

Another member of this group, Jean-François Millet, was concerned particularly with depicting peasant life. His small but monumentally simple etchings are reminiscent of the 17th-century Dutch genre painter van Ostade at his best.

Political satire of Daumier

Honoré Daumier, one of the foremost political satirists of printmaking, was associated with the Barbizon school only through friendships. He produced over 4,000 lithographs (many of them newspaper illustrations), which are visually powerful expressions of his passionate convictions. His best work ranks with that of the greatest masters of printmaking.

A number of French artists were solitary figures working outside of any school; Charles Méryon, Rodolphe Bresdin, and Odilon Redon, for example. Méryon led a short, tragic life, living in poverty and dying insane. His major work is a series of landscapes of Paris—powerfully drawn, moody prints combining an air of mystery with morbid poetry. Bresdin was also a solitary figure, unappreciated and misunderstood most of his life. His etchings and lithographs are characterized by completely personal and fantastically rich imagery. The great symbolist

"Rue Transnonain, April 15, 1834," lithograph by Honoré Daumier. 44.5 cm × 29 cm.
By courtesy of the National Gallery of Art, Washington, D.C., Rosenwald Collection

painter Redon initially made prints under the influence of Bresdin. His graphic work—a few etchings but mostly lithographs—consists of about 206 prints, whose strange, often bizarre imagery powerfully influenced the Surrealists of the 20th century.

Although, basically, the Impressionists were concerned with the creation of light through colour, several artists identified with them made major contributions to printmaking. Of these, Édouard Manet and Edgar Degas are the most important. Both were superb draftsmen, and, in spite of their association with an avant-garde movement, their roots were firmly planted in traditional art. Manet made a few fine etchings, but his best and most personal works are lithographs, in which his swift but astonishingly precise drawing found its proper medium. Degas's drawings of horses and ballet dancers are miracles of observation and precision—as are his etchings and lithographs. Degas also made a series of monoprints, including a group of remarkably abstract landscapes. The grand old man of the Impressionists, Camille Pissarro, made 194 prints, both etchings and lithographs. His fine graphic work is representative of forceful Impressionist drawing.

The discovery of Japanese colour woodcuts was a revelation that profoundly influenced European art. Until the middle of the 19th century, Japanese printmaking was unknown to the West. As trade relations opened up with Japan, some colour prints came into the hands of young Parisian artists, who responded to the exotic images with great enthusiasm. The simple, abstract handling of colour and design represented a totally new visual experience. Paul Gauguin was one who profited greatly from their influence, which is perhaps more evident in his paintings than in his prints. Following centuries in which the woodcut was used for reproduction, Gauguin's powerful, boldly cut wood blocks were like a breath of fresh air. In the prints of Henri de Toulouse-Lautrec, Japanese influence is more immediate. Although most of his prints were lithographs, the simple bold design, the flat, decorative colour, and the startling disposition of blacks clearly show this influence, which he assimilated and turned into a thoroughly personal expression. A very strong Japanese influence can be seen also in the brilliant color aquatints of the American-born Impressionist Mary Cassatt.

"Mahana Atua," woodcut with touches of watercolour by Paul Gauguin, *c.* 1893–95. 18.3 cm × 20.5 cm.

Influence of Japanese woodcuts on European art

The giant of Postimpressionism, Paul Cézanne, made three etchings and three lithographs. His immense influence on modern art makes his colour lithograph "The Bathers" (*c.* 1900) an important graphic document. The Dutch artist Johan Barthold Jongkind lived in France, creating sensitive landscapes and marine etchings that were a transition between the Barbizon school and Impressionism.

"Le Bon Samaritain" ("The Good Samaritan"), etching by Rodolphe Bresdin (1825–85). 56.3 cm × 44.3 cm.

Japan. The most famous Japanese master of woodcut, Katsushika Hokusai, was born in Hōjō, a suburb of Edo. From the age of 13, when he became an apprentice, until his death in 1849 at the age of 89, he produced an unending stream of masterpieces—about 35,000 drawings and prints, a staggering figure even considering his long life. He also wrote books and poems. There are few masters in the history of art whose work is comparable to Hokusai's in variety and depth. His interests encompassed history and mythology, popular customs, animal life, and landscape. His output was so enormous and the quality of his work so high that it is difficult to single out individual pieces. The "Thirty-six Views of Fuji" (*c.* 1823–29) is probably his most popular set of prints. The 15 volumes of the "Mangwa" (1819) is a fascinating work, for in these rather informal woodcuts the artist gives a comprehensive record of Japanese life and culture. Of all the Japanese masters, the universal genius of Hokusai had the greatest impact on European art.

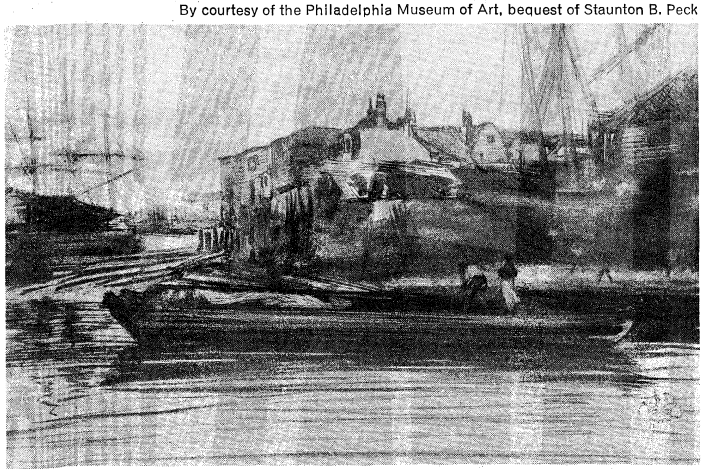
Hokusai's woodcuts

The last master printmaker of Japan was Hiroshige, whose death in 1858 ends the remarkable dynasty of art-

ists that had begun two centuries earlier. He was a great landscape painter and, with Hokusai, the first to capture the European imagination. He was also a versatile artist, famous in Europe as a painter at a time when in Japan he was known mainly as a poet. A river inspector in the Hokaido district, Hiroshige constantly sketched the landscape during his frequent trips to the river stations. These sketches formed the basis of "Fifty-three Stages of the Tōkaidō Highway," his most important series of landscapes.

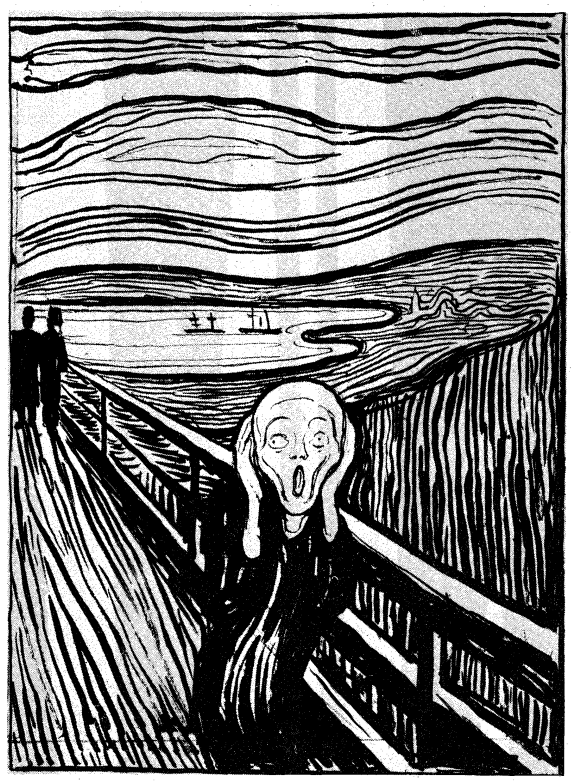
Like the work of the Impressionists in Western art history, Hiroshige's prints are spontaneous both in style and in atmosphere, capturing the essence of the fleeting moments of nature.

Other countries. In Germany, Max Liebermann made a few etchings of real individuality, but the most important German achievement of the period was the invention of lithography (*c.* 1796) by Aloys Senefelder, who was not an artist. Although the Belgian artist Félicien Rops lived outside France, he was strongly influenced by the school of Paris. His witty, erotic etchings represent a minor but personal expression of the period. In Sweden, the enormously successful Anders Zorn made etchings and drypoints with great virtuosity.



Contributions of Haden and Whistler

English printmaking of the 19th century centred around two great personalities, Sir Francis Seymour Haden and his brother-in-law, James McNeill Whistler. Haden was a Victorian country gentleman, a surgeon who loved and collected etchings. He started to make prints in his leisure time—and ultimately produced over 200 plates. His etchings, sensitively observed documentations of his environment, represent a significant contribution to the English landscape tradition. Whistler was born in America and attended West Point for a period; but he left to study art in Paris, where he met many of the leading artists, including Degas. In 1859 he went to London, where he resided until his death. Whistler was an immensely gifted, complex personality. Simultaneously with his fashionable portraiture, he did a great deal of experimentation; in the nearly abstract paintings and prints that he called "Nocturnes" (begun in 1866), for example, he was far ahead of his time. His graphic oeuvre, 442 etchings and drypoints and 150 lithographs, had great impact on modern printmaking; in particular, the freedom and painterliness of his etchings acted as a strong liberating influence.



Printmaking in 19th-century America was still provincial and did not produce any artist comparable to the European masters. The colour engravings of flora and fauna executed by the naturalist John James Audubon constitutes a significant body of work, however.

In Mexico, the popular illustrator José Guadalupe Posada produced thousands of woodcuts and lead cuts for newspapers in a completely original style—a mixture of sophistication and the naïveté of popular art. His work had a substantial influence on the young Mexican revolutionary art movement.

PRINTMAKING IN THE 20TH CENTURY

Impact of photography on printmaking

The invention of photography (1826) had a great impact on the development of the visual arts. Its effect was the most immediate on printmaking: photographic reproduction processes made reproductive printmaking obsolete, and printmaking was returned to the creative artist.

The experimental attitude that originated with the Impressionists accelerated in the 20th century. The new styles and new directions that arose with bewildering rapidity made the first half of the century one of the most exciting periods in the history of art.

Continuing the pattern set in the 19th century, France dominated the art world. Attracted by its creative climate, young artists like the Spaniard Pablo Picasso flocked to Paris from other countries and, together with the French, formed the school of Paris, which produced many first-rate artists.

At the same time, Germany became again a vital art centre. German Expressionism and later the Bauhaus school not only produced a number of distinguished artists but eventually exerted international influence.

The following discussion deals only with the "old masters" of contemporary art, those in historically secure positions. Four transitional figures are of particular importance because they represent a bridge between the 19th and 20th centuries. Edvard Munch was an extraordinarily gifted Norwegian painter and printmaker who worked in Paris and in Berlin. His intense imagery, with psychological undertones, relates him to German Expressionism. A versatile artist, he made outstanding etchings, drypoints, colour lithographs, and experimental woodcuts. The Belgian artist James Ensor made superb etchings in a style related to Impressionism, but with fantastic imagery that was close to Surrealism. Close friends, the Frenchmen Pierre Bonnard and Édouard Vuillard produced similar graphic works. Inspired by the Japanese, both made sensitive, beautiful colour lithographs.

France. Pablo Picasso is without doubt the most dramatic and monumental figure of contemporary graphic art. Besides being a superb painter and sculptor, he has created a graphic oeuvre so rich and all-encompassing that he stands alone. He has made well over 1,000 prints,

including etchings, engravings, drypoints, woodcuts, lithographs, and linoleum cuts. Georges Braque, the cofounder with Picasso of Cubism, produced ten major Cubist etchings. The distinguished French painter Henri Matisse was a remarkable colorist and a highly accomplished draftsman. Although the majority of his more than 500 prints are lithographs, he also made some outstanding line etchings and, late in his career, some cutout prints that are masterpieces of design and colour orchestration. Georges Rouault, the French Expressionist, was a solitary figure in contemporary art. The most important graphic work of this religious painter was the "Miserere," a set of etchings published in 1948. Jacques Villon, a major French printmaker, was recognized late in his life as a great painter. Early in his career he made colour aquatints, after the paintings of his more celebrated contemporaries, that raised the level of intaglio colour printing to new heights. Later he developed a completely personal style within the Cubist tradition. He made over 600 prints including engravings, etchings, drypoints, and colour lithographs. The poetic, naïve, and, at the same time, sophisticated style of Marc Chagall, a Russian Jewish member of the school of Paris, sets him apart from any art movement. In his significant body of graphic work, the most accomplished prints are illustrations of the Bible, the works of the Russian writer Nikolay Gogol, and the fables of the Frenchman Jean de La Fontaine. Like his compatriot Picasso, the Spanish painter and sculptor Joan Miró was a prolific printmaker. His witty colour etchings and lithographs represent an achievement equal to his paintings. Max Ernst was a founder of Surrealism and one of the most inventive and influential members of the group. In his extensive graphic work, he introduced a number of new techniques; most notable was his imaginative use of the "collage" in printmaking. Stanley William Hayter, an English painter-printmaker who lived in Paris, has an important position in the development of contemporary experimental printmaking. His significance lies not only in his work as an artist but also in his influence as a teacher. In the 1930s his "Atelier 17" printmaking group was the centre of experimental intaglio work in Paris. In the 1940s he came to the United States and, through his teaching in New York, exercised a powerful influence on contemporary American printmaking. Other artists who did noteworthy graphic work in France include Jean (Hans) Arp, Salvador Dali, André Derain, Jan Dubuffet, André Dunoyer de Segonzac, Alberto Giacometti, Fernand Léger, André Masson, Louis Marcoussis, and Jules Pascin.

Influence of Hayter on printmaking

Germany. Unlike the extremely varied school of Paris, German Expressionism was quite homogeneous and also much less international. The Expressionists were not united by an aesthetic theory but by their human attitudes and spiritual aspirations. Nearly all of them were active in printmaking; and, although they worked in every contemporary graphic medium, the directness of drypoint and woodcut most appealed to their temperaments.

Lovis Corinth represents a transition from 19th-century naturalism to the Expressionist movement. Although Corinth made etchings, woodcuts, and lithographs, his rich, virile drypoints are his best work. Although not innovative, Käthe Kollwitz's moving, powerful protest prints against war and poverty are significant graphic statements. Ernst Ludwig Kirchner, one of the major figures of German Expressionism, produced a rich graphic oeuvre consisting of etchings, lithographs, and woodcuts. His experimental colour woodcuts represent one of the most distinguished achievements in contemporary graphic art. Emil Nolde produced prints characterized by violent imagery. He worked spontaneously, often making woodcuts without preliminary drawings. Although Nolde came late to graphic work, he left an impressive number of woodcuts, etchings, and lithographs. Max Beckmann was an outstanding draftsman, who made many woodcuts and drypoints. In the latter technique he created some of the finest portrait prints of the 20th century. During World War II, Beckmann came to the United States, where he exerted considerable influence through his teaching. George Grosz used etchings and lithographs to give savage expression to his social criticism of Germany between the wars. The following Expressionists also left significant graphic work: Ernst Barlach, Erich Heckel, Oskar Kokoschka, and Karl Schmidt-Rottluff.

Artists of the Bauhaus group

Other artists moved in a more formal, abstract direction. Based on their philosophy of "new objectivity," they founded the Bauhaus school in Germany in 1919. The two major artists in this group were the Russian Wassily Kandinsky and the Swiss Paul Klee. Kandinsky was one of the great innovators of contemporary art. In his early, lyrical paintings he was a forerunner of Abstract Expressionism, and in his late mature work he introduced Geometric Abstraction. His graphic work consists of an impressive number of woodcuts and lithographs. The whimsical, lyrical abstractions of Klee also had great influence on the course of modern art. His work—about 120 etchings and lithographs—is full of graphic invention and a rare sense of humour. Lyonel Feininger, born in the United States of German parents, studied in Europe and worked most of his life in Germany. He was associated with the Blaue Reiter group (artists who wished to express through their work the spiritual realities they felt had been ignored by the Impressionists) and then in 1919–33 with the Bauhaus. Feininger concentrated mostly on landscapes, executed in a very personal Cubist style, and was one of the most productive graphic artists at the Bauhaus. In the beginning, he made some etchings and lithographs but from 1918 worked mainly in woodcuts. Josef Albers, also associated with the Bauhaus, was born in Germany and moved to the United States in 1933. He has made a considerable number of prints including, recently, colour silk-screen prints. Rolf Nesch was born in Germany, where he started printmaking with the encouragement of Kirchner. He fled to Oslo from Germany in 1933. One of the most gifted experimental printmakers of the 20th century, Nesch developed the method called metal graphic, which he uses to make extremely intricate, heavily embossed colour prints.

Other countries. Printmaking in Italy was far behind France and Germany. The Futurist artist Umberto Boccioni made a few interesting etchings and the Cubist Gino Severini published a number of rather manneristic etchings and colour lithographs, but neither could be considered important printmakers. Giorgio Morandi is the only major Italian printmaker of this period. His intimate, delicate still-life and landscape etchings occupy a very special position in contemporary graphic art.

In Great Britain, Henry Moore, one of the great sculptors of the 20th century, published a number of strong lithographs. Graham Sutherland, a painter, made over 100 etchings and lithographs in a distinctly personal style. Anthony Gross, one of the most talented and prolific English printmakers, has published an impressive body of excellent landscape etchings and engravings.

In the United States, after the turn of the century, most

of the prominent painters became fairly active printmakers: George Wesley Bellows, in lithography; John Sloan and Reginald Marsh, in etching; Milton Avery, in drypoint; and Stuart Davis, in colour lithography. Among these painter-printmakers, two artists are particularly notable: Edward Hopper, whose few etchings are very personal and of unusually high quality; and Ben Shahn, an extremely prolific printmaker, who left an impressive graphic oeuvre in practically every medium.

Revival of the Japanese woodcut

A revival of the art of the woodcut began in Japan in the late 1920s as part of the modern art movement. Onchi Kōshirō and Hiratsuka Un-ichi were early exponents who, though working in different styles, did most for the renaissance of this national art, which thrived once again after World War II. Among the notable woodcut artists of the postwar period are Munakata Shikō and Saitō Kiyoshi.

Since the mid-20th century, there has been a spectacular increase in printmaking activity. Artists all over the world are enthusiastically working and experimenting in every conceivable medium. In this period probably more prints were made and more technical innovations introduced than in the previous history of printmaking.

BIBLIOGRAPHY. ARTHUR M. HIND, *A History of Engraving and Etching from the 15th Century to the Year 1914*, 3rd ed. rev. (1923, reprinted 1963), and *An Introduction to a History of Woodcut, with a Detailed Survey of Work Done in the Fifteenth Century*, 2 vol. (1935, reprinted 1963), cover brilliantly the whole history and development of Western printmaking. Other studies particularly recommended are: JEAN LARAN, *L'Estampe*, 2 vol. (1959), excellent documentation coupled with a volume of fine reproductions; WILLY BOLLER, *Masterpieces of the Japanese Color Woodcut* (1957), not a scholarly book but it covers well the high points of Japanese printmaking; CARL ZIGROSSER, *The Book of Fine Prints*, rev. ed. (1956), an easy-to-read introduction into the history of printmaking; *De Meisterwerken van de Europese Prentkunst 1410–1914*, Rijksmuseum, Amsterdam (1966), catalog of one of the finest shows of master prints ever assembled; A. HYATT MAYOR, *Giovanni Battista Piranesi* (1952), a fine biography of Piranesi with an excellent selection of illustrations; WOLF STUBBE, *Die Graphik des zwanzigsten Jahrhunderts* (1962; Eng. trans., *Graphic Arts of the Twentieth Century*, 1963), good introduction into the history of contemporary printmaking; E.S. LUMSDEN, *The Art of Etching* (1929, reprinted 1962), excellent document on the traditional etching techniques; WILLI KURTH (ed.), *The Complete Woodcuts of Albrecht Dürer* (1946), primarily a picture book with historical background; CARL ZIGROSSER and CHRISTA M. GAEHDE, *A Guide to the Collecting and Care of Original Prints* (1965), a wealth of indispensable information for the collector; STANLEY W. HAYTER, *About Prints* (1962), challenging ideas about printmaking by an important artist and teacher; LEO C. COLLINS, *Hercules Seghers* (1953), an excellent, well-documented book on one of the most important printmakers; J.R. HILLIER, *Hokusai*, 2nd ed. (1957), not a definitive biography but it captures the spirit of Hokusai; LUDWIG MUNZ, *Rembrandt Etchings*, 2 vol. (1949), interesting because it documents Rembrandt's influence as a teacher; K.G. BOON, *Rembrandt: The Complete Etchings* (1963), one of the finest books on Rembrandt with excellent rich reproductions; GABOR PETERDI, *Printmaking*, rev. ed. (1971), a simple but thorough book on both the traditional and experimental intaglio methods; *Redon, Moreau, Bresdin*, Museum of Modern Art, New York (1961), primarily interesting for the Bresdin documentation; CARL W. SCHRAUBSTADTER, *Care and Repair of Japanese Prints* (1948), useful information for the collector; ALBERT KOSLOFF, *Screen Process Printing*, 3rd ed. (1964), a simple, clear description of the basic techniques of screen printing; *The Complete Etchings of Goya* (1943), primarily a picture book; ANDRE MALRAUX, *Saturne: Essai sur Goya* (1950; Eng. trans., 1957), a very subjective responsive to Goya by a great writer, richly illustrated; MAXIME LALANNE, *Traité de la gravure à l'eau forte*, 2nd ed. (1878; Eng. trans., *A Treatise on Etching*, 1880), primarily interesting as a historical document on technique; FRANK and DOROTHY GETLEIN, *The Bite of the Print: Satire and Irony in Woodcuts, Engravings, Etchings, Lithographs and Serigraphs* (1963), an interesting book highlighting the militant, political aspect of prints; BERNARD S. MYERS, *The German Expressionists* (1957), a good introduction to the history of German expressionism, well illustrated; JEAN ADHEMAR, *Toulouse-Lautrec, lithographies, pointes sèches* (1965; Eng. trans., 1965), the definitive book on Toulouse-Lautrec as a printmaker; MICHAEL KNIGIN and MURRAY ZIMILES, *The Technique of Fine Art Lithography* (1970), an excellent, well-organized book on a complex subject; RALPH E. SHIKES, *The Indignant Eye: The Artist As Social Critic in Prints and Drawings from the Fifteenth Century to Picasso* (1969).

(G.F.P.)

Pripet Marshes

A vast, soggy, river-laced, and thickly forested region, the Pripet Marshes (Pripet Polesye ["woodlands"] in Russian; Polesje in the Akademiya Nauk transliteration system) sprawl across the great flat expanses of the western portion of the East European Plain (Vostochno-Yevropeyskaya Ravnina) of the Soviet Union. As Europe's largest swamp, they form a remarkable natural feature of major interest to scientists and are in large measure a legacy of the physiographic activities of the last Ice Age. For centuries their inhospitable terrain was of little interest to man, but huge reclamation projects have attempted to win some economic reward from the area during the Soviet period. Though the landscapes of the region are unique, their scientific interest is heightened because they do have parallels in other natural regions of the Soviet Union, both in the eastern European plains (Meshchorsk Lowlands and the Privetluzhye) and in the western Siberian plains (the Vasyuganye), as well as in regions of Poland contiguous to the Soviet Union. Such landscapes are often called *polesski* (*i.e.*, similar to Polesye).

Extent of the Marshes

The Pripet Marshes occupy the south of the Belorussian Soviet Socialist Republic, and the northern *oblasti* (regions) of the Ukrainian S.S.R. Physiographically, the region lies in the basins of the Pripyat and Dnepr rivers. The region is bounded on the north by the Belorussian Ridge (Belorusskaya Gryada) and on the south by the Volya, Podolsk (Podolskaya), and Dnepr uplands.

Physiography. The distinctive natural traits of the Pripet Marshes are a wide development of saturated sandy lowlands, intersected by a dense network of rivers with weakly cut river beds and wide floodlands; a prevalence of pine forests amid wide expanse of low-lying bogs and marsh-ridden lands; and a variegated and difficult landscape impeding full economic use of the land.

The underlying geological structure of the region is formed in large part by a syncline, or great downwarp, in a slab of the ancient rock structure known as the East European Platform; the downwarp is known as the Pripyat Hollow and the Brest Depression. The younger geological areas lie on the southern part of the hard mass known as the Ukrainian crystalline shield. The rocks of the region include ancient granite, gneiss, calcareous marl (a crumbly material consisting mainly of clay, sand, and calcium carbonate), and large quantities of geologically recent sandy–clayey deposits.

The natural peculiarities of the Pripet Marshes are derived in part from the environmental conditions existing in the Ice Age, when the region was smothered in ice and ice-carried material, and also from the action of contemporary physiographic processes. The geologically recent deposits that have so influenced present-day conditions have an average depth of 82 to 164 feet and are mainly represented by glacial sands, sandy–clayey moraines (mounds of material marking the rim of former glaciers), alluvial sands, and lake loams.

As a result, the characteristic relief forms are uplifted plains, river valleys cut in a series of steplike terraces by water action (and merging into flat, weakly expressed watershed areas), morainic plains and ridges (as at Volyn and Mozyr [Mozyrskaya]), and ancient wind-sculpted relief forms. The younger areas are occupied by plains worn down into outcrops of ancient Precambrian rocks. The southwest and eastern areas are characterized by the deeply eroded, strangely shaped limestone rock forms known as karst topography.

Climate and drainage. The region experiences a warm temperate climate. The average January temperatures range from 24° F (−4.5° C) in the southwest to 19.4° F (−7° C) in the east, and the average July temperature is almost 65° F (18 or 19° C). The average annual precipitation reaches 22–26 inches (550–650 millimetres) and exceeds evaporation, giving sufficient—and in some places quite abundant—moisture. In conjunction with an

abundance of subsoil waters and their close proximity to the surface, a virtually unique soil saturation and associated bogging down of the surface are thus produced.

Rivers and streams

The region is also noted for its extensive network of rivers and streams. Numerous tributaries of the Pripyat (including the Stokhod, Styr, Goryn, Ubort, Yaselda, and Ptich), the Dnepr (Sozh, Teterev, Irpen), course down into the swamps from the surrounding highlands, carrying in large amounts of water. In the spring, when snowmelt occurs, the region's rivers overflow their low-lying banks and intensify the saturation of the land. Huge marshes are developed along the course of the Pripyat itself, while the middle of the river is marked by the soggy expanses of the Pinsk Marshes. The character of the marsh regions is shaped by the local topography, itself marked by floodlands, a layer of submerged former river terraces, a second layer of submerged terraces, and the morainic plains of very old valleys and lake hollows. Low-lying marshy grasses, sedges, and sedge bogs of the type known as *gipnovo* prevail, while small areas of mossy bog and the transitional, or mesotrophic, swamp occupy the upriver areas. The numerous lakes that dot the landscape are in various stages of choking up into more bogs. The soil cover of the region consists mainly of the turf type of podzol soils, peat bog, and floodland soils: all need land reclamation measures before they can be used for agricultural purposes.

The human imprint. About one-third of the region is forested, consisting of pines (about 60 percent of the wooded area), birch, alder, oak, aspen, white spruce, and hornbeam, all of which add occasional splashes of lighter colouring against a generally dank and sombre background. The region has thus supported—where conditions permit—a diversified lumbering industry. Elk, lynx, wolf, fox, wild boar, roe, beaver, badger, and weasel are to be seen and are sometimes hunted within the forest fastnesses, and the somewhat gloomy appearance of the area is also brightened by the sounds and movements of a host of birds, including black grouse, orioles, hazel grouse, woodpeckers, owls, blue tits, and wild duck. These, too, are hunted.

The mark of man is most evident, however, in the more promising sections of the region that are being developed and transformed into agricultural lands, where rye, barley, wheat, flax, hemp, potatoes, a variety of vegetables, and fodder grasses are cultivated.

Land reclamation

Land reclamation projects have only been initiated since the late 19th century. They were begun in 1872 by a state-sponsored "western expedition for the drainage of swamps" led by the famous Russian scholar I.I. Zhilinsky. A vast amount of land reclamation has taken place in the Soviet period, especially since the reunification of western Belorussia and the western Ukraine under a socialist government. A complex series of measures for achieving this formidable goal was underway by the early 1970s. They include the regulation of water drainage and the construction of reservoirs on the rivers, the regulation of river channels, afforestation of sandy uplands, and the clearing of shrubs and other undesirable vegetation cover. Reclamation is proceeding under an overall Soviet plan, and it is hoped that the ultimate transformation of the hitherto inhospitable natural conditions will have great significance for a wide range of economic activities.

Prisons and Penology

The prison is a relatively recent invention; as a means by which society deals with criminal behaviour, it has come into widespread use only within the last 300 years. In order to understand the nature of the prison, it must be seen as part of a larger pattern of penal practices that have undergone a number of transformations over the course of time.

Imprisonment as punishment

Imprisonment is essentially a form of punishment, although some have seen it as affording a means of reforming the criminal. Punishment is an ancient response to wrongdoing; but throughout man's history both the forms of punishment and the rationale for using it have changed markedly. Many of the changes can be traced to economic considerations, the development of a more humanitarian outlook, and the emergence of a secular viewpoint in human affairs, as well as to the development of new concepts about the nature of man and society. But if society's treatment of the lawbreaker has become, in theory at least, more rational, more benign, and more concerned with rehabilitation, this does not mean that society's reaction to the criminal has lost its punitive tone. Actually, there is little evidence as to the effect of punishment on the amount of crime in society. It is not known with any certainty that one mode of treatment is more or less effective than another. Penal systems everywhere remain largely based on tradition, untested assumptions, and inferences derived from inadequate data.

GENERAL CHARACTERISTICS OF PUNISHMENT

The rationales for punishment. Punishment inflicted by the state in response to a violation of the criminal law has been justified in various ways. It has been seen as society's vengeance upon the criminal, as atonement by the wrongdoer, as a means of deterring other criminals, as protection for the law-abiding, and as a way of rehabilitating the criminal.

Revenge. The individual who has inflicted harm on another, runs the revenge argument, must be made to suffer in return; for only an act of vengeance can undo the harm that has been done and assuage the suffering of the victim. The 19th-century English legal historian Sir Henry Maine held that punishment evolved from social necessity: in a primitive society private retaliation was all too likely to lead to feuds that could destroy the group, and, therefore, the group as a whole, acting as a formal collectivity, was slowly led to take on the role of the punishing agent. Although anthropology has not been kind to Maine's evolutionary theory, some modern commentators continue to see legal punishment as a device for forestalling disruptive acts of private retaliation.

Expiation. The concept of punishment as a form of expiation or atonement reaches far back into the history of human culture. The roots of the idea are religious; in the Judeo-Christian tradition punishment has been seen as the undoing of a wrong by means of the suffering of the wrongdoer, who thus brings his moral account with God back into balance.

Deterrence. The notion that the threat of punishment by the state will restrain the potential criminal is one of the most commonly accepted justifications for it. The idea has a philosophical base in the utilitarians' concept of the rational man acting upon a deliberate calculation of possible losses and gains. The Englishman Jeremy Bentham, the Italian criminologist Cesare Beccaria, and other members of the classical school of criminology sought to reform the criminal law of the 18th century with this idea of man as a hedonistic calculator. If men chose rationally among possible future courses of action, then surely the likelihood of a criminal course of action could be decreased by attaching to it a quick, certain, and commensurate penalty.

The use of punishment as a deterrent has been justified not only for the convicted criminal. The law-abiding man who totters on the edge of illegal behaviour is also deterred, it is said, and one must calculate the effect of society's penal system not simply in terms of its impact on the known offender who is punished but also in terms of its influence on the great mass of those who conform. As the philosopher Morris Cohen pointed out, this is ethically unsatisfactory: to justify punishment of the criminal by its effect on the noncriminal is a little like hurting Peter to keep Paul honest. As a practical matter, however, an accurate assessment of the efficacy of legal punishment would have to measure its influence on both criminals and noncriminals.

Protection of the public. Insofar as punishment by the state isolates the criminal from the ranks of the law-abiding, it has been argued, the amount of crime in society is likely to be diminished. Such isolation may include branding or otherwise marking the criminal, so that honest men may avoid him; or it may involve thrusting the criminal beyond the pale in some form of exile or con-

fining him in a prison. This argument assumes that the isolation of the offender is not outweighed by his becoming more criminal while in prison. It also assumes that the social and economic costs of isolating the criminal from the rest of society are less than those of the crimes he might have committed if he had been left free. Both of these assumptions have been seriously questioned.

Rehabilitation of the criminal. Some writers have maintained that punishment ought to be designed to transform the values and attitudes of the criminal so that he no longer wishes to commit illegal acts. The problem, of course, has been to discover how to do it. Those with a psychiatric bent have pinned their faith on programs of individual and group counselling and on the creation of what they have called a therapeutic milieu. Others, more sociologically inclined, have looked to such measures as education and job training. Still others have taken a more radical view and argued that the causes of crime do not lie with the individual so much as with the community that shapes him; if criminal behaviour is to be diminished, they say, the social context within which it occurs must be changed. Theories of rehabilitation are largely speculative, since there is a lack of scientific evidence to support them. The paucity of research funds, restrictions on social experimentation, political considerations, and other difficulties have prevented any thorough appraisal of the merits of this approach. Nevertheless, it has been influential in the development of modern penology.

The forms of punishment. Men have shown much ingenuity in devising forms of punishment. Throughout history these have ranged from ostracism and ridicule to flogging, burning, branding, mutilating, disemboweling, crushing, beheading, and mass extermination. In general, however, the many forms of punishment can be classified into five major types.

The decline of corporal and capital punishment

Corporal punishment. The infliction of physical suffering is nowadays regarded as barbarous and has been generally abandoned as a form of punishment in most modern industrial countries. The use of such devices as the knout, the cat-o'-nine-tails, the sweatbox, and deprivation of food and water were abandoned partly because of an increasing value attached to the individual and his person, as well as a growing sense that the person who had broken the law maintained his humanity despite his crime. In addition, there was an increasing acceptance of the idea that much of the physical suffering inflicted in the name of punishment was little more than sadistic torture, as degrading to the society that inflicted it as to the criminal who bore it. Cruel punishments produce cruelty in people, argued the English reformer Sir Samuel Romilly in the 18th century; and modern societies have tended to agree.

Capital punishment. The execution of criminals was carried out in the past by such methods as drowning, stoning, burning, and decapitation; in modern times, hanging, electrocution, and the gas chamber have been the most common techniques.

The use of capital punishment has declined in recent times, although in many places it is still permitted by the law. The issue of abolishing it has aroused much controversy. The advocates of capital punishment claim it is a necessary deterrent to crime and relatively painless if done properly. Their opponents argue that executions are far from physically painless, involve extreme mental anguish, may entail irrevocable miscarriages of justice, and are ineffective as a deterrent since the crimes for which capital punishment is imposed are frequently crimes of impulse or emotion beyond the individual's control.

Even where it has been legally retained, capital punishment is now seldom employed. Fewer crimes are punishable by death than formerly; the courts increasingly choose alternative penalties; and many death sentences are not carried out. In the U.S. the annual number of executions dropped from about 155 in the period 1930–34 to about 26 in 1961–65, and in some subsequent years there were none. The death penalty has been eliminated in such nations as the Scandinavian countries, West Germany, The Netherlands, Austria, Italy, Portugal, and Switzerland.

Penal colonies

Transportation. Exile and banishment have been known since ancient times and were often tantamount to a death sentence. The practice of transporting criminals beyond the national boundaries did not appear, however, until the beginning of the 17th century, when England began shipping offenders to America. The American Revolution forced the British to seek a new dumping ground in Australia. With the discovery of gold and the emergence of sheep raising and wheat growing as profitable ventures, which brought new settlers resentful of the criminal population, the English system of transportation came to an end. France established penal colonies in Africa, New Caledonia, and French Guiana (the latter the location of the famed Devil's Island). Russia set up penal colonies in Siberia under the tsars, and the system was greatly expanded by Stalin. Since World War II transportation as a method of punishment has been generally abandoned. The brutal conditions of life in convict communities, their economic inefficiency, and the lack of space in a world growing ever more populated have been factors in its decline. Rather than expelling the criminal, society has found it more convenient to imprison him.

Fines. The imposition of fines upon criminal offenders has long played a role in many societies. A number of early cultures, including the Anglo-Saxon, had intricate systems of blood money that defined in money terms the value of a man's life—for which his murderer would be forced to pay. There were also fines for personal injuries and larcenies, varying according to the social rank of both the victim and the wrongdoer. As crimes came to be defined as public wrongs against the state rather than private wrongs done to a particular individual or family, fines tended to become a subsidiary form of punishment.

In the modern era, fines remain as a penal sanction for a large number of relatively minor offenses but are seldom considered as the major element in a system of punishment except in the case of a limited number of white-collar crimes; and the money is only occasionally handed over to the person who has suffered an injury. Unless money payments are carefully regulated with regard to the ability to pay, they weigh unequally on persons from different socioeconomic levels, and may even become an informal method of licensing illicit activities. A systematic use of fines is made in some countries; for example, in Sweden, where fines are adjusted to the income of the offender and may be paid on the installment plan. The state of Wisconsin in the U.S. allows prisoners to work off their fines by holding jobs outside the institution in which they reside, paying for their maintenance and the support of their families. In general, however, in the U.S. fines remain a rather haphazard adjunct to the penal process.

Early prisons

Imprisonment. Locking up criminals in dungeons and jails is a practice that goes as far back as recorded history. Before the 18th century, however, such confinement was largely reserved for suspected offenders awaiting trial or for convicted criminals awaiting the lash or the hangman's noose. Only in the last 300 years or so has the prison been an important penal sanction. Even today it is not the method applied to most criminals: approximately two-thirds of the offenders in the U.S. penal system, for example, are under supervision in the community rather than behind walls.

Although some institutions akin to the prison existed at an early date, such as the Delle Stinche in Florence in 1300, the first modern prison is thought to have been the Walnut Street Jail built in Philadelphia in 1790. Its antecedents are to be found in the workhouses and houses of correction established in London (1557), Amsterdam (1596), Rome (1704), and Ghent (1773). In these institutions there was little segregation by age, sex, or other characteristic. The main emphasis was on strict discipline and hard labour. Those who operated the houses of correction depended for their living on fees paid by the prisoners.

By the end of the 18th century, the modern concept of the penitentiary had taken firm shape, partly through the work of John Howard in England. Upon becoming high sheriff of Bedfordshire in 1773, Howard was appalled by the conditions of the county jail and spent a number of

years travelling through Europe to study methods of penal treatment. The squalid living conditions, idleness, and immorality that he found in the crowded houses of correction distressed him. Like other prison reformers of the time, he also had a strong belief in the beneficial effects of solitary confinement. He conceived of the penitentiary as a firmly ruled institution where criminals would be kept completely apart from one another and would work at regulated labour. In the 1790s Jeremy Bentham designed the "panopticon"—a circular, glass-roofed structure with cells in tiers around the wall facing a central rotunda where guards could keep the prisoners under constant surveillance. It was a monstrosity by modern penological standards and was never built in England, although its influence is to be seen in the maximum security institutions at Breda in Holland and at Joliet, Ill., in the U.S.

THE DEVELOPMENT OF MODERN PENAL SYSTEMS

The "separate" and "silent" systems

Cherry Hill and Auburn. The ideas of solitary confinement and penal labour were first tried out in the U.S. The early part of the 19th century saw a sharp debate between two schools of penal philosophy, that of the "separate system" and that of the "silent system." The former argued for complete isolation, with each inmate working, eating, and sleeping in his own cell. The latter believed that prisoners should be permitted to work together in silence but be locked in individual cells at night. The separate system, widely known as the Pennsylvania system, was embodied in a prison architecture with rows of cells radiating from a common centre. In the Eastern State Penitentiary built on Cherry Hill in Philadelphia in 1829, seven cell blocks were arranged like the spokes of a wheel around a central administrative structure; the cells were about 16 feet high, 12 feet long, and 7½ feet wide. An enclosed exercise yard was attached to each cell, and the prisoner saw no one but his captors.

The silent system gave rise to prisons made up of cell blocks, with many small cells piled in tiers in single buildings. A model prison was built at Auburn in New York in 1825. The advantage claimed for the Auburn system over the Pennsylvania system was that it allowed prisoners to work together at industrial tasks rather than restricting them to solitary handicrafts such as weaving or shoemaking. Communication among the prisoners was forbidden, however; and as they moved back and forth between their cells and the workshops, they were required to march in lockstep to ease the guards' task of surveillance.

In retrospect, the two schools of thought seem barely distinguishable. Both emphasized strict discipline, hard labour, and elemental living conditions; both sought to prevent the inmates from associating with one another. The Auburn system came to dominate most of the thinking in the U.S. even though European observers believed the Pennsylvania system superior and promoted its adoption in Europe, where it still exists in some places in modified form.

Experiments elsewhere in the 19th century played a significant part in the further development of penological thought. At Norfolk Island, an English penal colony off the coast of Australia, Captain Alexander Maconochie developed the "mark system" through which confined criminals could reduce the length of their sentence by means of conscientious work and good conduct, for which they earned marks or credits. In France, Bonneville de Marsangy advocated the use of conditional release, or parole, for good behaviour. Occupational training for confined criminals was emphasized by a number of prison administrators, notably in Spain and Austria, not simply as a device to help make the penal institution self-supporting but as a crucial element in the offender's rehabilitation.

The "intermediate system"

The reformatory movement. These innovations were brought together in Ireland by Sir Walter Crofton in what he called the "intermediate system" to stress the place of the penal institution as a halfway point between the free community and strict confinement. Depending on the inmate's behaviour and his degree of reformation, he could move either toward greater liberty or toward greater restraint. This new ideal of the penitentiary as a place of training and performance captured the imagination of prison officials in America and in the 1870s gave rise to the reformatory movement.

The National Prison Association established in 1870 adopted a declaration of principles that called for a wide range of reforms, including the classification of prisoners, indeterminate sentences, professional education for prison administrators, industrial training for prisoners, a reward system for good conduct, and changes in prison architecture. The reformatory philosophy soon permeated most thinking in the U.S. and Europe. In practice, however, many of the world's penal institutions are quite far from being reformatories. Social inertia, lack of funds, the growth of the criminal population, and a continuing unwillingness on the part of the general public to abandon punishment as a policy have meant that a large number of prisons and reformatories make no more than a gesture in the direction of rehabilitation.

There have been some imaginative efforts. In the U.S., for example, the Highfields project in New Jersey has made thoroughgoing efforts at the reformation of juvenile delinquents, providing psychological therapy and intensive guidance. The number of offenders that can be handled in such an experimental institution is small. Some state correctional systems, including those of California and Wisconsin, have pursued policies designed to rehabilitate the inmate rather than merely keep him confined; and the federal penal system has long had a reputation for well-administered and enlightened programs.

The picture in England and western Europe is perhaps even more varied. Some institutions—such as the Herstedvester Detention Center at Albertslund, Denmark, which provides a therapeutic environment for 200 men with long criminal records and serious problems of social adjustment—are in the forefront of penological innovation. Others are relics from the 19th century, still imposing solitary confinement and lacking even the pretense of a rehabilitative program.

The trend toward small, informal, treatment-oriented institutions is probably most advanced in the Scandinavian countries, particularly among the well-staffed residential schools for juveniles.

Other approaches. An alternative theory of rehabilitation, that of the "short sharp shock," gained some adherents after World War II. According to this view, offenders of the delinquent gang type ("teddy boys") do not require residential treatment; but neither do they benefit from supervision outside the prison. The solution, it is argued, is a short, severe experience in a sternly administered detention centre of the kind found at Kidlington in England and at Hammargarded in Sweden. The merits of the theory are in dispute, and the effectiveness of the treatment remains to be demonstrated.

Labour colonies exist in Finland and the Soviet Union. Descriptions of the Soviet labour colony at Kryukovo suggest that the psychiatric interpretation of criminal causation and rehabilitation is largely ignored. The institution possesses three regimes characterized as mild, general, and strict—a modern version of the intermediate system. Inmates serve long terms and are employed in a program of industrial production geared to the economic needs of the society. Discipline is said to be maintained by a deliberate use of group pressures and political indoctrination.

The Borstal system

The Borstal system for young offenders in England is probably the most noteworthy example of an attempt to build a large-scale correctional program incorporating modern penological theories. It was established in 1908 by Sir Evelyn Ruggles-Brise, director of English prisons, after he had studied several U.S. reformatories. It consists of a variety of small institutions (usually with no more than 50 inmates) designed for specific types of offenders. Sentences are indefinite. There are facilities for investigation and diagnosis, a relatively well-trained staff including a number of psychiatrists and psychologists, extensive vocational training, and a program of lengthy aftercare that is well integrated with institutional treat-

ment. The Borstal system represents a major effort to free penal practices from the traditional punitive orientation. Its results, however, do not seem to support the hopes of its proponents. Critics have pointed out that the percentage of inmates released from the Borstal system who reappear in court for new offenses is almost identical with the percentage of inmates released from the regular prison system who run afoul of the law. In general, there is little evidence that any method of penal treatment is superior to others, as measured by the numbers of repeaters. This is not to say that one method may not be preferable on humanitarian grounds or on some other basis; it is simply that no convincing proof of rehabilitative effectiveness has been produced.

Appraisal is made all the more difficult if, as seems likely, the patterns of crime change over time. The official designation of the illegal act remains the same, but the motive for committing it changes. A case in point is the increase in serious crimes committed by delinquent gangs in Sweden and other European countries in the 1960s—gangs made up of youths alienated from modern mass society. Juvenile criminals of this sort are not likely to respond to the correctional methods that have worked with other juvenile offenders.

PENAL INSTITUTIONS

The diversity of penal practices

Penal practices. Prisons, reformatories, and other correctional institutions are extremely diverse, ranging from decaying fortresses to mobile forestry camps. It is possible, however, to make some generalizations about institutional penal practices in Western countries, keeping in mind the fact that there are numerous exceptions.

Custody. Few penal institutions can avoid a concern with maintaining custody. Juvenile reformatories are the least stringent. Many countries separate their other institutions into categories of maximum, medium, and minimum security. Preventing escapes, however, remains of primary importance and accounts for many of the rules governing the inmates. Penologists may disagree as to whether keeping the offender confined is for the purpose of punishment, deterrence, or rehabilitation. The general public usually shows no such uncertainty and quickly becomes indignant at news of any escape. It is not surprising that custody is so often given the highest priority and that the overwhelming majority of institutional personnel are devoted to maintaining it.

Work. The inmates of institutions must somehow be supported, and the traditional solution has been that they should support themselves as far as possible. There are various difficulties in this. The organization of an efficient labour force can create serious custodial problems and also arouse opposition from private enterprise outside. Many institutions limit themselves to so-called state-use industries (such as the manufacture of automobile license plates and highway signs) to avoid competing with nonprison labour, and to the routines of institutional housekeeping. These do not provide much training for employment in a modern industrial society. Special efforts in this direction are often hampered by a lack of equipment.

Reduction of sentence. It has long been the custom to reduce the offender's time in confinement as a reward for good behaviour and conscientious performance at work. The prisoner may go through the necessary motions in the hope of reducing his sentence, but the original hope that a carefully graded system of rewards would lead the offender along the path of rehabilitation has not been fulfilled. One experiment at the National Training School in Washington, D.C., has permitted inmates to earn "points"—equivalent to money—for good behaviour, and these can be used to obtain such things as individual sleeping quarters, better meals, and recreational equipment. Whether this conduces to reformation, however, is not yet known.

Education. A large proportion of offenders have a history of failure and retardation in school; and many institutions offer educational programs in the hope of remedying these deficiencies. One difficulty is that prisoners often dislike schooling; another is the prevailing low quality of the teaching.

Self-government. Approximately 95 percent of the offenders committed to penal institutions eventually return to the outside world, and it has seemed essential to many penologists that inmates learn to live in the free community by participating in some form of democratic social structure while still in the institution.

One of the first major attempts to introduce self-government was made in the Auburn and Sing Sing prisons of New York shortly before World War I. Since that time it has been tried at many institutions, particularly at honour farms and juvenile reformatories. The efforts have met with varying degrees of success, but it would appear that in many institutions it has been little more than a formality. Like the trusty systems that give power and responsibility to a few individuals, inmate self-government is subject to the sort of abuse in which some inmates exploit their fellow prisoners and use their privileged position as a means of avoiding institutional rules.

Visiting. The privilege of seeing family members and friends from the outside world exists in almost all penal institutions, although it has never achieved the clear status of a right and is hedged about with numerous restrictions. In many cases, inmates are separated from their visitors by glass partitions through which they communicate by phone. In a few institutions, such as the California Institution for Men at Chino, inmates and members of their families are allowed to mingle freely in an open setting.

The practice of conjugal or sexual visits is established in Latin America, Scandinavia, Eastern Europe, and some countries of Asia. In the U.S. it is permitted on an experimental basis under special conditions in Oregon, Mississippi, and California. A number of penologists have argued for such visits as a means of combatting the homosexuality that flourishes in prisons. An alternative approach is to allow prisoners to go home on furlough. This is easily integrated with the concept of the halfway house or prerelease detention centre that is being adopted in some countries.

Rehabilitation. As noted earlier, the view that a penologist takes of rehabilitation is likely to depend on his general approach to the problem of crime. Some institutional practices—such as vocational training, education, visiting, and self-government—are compatible with a sociological view of rehabilitation; that is, such programs presumably help the offender fit himself for the social and economic roles he must play in society. For penologists more inclined to psychology, however, such programs hardly touch the causes of most criminality. These penologists point hopefully to the many institutions that make some effort at psychological therapy. But no country has yet been able to muster the staffs that would be necessary to make psychological treatment a reality. In 1970 there were fewer than 700 psychiatrists and psychologists employed in all the prisons, reformatories, and jails of the U.S. Four times as many would be needed to meet the standards laid down by the President's Commission on Law Enforcement and Administration of Justice (1967).

A form of psychological therapy that has been regarded with much favour is guided group interaction, which seeks to involve inmates in prolonged and intensive group discussions of their behaviour and motivation. It is less demanding of staff resources than individual counselling. It also bears directly upon the nature of the offender's difficulties with the law, which generally have to do with the social groups to which he belongs and his relationships with other group members.

Institutional design. The design of the penal institution is important to the penologist from an aesthetic as well as a practical view, since the outward appearance of the prison is often taken as a symbol of its philosophy. The fortress-like buildings of the past are giving way to smaller, more informal institutions with an educational or camplike atmosphere. This trend is limited, however, by the desire to control interaction among the prisoners. Dormitory sleeping facilities in juvenile institutions, for example, are considered undesirable by many officials, not only for their lack of privacy but also because they are thought to foster the development of an independent

youth culture that can run counter to the aims of the custodians. Some institutions have provisions for single sleeping quarters that can be locked and unlocked by the inmates, although the guards hold master keys.

The prison community. There have been many illuminating accounts of life in prison by first-rate writers who have been prisoners: Fyodor Dostoyevsky, Arthur Koestler, Oscar Wilde, Miguel de Cervantes, e.e. cummings, Brendan Behan, and Jean Genet, among others. Social scientists, in their more pedestrian way, have provided a large number of detailed studies of prisons that add up to a fairly unified picture of prison life, although most of these investigations have concentrated on large institutions for adult male offenders.

The repressive nature of the prison regime

The regime of the custodians. The social order that the custodians attempt to impose on their captive population is designed to achieve a number of objectives that are often in conflict. The task of custody is frequently assigned the highest priority and is likely to dominate all other concerns. The continual checking of cells, searches for contraband, the detailed regulation of inmates' movements about the prison, the 24-hour surveillance—all are necessary, in the opinion of the custodians, to prevent escapes.

There is also the task of maintaining internal order. Under the best of circumstances it would be difficult to keep peace in a population of men with long criminal histories. The task is doubly difficult in a prison, where the irritations and frustrations of life are harder to avoid. In order to forestall thievery, sexual assaults, and other kinds of prison crime, the inmates are subjected to rules governing every aspect of life. These do much to give the social structure of the prison its authoritarian character.

A third task is self-maintenance: the cleaning, cooking, barbering, record-keeping, and providing of medical services that are needed to keep the institution running. Many inmates are employed at these functions. Others work at tailoring, the manufacture of license tags and office furniture, and whatever industrial occupations are permitted to prisoners. These are limited, both by the need to avoid competing with outside industries and by the requirements of custody and security. The prison often finds itself with too many men and too few jobs.

Finally, there is the task of rehabilitation. Limited as they are in methods and resources, many prisons can only hope that if they do not make their inmates better they at least will not make them worse. Education, recreation, visiting privileges, and similar measures may be provided not in any coherent program of rehabilitation, but simply in the hope of mitigating the more corrosive aspects of the prison environment. Even these will be carefully hedged about with restrictions.

In summary, the regime of the custodians tends to be severely repressive, requiring the minute regulation of inmates' lives. Meaningful activity is at a minimum, and the aim of reformation is likely to be honoured in words rather than in coherent programs.

The difficulty of maintaining control

The prison bureaucracy. The organization designed to put this regime into effect is what sociologists call a typical bureaucratic structure, with written rules, well-defined areas of responsibility, and impersonal standards of performance and promotion. At the bottom are the guards. Immediately above them are the sergeants and lieutenants, who in turn are responsible to the warden and his assistants. A staff of treatment employees, including teachers, clinical psychologists, group therapists, and social workers, is also under the warden's control.

In the effort to carry out their program the prison administrators encounter a number of difficulties. Their power rests on the authority of the law, but it lacks moral support among the inmates. The custodians confront a population that must be forced, bribed, or cajoled into obedience. If they attempt to rule by force they quickly discover how ineffective this is in getting the normal activities of the prison community performed. A straitjacket or a pair of handcuffs may control one rebellious inmate in an emergency, but these will be of little aid in moving hundreds of men through a mess hall. A blow with a club may check an imminent revolt, but it will not ensure the operation of machines for industrial production. If physical coercion as a means of securing compliance proves to be something of an illusion, so also does the use of punishments and rewards. The inmates of the prison are already close to the bounds of punishment allowed by society and the few restrictions left, such as solitary confinement, are limited in their use. Permissible rewards are similarly restricted, since society is opposed to indulging criminals. The consequence is that prison administrators are seldom the unquestioned rulers they are assumed to be by the public; they can maintain control over their community only by reaching a modus vivendi with the inmates.

Guards and inmates

The guard is a pivotal figure in the social structure of the prison community. He is expected to be a combination of policeman, foreman, magistrate, counsellor, and boss. But the guard, too, is in a certain sense serving time in prison. He is frequently reluctant to enforce the full range of the prison's regulations. He may fail to report infractions that he has seen; he may transmit forbidden information to inmates, neglect elementary security measures, or join the inmates in outspoken criticism of the prison administration. This "corruption" of the guard's position is seldom the result of bribery; in fact, bribery is not necessary, for there are other forces at work to bridge the gap between guards and inmates.

First, the guard is in close and intimate association with the prisoners, making it difficult for him to maintain a great social distance. He cannot physically withdraw in symbolic affirmation of his superior position, and he has no intermediaries to absorb the resentment generated by orders and regulations that are disliked. Furthermore, the guard is not necessarily hostile to all inmates, nor does he feel that all prisoners must be rigidly controlled. Some of the inmates, such as those convicted of wife desertion, are not likely to appear to him as dangerous criminals. The guard and the inmate are thus pushed in the direction of a nonauthoritarian relationship.

Second, the guard in prison is frequently dependent on the inmates for the satisfactory performance of his duties, since, like many persons in positions of power, he is evaluated in terms of the men he controls. A troublesome, noisy, dirty cell block reflects on his ability to "handle" prisoners, and this ability is an important component of the merit rating used in pay raises and promotions. The guard often finds it necessary to "trade" with the inmates, tolerating or ignoring "minor" infractions of the rules in exchange for compliance in "important" areas. Permission to gamble, pursue a forbidden hobby, or be out of the cell without authorization may be exchanged for orderly movement to and from work, good behaviour toward the guard, or a well-swept cell block before an inspection.

Finally, much of the guard's authority tends to be whittled down by the innocuous encroachment of inmates on the guard's duties. The making out of reports, the examination of cells during the periodic counts, the locking and unlocking of doors—these minor chores that the guard must perform each day may gradually be transferred into the hands of inmates whom the guard trusts.

The prison administration, in short, cannot function without some degree of uncoerced cooperation from the prisoners. What one may call the corruption of authority is greater in some institutions than in others and varies in its consequences: in some prisons the inmates may exploit one another and violate regulations with little interference from the guards, while in others there is only a slight amount of relaxation. But few prison communities bear much resemblance to the common picture of the prison in which a brutal guard tyrannizes over a criminal locked by himself in a cell.

Relationships among inmates. If interaction between guards and inmates is part of the reality of prison life, the relationships among the inmates are equally significant. Students of penology have long recognized the importance of the daily struggles and deceits, the acts of submission, friendship, and leadership that take place in the inmate social system.

A central problem is prolonged deprivation. One of the

The deprivations of imprisonment

most obvious deprivations of the prisoner is the loss of material goods and services. When he enters his civilian possessions are taken away and he is given a prison uniform. Later he will be given other things—a cup, a spoon, blankets—but never much above the level of bare necessity. Poverty is a part of prison policy.

A second deprivation is in the sexual sphere. The prisoner is denied any heterosexual contact, and the prison administrators must contend with the resulting homosexuality as best they can. Some prisoners will have been homosexuals before their confinement; but these are likely to be relatively few in number and may well be victimized or raped by aggressive prisoners who have turned to homosexuality as a temporary resort. The deprivation of heterosexual relationships must be viewed not only as a physiological loss but also as a psychological one: the inmate is shut off from the world of men and women that by its very polarity gives the word male (or female) much of its meaning.

Third, the great mass of regulations that make up the custodial regime deprives the inmate of much of his autonomy as an individual. For some inmates, of course, the authoritarian character of prison life may offer a welcome escape from autonomy; it has even been argued that certain prisoners find in the rules of the institution an external support that serves to reduce their inner anxieties. The great majority of inmates, however, feel the restrictions as a painful attack on their self-respect. As some social scientists have noted in analyzing the concentration camp, prisoners stand in constant danger of losing their identification as adults; and the imprisoned criminal is likely to find himself reduced to the weak, helpless status of childhood.

Fourth, men (or women) in prisons are forced into intimate association with other criminals for months and years. Whatever this may mean for their reformation, one important consequence is that they are deprived of the sense of security that springs from living among men who can be expected to abide by the rules of society. Living with murderers and thieves may provoke anxiety in even the most hardened criminal.

Fifth, the inmate of the prison is an outcast. For a few criminals, such as professional thieves, society's rejection may have little significance. But the evidence suggests that in most cases the moral condemnation of society is a profound threat to the individual's sense of worth. He is reminded of his degradation in many ways—his uniform, his number—and is seldom allowed to forget that by committing a crime he has forgone his claim to be a member of society in good standing.

These are the common frustrations or deprivations to which men in prison must somehow respond. To some extent they can be dealt with through the patterns of criminal behaviour that the inmates have brought with them. Some of the amenities of life can be won by physical coercion, chicanery, or simple thievery: an important feature of life in many prisons is the exploitation of one prisoner by another.

Inmate social systems

Students of the prison community have noted the argot in which the inmates describe their social roles. In the U.S. the argot includes terms such as square Johns, right guys, outlaws, gorillas, wolves, punks, fags, hoosiers, and so on. The vocabulary varies, but in penal institutions of the same type the structure of roles is evidently very similar. In adult, male prisons for serious offenders, those who use violence or the threat of violence to take things from others are called gorillas or outlaws. Those who exploit their fellows by sharp dealing and skillful trading in the stream of illicit goods that moves beneath the surface of institutional life are termed merchants or politicians. Prisoners playing these exploitative roles may in turn be exploited by an inmate—the so-called rat or squealer—who reveals their activities to the prison officials in hope of preferential treatment.

Patterns of exploitation, however, are but one answer to a threatening social environment; it is also possible to neutralize some of the frustrations of prison life through solidarity. Mutual aid, group loyalty, reciprocal protection against the inquiries of officials, and a united front against the threat of coercion exerted by other, more aggressive inmates can lessen the rigours of imprisonment. Yet such solidarity is usually more verbal than actual, and the loyalties of men in prison are fragile at best. They have no common set of beliefs, for one thing. Friendship might provide a basis for a sort of cooperative alliance, but the inmates of prisons are usually failures at interpersonal relationships. Exploitation is more common than cooperation. Faced with severe frustrations, together but apart, ill-equipped by previous experience to live in harmony, the inmates of the prison exist by manipulating their captors, coercing and defrauding one another, or withdrawing in apathy.

Empirical studies of penal institutions are too few in number to show with any precision the amount of corruption, solidarity, or exploitation that exists in different types of institutions. It is also not clear to what extent the norms of the inmate social system are derived from the world outside and to what extent they are a special product of imprisonment. Enough studies have been made, however, to indicate that women's penal institutions differ from the picture presented above. The inmate social system in prisons for women is likely to be built around artificial families. Homosexual relationships between women taking the roles of "husbands" and "wives" or "fathers" and "mothers" play a major part in organizing inmate behaviour. There is less emphasis on custody and security, and the problem of work is much changed by the ready acceptance of institutional housekeeping as appropriate employment.

In jails, the inmate social system is likely to be less clearly developed than in prisons, many of the inmates simply withdrawing into themselves and awaiting release. Jails notoriously subject their inmates to unsanitary conditions, brutality, corrosive idleness, and poor management. They usually make no effort at rehabilitation, since most of the prisoners are serving short sentences or awaiting trial.

Juvenile reformatories commonly assign custody and security a lower priority than do prisons for adult males; their rehabilitative resources are greater, and opportunities for vocational training are frequently more numerous. The inmate social system takes different and more subtle forms than in adult prisons, but it would be too much to say that coercion and exploitation do not exist in juvenile penal institutions. Some degree of coercion is made likely by the fact that many young offenders suffer more severe personality disturbances; if close supervision is abandoned, on the ground that juveniles do not require it or that it is inimical to therapy, serious disorders may result.

It is frequently argued that penal institutions cannot be expected to succeed at the task of reformation, as shown by the fact that more than two-thirds of confined criminals commit new crimes after they are released. Others answer that this figure is grossly exaggerated, that with proper resources and personnel many of the problems of penal institutions could be overcome. They also argue that it is sentimental to assume that a great many of the criminals sent to prison can be reformed, since those most likely to be confined are the hardened offenders with long careers of lawbreaking. The debate as to the efficacy of prisons revolves upon a lack of concrete evidence. If an individual does not commit a crime after being imprisoned, has he reformed because of his experience in the penal institution or in spite of it? If he does commit a crime after being imprisoned, has the penal institution exercised a harmful influence or no influence at all? It is possible that the prison reforms but that its achievements are negated or undone by other forces that come into play when the offender returns to the community.

Whatever the merits of these arguments, the fact is that many criminals are dealt with outside of institutions. Any discussion of penology must take account of the trend away from institutional treatment.

CORRECTION OUTSIDE THE PRISON

Of the nearly 1,300,000 offenders handled by the penal systems of the U.S. each day more than half are under

Probation and parole

supervision in the free community. The great majority of these convicted criminals outside penal institutions are on probation rather than parole—that is to say, they have been placed under supervision in the community directly after conviction—rather than, as in the case of parolees, being first sent to prison and then given an early release. The number of offenders on probation will probably continue to increase relative to the number who pass through prison.

The theory underlying the use of probation and parole is that the best path to rehabilitation for most criminals lies in the community, where the offender can be reintegrated into society, and that the problems of the criminal are better dealt with in their social context than in the artificial environment of the penal institution. Probation and parole are also far less expensive, it is argued; the cost of supervising a youthful offender on probation, for example, is less than a tenth of what it costs to keep him in a training school.

The development of probation. Probation evolved from Anglo-American judicial practices worked out to avoid automatic application of the harsh penalties prescribed in the statutes. These practices originated in the early 1800s in response to humanitarian concern over the effects of imprisonment on the young or first offender. Magistrates in such cases imposed only token sentences, remanding the offenders to the custody of their parents or other guardians for more careful supervision. As the practice evolved, an offender could be released on his acknowledgment of obligation until some later date set by the court for final action. He was often required to post bond or deposit bail to guarantee his reappearance.

John Augustus, a Boston boot maker, initiated the practice he called "probation" when in 1841, through his interest in the temperance cause, he appeared in court and posted bail for a man charged with drunkenness. Successful in helping the man get established, he proceeded to assist hundreds of men, women, and children charged with various offenses.

The voluntary work of Augustus and his successors led the Massachusetts legislature to authorize in 1878 the appointment of a paid probation officer to serve the Criminal Court of Boston. Subsequent legislation made probation services mandatory in most Massachusetts courts. Other states were slow to follow the example until the turn of the century, when the children's court movement began to sweep the U.S. In England, the efforts of temperance volunteers in the police courts paralleled the development of probation in the U.S. On the continent of Europe progressive elements had also long supported the mitigation of punishment for juvenile and first offenders. Europeans were primarily interested in a substitute for short-term imprisonment rather than in extended probation services. They adopted a procedure whereby sentence was imposed but contained provision for suspending execution of the punishment subject to the offender's good behaviour. First authorized by Belgian law in 1888, the conditional sentence was adopted by France shortly thereafter and eventually spread to nearly every European country.

Most continental European countries have delegated the personal supervision of probationers to social welfare organizations dependent on volunteer services. A general trend toward professional probation services has appeared in the Belgian, French, Dutch, and Swedish systems, where trained consultants are responsible for indoctrinating volunteer agents, supervising their work, and in many cases giving direct services to probationers. The move toward professionalization has been accompanied by increased central government responsibility for coordination, regulation, or administration of probation services. In most English-speaking countries probation is under the supervision of professional probation officers.

Problems of supervision. Seldom, however, do the courts and prosecutors adhere to all of the principles that are considered essential to the proper adminstration of probation: (1) careful selection of cases amenable to supervision, with consideration given on the basis of the offender's likelihood to improve under treatment, rather than the seriousness of his offense; (2) suspension of sentence for persons so selected; (3) supervision by professionally trained personnel; and (4) release of the probationer at the end of a specified period set by the court, provided his behaviour has been satisfactory, or revocation of his probation if he has committed a new crime or failed to comply with the conditions of his probation. It is widely agreed that a probation or parole officer should supervise no more than 35 to 40 persons at a time, but case loads are rarely that small. Successful supervision also requires a professional staff, a wide range of community services and facilities, and careful administration.

The administration of probation and parole must guard against two types of error. On the one hand, offenders who should be incarcerated may be set at large in the community; on the other, offenders who can be rehabilitated in the community and present no danger may be kept locked up when they should be free.

An accurate means of predicting criminal behaviour would be invaluable in deciding when offenders should be released from prison on parole and which offenders should be placed on probation rather than in a penal institution. The efforts of criminologists to develop statistical methods for predicting criminal behaviour have not succeeded in providing officials with practical guidance. Aside from the scientific difficulties in making accurate predictions, parole and probation officials often are suspicious of statistical formulas. The administrators of penal systems, for reasons of training and intellectual orientation, are far more receptive to clinical judgments, informed guesses, and the "wisdom of experience." As a consequence, prediction tables have generally remained an adjunct to the decision-making process, when they have been used at all.

Among the services needed for the supervision of the offender in the community, job training and job placement are viewed by many penologists as of prime importance. The problem of employment for convicted offenders is not easily solved, since they tend to come from minority groups and the poor, have little education, and often suffer from behaviour disorders, mental retardation, and poor health. To these disabilities must be added the stigma of the criminal that makes many potential employers turn them away. Penologists have given increasing attention to the importance of working with the family of the offender, particularly in the case of juveniles.

TRENDS IN PENOLOGY

There are many indications that modern societies are at the beginning of a significant transformation in their penal systems. Imprisonment as a principal method of handling the convicted criminal has proved to be costly, and its effectiveness has been increasingly questioned. Theories of the causation and prevention of crime now place less stress on moral factors that might be dealt with by awaking penitence or fear in the criminal. The segment of the population from which the majority of convicted criminals are drawn has ceased to be regarded as an alien, subhuman lower class, and the demands for just and humane treatment have increased.

The need for professionally trained people in the field of correction is recognized; there is a growing demand for the services of social workers, psychologists, sociologists, and persons with a background in public administration. The field is extremely diverse, and it cannot be said that there is a clear-cut correctional career; but the cynicism and sense of futility so common in the past are diminishing. It seems probable that in the near future penal institutions will come to be used to a greater extent as diagnostic and classification centres rather than as places of long-term confinement. The variety of institutions will continue to grow; there will be more use of temporary detention homes and halfway houses where custody and security no longer take first precedence. Finally, it is likely that institutional treatment will diminish in importance in comparison with supervision in the community.

Probability, Theory of

A description of probability that was first presented by the French mathematician Pierre-Simon Laplace (*q.v.*) in 1795 reads as follows: If an experiment (or operation or trial) can produce a number of different and equally likely outcomes, some (but usually not all) of which can be considered favourable, then the probability p of a favourable outcome is defined as the ratio of the number of favourable outcomes to the total number of possible outcomes. The most familiar example of such an experiment is the tossing of a coin. If the call is heads, then of the exactly two possible outcomes, a head or a tail, one is favourable to the caller. Provided the coin is fair, the probability of success for him is thus $\frac{1}{2}$. If a player is to bet that an ordinary cubical die will fall with the one spot uppermost, he wishes to know the odds, or probabilities. The assumption is that there are six equally likely ways in which the die can come to rest, only one of which is favourable; hence the probability of throwing a one is $\frac{1}{6}$.

While Laplace's description of probability cannot be considered a mathematical definition because it depends on the non-mathematical idea of "equally likely outcomes," it can be used as a guide in the calculation of many simple problems. An acceptable mathematical definition was formulated in the 20th century (see below *Foundations of 20th-century probability theory*).

The requirement that all the possible outcomes be equally likely is of major importance. There may be, for example, three cards, one red on both sides, one red on one side and white on the other, and the third white on both sides. After shuffling them in a closed bag, the experimenter reaches into the bag, draws out one card, and without looking at it, lays it on the table. Only then does he observe that the visible (upper) side of the card he has drawn is white. The problem is to find the probability that among all such experiments the underside is red. It is certain that the card in view is not the red-red card. Therefore it is either the white–red card or the white–white card. In the one case the underside is red; in the other case it is white. It follows that the face that is showing is one of the three white faces and, because of the way the cards are shuffled and drawn, each is equally likely. For only one of the three is the other side red, resulting in a probability of $\frac{1}{3}$.

Inadequacy of Laplace's definition

Unfortunately, an attempt to define what is meant by the phrase "equally likely" leads into a logical trap, and for this reason Laplace's approach is mathematically inadequate. In the coin-tossing experiment it can be assumed that the coin is unbiassed; that is, it is just as likely to fall heads as tails. If it is said, however, that this means that the two probabilities are equal, the reasoning is circular. The experiment is so simple and the result so obvious that the dilemma is concealed or overlooked. To define probability empirically in some such way as this might be tried: "Toss a coin a large number of times and divide the number of heads that appear by the total number of tosses. If this quotient approaches a fixed limit as the number of tosses is increased, call that limit the probability of obtaining a head in one toss." The difficulty with this definition is that it is not well suited for calculation. It is at the root, however, of the mathematical concept of probability. Along with a modified form of Laplace's description, it has been incorporated into a basic law of probability, "the law of large numbers," that essentially identifies probability in the Laplace sense (stripped of the "equally likely" ambiguity) with this limit of a quotient.

Probability on finite-dimensional spaces

ELEMENTARY PROBLEMS

An important principle of probability theory concerns the concept of statistical independence and is suggested by the statement that "the coin doesn't remember." Even if there has just been a run of 10 heads in a sequence of tosses of a fair coin, the probability that the next toss will be a head is neither greater nor less than usual: it is still exactly $\frac{1}{2}$. After a long run of red at roulette, if the wheel is fair, red is exactly as likely as black to win the next play. A formalization of this principle states that two events, such as outcomes of tosses of a coin or spins of a wheel, are statistically independent if and only if the probability of their joint occurrence is the product of their separate probabilities.

Statistical independence in dice problems

If two dice are tossed, an interesting problem is to determine the probability that they will both turn up ones. Resorting to Laplace's approach, it is found that there are altogether 36 outcomes of this experiment: six ways for the first die to fall, and each of these paired with six ways for the second. Only one of all these shows two faces turned up ones so that the probability is $\frac{1}{36}$. Another way to solve the problem using the principle of statistical independence is to think of the outcomes of two dice as two statistically independent events. The probability of an ace in the first throw is $\frac{1}{6}$; that is, using the law of large numbers referred to above, in a large number of throws $\frac{1}{6}$ of the throws will be successes and $\frac{5}{6}$ failures. A product of two such separate probabilities is $\frac{1}{6} \times \frac{1}{6} = \frac{1}{36}$. In general, if two independent events have probabilities p_1 and p_2, respectively, then the probability of both occurring jointly is p_1p_2.

In another problem the 13 cards of one suit in a 52-card deck are shuffled together. The probability of drawing first the ace and then the king in exactly two draws is desired. The probability of the ace on the first draw is $\frac{1}{13}$, but now the pack has been reduced to 12 so that the probability of the king on the second draw is $\frac{1}{12}$. It is not possible to solve the problem with the principles introduced thus far because the second drawing of the card was not independent of the first. The principle of conditional probability can be introduced in which the probability of two events occurring jointly can be calculated as the probability of one event times the conditional probability of the second event given the first. In this example, the desired probability becomes $\frac{1}{13} \times \frac{1}{12} = \frac{1}{156}$.

Next, the probability of drawing the ace and the king in either order from the 13 cards of one suit is desired. Stated another way, two cards are picked, face down, from the 13 cards. The probability that they are the ace and the king is needed. Problems of this kind are most simply answered in terms of permutations and combinations, which are discussed under COMBINATORICS AND COMBINATORIAL GEOMETRY. The total number of ways (combinations) of drawing two cards from the 13 cards is 78, of which only one consists of the ace and the king (remembering that order does not matter). Therefore $p = 1/78$.

The birthday problem

There is an amusing and instructive probability question that has become known as the "birthday problem." Among 24 people chosen at random (say, a dozen couples at a party), it is difficult to estimate the probability that some two of them will have the same birthday. Contrary to intuition, the probability is slightly larger than ½ and rises rapidly if the number (at the party) is increased. The probability that some two among 40 people will have the same birthday is about 8/9. The proof illustrates a principle upon which the solution of many probability problems is based: if p is the probability of an event, then $1 - p$ is the probability of the negation of that event. In the stated problem the ways in which it is possible for no two of the 24 people to share a birthday can be examined. For simplicity, anyone born on February 29 may call his birthday February 28. There are, consequently, 365 days on which the first person in the party can have a birthday, and the probability that his birthday is on some day is certain, or $^{365}/_{365}$. The conditional probability that the second person has a birthday on some other day, given that the first birthday is specified, is $^{364}/_{365}$. The conditional probability that the third person has a birthday on some day other than these two, given that the first two birthdays are specified, is $^{363}/_{365}$, and so on. Thus, using the principle of conditional probability, the probability that no two have the same birthday is $q = 365 \cdot 364 \cdot 363 \cdot \cdots 342/365^{24}$. It is this fraction that is slightly less than ½ so that $p = 1 - q$ is slightly greater than ½.

If six coins are tossed simultaneously (or one after the other), it is of interest to know the probability that just three will show heads. The possible successful outcomes are the ways of finding three heads among six coins, or the combinations of six things taken three at a time, which is 20. The total number of outcomes is the totality of ways of tossing six coins, or 2^6. Hence, the required probability is $20/2^6 = 5/16$.

If a perfectly fair coin were tossed a large number of times, say, 1,000, it would be difficult (though possible) to calculate the probability of exactly 500 heads. If two coins are tossed ($n = 2$), the probability of half heads is ½, but this probability is never again so high and decreases indefinitely with increasing n. For $n = 6$ it is only 5/16, as calculated above. The probability of obtaining exactly half heads can be made arbitrarily small by tossing a sufficiently large number of coins. The intuitive reason for this is, of course, that there are many ways of tossing almost exactly half heads when n is large. Mathematically, the reason is concerned with the coefficients in a binomial expression, $(a + b)^n$, that is written as a sum of powers of a and b. A deep understanding of these facts was obtained in the first quarter of the 18th century and led to approximations of the binomial coefficients in terms of what is now known as the probability density of the normal distribution. The normal plays a central role in modern probabilistic and statistical theory.

BASIC CONCEPTS

Contributions of Pascal and Fermat

In the early contributions to mathematical probability theory, primarily those of the French mathematicians Blaise Pascal (*q.v.*) and Pierre de Fermat (*q.v.*) and the Dutch mathematician, astronomer, and physicist Christiaan Huygens (*q.v.*), the main consideration was the expected gain in games of chance and considerations other than the direct calculation of probability itself. In Huygens' treatise *De Ratiociniis in Ludo Aleae* (1657; "On Ratiocination in Dice Games") there appeared the first documented reference to the concept of mathematical expectation. Huygens' formulation was if, among N cases all having equal chances of occurring, a player can gain the amount a in n of them and the amount b in the rest of them, then his expectation is given by $[na + (N - n)b]/N$. Historically, calculation concerning expectation came first, and these calculations implied secondary consequences about chance. Though the presentation of the subject is now frequently in the other order, probability first and expectation second, probability is logically a special case of mathematical expectation. To illustrate, it is possible to let C be a symbol to designate a particular collection of n equally likely events (or cases) out of a total of N. In the language of mathematical expectation, a player may receive amount 1 if any of the events composing C occur and the amount 0 otherwise. For such a game the expectation according to Huygens becomes $[n \cdot 1 + (N - n) \cdot 0]/N = n/N$, which is precisely the chance (or probability) for some one of the events composing C to occur. In modern notation if X is the amount that a player in such a game is to receive (X assuming the values 1 or 0 in the contingencies described), then $\mathbf{E}X = \mathbf{P}C$, showing the basic relationship between mathematical expectation, **E**, and probability, **P**.

Mathematical expectation. As an example from Huygens in the use of his concept of expectation, the following game is useful. Two dice are rolled. If a seven is thrown, player A wins the amount a; if a ten is thrown, player B wins the amount a; and if any other number is thrown, the amount a is divided evenly between the two players. The objective is to show that the ratio of the expectations of the two players is 13/11. The symbols "X_A" and "X_B" may be used to stand for the amounts that players A and B will receive, respecitvely. (The same convention will be used also in another example given below.)

Contribution of Huygens

There are six out of 36 equally likely ways to roll a seven, three out of 36 equally likely ways to roll a 10, and a remaining 27 ways for the dice to fall. From Huygens' definition of expectation, it follows that the expectations of A and B, respectively, are $13a/24$ and $11a/24$ (see Box, formula 1) so that the ratio of the two is 13/11.

The following is another example: Two players, A and B, play with a pair of dice on the condition that A is to win the stake of amount b if he throws a six before B throws a seven and B is to win the stake b if he throws a seven before A throws a six. The rules of the game specify that they are to throw alternately, with A beginning. It is desired to find the expectations of A and B.

It is possible to fix attention on B's expectation and to note that it will have one value when A is about to throw and another value when B is about to throw. These two expectations of B's can be designated x and y, respectively. When A is about to throw the chances for each player to win and their expectations are the same as at the beginning of the game, and whenever B is about to throw the two players' chances and expectations are as they were just before the second toss. Whenever A is about to throw, then, there are five cases in which B can win nothing (A throws a six), but there are 31 cases (those in which A would fail to throw a six) in which B can win the amount y, namely, the expectation that accrues to him when his throw comes up. Thus, according to Huygens' definition of expectation, B's expectation whenever A is about to throw is expressible in terms of y (see 2). By the same reasoning, whenever B is about to throw there are six cases in which he can win b and 30 cases in which he can win the amount x, namely, the expectation that accrues to him when A throws. Thus y is

$$(1)\quad \begin{cases} \mathbf{E}(X_A) = (6a + 27a/2)/36 = 13a/24 \\ \mathbf{E}(X_B) = (3a + 27a/2)/36 = 11a/24 \\ \text{in which } \mathbf{E} \text{ stands for "expectation of"} \end{cases}$$

$$(2)\quad x = (5 \cdot 0 + 31 \cdot y)/36$$

expressible in terms of x (see 3). There are two linear equations in two unknowns x and y, b being a known constant. Their solution is obtainable by elementary methods (see 4). Only the x value is needed because, if B's expectancy is x, A's must be $b - x$, and the desired expectations are determined (see 4). In this problem in which some one player gets all the stakes and in which there is no case in which the stake is divided, expectation is proportional to probability with proportionality constant b (see 4). This proportionality is a guide in the derivation of probabilistic laws below.

The additivity assumption. Alternate methods of solution to some of the same problems that occupied Huygens were later given by the Swiss mathematician Jakob Bernoulli (see BERNOULLI FAMILY) in his famous *Ars Conjectandi* ("The Conjectural Arts"), written in 1705 and published in 1713. By Bernoulli's reasoning player A in the above problem can win in any one of an infinite number of ways: six on the first toss; or no six on the first toss, no seven on the second toss, and six on the third toss; and so forth. A bar over a word can be used to symbolize its negation and a dot between words to symbolize succession of events; thus, a list of these separate ways for A to win reads as follows:

Contribution of Jakob Bernoulli

six; $\overline{\text{six}} \cdot \overline{\text{seven}} \cdot$ six; $\overline{\text{six}} \cdot \overline{\text{seven}} \cdot \overline{\text{six}} \cdot \overline{\text{seven}} \cdot$ six; $\cdots$.

The number of distinct configurations can be counted in the successive rolls of two dice that would lead to each of these ways for player A to win (see 5). These numbers, when taken relative to the total number of possible configurations of one roll of two dice, three rolls of two dice, five rolls of two dice, etc., yield a list of probabilities for all the separate ways in which player A can win, the sum of which should be the total probability (or chance) for A (see 6), the symbol "A" also being used in this context to stand for the event that player A wins. Applying the formula for the sum of a series yields $^{30}/_{61}$ as the chance for A to win (see 7). A similar line of reasoning for player B yields $^{31}/_{61}$ as the chance for B to win.

In Huygens' use of the definition of expectation he allowed that the amounts that could be gained by a player under various circumstances might well be, themselves, expectations. In fact, it was this flexibility of interpretation that led to the two simultaneous equations of his solution. If it is observed further that in some cases, notably in the problem Huygens was concerned with, that expectation is proportional to probability, an equation applicable to a variety of cases can be found that involves products of probabilities. To be precise, either of the two simultaneous equations of Huygens' solution (see 2, 3) involves probabilities instead of expectations when both sides of the equation are divided by the amount a (see 8). The resulting analysis of a probability into additive and multiplicative parts definitely entails an assumption about the ways in which probabilities can be composed. Such an assumption would be as follows:

If an event A, the chance of which occurring is $\mathbf{P}(A)$, will be realized in the presence of either of two mutually exclusive events, A_1 and A_2, with corresponding probabilities $\mathbf{P}(A_1)$ and $\mathbf{P}(A_2)$; and if the realization of A in the presence of A_1 has probability $\mathbf{P}(A|A_1)$ and in the presence of A_2 has probability $\mathbf{P}(A|A_2)$, then the relationship (see 9) between the probabilities of these events identifies $\mathbf{P}(A)$ with the sum of the two products $\mathbf{P}(A|A_1)\mathbf{P}(A_1)$ and $\mathbf{P}(A|A_2)\mathbf{P}(A_2)$.

Though Huygens did not formulate the statement as precisely as this in terms of probabilities, his thinking, as well as that of probabilists to follow him, was consistent with such a formulation, which will be used in the discussion below of Huygens' important "fifth problem."

Bernoulli, in achieving his solution to the problem already presented above (see 6), made the infinite addition of probabilities a plausible step in his solution. Bernoulli assumed that if an event A can be realized in any one of a possibly infinite number of mutually exclusive ways, $A_1, A_2, A_3, \cdots$, then the probability $\mathbf{P}(A)$ and the probabilities $\mathbf{P}(A_1), \mathbf{P}(A_2), \mathbf{P}(A_3), \cdots$ are related by identifying $\mathbf{P}(A)$ with the sum of the latter (see 10).

(3) $y = (6b + 30x)/36$

(4) $\begin{cases} \mathbf{E}(X_A) = 30b/61 \\ \mathbf{E}(X_B) = 31b/61 \end{cases}$

(5) $5,\ 31 \cdot 30 \cdot 5,\ 31 \cdot 30 \cdot 31 \cdot 30 \cdot 5, \cdots$

(6) $\begin{cases} \mathbf{P}(A) = (5/36) + (31 \cdot 30 \cdot 5/36^3) + \\ \qquad + (31^2 \cdot 30^2 \cdot 5/36^5) + \cdots \\ \text{in which P stands for "chance of"} \end{cases}$

(7) $\begin{cases} \mathbf{P}(A) = (5/36)[1 + 31 \cdot 30/36^2 + \\ \qquad + 31^2 \cdot 30^2/36^4 + \cdots] \\ \qquad = (5/36)[1 + (31 \cdot 30/36^2) + \\ \qquad + (31 \cdot 30/36^2)^2 + \\ \qquad + (31 \cdot 30/36^2)^3 + \cdots] \\ \qquad = (5/36)[1 - 31 \cdot 30/36^2]^{-1} = 30/61 \end{cases}$

(8) $p = p_1p_2 + p_3p_4$

(9) $\mathbf{P}(A) = \mathbf{P}(A|A_1)\mathbf{P}(A_1) + \mathbf{P}(A|A_2)\mathbf{P}(A_2)$

(10) $\mathbf{P}(A) = \mathbf{P}(A_1) + \mathbf{P}(A_2) + \mathbf{P}(A_3) + \cdots$

It was a Soviet mathematician, A.N. Kolmogorov (*q.v.*), who formulated this assumption, called "the additivity assumption," of the addition of an infinite number of probabilities as an unqualified postulate in his *Grundbegriffe der Wahrscheinlichkeitsrechnung* (1933; Eng. trans., *Foundations of the Theory of Probability*, 1950), but it is important to notice that when he did so he said, "It is almost impossible to elucidate its empirical meaning." Notwithstanding the fact that the assumption has now been cast into a basic postulate of measure-theoretic probability theory, there are later probability problems (particularly in reference to chance phenomena as they evolve on computing machines) in which a Bernoulli-like operation would lead one into contradiction (see AUTOMATA THEORY: *Computable probability spaces*). Such problems may arise when a computing machine generates an infinite (but countable) sequence of random numbers, each one of which has an associated probability of 0 but all of which combine to make an event with probability of 1. Interestingly enough, it follows that the acceptability or unacceptability of the additivity assumption in unqualified form rests upon the tacit assumption that random phenomena are not generated by automata and is, thus, allied with the tenability or untenability of a theory of nature in which chance and causality are distinct. That is, the Bernoulli postulate, as stated in modern terms by Kolmogorov, is in keeping with the classical bifurcation of the Greek goddesses Tyche (chance) and Moira (fate), which still permeates scientific thinking, rather than with the postulates of computability that have been formulated in the 20th century.

Huygens' fifth problem

As an illustration of the use of products of probabilities, Huygens' famous fifth problem will be considered. This problem evolved through various generalizations and extensions into the problem of gambler's ruin, duration of play, simple random walk, and many others that have occupied many mathematicians on different occasions from the time of Huygens to the middle of the 20th century. In its simplest original form, it is as follows:

Two players each take 12 counters and play with three dice on the condition that if 11 is thrown the first player gives a counter to the second and if a 14 is thrown the second player gives a counter to the first. That player wins the game who first obtains all the counters. The chances of each player to win are desired.

A difference equation from which will follow the desired chances for the first player to win can be deduced

from the composition of probabilities developed above. If $P(n)$ is the chance for the first player to win when he has n counters (or, in alternate convenient language, when the game is in state n), then in the next play of the game following state n the first player must either give or receive a counter, and these eventualities have the corresponding probabilities $27/216$ and $15/216$, respectively (as an enumeration of the various ways three dice can fall easily shows). In the terminology of the above assumption involving products of probabilities (see 9), these two eventualities comprise two mutually exclusive events, and the event that the first player will win will be realized in the presence of either one or the other of the two with corresponding probabilities $P(n-1)$ and $P(n+1)$. A direct application of the above reasoning yields an equation in which $P(n)$ is expressed in terms of $P(n-1)$ and $P(n+1)$. Such an equation, called a "difference equation," is first supplemented with boundary values of $P(n)$ for values of $n=0$ and $n=24$ (see 11). It is then solved by known methods (see NUMERICAL ANALYSIS), and the chance of the first player winning is obtained by setting $n=12$ in $P(n)$.

Conditional probability. There is an advantage in noticing that the term $\mathbf{P}(A|A_1)\mathbf{P}(A_1)$ used above is the probability for both A and A_1 to occur, with a similar meaning holding for the second term, $\mathbf{P}(A|A_2)\mathbf{P}(A_2)$. This fact is an immediate consequence of the rule on the addition of probabilities (see 10) applied to two mutually exclusive events, namely, the events "A and A_1" and "A and A_2." For any two events A and A_1, the probability for the occurrence of both A and A_1, $\mathbf{P}(AA_1)$, and the product, $\mathbf{P}(A_1)$ times $\mathbf{P}(A|A_1)$, are equal (see 12), the latter being the probability for the occurrence of A in the presence of A_1. In this statement the events A and A_1 are any events and may be interchanged without changing the meaning (see 13). In contemporary terminology, $\mathbf{P}(A|A_1)$ is the probability of A conditioned on the occurrence of the event A_1 or, more briefly, the conditional probability of A given A_1.

Contribution of De Moivre

Following Bernoulli, the work of a French-born British mathematician, Abraham De Moivre, explicitly introduced the concepts of statistical independence and conditional probability. Though probabilistic statements such as the above are implicit in the writings of Huygens and Jakob Bernoulli, it was unequivocally presented in De Moivre's *The Doctrine of Chances* of 1718. In the symbolism $\mathbf{P}(A|A_1)$, used above, De Moivre's definition becomes equivalent to its modern formulation:

Two events A and A_1 are statistically independent if and only if the conditional probability of A given A_1 is equal to A and the conditional probability of A_1 given A is equal to A_1 (see 14). Equivalently, A and A_1 are statistically independent if and only if $\mathbf{P}(AA_1)$ is equal to the product of the separate probabilities (see 15).

It is interesting to see that in the same way that Pascal and Huygens derived many of their results on probability from a formulation predicated upon the more intuitively immediate concept of expectation, so also De Moivre derived the relation of independence from a rule on the composition of expectations:

> If the obtaining of any sum (amount) requires the happening of several events that are independent of each other, then the value of the expectation of that sum is found by multiplying together the several probabilities of happening, and again multiplying the product by the value of the sum.

As an important corollary to the above principle, De Moivre adds:

> If we make abstraction of the value of the sum to be obtained, the bare probability of obtaining it will be the product of the several probabilities of the (independent) events.

De Moivre also pointed out, but less clearly, that the principle of composition of probabilities for independent events can be extended to more than two events. A modern formulation is the following:

The events $A_1, A_2, A_3, \cdots$, are mutually independent if and only if every pair, as well as every pair of single or joint occurrences, B and C, is independent (see 16). For example, B or C in the above definition could be chosen as A_1 or as A_5 or as "A_1 and A_5" or as "A_2 and A_7 and A_9," or as any joint occurrence of one or more events. For N mutually independent events $A_1, A_2, \cdots, A_N$, it follows from the last definition that, in particular, $\mathbf{P}(A_1A_2\cdots A_N)$ is the product of the probabilities for separate events (see 17).

$$(11)\quad \begin{cases} P(n)=(27/216)P(n-1)+ \\ \qquad +(15/216)P(n+1), \qquad n=1,2,\cdots,23 \\ P(0)=0, \qquad P(24)=1 \end{cases}$$

$$(12)\quad \mathbf{P}(AA_1)=\mathbf{P}(A|A_1)\mathbf{P}(A_1)$$

$$(13)\quad \mathbf{P}(AA_1)=\mathbf{P}(A_1|A)\mathbf{P}(A)$$

$$(14)\quad \mathbf{P}(A|A_1)=\mathbf{P}(A) \text{ and } \mathbf{P}(A_1|A)=\mathbf{P}(A_1)$$

$$(15)\quad \mathbf{P}(AA_1)=\mathbf{P}(A)\mathbf{P}(A_1)$$

$$(16)\quad \begin{cases} \text{The events } A_1, A_2, A_3, \cdots \text{ are mutually independent} \\ \text{if and only if} \\ \mathbf{P}(BC)=\mathbf{P}(B)\mathbf{P}(C), \\ \quad B=A_iA_j\cdots A_k, \qquad C=A_mA_n\cdots A_p, \\ \text{for any choice of distinct subscripts } i,j,\cdots,k, \\ m,n,\cdots,p \text{ from the integers } 1,2,3,\cdots. \end{cases}$$

$$(17)\quad \mathbf{P}(A_1A_2\cdots A_N)=\mathbf{P}(A_1)\mathbf{P}(A_2)\cdots\mathbf{P}(A_N)$$

FOUNDATIONS OF 20TH-CENTURY PROBABILITY THEORY

Toward the end of the first quarter of the 19th century most of the significant work on the theory of probability had been summarized by Laplace in his great *Théorie analytique des probabilités* (1812; "Analytic Theory of Probability"). It was in Laplace's introduction to this work on chance that the striking pronouncement for causality was found. For Laplace, probability theory was a device for coping with reality, in view of the inadequate nature of man's knowledge, and his reasoning was entirely mechanistic:

Contribution of Laplace

> We ought then to regard the present state of the universe as the effect of its anterior state and as the cause of the one which is to follow. Given for one instant an intelligence which could comprehend all the forces by which nature is animated and the respective situation of the beings who compose it—an intelligence sufficiently vast to submit these data to analysis—it would embrace in the same formula the movements of the greatest bodies of the universe and those of the lightest atom; for it, nothing would be uncertain and the future, as the past, would be present to its eyes. The human mind offers, in the perfection which it has been able to give to astronomy, a feeble idea of this intelligence. Its discoveries in mechanics and geometry, added to that of universal gravity, have enabled it to comprehend in the same analytical expressions the past and future states of the system of the world.

With the beginning of the 20th century, striking discoveries in the physical sciences and in mathematics were responsible for basic innovations in probability theory. The statistical mechanics of the German and U.S. physicists Ludwig Boltzmann and J. Willard Gibbs (*q.v.*) expressed in more far-reaching fashion Laplace's conviction that the approximate nature of measurement was responsible for chance phenomena. The Boltzmann ergodic hypothesis, which identifies two types of averages, as does the weak law of large numbers, and Gibbsian phase space (appropriate for the statistical description of gases) provided the physical starting point from which, in 1923, the U.S. mathematician Norbert Wiener (*q.v.*) formulated the first mathematically precise description of Brownian motion (the motion seen in a microscope to be conveyed to tiny particles by the action of surrounding molecules). The mathematical tools used by Wiener were those of the

Contribution of Wiener

(18) A function f defined on S to R is interval measurable if and only if it possesses the following two properties:
(i) The function f has at most a countable number of discontinuities,
(ii) The sets $\{w:f(w)=t\}$ that are inverse images of points in the range of f are interval measurable.

(19) $$\mu(A)=(b_1-a_1)+(b_2-a_2)+\cdots+(b_n-a_n)+\cdots$$

French mathematician Henri-Léon Lebesgue and included measure theory, a formal extension of the idea of length (see below *The measure-theoretic reasoning*). While Wiener's analytical approach was being placed on a postulational basis by Kolmogorov in 1933, the German and Austrian quantum theorists Werner Karl Heisenberg and Erwin Schrödinger (*qq.v.*) discovered that probability was entering in the description of atomic phenomena. The measure-theoretic ingredients of probability, known to the mathematicians, did not seem to be a part of the quantum theory. This apparent paradox continues to inspire mathematical research into the nature of probability theory even today, and for that reason introductory remarks will be made about each approach, the measure-theoretic and the quantum-theoretic.

For other approaches to probability including the frequency theory of probability, the range theory of probability, and the belief theory of probability, see MATHEMATICS, HISTORY OF: *Various mathematically based probabilities.*

The measure-theoretic reasoning. The present discussion will be concerned with functions f defined on the space S composed of the unit interval, such that each set in S, constituted of all points that are mapped by f into the same real value, is of simple enough structure and provided there are not too many such sets. (Both these qualifications are to be defined more rigorously.) In physical language, such a function f corresponds to a measurable property of a system. A function f is thus being used to label sets in S, and it is assumed that the values that serve as labels are real numbers. It is seen that distinct values of f correspond to disjoint sets of points in S. That is to say, f induces a partition of S in the following sense: For each function f and for each real number r there is a set $A^{(r)}$ of points in S, such that $f(a)=r$ if and only if $a \in A^{(r)}$; moreover, each point of S will belong to one and only one $A^{(r)}$. Now if all investigations could be confined to one function and to simple statements involving it, then the sets $A^{(r)}$ of the partition induced by f would be as large a class of sets as necessary. On the contrary, it will be found necessary to consider many functions, and, once these are available, it will be necessary to observe complicated functions of these. This situation means that not only the partition induced by one f but the sets composing many partitions, as well as various combinations of these, must be considered. It is not enough to define the functions individually, but they must be defined as a class, and strict cognizance must be taken of the logical structure of the sets induced on S by this class. In order to do this, it may be convenient first to establish a class of sets in S and afterward to define a function f in reference to this class. It is this class of sets in S that it is desirable to define in more detail and use as an essential mathematical ingredient in the study of probability theory.

In the above approach to a class of sets in S it has not been specified what is meant by "simple structure" and "not too many." With some arbitrariness the conditions will be imposed that the sets of the class be simple in the following sense: they are to be built out of intervals with end points a, b contained in (the closure of) S. By the term interval is understood either open, closed, or half-open interval. It can now be made specific what is meant by an interval-measurable class of sets in the real line R. (An equivalent definition holds for the interval-measurable class of sets in any interval subset of R, such as S.) The interval-measurable class of sets in R is the class $\mathfrak{F}$ composed of the empty set and all sets in R that can be partitioned into at most a countable number of intervals in R. In this definition it is understood that a set A is partitioned into subsets $A_1, A_2, \cdots, A_n$ if and only if each point of A is a member of one and only one A_k and each point of any A_k is a member of A. In order to extend measurable concepts to functions, it is necessary to use the concept of an inverse image of a set. The inverse image of a set A, as mapped through f, is composed of the set of points a, such that $f(a)$ belongs to A.

Interval measurable sets and functions

A function f defined on S to R is interval measurable if and only if for any set A in $\mathfrak{F}$ the inverse image of A, as mapped through f, is in $\mathfrak{F}$. A basic theorem can be proved that gives deeper insight into the meaning of interval-measurable functions than the definition does (see 18).

The definition of $\mathfrak{F}$, in this simplified context, can be used as the first building block for the more complicated idea of the class of Lebesgue measurable sets, named after Lebesgue. The fact will later be used that most of the more complicated sets required by probability theory can be approximated to arbitrary accuracy (assuming an appropriate definition of approximation is given) by sets in $\mathfrak{F}$. Thus, $\mathfrak{F}$ will be considered intuitively meaningful and at the same time representative of abstractly defined classes of sets. Similarly, an interval-measurable function has explicit meaning for probability theory and is close to the idea of a random variable. According to a reasonable criterion, most of the more complicated functions of probability theory can be approximated to arbitrary accuracy with the interval-measurable functions defined here.

The Lebesgue measure $\mu(A)$, defined on sets A in $\mathfrak{F}$, is simply length in the case where A is an interval and sums of lengths in the case where A is partitioned into a countable number of intervals. Thus, in general, if A is partitioned into subsets $A_1, A_2, \cdots, A_n, \cdots$, a subset A_k being an interval from a_k to b_k, the Lebesgue measure of A is defined to be the sum of differences of the type $(b_k - a_k)$ (see 19).

Though S has been identified with the unit interval, a similar definition for a measurable function, with a more general class of sets replaced for $\mathfrak{F}$, would be meaningful if no topology had been imposed to define distance between points in S. The freedom from a topology in S (or a means of defining distance in S) is characteristic of measure-theoretic approaches. Significantly, it will later be convenient to use just such a topology in studying what is meant by measurement in the quantum-mechanical sense.

The quantum-theoretic reasoning. It is important to consider some of the aspects of an individual precision measurement, either classical or quantum-mechanical. First, it must be performed at an instant of time or over a period of time. Because an instant of time cannot be known to an arbitrary degree of accuracy, it must be assumed, in effect, that the measurement relates to a period of time. Next, a single measurement has the interpretation that, if it were performed again under the same circumstances, it would yield the same result or a second sample value from a fixed statistical distribution. If this were not the case and if experiments were not at least conceptually repeatable, an individual measurement and thus all measurement would be meaningless. Finally, the repetition of a precision measurement can at most be expected to give an identically repeated answer in the case in which a measured value is one of a finite or countable number of values. It is significant that it has not been possible to describe precision measurement without reference to time and that, with the exception of countably many possible measured outcomes, precision measurement has attached to it some error.

Effect of time on measurement

The system composed of the measured object and the measuring device must next be considered. The theory is to be guided with sufficient generality to ensure meaningfulness in quantum theory as well as classical science. Probabilistic analysis will be of basic importance in the study. Curiously enough, the purely mathematical works

on probability theory that relate directly to the lineage of Pascal, Laplace, Lebesgue, Wiener, Kolmogorov, and others have to a large extent become isolated from the physical sciences that reason in terms of quantum theory. In the words of the U.S. physicist Richard P. Feynman:

> The quantum mechanical laws of the physical world approach very closely the laws of Laplace as the size of the objects involved in the experiments increases. Therefore, the laws of probabilities which are conventionally applied are quite satisfactory in analyzing the behaviour of the roulette wheel but not the behaviour of a single electron or a photon of light.

On the other hand, a mathematical theory of chance phenomena that draws from the best mathematical work of the past and that is to be consistent with the physical postulates of 20th-century physics, including quantum theory, considers at the outset what is meant by the measurement process in all generality.

The space S composed of the points a in the unit interval $(0, 1)$ can now be re-examined. It is possible to retain the concept that points in S can be put into correspondence with the states of a physical system (though the phrase classical-physical system is avoided) and to retain the concept that the real value $f(a)$ of a function corresponds to a set in S and thus, intuitively, identifies incomplete information about the system.

Many-one functions and incomplete information

In the mathematical description of the classical process of measurement, a function f defined on S assumes a value when the system being measured occupies a specific state. From the many-one character of a function f, it can be inferred that a given value r of f is consistent with a set $A^{(r)}$ of points in S. This statement, though phrased in the classical setting, is meaningful whether the entity f, representing the property being measured, is characterized mathematically as a measurable function or as a function possessing certain local properties such as continuity.

The condition $f(a) = r$, for some fixed real value r, may be considered. This condition determines the set $A^{(r)}$, and the points composing $A^{(r)}$ will be called the roots of the equation $f(a) = r$. Physically, these roots are separate states of the system under observation that, individually, would contribute to the measured value r. There may be a finite, a countably infinite, or an uncountably infinite number of roots composing a set $A^{(r)}$. Whatever the case, they are not distinguishable in terms of f—that is, no condition imposed on f alone characterizes a subset of an $A^{(r)}$. To speak again in physical language, the condition $f(a) = r$ has reference to information about the state of a physical system, this information being nevertheless incomplete.

If in the spirit of 20th-century physics measurement on a space-time system is considered, a condition of the type $T(a) = t$, in which T is a real-valued function on S, can represent an observation on time. Consistent with the above remarks, a set $A^{(t)}$ that is the inverse image of the point t, as mapped through the function T, thus takes on the interpretation of incomplete information about the time of an observation. In this more general setting, in which time is represented mathematically as a function rather than a parameter, measurement on a physical system that, realistically, is inexact both in space and time is represented in terms of restrictions on two functions. If the function f represents one measurable (spatial) property of the physical system and T represents time, averages become replaced by a sum of all terms of the type $w_k f(a_k)$, for which a_k belongs to $A^{(t)}$ (see 20), in which, for the present discussion, it is assumed that the a_k are all the roots of the equation $T(a) = t$, and in which the w_k are weights, to be determined from the theory or observation, that depend on the functional structure of the time function T. Such averages are interpreted as the average (or expected) value of f, given that $T = t$.

Use of time as a function

It will occur that a knowledge of the coefficients w_k can be made tantamount to a knowledge of the square of the absolute value of the wave function—that is, the solution of the central equation of quantum mechanics. Thus, it may be expected that some analytic structure in the time function T similar to the analytic structure of the quantum-mechanical wave function is essential in deducing knowledge about these coefficients. The time function T is also needed to obtain the roots a_k, just as knowledge of the set of equations known as the Hamiltonian dynamics is essential to obtain the successive state values of a classical mechanical system. At least one way to obtain such structure in T is to make use of a topology in S for exploring the continuity and differentiability of T, considered as a function. From the discussion of the above section, however, it is seen that measure theory makes no essential use of a topology on S or of differentiability or continuity of functions defined on S. For these reasons it has already been emphasized that alternatives to the measure-theoretic approach are of value particularly in grasping the aspects of physical observation and measurement that supersede the classical approach of the last century and the early part of the present one.

Probability on infinite-dimensional spaces

It was clear from the work of Wiener in 1923 that, if any precise mathematical description of a random phenomenon as important to science as the Brownian motion (see above *Foundations of 20th-century probability theory*) was to be achieved, then Lebesgue measure must be extended to infinite dimensions. The reason for this was clear: The Brownian motion paths were observed in the laboratory to be highly irregular, and mathematically they were found to be expressed by functions that were so irregular as to be non-differentiable (that is, without tangents) except for a set that is negligible, technically of Lebesgue measure zero. The mathematical analysis of the Brownian-motion process could be achieved by dividing the time axis into a finite number of parts, by imposing a probability measure to the class of functions that conformed to certain spatial restrictions during those specified finite segments of time, and by passing to the limit in the number of temporal subdivisions. (Other techniques have since been found possible but are equivalent to this one, which was Wiener's first approach.) This analysis meant that probability measure, applied to as many dimensions as there were time intervals, namely, a finite number, must be extendible, in the limit, to infinite dimensions. Wiener found that the Daniell integral, already defined in order to treat functions in infinite dimensions, was a suitable tool with which to compute averages of functionals over the function space of Brownian-motion paths.

Brownian motion

The mathematical description of the Brownian motion constituted the first construction of an infinite collection of random variables ordered with increasing time and jointly satisfying certain measurability properties, now called a stochastic process. The techniques of Lebesgue measure theory, including the theorem that extends measure to infinite dimensions, are now the familiar beginning to the study of stochastic processes in general.

ADVANCED PROBABILITY AND STOCHASTIC PROCESS THEORY

Succeeding remarks will require some notation from the algebra of sets (see 21).

The definition of the interval-measurable class $\mathfrak{F}$ can be formulated by saying that $\mathfrak{F}$ is the smallest collection of sets in the unit interval that is "closed under countable unions" (made no larger by forming such unions)

(20) $$\sum_{a_k \in A^{(t)}} w_k f(a_k)$$

(21)
- $A \cup B$ is the set of points in A or B or both.
- $A \cap B$ is the set of points in both A and B.
- A^c is the set of points not in A.
- $A \supset B$ if and only if each point in B is also in A.
- $B \subset A$ if and only if $A \supset B$.

and that includes the empty set, $\emptyset$, the whole space, S, and all subintervals within S. The same definition for $\mathfrak{F}$ can also be stated symbolically (see 22).

The importance of this expression for $\mathfrak{F}$ is that it brings into evidence the close relationship between $\mathfrak{F}$ and two important classes of sets in S that are widely used throughout probability theory. Specifically, in the language of the above definition, there can be the introduction of classes $\mathfrak{A}$ and $\mathfrak{B}$, such that $\mathfrak{A} \subset \mathfrak{F} \subset \mathfrak{B}$ (see 21).

Let $\mathfrak{B}$ be defined as the smallest collection of sets in S including $\mathfrak{F}$ that is closed under countable-set operations. An equivalent symbolic definition is also possible (see 23). The existence of a smallest field with these properties follows from the fact that the class of all subsets in S includes $\mathfrak{F}$ and is closed under countable-set operations and the fact that the intersection of any two classes possessing such properties yields a class with the same properties.

In a definition similar to that for $\mathfrak{F}$, it is possible to define $\mathfrak{A}$ as the smallest collection of sets in the unit interval that is closed under finite unions and that includes the empty set, $\emptyset$, the whole space, S, and all subintervals within S. As a consequence, $\mathfrak{A}$ is closed under all finite set operations and is contained in $\mathfrak{F}$. Defining properties for $\mathfrak{A}$ can be expressed purely symbolically (see 24).

The class $\mathfrak{A}$ or any collection of sets with the same closure properties is called a field, while class $\mathfrak{B}$ that has more extensive closure properties is called a σ-field. If $\mathfrak{J}$ is the class of subintervals in S, then F is sometimes denoted $\mathfrak{J}_\sigma$, consistent with the notation of classification of sets due to the French mathematician Émile Borel, to indicate that it is composed of all countable unions of sets from $\mathfrak{J}$. As such, members of $\mathfrak{F}$ are identified to be of rather simple structure compared to sets in a hierarchy of more and more complicated sets leading up to those comprising $\mathfrak{B}$.

σ-field of sets

In the present context $\mathfrak{B}$ could be called the σ-field generated by $\mathfrak{F}$ or $\mathfrak{A}$. It should be emphasized, as it was by Kolmogorov, that, while a field can be considered observable, the generated σ-field is purely a mathematical convenience. In Kolmogorov's words:

> Even if the sets (events) A of $\mathfrak{A}$ can be interpreted as actual and (perhaps only approximately) observable events, it does not, of course, follow from this that the sets of the generated field, $\mathfrak{B}$, reasonably admit of such an interpretation. . . . Thus, sets of $\mathfrak{B}$ are generally merely ideal events to which nothing corresponds in the outside world. However, if reasoning which utilizes the probabilities of such ideal events leads us to a determination of the probabilities of an actual event of $\mathfrak{A}$, then, from an empirical point of view also, this determination will automatically fail to be contradictory.

The intermediate class $\mathfrak{F}$ has been chosen because it is still close to the intuition and to a class of actual events in Kolmogorov's sense and, at the same time, it comes closer to providing the mathematical flexibility of the more complex class $\mathfrak{B}$. Deeper reasons for considering $\mathfrak{F}$ have to do with the basic fact that the measure-theoretic approach to the concept of probability is not sufficiently general for some purposes in quantum theory (see above *The quantum-theoretic reasoning*) and automata theory (see above *The additivity assumption*).

The broadening from $\mathfrak{F}$ to $\mathfrak{B}$ calls for an extension of the domain of definition of the Lebesgue measure. Earlier (see above *The measure-theoretic reasoning*), so long as sets in $\mathfrak{F}$ were the only ones involved, the intuitive notion of Lebesgue measure as the length of an interval or the sum of such lengths sufficed. It now becomes necessary to invoke the extension theorem (reserving the complete statement until later; see below *Extension of probability measure to infinite-dimensional spaces*) that assures that a measure can be defined uniquely for all sets in $\mathfrak{B}$ in such a way that it coincides with the intuitive notion of Lebesgue measure for sets of $\mathfrak{F}$. This theorem depends strongly on the property of Lebesgue measure on $\mathfrak{F}$ called complete additivity and defined by identifying the measure of the union of sets with the sum of the measures (see 25), for every disjoint sequence $F_1, F_2, \cdots$ of sets in $\mathfrak{F}$ the union

(22) $\mathfrak{F}$ is the collection of sets in S such that:
(i) $\emptyset \in \mathfrak{F}, S \in \mathfrak{F}$.
(ii) $I \in \mathfrak{F}$, for I any interval in S.
(iii) If $A_k \in \mathfrak{F}, k = 1, 2, 3, \cdots$, and $A = A_1 \cup A_2 \cup A_3 \cup \cdots$, then $A \in \mathfrak{F}$.
(iv) If $\mathfrak{F}'$ satisfies i), ii), iii), then $\mathfrak{F}' \supset \mathfrak{F}$.

(23) The collection $\mathfrak{B}$ has the three properties:
(i) $\mathfrak{B} \supset \mathfrak{F}$.
(ii) If $B_k \in \mathfrak{B}, k = 1, 2, 3, \cdots$, and if $B = B_1 \cup B_2 \cup \cdots$, then $B \in \mathfrak{B}$ and $B_k^c \in \mathfrak{B}$.
(iii) If $\mathfrak{B}'$ has properties i) and ii), then $\mathfrak{B}' \supset \mathfrak{B}$.

(24) Defining properties for $\mathfrak{A}$:
(i) $\emptyset \in \mathfrak{A}, S \in \mathfrak{A}$.
(ii) $I \in \mathfrak{A}$ for I any interval in S.
(iii) If $A_k \in \mathfrak{A}, k = 1, 2, \cdots, n$, and $A = A_1 \cup A_2 \cup \cdots \cup A_n$, then $A \in \mathfrak{A}$.
(iv) If $\mathfrak{A}'$ satisfies i), ii), iii), then $\mathfrak{A}' \supset \mathfrak{A}$.

(25) $$\mu(F_1 \cup F_2 \cup \cdots) = \sum_{k=1}^{\infty} \mu(F_k)$$

of which belongs to $\mathfrak{F}$. The complete additivity assumption had been anticipated by Bernoulli (see above *The additivity assumption*). With the use of the extension theorem, there is a mathematical entity, the Lebesgue measure, $\mu(B)$, to go with the members, B, of the mathematical abstraction $\mathfrak{B}$. The Lebesgue measure is simply a non-negative set function satisfying the property of complete additivity on $\mathfrak{B}$ and coinciding with the intuitive notion of measure on $\mathfrak{F}$.

Lebesque measurable sets

The distinction between the σ-field, $\mathfrak{B}$, and the class of Lebesgue measurable sets can be found only by examination of the subsets of measure zero in $\mathfrak{B}$. The broadening from $\mathfrak{B}$ to the class of Lebesgue measurable sets is called completing the field, $\mathfrak{B}$, and the extension of the measure to the completed field is called completing the measure.

Probability spaces, random variables, and distribution functions. The two entities $(S, \mathfrak{B})$ when taken together are a special case of a Borel measurable space, and the three entities $(S, \mathfrak{B}, \mu)$ when taken together are a special case of a Borel measure space. Because $\mu(S) = 1$, the term probability space also applies, and $(S, \mathfrak{B}, \mathbf{P})$ is written for the previous triplet. The restriction of S in these definitions to the unit interval rather than to an abstract space is seldom a limitation, and in many cases it offers an enormous simplification. Not only can almost all of the mathematical ingredients of theorems and proofs of theorems be found in this setting, but they appear without the complications of generality that sometimes obscure the meaning. The results achieve no greater generality when stated with the aid of measure spaces $(\Omega, \mathfrak{B}, \mu)$, for which Ω can be carried onto S by a one-to-one mapping that preserves measure (sets that correspond through the mapping having equal measure). Such measure spaces are called regular.

Just as a class of sets wider than $\mathfrak{F}$ is mathematically essential, the class of Lebesgue measurable functions is an essential generalization of the interval-measurable class. (In the following definition, as anticipated above, the σ-field, $\mathfrak{B}$, is assumed to be completed and, thus, is composed of the class of Lebesgue measurable sets in the unit interval.)

A function f defined on S to R is Lebesgue measurable if and only if for any set A in $\mathfrak{F}$ the inverse image of A, as mapped through f, is in $\mathfrak{B}$. (The term measurable func-

tion, if not otherwise qualified, will mean Lebesgue measurable function.)

A measurable function defined on S is called a random variable.

In a purely mathematical sense, the class $\mathfrak{F}$, however simple, is representative of $\mathfrak{B}$ in a way that formal definitions and theorems make precise (see 26, 27). Similarly, though interval-measurable functions appear to be rather special in comparison with measurable functions, they are representative of the latter in the sense of a formally expressed theorem (see 28).

After the sets that are to provide the mathematical generalization of events are defined, it is necessary to introduce a convenient means of calculating probabilities for representative sets. Such means are supplied by distribution functions F, which are defined over the entire real line and possessing the following properties: A distribution function F vanishes at negative infinity, it is a monotone nondecreasing function as its argument increases, it is continuous from the left (though continuity from the right is also acceptable), and it is bounded by unity (that is, it converges to 1 as its argument approaches positive infinity). A distribution function is generated by each random variable X, though more than one random variable can possess the same distribution function. For a given random variable X, one of the familiar algorithms that is used to produce the relevant distribution function F_X identifies the value of the distribution function at point t with the probability measure of the set of points in the space S, for which X assumes a value less than t (see 29). Thus, with the device of distribution functions, measure relevant to X is transferred from the space S to the real line. A number of calculational details concerning special distribution functions, particularly in the n-dimensional case, can be found in the article STATISTICS.

Distribution functions

It is not incidental that the properties of a distribution function are the same (except for the unity bond) as the properties of a Lebesgue–Stieltjes measure that associates a number, not necessarily the length, with each interval of the real line (see ANALYSIS, REAL: *Measure and integral calculus*). The importance of this fact from the probabilistic point of view is found in a basic theorem concerning the mathematical expectation.

The mathematical expectation $\mathbf{E}X$ of any random variable X is defined as the Lebesgue integral of the random variable over the space S, integrated with respect to the probability measure $\mathbf{P}$ (see 30).

The basic theorem just referred to states that mathematical expectation of a random variable X, or a function h of it, can be calculated as the Lebesgue–Stieltjes integral of the identity function, or the function h, integrated over the whole real line with respect to the measure induced by the distribution function of X (see 31). This integral is the more familiar form of expectation.

Random variables that assume only a finite number of values—examples can be constructed from elementary problems in games of chance (see above *Elementary problems*)—have distribution functions composed of "steps" and "jumps." The random variable with binomial distribution function F_B (see 32) is especially important and is used in the calculation of probabilities for the number k of successes in a sequence of N experiments (such as flips of a coin) that are statistically independent events with constant probability p of success in a single trial. For such variables the Lebesgue–Stieltjes integral in the basic theorem cited reduces to a sum (see 33) and the mathematical expectation becomes identified with the form first discovered by Huygens (see above *Mathematical expectation*).

Binomial and normal distributions

Random variables that assume a continuum of values generally have distribution functions that are absolutely continuous. An important example is the random variable with normal distribution function F_N (see 34), first discovered by De Moivre, studied by Laplace and by the German mathematician Carl Friedrich Gauss (*q.v.*), incorporated in the basic work of the French mathematician Paul-Pierre Lévy, and found by Wiener to be an integral part of the stochastic process that is used to describe the Brownian motion. For such random variables the mathematical expectation reduces to a Lebesgue–Riemann integral (see ANALYSIS, REAL) of the product of the identity function and the derivative f_X of the distribution function called the probability density function (see 35).

The concept of statistical independence generalizes in a natural way from independent events (see above *Conditional probability*) to independent random variables by defining the variables as mutually independent if representative inverse images, as mapped through the variables, are mutually independent events. Basic theorems concerning sequences of mutually independent random variables can then be stated and proved.

Law of large numbers and central limit theorem

One of the most important of these theorems is a generalization of the law of large numbers that was discovered by Bernoulli called "the strong law of large numbers." One form of the generalization (see 36) states that, for a sequence of mutually independent random variables $\{X_k\}$ with common distribution function and finite mathematical expectation $\mathbf{E}X$, the difference between the arithmetic average of the number N of the variables $(X_1 + X_2 + \cdots + X_N)/N$ and the expectation common to the variables converges to (or intuitively comes closer to) zero as N increases (except for certain points in the space S, the totality of such exceptional points constituting a set with zero probability measure).

(26) Let the measure space $(S, \mathfrak{B}, \mu)$ be given. A class $\mathfrak{F}$ of subsets of S is dense in $\mathfrak{B}$ if $\mathfrak{B} \supset \mathfrak{F}$ and if for each $B \in \mathfrak{B}$ and for any positive number ϵ there exists a set $F \in \mathfrak{F}$ such that $\mu(F \Delta B) < \epsilon$, where $F \Delta B = (F \cap B^c) \cup (F^c \cap B)$ is the symmetric difference.

(27) The interval measurable class, $\mathfrak{F}$, is dense in the Lebesgue measurable class $\mathfrak{B}$.

(28) Let f be a measurable function defined on the measure space $(S, \mathfrak{B}, \mu)$. For any positive number ϵ, there is a set $B \in \mathfrak{B}$, $\mu(B) < \epsilon$, and an interval measurable function g (dependent upon ϵ) defined on $(S, \mathfrak{F}, \mu)$ such that $|f(a) - g(a)| < \epsilon$, except for $a \in B$.

(29) $$F_X(t) = \mathbf{P}[X < t], \qquad -\infty < t < \infty$$

(30) $$\mathbf{E}X = \int_S X \, d\mathbf{P}$$

(31) $$\mathbf{E}X = \int_{-\infty}^{\infty} t \, dF_X(t), \qquad \mathbf{E}h(X) = \int_{-\infty}^{\infty} h(t) \, dF_X(t)$$

(32) $$F_B(t) = \sum_{k<t} \binom{N}{k} p^k (1-p)^{N-k}$$
$$0 \leq t \leq N, \qquad 0 < p < 1$$

(33) $$\int_{-\infty}^{\infty} t \, dF_X(t) = \sum_{k=1}^{N} x_k \, \mathbf{P}[X = x_k],$$
if X assumes only the values $x_1, x_2, \cdots, x_N$.

(34) $$F_N(t) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{t} e^{-x^2/2} \, dx, \qquad -\infty < t < \infty$$

(35) $$\int_{-\infty}^{\infty} t \, dF_X(t) = \int_{-\infty}^{\infty} t f_X(t) \, dt$$
if F_X is absolutely continuous

(36) Strong law of large numbers: If the random variables $\{X_k\}$ are mutually independent with common distribution function and finite mathematical expectation $\mathbf{E}X$, and if $\overline{X} = (X_1 + X_2 + \cdots + X_N)/N$ with values $\overline{X}(a)$, then except for points a in a set O for which $\mathbf{P}(O) = 0$:
$$[\overline{X} - \mathbf{E}X] \to 0.$$

(37) Central limit theorem: If the random variables $\{X_k\}$ are mutually independent with common distribution function, if $\mathbf{E}X < \infty$, $\mathbf{E}[X - \mathbf{E}X]^2 < \infty$, and if $\overline{X} = (X_1 + X_2 + \cdots + X_N)/N$, then for $-\infty < t < \infty$ it follows that as N increases:

$$\mathbf{P}[\sqrt{N}\,(\overline{X} - \mathbf{E}X) < t\,\mathbf{E}^{1/2}(X - \mathbf{E}X)^2] \rightarrow \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{t} e^{-x^2/2}\,dx.$$

Another important theorem attributed to De Moivre and Laplace, called the central limit theorem, is also expressed in terms of a sequence $\{X_k\}$ of mutually independent random variables. One of the generalized forms of this theorem (not the most general) states that, if the variables have common distribution function, finite expectation $\mathbf{E}X$, and finite variance $\mathbf{E}[X - EX]^2$, then a modified form of the difference between the arithmetic average of the number N of the variables and the expectation common to the variables (a form of the difference that is in effect multiplied by the square root of N) behaves like a random variable with normal distribution for large enough value of N (see 37). The applications of this theorem, particularly in the field of statistics (*q.v.*), are multifold.

Extension of probability measure to infinite-dimensional spaces. If two set functions s_1 and s_2 are defined on $\mathfrak{F}$ and $\mathfrak{B}$, respectively, it may be said that s_1 is the restriction of s_2 on $\mathfrak{F}$, provided s_1 and s_2 agree on $\mathfrak{F}$. Similarly, s_2 is the extension of s_1 to $\mathfrak{B}$, provided s_1 and s_2 agree on $\mathfrak{F}$. The concepts of restriction and extension are used similarly in reference to set functions defined on any two classes of sets, one of which is contained in the other.

A class of sets closed under formation of monotone limits is sometimes naturally associated with a field or a σ-field. A class of sets in S is closed under formation of limits of monotone sequences if the logical union of the sequence of sets $\{A_n\}$ belongs to the class, whenever $\{A_n\}$ belongs and $\{A_n\}$ is nondecreasing; and the logical intersection of the sequence of sets $\{A_n\}$ belongs to the class, whenever $\{A_n\}$ belongs and $\{A_n\}$ is nonincreasing.

A monotone field has the properties of a monotone class given above as well as the field properties. A monotone class generated by a field is the smallest monotone class containing the field.

It can be shown that a monotone field is a σ-field (the converse being obvious). It can also be shown that the monotone class generated by a field and the σ-field generated by the same field are identical. These facts are important in the construction of proofs of relevant theorems.

In the terminology of this section, the smallest σ-field containing the class of open sets in the n-dimensional Euclidean space R^n is the Borel field in R^n. The Borel field can also be obtained by starting with the class of closed sets in R^n or the class of closed or open intervals (n-dimensional intervals in the case of n dimensions). The elements of the Borel field are Borel sets.

An important example in the relation between fields and σ-fields is built up from the concept of a product set. Given two spaces S_1 and S_2, and two sets A_1 and A_2 chosen from fields of sets in S_1 and S_2, respectively, the product set $A_1 \times A_2$ is composed of the set of all ordered pairs (a_1, a_2), with a_1 in A_1 and a_2 in A_2. The class of all finite unions of product sets composed in this way is a field of sets in $S_1 \times S_2$. It is called a product field. If the field from which A_1 is chosen is $\mathfrak{F}_1$ and the field from which A_2 is chosen is $\mathfrak{F}_2$, then the product field is written $\mathfrak{F}_1 \times \mathfrak{F}_2$.

If $\mathfrak{B}_1$ and $\mathfrak{B}_2$ are σ-fields, the product σ-field $\mathfrak{B}_1 \times \mathfrak{B}_2$ is obtained by first composing the product field and then identifying $\mathfrak{B}_1 \times \mathfrak{B}_2$ with the smallest σ-field containing the product field.

Generalizations of these concepts to countable and even uncountable dimensional spaces will be of importance in studying measure on function space. For example, if the spaces S_t and sets within them A_t are indexed by a parameter t, in which t belongs to a countable or uncountable subset T in the real space, then the above definitions are extended in the obvious way to product sets ΠA_t, product fields $\Pi\mathfrak{F}_t$, and product σ-fields $\Pi\mathfrak{B}_t$, in which the product is extended to all choices of the parameter t in the index set T. In more detail, if the index set T is composed of the positive integers, a product set ΠA_t will be defined as the collection of all sequences $(a_1, a_2, \cdots)$, with a_k in A_k, the A_k belonging to the fields $\mathfrak{F}_k$, and $A_k = S_k$ for all but a finite number of values of k. The class of all finite unions of product sets formed in this way is the product field $\Pi\mathfrak{F}_t$. The smallest σ-field containing this field is the product σ-field $\Pi\mathfrak{B}_t$. As another example, if the index set T is composed of all finite real numbers, the product field $\Pi\mathfrak{F}_t$ is formed of all finite unions of sets ΠA_t, in which a typical set ΠA_t is defined as the collection of all sequences of elements, each from some A_t, with subscripts of such a sequence constituting a countable set of points $(t_1, t_2, \cdots)$. (Restrictions on the choice of the A_t hold as before.) From such a field the product σ-field is defined as before.

The construction of measure on product measurable spaces as well as on σ-fields in general can follow in a unique sense from the properties of a (σ-finite) measure on the generating field. This fact, at the root of much of the work in measure theory, is expressed in the extension theorem.

Techniques of the extension theorem

The techniques that make up the statement and proof of the extension theorem come from the properties of outer measure as defined on real point sets. The discussion of extension of measure in the article ANALYSIS, REAL should also be consulted. If one identifies (following Lebesgue) with any set of real points the infimum (greatest lower bound) of sums of lengths of sequences of open intervals the union of which contains the given set, one obtains the real-value set function m^* called outer measure. As immediate properties of outer measure defined in this real setting, one obtains: first, $m^*(0) = 0$; second, $m^*(A) \leq m^*(B)$ for sets A and B, such that $B \supset A$; and third, $m^*(\cup A_k) \leq \Sigma\, m^*(A_k)$ for any sequence $\{A_k\}$. Moreover, having proved these properties, it is natural (after the ingenious stroke of the German mathematician Constantin Carathéodory) to consider the behaviour of m^* on the class of sets A that satisfy, for every set D, the relation: fourth, $m^*(D) = m^*(A \cap D) + m^*(A^c \cap D)$ for every set D. If a motivation is sought for the Carathéodory property, it might ensue from the inequality (not strict) of property preceding, together with the equality that might be expected to result if the sets A and D are not too much more complicated than intervals.

It is proved—still in the context of the real space—that the class of sets A satisfying the Carathéodory property is a σ-field and m^* on this σ-field is countably additive.

Clearly, the class of sets satisfying the fourth property includes all intervals, and thus, by restriction of m^* to the smallest σ-field including all intervals, $\mathfrak{B}$, an extension of measure is obtained from the class of intervals to the Borel field $\mathfrak{B}$.

These are the techniques that suggest the following theorem, which is known as the extension theorem:

If a measure m is defined on a field $\mathfrak{F}$, there exists a measure m' on the σ-field $\mathfrak{B}$ generated by $\mathfrak{F}$ that is an extension of m to $\mathfrak{B}$; and if m is σ-finite, then m' is σ-finite and unique.

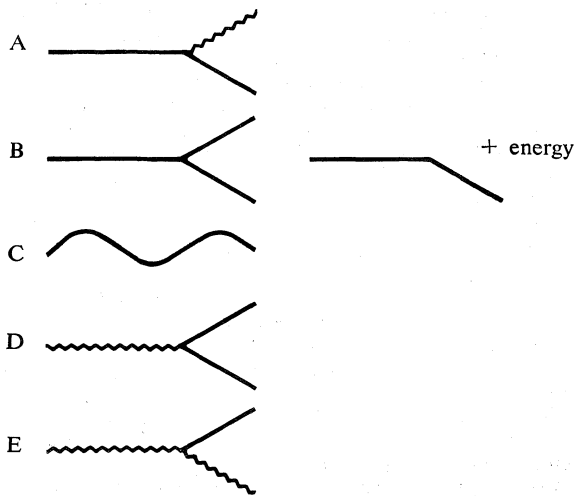
The mathematical analysis represented by the extension theorem, or a technique that is equivalent, provides sufficient generality to define a random function or, equivalently, a stochastic process. Knowledge of stochastic processes is largely composed of knowledge of certain classes of processes. It is convenient to define certain properties and then confine attention to the processes, the second-order processes, the Markov processes that satisfy these properties. Other classes are processes with independent increments, processes with orthogonal increments, martingales, and stationary stochastic processes. A discussion of an important part of the theory of stationary stochastic

Major classes of stochastic processes

processes is included under the headings *Control and single-series prediction* and *Multiple prediction theory* in the article AUTOMATA THEORY. In view of the breadth of the subject matter that has now developed in this field, it is necessary to limit the scope of the remarks to be presented here. Of basic significance are the Markov processes. Moreover, in the literature there are theorems that suggest an underlying relationship between Markovian and non-Markovian processes. It would seem valuable to review the precise meaning of these theorems not only in order to convey an introductory idea of the Markovian class but to characterize the nature of other processes as well.

MARKOVIAN AND NON-MARKOVIAN PROCESSES

Just as the historically important problems that drew Pascal and others to the theory of probability served to illustrate the basic concepts of probability theory in an elementary sense, an important modern problem in cosmic-ray physics will serve to illustrate the relationship of Markovian to non-Markovian processes.



The electron–photon shower problem. In the early 1930s a number of experimental observations on cosmic rays (the radiation detected from outer space) suggested some kind of multiplication, or population-growth process specific to the cosmic rays as they passed through the Earth's atmosphere. Principal experimental observations were those of the Italian-U.S. and German-U.S. physicists Bruno Rossi and Victor Regener. Such experiments led to a long-standing problem in theoretical physics that was to explain the growth and death of a population of fast electrons and photons, two of the components of the cosmic rays, as they passed through matter. Work on the theoretical problem began in about 1934 with the ideas of men in Germany, Scotland, India, and other countries, primarily the physicists Lothar Nordheim, Hugh Carmichael, Homi Bhabha, and Walter Heitler. It became apparent that the growth of cosmic-ray populations was caused by successive branching processes and that these processes, the radiation loss by electrons and materialization by photons, could be predicted from what was then the new quantum theory.

Increasing evidence for a shower phenomenon in cosmic rays accumulated with more experimentation so that by 1937 the cascade-shower problem, as it came to be called, could be enunciated as a theoretical, though physically meaningful, objective: under the assumption of well-specified initial conditions, to predict the number of electrons and photons, descendants of an initial high-energy particle, that emerge with specified energies from a given thickness of absorbing material. The clear statement and partial solution of this problem were accomplished in 1937 by two teams of research physicists, Bhabha and Heitler as well as J. Franklin Carlson and J. Robert Oppenheimer (*q.v.*).

The reasons for the mathematical difficulties in the cascade-shower problem will be clear after the process for electron-photon development has been described mathematically and a general equation for it has been written down. First, it is necessary to remark that the basic processes that contribute to the development of a shower are: (A) radiation loss by an electron (an electron branches into an electron and a photon); (B) collision loss by an electron (an electron branches into two electrons, as in collision with a free electron, or it simply loses a fraction of its energy to excitation of an atom, as in collision with a bound electron); (C) deflection of an electron in the Coulomb field of a nucleus without the electron losing any energy (the electron path becomes curved at random from multiple scattering); (D) pair production by a photon (a photon branches into two electrons); and (E) Compton collision by a photon (a photon branches into an electron and a photon).

Basic processes of electron–photon interaction

Although only two of these processes, (A) and (D), are important at high energies in which the shower begins, all of the processes will contribute before the energy of the shower has been completely dissipated through excitation. Pictorially, these processes can be illustrated in the following way:

Ignoring for the time being process (C) and ignoring the fact that there is actually an angle of emission at each branch point, it is possible to specify the state, σ, of a shower at the point $t \geq 0$ of penetration by giving some particular values to a set of parameters. A suitable set of parameters might be n, m, $\bar{e}$, and μ, representing, respectively, the number of electrons, the number of photons, an $(n+m)$-dimensional energy vector, $\bar{e} = (e_1, e_2, \cdots, e_{n+m})$, and the ordering of electrons and photons among the energy components of $\bar{e}$. The ordering parameter μ can take on any of 2^{n+m} permissible values, each value representing one of the 2^{n+m} ways in which $n+m$ particles can be distributed among $n+m$ energies. A possible state of a shower is written: $\sigma = (n, m, \bar{e}, \mu)$. If I is the initial energy of the shower at zero penetration, then no individual energy, e_k, can exceed it.

In what follows, the random function $W(t)$ can be thought of as a random variable for each fixed value of t. (For a rigorous definition of random function, see below *Stochastic processes: general definitions.*) With these conventions, it can be said that a shower is completely described by the random function $W(t)$, in which $W(t)$ may take its values in the space $\Sigma = \{\sigma\}$ of all possible states σ. The mathematical problem is to determine the conditional probability, $P(\Delta\sigma, t|\sigma_0, 0)$, that $W(t)$ will belong to some set of states $\Delta\sigma$, given that $W(0)$ coincided with some initial state σ_0. This will be written as $P(\Delta\sigma, t)$, without the initial condition appearing explicitly when the initial condition is constant and understood. The symbol $\Delta\sigma$ will be understood as the set of states, σ, with common n, m, and μ but with energy components taking values anywhere in the intervals $(e_k, e_k + e'_k)$, $e'_k \geq 0$, $k = 1, 2, \cdots, n+m$.

Because it can be assumed, first, that the processes (A, B, C, D, E) all occur at some discrete points in space, namely, the points of impact with the Coulomb field of the

(38)

$$P(\Delta\sigma, t|\sigma', s) = [1-\alpha(\sigma')(t-s)]\delta(\sigma', \Delta\sigma) + \pi(\sigma' \to \Delta\sigma)(t-s) + o(t-s),$$

$$\delta(\sigma', \Delta\sigma) = \begin{cases} 1 & \sigma \in \Delta\sigma \\ 0 & \text{Otherwise.} \end{cases}$$

In general $o(t-s)$ will depend on σ' and $\Delta\sigma$. The explicit forms of $\alpha(\sigma')$ and $\pi(\sigma' \to \Delta\sigma)$ can be given when they are needed for calculation. If $\Delta\sigma$ is fixed, $\pi(\sigma' \to \Delta\sigma)$ is measurable with respect to some σ-field, $\mathfrak{B}$, of sets in Σ. For fixed σ', $\pi(\sigma' \to \Delta\sigma)$ is a completely additive, non-negative function of sets in $\mathfrak{B}$ with

$$\pi(\sigma' \to \Sigma) = \alpha(\sigma'),$$
$$\pi(\sigma' \to \sigma') = 0.$$

$\pi(\sigma' \to \Delta\sigma)$ is independent of s and t.

nucleus or the electron, and, second, that before each process the particle "remembers" only what its energy is and whether it is an electron or a photon, the following assumptions I and II can be made.

Purely discontinuous Markovian processes, the diffusion equation. I. The process is purely discontinuous and temporarily homogeneous. That is to say, the conditional probability of $W(t)$ being contained in $\Delta\sigma$, given that at the fixed point s, $0 \leq s < t$, the variable $W(s)$ coincided with the state σ', is a continuous function of t and s, independently, and has a specific limiting form (see 38).

II. The process is Markovian. That is to say, the conditional probabilities of $W(t)$ being contained in $\Delta\sigma$, given $\{W(t): t \leq s\}$ and given $W(s)$, are the same. In other words, the future state of the system is independent of the history prior to s, so long as $W(s)$ is known (see 39).

Once properties I and II are assured, the most obvious approach to the calculation of $P(\Delta\sigma, t)$ is to write down and solve the diffusion equation that it satisfies (see 40). Following the treatment of the U.S. mathematician William Feller for a purely discontinuous Markov process, it is possible to write $P(\Delta\sigma, t)$ as an infinite sum (see 41) of probabilities, $P^{(N)}(\Delta\sigma, t)$, each summand thus being given in terms of an integro-differential-difference equation that can be solved in successive steps in N. The $P^{(N)}(\Delta\sigma, t)$ can be interpreted as the compound probability that, while penetrating x thickness of material, the system will experience exactly N transitions and that $W(t) \in \Delta\sigma$, if it is known that $W(0) = \sigma_0$.

The integro-differential-difference equation that appears in this context evolved first in the researches of Sydney Chapman, an English mathematician, and Kolmogorov and is called the Chapman–Kolmogorov equation. It might appear here that one had only to solve this equation and the electron-photon problem would be completed. In reality, this method of solution presents too difficult a procedure because the variety of energies that the electrons and photons might assume at each point in the development of the cascade shower is too large. Though, as a Markov process, the structure of the cascade shower is describable in mathematical terms, the detailed nature of the state space Σ makes the solution of the equation unduly complicated.

Chapman–Kolmogorov equation

By omitting detailed reference to the energies, the complicated structure of each state disappears. The simplification of the state space is accomplished, however, at the possible expense of the Markov character of the process as a whole. For this reason, the cascade-shower problem was one of the earliest sources of ideas for handling non-Markovian problems and problems that could be expressed in terms of functions of Markovian processes that resulted from providing an incomplete description of an underlying Markovian process. Other sources of ideas of this kind became apparent in the probabilistic studies on growth of biological populations.

Stochastic processes: general definitions. It is possible to suppose that the set of possible states that a stochastic process assumes at a fixed time t forms a space and that this space is the same for any time t. As time progresses the process will experience transitions from point to point in the space. This space may now be partitioned into subsets, and it is possible to consider the event that at time t the state of the process belongs to a specified set of the partition. This and other like events corresponding to all different points in time, if collected, will form a sample value of a new stochastic process. The new process is, of course, determined by the first and by the partition and may be said to describe the transitions of the original process from set to set of the partition. The particular transformation involved in relating two processes in the above way is simply a mapping of the space of states of the original process onto a partition. Such a mapping is an appropriate tool with which to study the interrelation between processes and, more specifically, Markovian and non-Markovian processes.

Let $(\Omega, \mathfrak{B}_\Omega, \mathbf{P})$ be a probability space, (Γ, B_Γ) a measurable space, and R^+ the space of positive real numbers. Let $G(t)$ be a measurable function defined on $\Omega \times R^+$ to Γ. The symbols Ω and Γ represent some general spaces made up of points ω and γ, respectively, while $\mathfrak{B}_\Omega$ and B_Γ are some σ-fields of sets in Ω and Γ, respectively. $\mathbf{P}$ is a probability measure defined for all sets in $\mathfrak{B}_\Omega$. The function $G(t)$ defined above will be called a random function or a stochastic process. Γ will be called the range space of $G(t)$.

$$\mathbf{P}[W(t) \in \Delta\sigma \mid W(s)] = \mathbf{P}[W(t) \in \Delta\sigma \mid W(r), r \leqslant s], \qquad t \geqslant s \geqslant 0 \tag{39}$$

$$(\partial/\partial t)P(\Delta\sigma, t) = \int_\Sigma P(d\Sigma_{\sigma'}, t)\pi(\sigma' \to \Delta\sigma) - \int_{\Delta\sigma} P(d\Sigma_{\sigma'}, t)\alpha(\sigma'). \tag{40}$$

$$P(\Delta\sigma, t) = \sum_{N=0}^{\infty} P^{(N)}(\Delta\sigma, t) \tag{41}$$

It should be further noticed that, if Λ is chosen to be a measurable partition of Γ, and if the random function $G(t)$ is given, then it is always possible to treat (Λ, B_Λ) as a new measurable space and to define a new random function $L(t)$ as follows: $L(t)$ is the measurable function on $\Omega \times R^+$ to Λ, such that $L(t) = \lambda$ whenever $G(t) \in \lambda$. In other words, if $\phi(\gamma)$ denotes the function on Γ to Λ defined by: $\phi(\gamma) = \lambda$ for all $\gamma \in \lambda$, then $L(t) = \phi[G(t)]$.

Functions of Markovian processes. Two important facts about the related random functions $G(t)$ and $L(t)$ can now be expressed. First, the $G(t)$ process may be such that the probability of its future is equally well conditioned on the present or the present combined with the past—that is, it may be Markovian. If so, the Markovian assumption relating conditional probabilities, as expressed for $W(t)$ above, applies (see 39). If such is the case, $L(t)$ may or may not be Markovian. The information in the process $L(t)$ is not, in general, sufficiently complete to permit a reconstruction of the process $G(t)$, and, as such, that component of it that relates to the present state may not offer a sufficiently rich condition on which to evaluate the probability of the future without the addition of information from the past. Second, though in general a stochastic process is not Markovian, any stochastic process, say, $L(t)$, can be analyzed in such a way that it is related to a Markovian process $G(t)$ through some function ϕ. These facts provide guidelines for extending analytical methods that were originally established by Kolmogorov for Markovian processes to functions of Markovian processes and, thus, potentially to many types of processes.

Loss of information and loss of the Markovian property

The class of sets $\Lambda = \{\lambda\}$ in the space Γ is said to be enchained by the random function $G(t)$ if the following conditions hold:

A. Λ is measurable in the sense that $\lambda \in B_\Gamma$ for each $\lambda \in \Lambda$.

B. Λ forms a partition of Γ. That is to say, the sets of Λ are disjoint and their union covers the whole space Γ.

C. If $L(t) = \phi[G(t)]$ is the random function defined earlier, then for all t, s, $0 \leq s \leq t$, and for all sets $\Delta\lambda \in B_\Lambda$: $\mathbf{P}\{L(t) \in \Delta\lambda | L(s)\} = \mathbf{P}\{L(t) \in \Delta\lambda | G(s)\}$, with probability 1.

The purpose of this definition is to place conditions on Λ and $G(t)$ that permit the random function $L(t)$ to be Markovian if $G(t)$ is Markovian. This conditioning is done essentially through C, which is equivalent to asking that, for each fixed t and s, the conditional probability $\mathbf{P}\{L(t) \in \Delta\lambda | G(s)\}$ is measurable not only with respect to the smallest σ-field generated by $G(s)$ but also with respect to that generated by $L(s)$. Intuitively speaking, condition C extends the Markov property from $G(t)$ to $L(t)$ by demanding that any transition of the process $G(t)$ from points in $\lambda \in B_\Gamma$, at t_1, to a set $\Delta\lambda \in B_\Lambda$, at t_2, $t_2 > t_1 \geq 0$, have the same probability. Though one ultimately wishes to write down an equation for the transitions of the process $G(t)$ through the sets of Λ, the new

Implications for calculational methods

(42)

$$\begin{cases} (\partial/\partial t)P_1(\Delta\lambda, t \mid \lambda_0, 0) \\ \qquad = \int_\Lambda P_1(d\Lambda_{\lambda'}, t \mid \lambda_0, 0)\,\pi'(\lambda' \to \Delta\lambda) \\ \qquad\quad - \int_{\Delta\lambda} P_1(d\Lambda_{\lambda'}, t \mid \lambda_0, 0)\,\alpha'(\lambda') \\ \lim_{t\to 0} P_1(\Delta\lambda, t \mid \lambda_0, 0) = \delta(\lambda_0, \Delta\lambda) \\ \text{The functions } \pi'(\lambda' \to \Delta\lambda) \text{ and } \alpha'(\lambda'), \text{ as functions of } \lambda', \\ \text{are unique up to sets of measure zero and are defined} \\ \text{by:} \\ \pi'(\lambda' \to \Delta\lambda) = \pi(\gamma \to \Delta\lambda) - \pi(\gamma \to \lambda')\delta(\lambda', \Delta\lambda), \\ \alpha'(\lambda') = \alpha(\gamma) - \pi(\gamma \to \lambda'), \\ \text{for any } \gamma \in \lambda', \text{ where } \pi(\gamma \to \Delta\lambda) \text{ and } \alpha(\gamma) \text{ are the} \\ \text{functions appearing in the definition of } G(t) \text{ as a purely} \\ \text{discontinuous and temporally homogeneous process.} \end{cases}$$

function $L(t)$, itself a function of the process $G(t)$, becomes a conventional tool to help one do so.

The following facts can now be proved:

If (a) $G(t)$ is a Markovian random function with range space Γ and if (b) $\Lambda = \{\lambda\}$ is a class of sets in Γ that is enchained by $G(t)$, then $L(t)$ (the random function defined in condition C above) is Markovian.

Suppose (b) in the above statement is true. If (c) $G(t)$ is purely discontinuous and temporarily homogeneous, then $L(t)$ is also.

If (a), (b), and (c) in the above statements are true, then for each $\lambda_0 \in \Lambda$, for all $\Delta\lambda \in B_\Lambda$, and for all $t > 0$, the function $P_1(\Delta\lambda, t|\lambda_0, 0)$—that is, the conditional probability for $L(t)$ to belong to $\Delta\lambda$, given that $L(0)$ coincides with λ_0—satisfies an equation (see 42) of the Chapman–Kolmogorov type (see 40).

It can be seen in these facts that the Markovian property of $L(t)$ (and also its purely discontinuous property) leads to a diffusion equation, a linear equation for the transitions of the process $G(t)$ through the sets of Λ. As such, it provides a convenient alternative to the diffusion equation governing $G(t)$ because any specific realization of it will involve only enough parameters to specify the sets of Λ rather than the detailed structure of the states γ. When applied to the cascade-shower problem, for example, this technique of taking a function of a Markovian process makes solutions possible.
